Option three. Adopt a procedure for translating a general narrative toxic criterion, no toxics in toxic amounts, into chemical-specific numeric criteria. At a minimum, this procedure must be used to derive numeric criteria for priority toxic pollutants whose discharge or presence could reasonably be expected to interfere with a designated use.

This option provides the flexibility of calculating numeric criteria on an as-needed basis, reducing the time and cost of adoption and allowing the immediate use of the latest scientific information.

And then there is option four that EPA didn't state, and that's that no action is taken. The result of this is it's possible EPA could promulgate these standards, these criteria, for the State of New Mexico.

The Water Quality Standards Handbook indicates that the most appropriate use of option three is to supplement option one or two. This would provide numeric criteria for priority toxic pollutants with statewide

applicability to ensure precision in the calculation of effluent limitations for NPDES permits and total maximum daily loads, backed up by a predictable method for developing additional numeric criteria as needed.

Q. What option has the Department been implementing for the past decade?

A. Since 1990, the Department has followed option two. It selected this option because it called for a more limited collection of samples for analysis during some water quality surveys and therefore was less expensive.

However, since EPA issued the ROD in January, 2001, the Department has been collecting and analyzing more extensive samples for all priority toxic pollutants during all water quality surveys. Accordingly, the principal argument against option one, which was the expense of sampling and analyzing for all priority toxic pollutants during all water quality surveys, is no longer applicable because we're already doing that.

Q. What is the Department's preferred option today?

A. The Department recommends that the Commission adopt a combination of option one and option three. With respect to option one, the Department recommends the adoption of numeric criteria for all priority toxic

pollutants for which EPA has published Section 304(a) criteria for the consumption of organisms.

With respect to option three, the Department recommends the adoption of a translation procedure for the existing general toxic standard to allow EPA to derive a numeric criterion for priority toxic pollutants in NPDES-regulated discharges but for which the Commission has not yet adopted numeric criteria.

The translation procedure has many advantages for New Mexico. First, it would allow the Department to certify NPDES permits with a reasonable assurance that designated uses are being protected. The translation procedure requires the use of the IRIS data, which is consistent with the federal requirement to use the most current risk information in calculating criteria for the protection of human health. It also requires the Department to incorporate the appropriate EPA-approved formulae for calculating numeric criteria into the Water Quality Management Plan.

These formulae, recently revised by EPA, are established in EPA's Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health. That's Exhibit NMED 7, and also shown on the slide.

Second, the translation procedure ensures that

EPA will implement the Commission's policy choice regarding the appropriate risk level for cancer-causing priority toxic pollutants.

In this petition, the Department proposes a cancer risk level of ten to the minus fifth. That's one additional cancer in 100,000 exposed persons.

The proposal reflects the Commission's previous endorsements of this risk level. They have endorsed this specifically in the water quality standards under the section of domestic water supply and also in the regulations at 20.6.2.7.UU, which is the definition of a toxic pollutant as one that would cause a risk level of ten to the minus fifth.

Third, the translation procedure tells EPA how to calculate numeric criteria when none is provided in the state water quality standards.

Finally, as I'll explain later in my testimony, the translation procedure requires the Commission to review and approve the numeric criterion itself. Notwithstanding the advantages of the translation procedure, it should be noted that the approach is not new. The Commission already employs a similar translation procedure for calculating aquatic life chronic numeric criterion, and it's the Department's practice to petition the Commission to review and approve

criteria that have been derived through this process.

Q. How are you doing?

A. I'm fine.

Q. We're now going to go on and talk about the petition itself section by section. We'll try and focus on the primary sections. There are a number of changes in the petition that probably don't warrant a discussion.

So why don't we start with Section 10, one of the primary changes.

Can you please explain what the Department has proposed with respect to Section 10 of the water quality standards?

A. Yes, I can.

The Department proposes a new flow value for evaluating compliance with human health criteria. The new value, which is known as the harmonic mean flow, is defined in EPA's Water Quality Standards Handbook, which is Exhibit NMED 4.

This definition says, "Harmonic mean flow is the number of daily flow measurements divided by the sum of the reciprocals of the flows," and it restates it as it is the reciprocal of the mean of reciprocals.

The Department initially did not propose a definition for this term because the Commission had

indicated during the 1998 triennial review and deliberations that standard statistical terms should not be defined in the standards. However, during the Department's January meetings with interested groups, several persons recommended that a common reference be provided. In response, the Department selected the EPA Water Quality Standards Handbook, which is publicly available in hard copy and also electronically on the Internet.

Nonetheless, LANL has suggested that actual language from the Water Quality Standards Handbook be added. The Department supports this proposal on the condition that the definition be contained in Section 20.6.4.10, which is the section that would have the reference to the harmonic mean flow, and that's because in the public notification, we did not notify that there would be any changes to Section 7, which is where definitions would be contained.

If this is the case, we could recommend a definition be adopted in that section during the triennial review.

The Department's specification of the harmonic mean flow and the proposed reference to the EPA definition ensures that the application of water quality standards complies with federal requirements. Since

1992, EPA has developed a Section 304(a) criteria for cancer-causing pollutants using exposure assumptions which are best reflected by the harmonic mean flow.

Specifically, EPA's model for human health effects assumes long-term exposures to low concentrations. Recently, EPA amended its implementation procedures to require the use of harmonic mean flow for noncancer-causing pollutants as well. As a result, EPA now requires the use of harmonic mean flow to implement all human health criterion.

The Department's proposing to retain the existing flow value, the critical low flow, for all other criteria. This value is used to calculate the NPDES effluent limitations to ensure that discharges comply with the criteria during most flow regimes -- that is, during all flow regimes above a specified low point, the critical low flow.

The specification of this low point is important, because, without it, a discharge would have to comply with the applicable numeric criteria at the end of the pipe. The standard would become the effluent limit.

The current critical low flow is the 4Q3, the lowest four-day flow which has a return frequency of three years. The Commission adopted this value in 1991 in order to implement new aquatic life criteria for heavy

metals, which are a subset of the priority toxic pollutants listed pursuant to Section 307(a)(1) of the Clean Water Act.

Before 1991, the Commission had specified this low point, the critical low flow, as the 7Q10, the lowest consecutive seven-day flow which recurs once in a ten-year period.

The difference between the harmonic mean flow, the 4Q3 and the 7Q10 is illustrated by the graphs shown in Exhibit NMED 11, which is shown on the screen.

Generally speaking, for a given stream, the harmonic mean flow is higher than the 4Q3, and both are higher than the 7Q10.

Originally, EPA took their use of the harmonic mean flow from an article that was published in the Journal of Hydraulic Engineering, which gives more information on the harmonic mean flow. In here, they state flows for 60 different watersheds throughout the country, and in every single case, the harmonic mean flow is lower than the average. The shorter the term, the closer the two are together.

If you look at the average on the seven-day period, the two terms are no more than two percent apart. As the time length grows longer, the harmonic mean flow starts diverging from the average, but it's always less

than the average.

The graphs show these flows for two different streams. The first graph shown here represents data for the free-flowing Rio Chama at La Puente, which is near Tierra Amarilla. The flow shown for each day shows the average for all flows for that day from 1956 to 1997, as measured by USGS. The total average flow for all days in the entire period is 364 cfs. The harmonic mean flow is 62.6 cfs. The 4Q3 flow, which is used for all other standards now, is 17.5 cfs. The 7Q10 that we used to use is 7.4 cfs.

So you can see that the harmonic mean flow is a less stringent way of applying standards.

The second and third graphs present the data for the Rio Grande at Albuquerque. Since 1973, the flow of the Rio Grande at Albuquerque has been controlled by Cochiti Dam, dams on the Rio Chama, Willow Creek, Jemez River, Galisteo Creek, and also the irrigation diversion at Angostura. For this stretch of river, the total average flow from 1975 to 1999 is 1,489 cfs.

In order to get a clearer picture of the others, we have to enlarge that section that's there, and it shows the harmonic mean flow would be 161 cfs, the 4Q3 flow is down toward the bottom at 32.2 cfs, and the 7Q10 flow is right at the baseline at 7.8 cfs.

So the harmonic mean flow here, again, is a lot less stringent way of implementing these standards.

One recurring issue regarding the use of harmonic mean flow concerns the application of human health criteria to ephemeral waters. The Department's proposing to apply human health criteria for a small number of the priority toxic pollutants to ephemeral waters which are tributaries of those waters with existing, designated or attainable fishery uses.

Specifically, the Department seeks to prevent persistent toxic pollutants, such as dioxin, DDT, PCBs, and various heavy metals, from reaching waters which contain fisheries used by New Mexico residents.

In a moment, I'll explain the Department's rationale for this proposal. It's been pointed out that it's not possible to calculate the harmonic mean flow for ephemeral waters, and, therefore, it's not possible to apply the human health criteria to these waters except at the end-of-pipe basis.

LANL has proposed in these procedures using the modified harmonic mean formula currently used by the State of Texas, which accommodates ephemeral waters that have periods of zero flow. The original formula could not take zero flows because it has to have the reciprocal of the flow, which is a nondefined term.

The Department believes that LANL's proposal has merit and supports the use of this formula for those waters that are ephemeral.

Finally, San Juan Water Commission argues that the Department should have evaluated whether harmonic mean flow represents the long-term average flow on which the human health criteria are based and adopt a long-term average flow if it reflects the appropriate flow conditions.

EPA stated in the California Toxics Rule, which is their most recent promulgation of human health criteria, that it believes that the harmonic mean flow is the correct statistic to use in computing such design flows rather than any other averaging techniques. Since EPA has conducted extensive studies into this matter, the Department sees no reason to invest its resources and reinvent the wheel.

Q. Mr. Pierce, the Department has proposed a new subparagraph in Section 10 regarding the applicability of the human health criteria.

Can you please explain what the Department's proposal is?

A. Yes, I can.

The Department proposes this new section to identify the waters that are subject to the numeric

criteria for the protection of human health. Specifically, these criteria would apply to all waters with a designated, existing or attainable fishery use.

There is little dispute about the application of the criteria to this. This language was adopted at public meetings for our proposal.

The Department's proposed human health criteria were developed to protect humans consuming fish, so it's appropriate to apply these criteria to waters with a designated, existing or attainable fishery use. The Department also proposes to apply a small subset of these criteria to waters which are tributary to waters with a designated, existing or attainable fishery use. This application is more contentious, because some of these tributaries are ephemeral or have ephemeral reaches. Many of these waters may have aquatic organisms, but they do not generally have fish which are consumed by humans.

The Department believes that it's appropriate to apply the criteria for persistent toxic pollutants to these ephemeral waters in order to protect downstream waters which do have fish communities. As I previously stated, the purpose of the human health criteria is to protect human health from the consumption of fish with

toxic pollutants in their flesh.

For most of the toxic pollutants, this goal can be accomplished by protecting the water in which the fish live from direct discharges of these pollutants. These pollutants degrade into less toxic compounds in a relatively short period of time, a matter of days or weeks.

Other toxic pollutants are more persistent, or else they degrade to equally toxic components, such as DDT. These pollutants pose a substantial risk in the environment over a period of many lifetimes. In many cases, they adhere to sediments and are mobilized during runoff events and transported downstream to live waters. These pollutants are bioaccumulative. They accumulate in fish, which absorb them from the water and the aquatic organisms which they eat, who in turn have absorbed them from the water column and from the sediments. Over time, these pollutants bioaccumulate to concentrations which are dangerous to humans which consume the fish.

This problem is real and it exists currently in New Mexico. The table in Exhibit NMED 10 indicates high levels of PCBs and dioxin in ephemeral storm waters at Los Alamos National Laboratory. These data were collected by the NMED-DOE Oversight Bureau, and they were analyzed by the Access Analytical Laboratories in

Vancouver.

There also is evidence that these pollutants are being transported downstream into waters containing fish consumed by New Mexicans. Exhibit NMED 9 contains a February, 2002, data review which reveals high levels of PCBs and dioxin in fish that were caught in Cochiti Reservoir.

This is only an example, and it's not my intent to single out LANL. These are very hard-to-detect pollutants. They may be found in other locations of the state if these same precise sampling and analytical procedures, which are very expensive, are conducted. But the example illustrates a larger point. For persistent toxic pollutants in ephemeral waters, the most common control strategies in place do not work.

For persistent toxic pollutants, a different strategy is needed. To protect downstream fisheries, the pollutant load discharged to the ephemeral water must be controlled. To achieve this objective, the numeric criteria for persistent toxic pollutants must be applied to the tributary itself, even if it does not have fish or a designated fishery use.

Q. LANL opposes the applicability of human health criteria to ephemeral waters. What arguments does it make in this regard?

A. LANL argues that ephemeral waters do not contain fisheries, and that is true. However, the Department's proposal is designed to ensure that loads of certain highly persistent toxics do not reach fishery waters.

LANL argues that applying criteria to ephemeral waters is not the best way to protect the downstream uses. They talk about the Rio Grande, and if a domestic water supply use were designated, that every tributary upstream of that segment would be required to be designated as a domestic water supply. This is really a straw-man argument. Standards are set on upstream waters to protect downstream uses. Natural free-flowing streams have the ability to attenuate levels of pollutants. They clean themselves up over distance and time. That's why not all waters upstream from primary contact waters have to be designated as primary contact. In those cases, the standards that are in place in upstream waters do protect the primary contact use downstream. However, that would not be the case for these highly persistent subsets of contaminants. These will stay in the environment for generations and will bioaccumulate.

Under LANL's proposal, these persistent contaminants would not be regulated in ephemeral streams. The Department's proposal only applies to 15 -- the very

worst of the worst of the toxic chemicals -- to ephemeral tributaries. These substances persist in the environment and bioaccumulate to dangerous levels in fish. There is no good reason to release any of these 15 persistent toxic chemicals into the watersheds of the state.

LANL argues that existing approaches are effective. The current application of standards to effluent-dependent reaches only applies when discharges routinely reach classified waters downstream, and it excludes all those discharges which reach those classified waters during runoff events. This is a very large loophole in the standards.

The LANL proposal is a blank check for discharges which add loading of persistent toxics to waters of the state. Water flows downhill and it carries sediments with it, and the sediments -- the smallest sediments have the largest surface water area and tend to pick up the greatest number of those contaminants. It's these fine sediments that get moved most easily downstream.

Any of these persistent priority toxic pollutants that are allowed to enter ephemeral waters will move downstream over time. Allowing these contaminants to enter ephemeral waters is the same as allowing them to enter waters that have fish in them.

Q. Mr. Pierce, in its written testimony the San Juan Water Commission argues that the Department intends to apply the criteria to private waters.

What is the Department's response?

A. There is absolutely nothing in the Department's proposal that says this. Jim Davis did not say this during the public outreach meetings.

If the San Juan Water Commission believes that this was said, why did they not question this at that meeting at that time? The meetings were set up for the purpose of openly exchanging information in a non-confrontational situation and to arrive at the very best proposal for all parties.

Private waters are and will continue to be exempt under the New Mexico Water Quality Act. That's simply not a prerogative of the Surface Water Quality Bureau.

Q. Mr. Pierce, what method will the Department use to determine compliance with the human health standards?

A. The Department proposes to add this section in order to specify the method for determining compliance with human health criteria.

The single grab sample approach is consistent with the compliance method adopted by the Commission for

all the other numeric criteria, except for compliance with chronic aquatic life criteria, which is based on the arithmetic mean of analytical results using appropriate protocol.

Now, in practice, the Department doesn't make compliance determinations on fewer than two samples, even if the method does allow for a single grab sample. When the Department detects an exceedence of a numeric criteria in an analytical result, after all QA/QC requirements have been investigated and found to be in effect, it goes out and collects at least one second sample from the same location. Only if the Department confirms this exceedence in the second sample does it conclude that an exceedence has occurred. It doesn't even consider a violation at that point. For a full assessment of attainment of the use, our protocol requires seven sample results are needed, and this includes all the standards for which the Commission has specified that compliance is based on a single grab sample.

Q. Steve, let's move on to Section 12.F. This is the heart of the Department's proposal.

Could you please explain how the Department proposes to use the Section 304(a), recommended values that EPA has developed and as well the translation

mechanism, to derive such a criteria when the Commission has not adopted them?

A. Okay. The Department proposes to amend Section 12.F to establish a procedure for using new EPA Section 304(a) criteria for priority toxic pollutants to protect aquatic life and human health. The Department also proposes a procedure for deriving numeric criteria for those priority toxic pollutants when EPA has not published Section 304(a) recommendations.

The Department's proposal regarding human health criteria is new, but the proposed language regarding aquatic life criteria follows the existing Commission procedures and language in the standards. It's important to retain this procedure because new toxic pollutants are occasionally detected in our aquatic ecosystems.

EPA, the Department, the regulated community, the public, and the environment are served by the availability of a readily identifiable, Commission-approved procedure for calculating these numeric criteria. Without the procedure, the Department would have to request a hearing every time a new toxic pollutant is detected in ambient water, delaying protection of the environment, and taxing the resources of the Department and other interested persons.

I'm going to go through the Section 12.F paragraph by paragraph.

The first paragraph, we propose to amend paragraph one to clarify the general toxic standard, no toxics in toxic amounts, applies to all sources except natural causes.

Deletion of the term "attributable to discharges" is necessary to ensure the general toxic standard applies to the full range of activities which contribute toxic pollutants to state waters. Specifically, the word "discharge" substantially narrowed the scope of the standard. The state water quality standards do not define "discharge," but the EPA, at 40 CFR Section 122.2, excludes pollutants deposited in dry channels and upland areas which may be mobilized into state waters from this definition. The exception for natural causes was added to clarify the Department recognizes the concept of natural background for evaluating the conditions of state waters.

Finally, the Department proposes to amend paragraph one to clarify the general toxic standard applies to toxicity affecting humans, livestock and to other animals, as well as fish and other aquatic organisms.

The Department proposes to amend paragraph two

to establish the procedure be followed when the Section 900.M table, which we are proposing for inclusion in the back part of the standards, does not contain a human health criterion for a priority toxic pollutant.

First, under paragraph 2(a), the human health criteria would be the recommended human health criterion for the category "consumption of organisms only" published by the US Environmental Protection Agency pursuant to Section 304(a) of the Clean Water Act. Of particular importance, the procedure specifies the category of organisms only and the ten to the minus fifth risk level for cancer-causing pollutants.

The Department proposes the organisms only category because it believes these criteria adequately protect human health in New Mexico. EPA publishes two categories of recommended human health criteria. The first category is consumption of water and organisms together, and the second is the consumption of organisms only.

The difference between the categories is the exposure route. The first category assures that the public -- I'm sorry, assumes that the public is consuming raw, untreated surface water and consuming fish caught in that same water. Because conventional drinking water treatment methods can remove the priority toxic

pollutants that might be found in surface waters of New Mexico, the Department does not consider the criteria based on the consumption of untreated surface water is necessary to protect human health in New Mexico.

The second category assumes that the public is exposed only through the consumption of fish, and other aquatic organisms, if appropriate. It assumes that the public obtains drinking water from a source which meets the requirements of the Federal Safe Drinking Water Act, which would limit the level of these priority toxic pollutants.

The Department concludes that this second category of criteria would adequately protect public health in New Mexico.

The Department proposes the ten to the minus fifth risk level because, as I've said previously, it's consistent with existing Commission policy. In at least two places, the Commission has endorsed this risk level.

When EPA has not published a Section 304(a) recommended criteria, under paragraph 2(b), the criterion would be derived using the appropriate formulae specified in the Water Quality Management Plan -- the New Mexico Water Quality Standards Management Plan.

These formulae were published by EPA in October of 2000 and are included in NMED Exhibit 7.

EPA has stated that the states may adopt Section 304(a) recommended criteria or criteria which have been calculated according to this formulae. Accordingly, in the absence of a Section 304(a) criterion, these formulae provide a method for deriving valid criteria.

Q. Does the Department address Los Alamos National Laboratory's concern by including these formulae by reference in its proposal?

A. Yes.

LANL argues that the formula implementing translation procedure should be included in the CPP and proposes language for such a formula.

The Department agrees with the thrust of these comments and of this proposal. We've modified the proposal in the notice of intent to present technical testimony to include the formulae in the Water Quality Management Plan instead of the CPP. We feel that the Water Quality Management Plan is the appropriate document in which to include this formula. We would also include the formulae that EPA published in October of 2000, which they state are the only supported formulae to be used now. So there would be no need for the recommended. It's there.

These again are the formulae -- these are the

new formulae that were revised by EPA. The difference is fairly slight, but EPA has stated that when they published the new formulae that they wouldn't accept criteria derived after that point by the old formulae.

Q. What other requirement does paragraph 2(b) impose on the translation procedure?

A. Paragraph 2(b) also requires the use of data available on the IRIS database. This requirement ensures that the latest information concerning reference doses for noncancer-causing pollutants and cancer potency slopes for cancer-causing pollutants is used.

As John Montgomery explained, EPA publishes these values on IRIS only after extensive peer review, and these numbers don't jump around. They are based on 20 years of data that have been in IRIS, and so at the most, there are very, very slight changes when new studies come out.

In most cases, the criteria that would be developed using these formulae, from IRIS figures, wouldn't show any change to any significant level that would affect a standard.

The Department does not expect that EPA, as the NPDES permitting authority for New Mexico, will invoke this procedure very often. Currently, there are only 17 priority toxic pollutants for which human health criteria

have not been published. EPA may add more toxic pollutants to the priority list under its Section 307(a)(1) authority. The Department is not aware of any pending proposals. Even if the EPA added more pollutants, the procedure would only apply if EPA also did not adopt human health criteria for those pollutants.

It's important to note that this procedure takes advantage of the confluence between EPA regulations authorizing a narrative criterion when numeric criteria cannot be established and another EPA regulation requiring EPA, as the NPDES permitting authority, to derive criteria from a state regulation interpreting the narrative criteria.

In this case, the Commission has adopted a narrative toxic criterion in Section 12.F(1) which prohibits toxic pollutants in toxic amounts, and it's adopted a procedure in paragraph F.2(b) which tells the EPA how to derive criteria to achieve that standard when EPA Section 304(a) criteria are not available.

In the absence of the procedure in Section F.2(b), EPA would have to calculate its own criterion without any guidance from the state regarding the category of protection -- i.e., water plus organisms versus organisms only -- and the risk level. By dictating the procedure and these categories, the

Commission constrains EPA's discretion to calculate and impose numeric criteria not consistent with the Commission's policy and practice. In other words, the Commission gets to say how EPA will develop those permit limits.

Nevertheless, some persons have questioned whether the procedure would result in the adoption of criteria without Commission review and approval.

Q. What is the Department's response to those arguments?

A. In the Department's view, the risk is no greater under paragraph 2(b) than under any of the other paragraphs in 12.F. The Department also questions whether EPA's use of the procedure to develop a numeric criterion for developing NPDES permit effluent limits constitutes, quote, adoption, unquote, under state law.

The real argument here seems to be that the Water Quality Control Commission has seen not to be able to adopt narrative criteria, and this is not true. Adoption of narrative criteria and the translation procedures to translate those narrative criteria are well within the scope of the authority.

The Commission has already adopted a narrative criteria, no toxics in toxic amounts, and this standard

has to be translated by someone. The numeric criteria that's derived would be subsequently presented to the WQCC for their adoption only after public notice and public hearing and all full notification requirements.

EPA already uses a translator to derive criteria for the statement no toxics in toxic amounts. However, they use the risk levels that they deem to be the best for New Mexico.

The Commission has the choice of specifying the translation used. The proposed procedure only clarifies how the narrative standard is to be applied. It specifies the procedure and the formula. It directs EPA to interpret a narrative standard in a specific way, rather than allowing the EPA to interpret the narrative standard as it wishes. The translator makes this narrative standard more understandable and its application throughout waters of New Mexico more consistent.

The WQCC has the authority to clarify this narrative standard and is doing so after public notice and during a public hearing.

Q. Now, Mr. Pierce, you earlier said that the numeric criteria that's derived from these, subsequently adopted by the Commission after public notice and hearing, or would be offered to the Commission for such

adoption.

Are you actually referring to paragraph 2(c), which is the Department's response to this concern?

A. Yes. This concern was voiced during our public outreach activities.

One of the suggestions that came from Mr. Hernandez was to have the Department petition the Commission after any kind of standard -- to petition the Commission after any numeric criteria have been calculated by EPA and implemented into any kind of effluent limits.

The section proposed as 2(c) would require the Department to do so within 90 days of the issuance of a final NPDES permit by EPA which contains numeric criteria that were calculated under paragraph 2(b).

So if EPA uses paragraph 2(b), that NPDES permit, we would then step forward within 90 days and request a hearing.

The petition would propose the adoption of the new criteria and would afford interested persons an opportunity for comment and the Commission an opportunity to thoroughly review and then to approve or disapprove the new criterion during a public hearing.

Q. Mr. Pierce, the Department proposed this new paragraph (c) in its notice of intent, is that correct?

A. Yes. This was included in the Department's notice of intent to present technical testimony filed on February 21st.

Q. Let's move on to paragraphs three and four of the Department's proposal. There are no changes in paragraph five, as I understand it, so why don't you just address three and four at this point.

A. Okay. Paragraph three would reflect the existing provisions that are in the standards right now for determining chronic criteria for the protection of aquatic life.

Only minor modifications have been made to the original language, primarily to parallel the language and format of paragraph two. The original language was moved in Section F, the no toxics in toxic amounts, which was at the end of Section F, and so in order to put it at this particular place in Section F, we had to strike it all out and show it as new language at this place in Section F.

As you may have remembered, over the last three or four years, Section F went from a very small paragraph to about a page long.

The Department proposes to amend paragraph four to specify the acute aquatic life criterion published by EPA may be used under the New Mexico Water Quality

Standards. This approach parallels the paragraph 3(a) for chronic aquatic life criteria, except for the calculation method that is afforded to the chronic criteria.

Although chronic criteria are almost always much lower than the acute criteria, and, therefore, are more protective, acute criteria may be important to determine the concentration of a toxic pollutant that would be immediately toxic to aquatic life. For example, in storm water runoff for which it may only be possible to get a single grab sample, but which could have very toxic impacts to the aquatic life.

Paragraph five just has minor changes.

Q. Those are simply -- I said no changes earlier, but those changes are very minor and simply intended to accommodate the changes that occur before it?

A. That is correct.

Q. Nothing substantive?

A. That's right.

Q. We've now reached Section 900, which is the last big section which changes -- in which changes are proposed.

Let's start with the cold-water fishery section. The Department has proposed some changes here. Would you explain them?

A. The Department proposes to amend this section to update references and to identify the specific parts of the new criterion table in Section 900.M which apply to this designated use, including the human health criteria.

The new heading for the criteria table in Section 900.M is "Aquatic Life." The term has caused great confusion, because it's not clear how aquatic life is related to the designated use of fisheries. In fact, the Department is not proposing any change in the designated uses. The designated uses refer to aquatic life, which is a shorthand term for the column in the table containing most of the numeric criteria.

The general standards refer to aquatic life because this is the EPA term of art that's been used ever since the Clean Water Act was first passed for the type of criteria used by New Mexico for the fishery designated uses.

When the Commission adopted numeric acute and chronic criteria to protect the fishery designated uses, it used EPA's aquatic life criteria and was fulfilling a federal requirement to protect aquatic life uses.

Q. Mr. Pierce, you mentioned that the use of the term aquatic life was confusing to some people. Can you explain why?

A. Some confusion may be caused by a misperception about the meaning of the term "fisheries." In some circles, the term has been read narrowly to exclude all other aquatic organisms. Such reading is contrary to the Clean Water Act, which requires the protection of fish and other aquatic organisms. It is also contrary to the Commission's history of designated uses.

In 1973, the Commission selected the term "fisheries" to identify the designated use commonly referred to by EPA as aquatic life. New Mexico's fishery designated uses are designed to protect both fish communities and the other aquatic organisms in a particular type of ecosystem. For instance, a cold-water fishery designated use was adapted from the 1967 water quality standards, in which these waters were called trout-producing waters, but the intent was to protect the entire aquatic life of such waters.

The warm-water fishery designated uses evolved from the earlier warm-water fish-producing waters designated use, which was an aquatic life use.

Q. There are some changes to this section on domestic water supply. I think these are accurately reflected in Mr. Pierce's written testimony, and none of them, as I understand it, are controversial, so we'll skip them for a moment and come back to them if we need

to on rebuttal, if necessary.

The same applies, I think, to high-quality cold-water fishery, in which the Department proposes to strike the criterion for total organic carbon. We'll skip that for the moment and move on to irrigation.

Mr. Pierce, what changes are proposed in the designated use of irrigation?

A. The Department proposes changes to this section to include irrigation storage in the title and direct users to the new criteria table in Section 900.M where the criteria that had been deleted here in this paragraph have been moved.

The title change is intended to clarify the long-standing assumption that these criteria apply to waters used directly for irrigation, but for the waters that are stored for that use as well.

The Department has consistently applied these criteria to irrigation storage designated uses when conducting water quality surveys, and irrigation storage facilities, reservoirs, and these are already subject to the far more stringent numeric criteria for fishery designated uses.

Accordingly, the title change does not substantively change the designated use. The relocated criteria values have not changed, but the units have been

converted from milligrams per liter to micrograms per liter to achieve consistency in the table. The one exception is selenium. Selenium will remain in this section because it requires explanatory information, and under the NMAC 2.0 rules, you can have no footnotes to any tables. They don't like tables themselves, you have to kind to beg them to put a table in, but they draw the line at footnotes.

Finally, the Commission should consider converting the selenium criteria that remain in this particular paragraph to micrograms per liter just to ensure consistency, but we did not indicate that change.

Q. Mr. Pierce, Los Alamos National Laboratories suggested the term "irrigation storage" should be defined.

What is your response?

A. Well, it appears to me that the term is pretty self-evident. "Irrigation storage" is the storage of water for irrigation. The definitions section of the standards again was not included in our public notice, and probably cannot be legally modified at this time, although I'm not one to speak on whether or not that would be legal.

Also, LANL has not proposed a definition for

this term at this time. In that light, these proposals could be brought up at the upcoming triennial review when all sections may be open for modification.

Q. Now, Mr. Pierce, I think we'll skip right through marginal cold-water fishery, warm-water fishery and limited warm-water fishery, as well as Section 900.J, livestock watering and wildlife habitat.

Those changes, as far as I'm aware, are not controversial and we can address any concerns people have later in this hearing.

Why don't we move on to Section 900.M. This is the table to which you refer. It contains many of the numeric -- or most of the numeric criteria which the Department is proposing. Let me rephrase that, it includes all of the numeric criteria which the Department is proposing. It includes many of the criteria from other parts of the Section 900.

Can you describe for the Commission the table and how it's organized?

A. Yes. This table, which we're calling Section M, is a table of all numeric criteria for priority toxic pollutants, except for those pollutants for specific uses which requires some type of explanation, but generally we would require a footnote to make it more understandable.

In those situations, this table includes a

reference to the subsection where the criteria and explanation can be found. This reference responds to LANL's concern that a person using the table might overlook some criteria applicable to a designated use.

The table contains most of the criteria for the priority toxic pollutants for easier reference. For each pollutant, the table identifies the Chemical Abstract System, shorthand is CAS, registry number assigned by the American Chemical Society. This doesn't make a lot of difference in a term such as mercury, but when you get to some of the long organic chemicals that can be stated by any of 150 different names, the CAS number becomes fairly important. Even in EPA documents, in some cases, they have recommended criteria under one name for one of these chemicals and IRIS has it under a different name.

MR. AMES: Steve, can you pause for us for a moment?

Is there some difficulty finding the table? I notice some Commissioners looking around frantically.

MS. BRANDVOLD: It's not in the testimony, but it is in Exhibit 20.

MR. AMES: Yes. It is in the Department's original proposal of November 29th and the revised one dated February 1st. It's toward the very end. It is at the very end, I believe. We did not include the table in

our written testimony itself.

MR. PIERCE: I have some extras.

MR. AMES: Mr. Secretary, are you looking for your copy?

MR. MAGGIORE: No, I'm looking for the adapter for my laptop. I've only got it for about ten more seconds.

MR. AMES: Okay.

MS. BRANDVOLD: Here, you can look at this copy.

MR. KEYES: There is no security on the Secretary's laptop.

MR. PIERCE: There are more copies of the February 1st proposal.

MR. AMES: Does anyone need a copy of our proposal so they can locate the table?

MR. JOHNSON: Yes. It's somewhere in this pile of stuff.

MR. AMES: Anybody?

MS. HUGHES: Give me one. Thanks.

MR. AMES: Okay.

MS. BRANDVOLD: Okay.

MR. PIERCE: If everybody can see the table now.

MR. KEYES: I don't see how anybody caught that

one mistake.

MR. AMES: There is another one we'll get to in a second.

MR. PIERCE: The table is composed of two alphabetical lists, and the way we propose it, the first alphabetical list is comprised of the first 24 priority toxic pollutants. They are all contained on the first page of these tables.

These pollutants are the inorganic compounds, and these inorganic compounds have the greatest number of criteria across all of the designated uses. For instance, the metal chromium has five numeric criteria for four different designated uses. By moving all of these pollutants to the first page of the table, the Department sought to make it easier to find these commonly applicable criteria. The remainder of the table, the next three pages, contains criteria for those organic priority toxic pollutants. The table also expresses all criteria in micrograms per liter. To achieve this consistency, the Department has proposed to convert the criteria for domestic water supply, irrigation and livestock watering designated uses from their current milligrams per liter to micrograms per liter. In converting these units, the Department did not intend to change any values. Any change in values that

might be detected would be corrected immediately.

The table contains all the new priority toxic pollutant criteria being proposed today. Most of the criteria, 92, are for the protection of human health, through the fish consumption pathway, while 21 are for the fishery designated uses. In the table, the fishery designated uses appear under the title "Aquatic Life," as they do under EPA recommended criteria tables.

The table contains 11 new acute and 10 new chronic criteria for priority toxic pollutants for the fishery designated uses.

The remainder of the new criteria are designated to protect human health based on fish consumption. In all, new human health criteria for 92 priority toxic pollutants are proposed. Of these 92 pollutants, the Department proposes to designate 56 of them as either carcinogens or persistent. The last column in the table indicates whether the pollutant is carcinogenic by a C or persistent by a P. Some pollutants are both carcinogenic and persistent.

Q. Mr. Pierce, Los Alamos National Laboratories suggested the term "human health" be defined. What is your response to that suggestion?

A. Here again, the term seems to be self-evident, and the Commission had indicated that self-evident

matters didn't need to be defined. However, it's been used at the federal level for about 25 years.

LANL has not proposed a definition at this time. If a definition appears warranted, it can certainly be proposed during the upcoming triennial review.

Q. What is the Department's basis for identifying certain pollutants as carcinogenic?

A. The Department based its determination of carcinogenicity on designations included in the 1999 EPA National Recommended Criteria, which is NMED Exhibit 5.

The designation is important because different formulae are used to derive human health criteria for carcinogens and noncarcinogens under Section 12.F. By providing this information in the table, the Department allows interested persons to use the appropriate formula to calculate criteria for their own purposes.

The Department based its determination of persistence on the EPA's identification of pollutants which are persistent, bioaccumulative and toxic, and which are the subject of an enhanced effort by EPA to eliminate all occurrences of these from the environment. This is Exhibit NMED 8.

The list of persistent toxic pollutants includes aldrin/dieldrin, benzopyrene, chlordane, DDT,

hexachlorobenzene, alkyl-lead, mercury, mirex, octachlorostyrene, PCBs, dioxins and furans, toxaphenes, and probably a few more that I couldn't even pronounce right now.

The designation of any new persistent toxic pollutants would require a hearing and rule-making before the Commission.

Q. Before we talk about the persistent toxics some more, is there a change to the list of carcinogenic pollutants identified by the Department?

A. Yes.

It was pointed out by LANL that for antimony, we had in our table a C and a P. It should have just been P; it was not a C.

Once again, it was not our intention to change any of the recommended designations that EPA had supplied in the recommended criteria. We thank them for finding that, and we do propose to change that.

Q. Now, in its testimony, Los Alamos National Laboratory suggested that there are some discrepancies between the Department's list of persistent toxic pollutants and the list published by the Environmental Protection Agency for the Great Lakes and Michigan.

What is the Department's response to that testimony?

A. We based our list of persistent toxics on the EPA list of toxics that's published on the Internet and is included as Exhibit Number 8. This is the list of priority PBTs, persistent, bioaccumulative and toxic compounds, currently being addressed by the PBT initiative by the EPA.

The New Mexico list also includes the toxic metals, which by their very nature are persistent.

The EPA Great Lakes Initiative list differs from the official EPA recommended list. This slide shows the GLI list. It might be very hard for you to see, and it's hard to see, but a number of these we put a black line through, and they indicate those that are also found on the Commission's list.

That's the next slide.

Then, also, delta-hexachlorohexane, which is indicated by a red line on the next slide, has no EPA recommended criterion at this time. Mercury, in the next slide, is indicated by a green line, and it's not been proposed, for reasons that I'll explain in a minute.

Q. Go ahead.

A. The three substances indicated with a yellow line, in the next slide, are not contained in the IRIS database and are not priority toxic pollutants. These were selected based on known problems in the Great Lakes

area.

The substances indicated by blue lines, which includes the rest of them on the GLI list, are nonpriority toxic pollutants, and New Mexico is not required to adopt criteria for these compounds.

That covers all the criteria that are in the Great Lakes Initiative list.

Q. Now, this is a little different -- that's much better. Before it was almost impossible to read.

Does the Commission want a summation of the differences between the two lists? We can perhaps do that.

Steve, do you think you can point to -- identify which pollutants on the GLI list are not included on ours, or vice versa, or would you need a moment to do that?

A. Okay. Which ones are not?

Q. Why don't we -- let's put that aside for a minute. I don't want to belabor the point. We'll go back and try and come up with an oral presentation that will supplement this, because this is a little difficult to read. We apologize. Let's just move on.

Mr. Pierce, where did the Department get the numeric criteria in table 900.M?

A. All new recommended numeric criteria in the

table were taken from the EPA 304(a) recommended values for priority toxic pollutants, with the exception of the recommended criterion for arsenic. EPA published these values in the National Recommended Water Quality Criteria, Corrected Version, that was published in April, 1999, and is NMED Exhibit 5.

There are many similarities between these values and the human health criteria for organisms only imposed by federal promulgation in the National Toxics Rule and the California Toxics Rules.

Q. Has EPA indicated whether it would approve these criteria?

A. EPA has indicated that it would approve these criteria. However, I note for the record that EPA is in the process of revising the criteria for human health based on a methodology that they published in October of 2000. This methodology takes into account the scientific knowledge gained since EPA developed the 1980 methodology on which the current criteria are based. In particular, the new methodology uses a bioaccumulation factor, a BAF, rather than the bioconcentration factor, BCF, that was used earlier.

The BAF considers the entire exposure of an organism to the toxic pollutant from water, sediment and food. However, EPA has not yet published peer review BAF

values for the priority toxic pollutants and has not said when it will do so, so it's not possible at this time, using the methodology, to calculate numeric criteria.

Q. Mr. Pierce, you said the Department deviated from EPA's Section 304(a) recommended values for one pollutant and you also said that the Department has not proposed a criterion for another pollutant.

Let's start with the deviation. Which pollutant are we referring to and what is the reason for the deviation?

A. The Department reviewed EPA's Section 304(a) recommended value for arsenic, and we believe that EPA's recommended value of 1.4 micrograms per liter, which is what their value would be expressed at ten to the minus fifth, is unreasonably stringent in light of natural background levels in New Mexico, which generally range from three to five and can at times be much higher.

On the other hand, the Department believes that Region 6's alternate recommendation of 20.5 micrograms per liter at ten to the minus sixth, which would be translated to 205 micrograms per liter at ten to the minus fifth, is not adequate to protect human health and would probably be disapproved by EPA.

Given the range between these EPA recommended values, 1.4 all the way up to 205, the Department sought

to derive a more appropriate criteria for arsenic for New Mexico. A recent federal study provided the basis for the Department's proposed criterion.

In 1997, USGS published a study of arsenic and other metals in the Rio Grande in the vicinity of Albuquerque. The study, conducted in conjunction with EPA, NMED, Isleta Pueblo, the City of Albuquerque, yielded some numbers that could be used to calculate an arsenic criteria.

The Department believes that this criterion protects human health and is realistic for New Mexico waters. The calculation uses a New Mexico-specific derived BAF for arsenic and the percentage of inorganic-to-total arsenic in fish tissue, 65 percent, which accounts for the toxic form of arsenic. Most arsenic criteria are developed to measure total arsenic because inorganic arsenic, the toxic form, is difficult and very expensive to detect through laboratory processes.

Q. Does the Department have any -- well, first of all, how much did this federal study cost?

A. The federal study went about $300,000.

Q. Is the Department aware of any similar studies for other pollutants in New Mexico -- other toxic pollutants and priority toxic pollutants, specifically,

in New Mexico?

A. No.

Q. The Department has not proposed one numeric criteria, you said earlier. Which metals or which pollutant is that?

A. That pollutant would be mercury. The Department has not proposed a numeric human health criterion for mercury. At this time it's simply not possible to do so.

On January 8th of 2001, EPA withdrew all Section 304(a) recommended human health criteria applied to the water column for mercury. In its place, EPA substituted a fish-tissue-based criterion that would require the calculation of watershed specific criteria.

To implement the standard, EPA stated that it would publish a guidance before the end of 2001. However, no guidance has been published at the time of this hearing. My staff says that it will be impossible at this time to implement that mercury criterion without the implementation guidance.

When EPA publishes the guidance, the Department will review the propriety of recommending a new criterion for mercury.

EPA's failure to publish the implementation guidance for its new criterion does not leave the state

without protection for mercury. The Commission adopted a chronic mercury criterion for aquatic life of 0.012 micrograms per liter in 1991. This was intended, at that time, to protect humans consuming fish in New Mexico. In other words, the Commission did adopt a human health criterion, but under a different label.

EPA has informed us that this criterion complies with federal requirements that were in place at that time, since the value is based on then-current EPA recommendations that were adopted to protect human health, and it was approved at that time by EPA. In other words, the water quality standards already contain the criterion to protect human health from the bioaccumulative effects of mercury in fish.

Q. Now, for the last question of Mr. Pierce.

How does the surface water quality in New Mexico compare to the Department's proposed human health criteria?

A. At this point, I'd like to describe how current water quality compares with our proposed criteria priority pollutants.

The data which I will present -- it's slide 79 -- are contained in the table labeled NMED 10. This table compares the Department's proposed human health criterion to information obtained from Section 308

effluent monitoring reports and ambient data collected by the Department and Los Alamos National Laboratory for all priority toxic pollutants detected in effluents or ambient water in New Mexico.

In all, 23 priority toxic pollutants are listed. 20 pollutants were found in effluent discharges from municipal wastewater treatment facilities. These were the data that the Commission and the Department had a long battle with the EPA to obtain during most of 2001.

The remaining three pollutants, gamma-BHC, PCBs and dioxin, were detected in ambient waters in New Mexico. For each of the 23 pollutants, the table identifies the Department's proposed criterion, the number of effluents containing that pollutant, the range of concentrations found in those effluents, the location of the highest concentration and the date of the sampling for the highest concentration, and then finally the magnitude of this concentration as a percentage relative to the Department's proposed criterion, whereas the same figure as the Department's criterion would be a hundred percent.

The table shows that most of the priority toxic pollutants detected currently in New Mexico are a very small fraction of the Department's proposed criterion. In fact, the majority, 13 out of 23 of these, are only a

fraction of one percent of the proposed criterion.

On the other hand, six priority toxic pollutants have been detected at levels which exceed the criterion. Arsenic was detected at 11 facilities, with the highest concentration in the effluent discharge at Jemez Springs, where the concentration was 364 percent of the proposed criterion. Two pesticides, chlordane and DDT, were detected in the effluent discharge at Cuba at concentrations greater than 40 times the proposed criteria.

Two persistent priority toxic pollutants, PCBs and dioxin, were detected at Los Alamos National Laboratory in ambient storm waters at concentrations that are hundreds of times higher than the proposed criterion. Thallium, a heavy metal, was detected in an effluent discharge from Los Alamos Bayo wastewater treatment facility at a level that's 190 percent of the proposed criterion.

It's important to note that the proposed human health criteria for ambient water quality -- are for ambient water quality and not effluent limits. So even though we're showing effluent data as a percentage of the standard, that would not be a direct relationship, because the standard would not apply to effluents, it would apply to the ambient waters after a dilution

factor.

The NPDES permittee might exceed the ambient water quality standard for a priority toxic pollutant in its effluent as long as the resulting in-stream concentration does not exceed the criteria. This in-stream concentration is a calculated value, taking into account ambient concentrations of the pollution, available dilution from the critical low flow, and other factors.

In the case of priority toxic pollutants, NPDES effluent limits would be calculated based on the harmonic mean flow dilution. For example, tetrachloroethylene, one of the priority toxic pollutants, was detected in the effluent discharge at Farmington's wastewater treatment facility in samples collected by Farmington at concentrations of 12 micrograms per liter. This exceeds EPA's Section 304(a) criteria at a ten to the minus sixth risk level, and, therefore, an effluent limitation would be required if the effluent caused a violation of the in-stream concentration. By comparison, the Farmington effluent discharge of tetrachloroethylene is only 13.6 percent of the Department's proposed numeric criterion and would not require an effluent limit under the Department's proposal.

That concludes my proposed testimony.

MR. AMES: Thank you, Mr. Pierce.

The Department has about 20 more minutes of testimony, ten minutes for Mr. Saums and ten minutes for Dr. Davis.

What is the Commission's pleasure?

MR. MAGGIORE: Commissioners, I suggest we get through the direct testimony and then we can decide if we want to go straight into cross or take a break.

Does that sound okay?

Please proceed, Mr. Ames.

MR. AMES: Okay.

GLENN SAUMS

after having been first duly sworn under oath, was questioned and testified as follows:

DIRECT EXAMINATION

BY MR. AMES:

Q. Mr. Saums, please state your full name for the record.

A. My name is Glenn Saums, S-a-u-m-s.

Q. Where do you work, Mr. Saums?

A. I work for the Surface Water Quality Bureau of the Environment Department.

Q. What do you do there?

A. I'm the program manager of the Point Source Regulation Section.

Q. How long have you done that?
A. I've been program manager of the section since 1985.
Q. What are your responsibilities there?
A. My responsibilities include preparing certifications of NPDES permits, under Section 401 of the Clean Water Act, and reviewing permits. Part of that review is to ensure that the permits are protective of state water quality standards and are consistent with the appropriate requirements of state law.
Q. Perhaps a little bit closer.
What is the subject of your testimony, Mr. Saums?
A. The subject of my testimony today will be a discussion of the EPA's approach for calculating numeric effluent limits for priority pollutants in NPDES permits in New Mexico, and the effect of the Department's modified petition on this approach.
Just for clarification and reminder, NPDES stands for National Pollutant Discharge Elimination System, which is the permitting program under the federal Clean Water Act.
Q. Let's move on to the legal framework.
How does EPA regulate toxic pollutants in NPDES permits?

A. Currently, Region 6 of the EPA must prepare the NPDES permits in accordance with all requirements of federal law, regulations, as well as EPA policy and guidelines.

To accomplish the Clean Water Act's goal of no discharge of toxic pollutants in toxic amounts, which was mentioned earlier in testimony, the EPA published a national policy which is applicable to NPDES permits being issued today.

The policy ensures that NPDES permits protect state narrative criteria for toxic pollutants, as well as chemical-specific numeric criteria.

Five years after EPA adopted that policy, they adopted regulations to implement this policy. In 40 CFR, Section 122.44(d)(1), the EPA required all permitting authorities to evaluate each NPDES-regulated discharge for the potential to exceed state narrative criteria for a toxic pollutant. You can refer to NMED Exhibit 3.

Discharges which might exceed these narrative criteria must have effluent limitations imposed in their NPDES permits. These effluent limitations should be chemical specific, but if the permitting authority determines that such limits are not sufficient, it must also impose effluent limitations based on whole effluent toxicity, also known as biomonitoring.

Q. Mr. Saums, these regulations established a process for translating state narrative criteria for toxic pollutants into chemical-specific numeric criteria, as necessary to evaluate discharges and write limits.

What are the four approaches that this regulation authorized for doing that?

A. I believe the four approaches are up on the slide being projected.

The first approach is to use the proposed state criterion or use a proposed state criterion.

The second approach would be to derive the criterion from an explicit state policy or regulation interpreting the narrative criterion.

The third option would be to use EPA's Section -- Clean Water Act Section 304(a) criteria for priority pollutants.

Last, the fourth option, would be the utilization of an indicator or surrogate parameter for monitoring, subject to several conditions which are stated in the regulation, which include reopening the permit if the monitoring no longer satisfies the narrative criterion.

Q. Mr. Saums, which approach has Region 6 adopted?

A. The EPA has described, in 40 CFR, 122.44(d)(1) --

Q. I think you can skip by that for the moment and just move on and describe the procedure that EPA Region 6 has adopted under this regulation.

A. Okay. Under this regulation, EPA has been reviewing NPDES permits on the basis of the national criteria of the -- as expressed in the National Toxics Rule. The EPA has expressed its intent to rely on Section 304(a) criteria when the state has not adopted a numeric criterion for the toxic pollutants or expressed a policy choice regarding derivation of the applicable values.

Region 6 also prohibited any regulated discharge which could endanger a drinking water supply, cause aquatic bioaccumulation which threatens human health, causes in-stream acute or chronic toxicity, causes a violation of a numeric water quality criterion.

The EPA Region 6, in order to accomplish these objectives, has stated that it would identify and address sources which may exceed the EPA water quality criteria for human health protection.

Q. What risk level is Region 6 using now to evaluate effluent discharges in New Mexico?

A. Currently, and for a number of years, the EPA has used the ten to the minus sixth risk level for carcinogenic pollutants.

Q. And that's applied to the EPA's Section 304 recommended values, correct?

A. That is correct.

Q. So give us a little more detail how EPA has actually implemented this approach for NPDES permits, some specific examples to put this in context.

A. EPA Region 6 has implemented the approach consistently in New Mexico. Between 1999 and the year 2001, Region 6 proposed to issue or reissue approximately 100 NPDES permits in New Mexico.

In the fact sheets that accompany these proposed permits, Region 6 stated that the criteria for the National Toxics Rule, which are identical to the Section 304(a) criteria, were used to evaluate the effluent discharge.

Region 6 also stated that it evaluated cancer-causing pollutants at the ten to the minus sixth risk level. In the majority of cases, there was no effect or result to the human health stream -- that is, no additional requirements were added to a permit.

For two NPDES permits, this practice could have resulted in more stringent effluent limitations. For example, in the case of Molycorp, Region 6 found a reasonable potential that the discharge would exceed the Section 304(a) criterion for arsenic, but ultimately the

more stringent technology-based effluent limitation was imposed in the permit.

In the case of the City of Roswell, Region 6 also found a reasonable potential that the discharge might exceed a 304(a) criterion for mercury, but later obtained additional data which controverted this finding.

The matter is still not settled with regard to a third NPDES permit. In this case, which is the case of the City of Rio Rancho -- in that case, Region 6 found a reasonable potential that the discharge would exceed the Section 304(a) criteria for pollutant, but the permit -- since the permit has not been issued at this time, it's unresolved, but it appears at this time, also, that it's likely that the issue will be resolved without the imposition of an effluent limitation based on the Section 304(a) criteria.

At this point in time, Region 6 has not imposed an effluent limitation in an NPDES permit based on Section 304(a) criteria using the ten to the minus sixth risk level; however, the possibility that that could happen concerns NPDES permittees who recognize the Commission has indicated a preference in previous actions for a lower risk level -- that is, ten to the minus fifth.

NMED Exhibit 74

Q. Now, Mr. Glenn, you've said that EPA Region 6 uses the ten to the minus sixth risk level for carcinogens.

Does Region 6 also use the harmonic mean flow?

A. Yes, they do.

Q. What effect will the Department's proposal have on EPA's current practice?

A. The EPA would begin to evaluate NPDES permits -- NPDES-regulated discharges differently if the Commission adopts the Department's proposal. That is that they would cease using their protocol and start using the Commission's.

First, the Department's proposed numeric criteria for priority toxic pollutants uses a risk level of carcinogens one order of magnitude less stringent than the EPA.

Second, the Department's proposal establishes a procedure for directing the EPA how to select or derive a numeric criterion in the absence of a value in the state water quality standards. Please refer to Section 20.6.4.12.F.2 of the water quality standards.

This procedure ensures that the EPA will use a consistent approach to selecting or deriving any numeric criteria for priority pollutant toxic -- priority toxic pollutants in the absence of approved values and is

expressly authorized by 40 CFR 122.44(d)(1)(vi), which also requires the EPA to select or derive missing criteria from Section 304(a) recommended criteria or a regulation interpreting the narrative criteria. Please refer to NMED Exhibit 4.

MR. AMES: Thank you, Mr. Saums.

Now, we will conclude with Dr. Davis.

JAMES DAVIS

after having been previously duly sworn under oath, was questioned and testified further as follows:

FURTHER DIRECT EXAMINATION

BY MR. AMES:

Q. Dr. Davis, what will be the effect of the numeric criteria on the TMDL program?

A. Minor, at best.

As the Commission knows, Section 303(d) of the Clean Water Act requires that the state survey state waters, anything that is found to be not in compliance with applicable standards is listed, and then a TMDL is developed.

As Mr. Pierce indicated in his testimony, we've been doing this on a routine basis. We simply don't think that this will have much of an impact on 303 lists, nor on the TMDL program.

Q. What effect will the Department's proposed

numeric criteria have on nonpoint sources?

A. We will survey all state waters regardless of source of pollution, as is our normal and current practice.

Mr. Pierce, in his testimony, indicated that we propose to delete the clause "attributable to discharges" from Section 12.F of the standards. Accordingly, these -- these -- I'm multi-tasking, excuse me -- these -- and I'm not doing it very well -- these criteria would apply to those waters, and we would -- we would survey them for the purpose of determining whether or not they are in compliance with these criteria.

It makes no distinction between point sources or nonpoint sources.

Q. And, finally, could you please sum up the Department's proposal one last time so it's fresh in the Commission's mind?

A. That's the slide that is currently up. We are asking -- we are proposing that numeric criteria for priority toxic pollutants be adopted, they consist primarily of numeric criteria for the protection of human health.

Again, to reiterate, this addresses the last pending issue for completion in the triennial review initiated in 1997. Specifically, as the slide indicates,

we propose 11 acute and 10 chronic numeric criteria for priority toxic pollutants to protect various fisheries designated uses and 92 numeric criteria for priority toxic pollutants to protect human health.

We propose a procedure for selecting and deriving numeric criteria when there are no such criteria in the water quality standards and a method of determining compliance.

We're also proposing to apply these human health criteria to waters with existing, designated or attainable fishery use and their tributaries, as explained by Mr. Pierce in his testimony.

Today, we've provided to the Water Quality Control Commission information that is both necessary and sufficient to support the decision to adopt these criteria.

MR. AMES: Thank you, Dr. Davis.

That concludes the Department's direct testimony.

I would now move the admission of the Department's exhibits, NMED 1 through 21, as well as the PowerPoint presentation, which is mostly for demonstrative purposes, but I'd move its admission now, too.

MR. MAGGIORE: Any objections for admission of

Environment Department Exhibits 1 through 21, and I guess we can go ahead and label the PowerPoint presentation Exhibit 22?

MR. AMES: Please.

Thank you.

MR. MAGGIORE: Can you take care of labeling that exhibit, Carolyn?

Seeing no objections, those exhibits have been entered.

(NMED Exhibits 1 through 22 admitted.)

MR. MAGGIORE: Thank you, Mr. Ames.

MR. AMES: Thank you, Mr. Chairman. That concludes the Department's case in chief.

MR. MAGGIORE: Commissioners, do we want to proceed with cross? Do we want to take a five-minute break? Do you want to take a supper break? What's the pleasure of the Commission?

MR. GLASS: At least a five-minute break.

MR. MAGGIORE: Five minutes for right now. Let's do a five-minute leg stretch and we'll move into cross.

(Recess held.)

MR. MAGGIORE: It's about 5:35. We're back on the record.

We will proceed with cross-examination of the

Department's witnesses.

I'll ask the Commissioners first, any cross-examination of the witnesses?

Do you wish to be crossed as a panel?

MR. AMES: Please.

MR. MAGGIORE: Okay.

MS. BRANDVOLD: This would be for whoever can answer, but adding all of these extra chemicals onto the list, what does that do to a dischargers' costs?

Does that increase their costs, or are those covered already in, say, a biomonitoring?

MR. SAUMS: Currently, EPA is -- when they are reissuing NPDES permits, they require -- they require the applicant to scan their effluent by sampling. So they are already sampling for all of these pollutants.

When EPA, we call it, screens the effluent against the standards, they only develop effluent limitations for those parameters for which there is a potential exceedence of a water quality standard.

So if for pollutant A, they screen it, and they determine that there is no reasonable potential that a water quality standard -- any water quality standard, whether it's human health based, or some other use -- if there is no reasonable potential, there is no effluent limitation.

Conversely, if there is a reasonable potential, then they would write an effluent limit, but since EPA is already scanning all effluent discharges against their human health criteria, our adoption of the same number of parameters is --

MS. BRANDVOLD: Doesn't matter?

MR. SAUMS: -- it comes out equal.

MS. BRANDVOLD: Thank you.

MR. GLASS: Except that, if I might --

MR. MAGGIORE: Commissioner Glass.

MR. GLASS: -- if I might add to that, in the process of obtaining an NPDES permit, there is a certain amount of effluent monitoring that has to be assembled by the municipality or dischargers, so to speak.

With this additional list of chemicals, is that cost going to increase? I mean, these are not inexpensive chemicals to test for.

So on whatever cycle it is, you know, ideally five years, more like 15 years, but, whatever, there is a time period during which you do have to possibly spend more money to do it.

MR. SAUMS: That's correct.

The EPA has already been asking permittees to run these pollutant scans as part of their reapplication. So since they are already doing that, and then they are

taking that data from those scans and running it against their numbers, they would continue to do that process, so it's not an increase, it would remain constant with what they are doing now in terms of asking for the data in advance.

Dr. Davis was just refreshing my memory that where there possibly was an increase is where there are now very few NPDES permits that are extremely old in terms of their expiration date, such as the City of Bernalillo, which was last issued by the EPA in 1988, and so there might be an increase for them because they haven't had a permit reissued in a long time.

There are other administrative and legal reasons that that's not happened, which are kind of outside of today's hearing.

Right now, the percentage of NPDES permits that are current has increased dramatically -- I don't have the numbers at my fingertips, I apologize for that, but EPA has, in the last three years, worked very diligently with the Department to update NPDES permits and bring them to be current -- current being within the five-year expiration date of a permit.

MR. GLASS: I guess from that you can conclude that -- we're on the third, is that true, the third round? Is that -- of NPDES?

MR. SAUMS: Third round, yes.

Third-round permits is a term that EPA uses to refer to NPDES permits where they are seeking to protect the -- particularly with regard to the discharge -- no discharge of toxics in toxic amounts.

MR. GLASS: So third-round permits will include the requirement for this?

MR. SAUMS: Most facilities in New Mexico are already into their third-round permit, and, arguably, I guess you could call it the fourth round.

MR. KEYES: May I ask a question --

MS. HUGHES: Commissioner Keyes.

MR. KEYES: -- along this line?

In your testimony on Exhibit Number 10, where you had the list of the dates when some of the items were, in fact, exceeded, some of the suggested levels, what are the termination -- or expiration dates of some of those communities that were listed in there?

Are their expiration dates way earlier than when these actually were collected?

MR. SAUMS: Most of the permits in NMED Exhibit 10 have been reissued within probably the last four or five years. I don't have the precise expiration dates in front of me, but my recollection is that we've gone through the effort to update NPDES permits, particularly,

in the last three years.

These all look familiar to me as having -- we've seen these in the last three or four years.

MR. KEYES: Thank you.

MR. MAGGIORE: Commissioner Hutchinson.

MR. HUTCHINSON: Just one quick question.

Dr. Davis, you said that there would be a negligible impact on TMDLs or 303(d) listings. Is that what I heard?

MR. DAVIS: Yes.

Mr. Chairman, Commissioner Hutchinson, I didn't use the word "negligible," but I said that I thought it would be, you know, a very small impact. I don't think it's significant.

MR. HUTCHINSON: So in that arena, we're proposing to apply these to ephemeral stretches.

Would that result in ephemeral stretches showing up on the 303(d) list that are not present there now because we don't classify them in that regard?

MR. DAVIS: Mr. Chairman, Commissioner Hutchinson, I don't know that it's correct to say that no ephemerals appear on the 303(d) list.

Wildlife habitat and livestock watering standards apply. When water is present, we measure it. It also depends on how the standards are actually

written. Some sections of the standards refer to perennial tributaries and other sections refer to all tributaries. Perennial tributaries, obviously, is self-explanatory. Ephemeral reaches, therefore, are not in that classified segment.

Where it says all tributaries, then ephemeral reaches are, by definition, included in that classified segment.

MR. HUTCHINSON: So it would just depend on the description of the reach?

MR. DAVIS: Yes, I think so.

Again, these chemicals that are in our proposal, typically, I think you would expect to not find them in most areas of the state that we're talking about, higher portions of a watershed or ephemeral tributaries to a -- you just typically would not expect to find them. That doesn't mean that we might not find them, but I would not expect it to occur very frequently.

MR. HUTCHINSON: That's what I was expecting. I just wanted to get a clarification on that.

Thank you.

MR. MAGGIORE: Thank you.

Any other cross-examination of the Department witnesses from the Commission?

Commissioner Whipple and then Commissioner

Keyes.

MR. WHIPPLE: Thank you, Mr. Chairman.

I have some questions for Mr. Pierce about his testimony.

One thing that I'm curious about that I don't understand is what does the harmonic mean flow have -- relate to anything physically?

Like the 4Q3 flow, I can visualize what that relates to physically.

MR. PIERCE: We do have the article in which the Journal of Hydraulic Engineering explained a little bit more about it and why they felt that it more accurately described long-term flow, kind of moderating out the highs and lows and a lot of the other methods, but, no, it doesn't -- there is nothing that you can visualize, like a 4Q3 or a 7Q10.

MR. WHIPPLE: So how would you describe how the exposure assumption used by EPA are best reflected by the harmonic mean flow?

MR. PIERCE: When they applied them to waters, they used the harmonic mean flow of those waters.

MR. WHIPPLE: So that's just the tie? Anything physically?

MR. PIERCE: Anything that was found based on the harmonic mean. It's like when they developed for the

chronic, they used four-day averages, and so most of the states, including New Mexico, went to a 4Q3, because that came closer to what EPA was using to determine those criteria.

MR. KEYES: Is that your question?

MR. MAGGIORE: Is this a friendly amendment to Mr. Whipple's question?

No problem.

MR. KEYES: When did Texas accept the harmonic mean flow and particularly in relation to the common reach? Do you know what year they accepted it in their review process?

MR. PIERCE: I don't know that answer, but it's possible that Mr. Meyerhoff from LANL would know that.

MR. MAGGIORE: Do you want to defer to -- is there someone that could help with the response to this question?

MR. MEYERHOFF: I do not have any answer to that question.

MR. MAGGIORE: Okay.

MR. AMES: That makes it easy.

MR. WHIPPLE: Mr. Chairman, I have a few more questions.

MR. MAGGIORE: Please.

MR. WHIPPLE: Mr. Pierce, on page 11 of your testimony, of your written testimony, in the second complete paragraph, it talks about high levels of PCBs and dioxin in ephemeral storm waters at Los Alamos National Laboratory, and then a February of 2002 analysis indicating high levels of PCBs and dioxin in fish caught in Cochiti Reservoir.

Are there other potential sources of those PCBs and dioxins other than from streams off the laboratory property?

MR. PIERCE: Mr. Chairman, Commissioner Whipple, certainly, particularly with the fire up in that area, there are lots of other potential sources than the lab itself.

We found elevated levels in Cochiti. We found elevated, but not nearly as high levels, in Abiquiu and in Navajo, but these are only places we've looked so far in the state.

We're looking a lot of other places, but the funding is quite low for us, unfortunately. We have a lot of fish that have already exceeded holding times that we're trying to get these kind of analyses on.

The PCB sampling, I believe, currently costs $1,200 a sample, and it doesn't take too many of those to go through a budget pretty quick, particularly when you

have to do QA, and you don't base it on one sample.

Yes, we're just starting to find these. EPA is looking for these contaminants in fish throughout the country. We're a part of that study. That's how Navajo Lake got -- our samples got analyzed for Navajo Lake.

The chemicals of concern that they are finding everywhere are mercury, of course, and dioxins and PCBs. So these are being found in other places, and, obviously, LANL is not at all those other places around the country, so, yes, there must be other sources.

MR. WHIPPLE: Okay. I have a question about the proposed changes to Section 20.6.4.900, Subsection D, in particular.

Is there a definition for irrigation storage?

MR. PIERCE: No, there is not.

MR. WHIPPLE: The reason why I ask is, I guess, I have a couple of concerns about the applicability to the standards, for example, where somebody may pump groundwater into an irrigation pond, where then it would become irrigation storage, or other instances where you might have a reservoir with no dedicated irrigation storage, per se, even though water flowing to the dam might be used for irrigation.

So I was wondering about the applicability of this standard to those types of surface waters.

MR. PIERCE: Mr. Chairman, Commissioner Whipple, irrigation storage is a designated use that this Commission has designated on 15 different waters of the state. Among those waters are Elephant Butte, Abiquiu, El Vado, Heron, Brantley, Sumner, Storrie, Avalon, Conchas and Navajo. These have been designated as irrigation storage for many years.

MR. WHIPPLE: So that's -- okay. Got you.

MR. PIERCE: So, I mean, there hasn't been a definition, but there hasn't been a definition for many years, either.

MR. WHIPPLE: Another question.

On ephemeral streams, would the human -- what I'm thinking of is a small reservoir that might be up along an ephemeral stream that might be supplied by diversions from a river or from groundwater, might have some surface water storage that could potentially spill during times of large rainfall runoff, but that would be the only times.

Would the criteria for the persistent toxic substances apply, I assume, to such a water body, as long as that was a tributary drainage to a stream segment that was designated fishery use?

MR. PIERCE: Mr. Chairman, Commissioner Whipple, that's correct, but currently also the livestock

watering and wildlife habitat all do apply to that.

Now, to be realistic, most of these little ponds aren't going to have dioxin, PCBs, or any of these priority toxic pollutants in them, so -- but those are currently subject to the standards. Unless there is a problem, probably nobody will go out and look at it, but they are -- they are already -- several of these are applicable if they happen to be in one of those segments for which the Commission has said that this stretch and all tributaries and they are also subject to fishery uses.

MR. WHIPPLE: Thank you.

MR. MAGGIORE: Dr. Davis.

MR. DAVIS: Thank you, Mr. Chairman.

To make sure I understand your question, Commissioner Whipple, are you referring to what could perhaps in common parlance be called a dirt tank, where a berm of dirt is placed in an arroyo to intercept intermittent or ephemeral flows and accumulate water for the purposes of livestock?

Is that the kind of thing you're referring to?

MR. WHIPPLE: No. But now that you've raised it --

MR. DAVIS: Okay. If you would, please,

explain in more detail what it is you're referring to.

MR. WHIPPLE: For instance, Morgan Lake, where PNM's water supply reservoir -- that are fed by the diversions off the San Juan River, but don't necessarily release water back into the system -- into the stream system.

MR. DAVIS: In any case, Mr. Pierce's answer is still a good one. I just -- I was visualizing, when you were describing -- when you described this, I was visualizing what -- what are known as dirt tanks, of which there are 30,000, 50,000, 100,000 of them around this state. I have no idea.

Nevertheless, in waters impounded like that, wildlife habitat and livestock watering standards apply. You don't expect to find these sorts of things in them, obviously.

Just a point of clarification. Thank you, Mr. Chairman.

MR. WHIPPLE: Thank you.

That's all I have.

MR. MAGGIORE: Any other cross-examination of Department witnesses from the Commission?

Commissioner Glass.

MR. GLASS: With apologies, I have a few questions, actually. I'm trying to trim them down.

The first issue that comes to mind is that your slide indicates that you have, for aquatic life, 11 acute and 10 chronic criteria being proposed. Those are new criteria, I suppose.

When I look at the table, I see many more than 10 acute and 11 chronic, and I just -- I assume that some of these existed prior and they've just been moved into the table.

Is there some way they could be -- the new ones could be highlighted so that the reader would know which are the new ones being proposed?

MR. PIERCE: Yes, Commissioner.

After the first 24, I believe everything is new.

MR. GLASS: Okay. The first 24 are old, just moved in from the textual tables, and then the ones --

MR. PIERCE: Except for the ones for human health, but for -- it's all the alphabet compounds that are on the next three pages that are new.

MR. GLASS: Okay.

MR. PIERCE: Except for chlordane and PCB, which we have existing standards, and DDT under wildlife habitat.

MR. GLASS: So everything in number 25 and after -- except for chlordane and DDT --

MR. PIERCE: And PCB.

MR. GLASS: Okay. I see the proposal is to include the formula, or the formulae -- there are several formulae for calculating criteria from the IRIS database -- to include those in the Water Quality Management Plan, and I guess I have kind of a timing problem with that in that one would publish -- we would adopt these standards when the formula isn't in the Water Quality Management Plan. Is that a problem? Do we have to revise the Water Quality Management Plan before these -- you see my point?

MR. DAVIS: Mr. Chairman, Commissioner Glass, yes, and we specifically thought about that, because as this Commission is very aware, we are undergoing a major update of the Water Quality Management Plan.

We looked at a calendar and anticipated a sequence of events, recognizing that in order to do this, we would need to modify the Draft Water Quality Management Plan that is currently in its 60-day public comment period.

This, obviously, is simply a proposed calendar. We anticipate that the Water Quality Management Plan -- see, this isn't going to work anymore. We do have a timing issue.

MR. GLASS: Maybe you can ask -- I was going to

ask counsel about that, but it's empty over there. Maybe I can ask their counsel.

MR. MAGGIORE: Is the question the concern that we will be adopting regulations that contain a formula which the Water Quality Management Plan is yet to --

MR. GLASS: Exactly.

MR. MAGGIORE: -- provide for?

MR. GLASS: The standards say that the formula will be used and give a reference to the location of the formula where it cannot be found.

MR. DAVIS: We would be -- Commissioner Glass, we would be able -- I believe we could approach the Commission in a very timely manner to make the change in the Water Quality Management Plan, such that action on this proposal would not be in effect yet, have no procedure specified in the plan, we would simply change the plan.

If the Commission adopts this approach that we're proposing and approves the inclusion into the Water Quality Management Plan, we would simply then move forward and make that change in the Water Quality Management Plan and approach the Commission at its next meeting to debate, discuss and adopt that change in the management plan.

I don't believe we can put something into the

management plan that references the standards if the standards have not yet been adopted by the Commission. So we have to -- we have to allow the Commission to act on the standards, and then following that, we would immediately act on the management plan.

MR. AMES: If I might add, Mr. Glass, if you recall, the EPA will either look to a state -- explicit state policy or a state regulation in deciding how to make the translation mechanism work, and I would suggest that if the Commission were to adopt this language into section 12.F.2(b) that the Department would point the EPA toward the transcript of the proceeding for evidence of the Commission's policy regarding the formula to use in the absence of those formulae in the management plan yet.

So there may be a gap in time, but EPA is not going to like run out and use whatever formula they want. After all, the formulae we're proposing for inclusion in the Water Quality Management Plan are EPA's current formulae, so the likelihood that we're going to hit the wall here, because the plan has not yet been amended to reflect what the standards require, I think, is extremely unlikely in these circumstances.

MR. DAVIS: And practically speaking, Commissioner Glass, it would be perhaps one month,

at the most two months, before we were able to do this. So, as a practical matter, I don't think it would be a problem.

It is very -- it is correct that it is a hypothetical problem, but I don't think it would be practical.

Glenn just pointed out that there is no prohibition for updating the Water Quality Management Plan more frequently than we have done in the past, and, accordingly, we would propose that the management plan be amended accordingly in a timely manner.

MR. GLASS: And I personally wouldn't have a problem with the approach here. I was just thinking more of a procedural or -- or something beyond my knowledge, if you will, just an issue.

But on the same page there, on the notice of intent, page five -- and I've flagged it elsewhere, too -- is the statement that -- actually you added it, I think, in response to a -- I forgot who expressed the concern, but it's on page five of your notice of intent to present technical testimony where you say that within 90 days of the issuance of an NPDES permit containing a numeric criterion calculated pursuant to, the Department shall petition the Commission to adopt such criterion into these standards.

My question is that if EPA establishes -- well, I guess that would be -- you're talking here about EPA establishing a stream criterion, right, a stream standard?

I mean EPA issues final permits, right, and it would be they that calculate the criterion? Is that true?

MR. SAUMS: Commissioner Glass, I think we're not talking about establishing a stream standard.

What we're talking about is them deriving a criterion for scanning in the permit issuance. When they are drafting the permit, if they don't have a number to scan the data against, as they review the permit, they would come up with a number according to that, and they would pursue their permitting action, and then upon the finalization of the permit, we would take that and come to the Commission to establish as a stream standard.

MR. GLASS: To propose a stream standard?

MR. SAUMS: As a stream standard, going through the full public participation process.

MR. GLASS: That was my concern, that we may be establishing here a mechanism to establish stream standards without the required public hearing, but that obviously is not the case, because the criterion that EPA would use for a permit is not tantamount to a standard.

It is a starting point for a standard, it would be proposed as a standard, but is not actually a standard?

MR. DAVIS: That's correct.

MR. SAUMS: I think that's correct, Commissioner Glass.

MR. GLASS: Okay. Got that. Thank you.

I guess just a last question. I did trim them down pretty well. There were 30 or 40.

In Mr. Pierce's testimony, on page 27, when discussing the issue of arsenic, as much as I hesitate to make Steve try to talk, you stated that you believed that Region -- it's in Pierce's testimony, page 27 -- you stated that the Department believes that Region 6's alternate recommendation of 20.5 micrograms per liter is not adequate to protect human health and would be disapproved by EPA.

I guess my question is that if EPA recommends it, why would EPA disapprove it, or is it a national or regional problem?

MR. PIERCE: That's part of it, Commissioner Glass.

Region 6 saw that there is a problem with arsenic -- as you're very aware, with the arsenic standard. National EPA is waiting for a study that's

being conducted to be finalized, which is already overdue.

Region 6 felt that they couldn't wait, so they put out what they called an interim recommended criterion of 20.5.

When you look at the basis, they based it on ten to the minus sixth. They don't say that this standard would be good if you went ahead and translated it to ten to the minus fifth. The standard they recommended was 20.5. So if we take it and change it to ten to the minus fifth, we kick it all the way up to 205, which is well above drinking levels, et cetera. So I'm pretty sure they would not approve that.

What they want people to do in the interim is to adopt the 20.5, but that wouldn't have the same basis as our other criterion, and so if we took it and changed it to 205, they wouldn't approve it at that level.

MR. GLASS: So it's the level of risk difference that really has the impact here?

MR. PIERCE: That's correct.

MR. GLASS: I understand that.

MR. PIERCE: Our calculated level is real close to that 20.5 at 24.2.

MR. GLASS: I noticed that. Yeah.

Thank you.

MS. BRANDVOLD: Is that your last question?
MR. GLASS: Yes.
MS. BRANDVOLD: Mr. Olson, you had some questions.
MR. OLSON: Just a couple.
I guess it's Mr. Pierce. I guess this is on the toxic pollutants, 20.6.4.12.F.
On removing that language "attributable to discharges," it sounds like that's going to be making nonpoint source activities and problems mandatory. Do you have any comment on that?
MR. PIERCE: Commissioner Olson, I don't believe that's the case.
Nonpoint sources aren't addressed by our standards and neither are point sources. Standards apply to the ambient water. So to the extent that there have been problems for nonpoint sources, they still need to be addressed, even though there is no mechanism except voluntary within the state, or the mechanism is they get a much higher priority rate when it comes to issuing 319 grants, but by removing that, it doesn't mean that nonpoint sources would be a mandatory enforcement.
It would just mean, you know, that we're applying the standard to the ambient stream.
MR. OLSON: Okay.

MR. PIERCE: And it wouldn't allow the loophole of being able to put large quantities out there that aren't coming specifically out of a pipe today that would get into the waters.

Did that answer your question?

MR. OLSON: Yes.

MR. DAVIS: Commissioner Olson, if I could, I'd like to expand a little bit on Steve's answer.

MR. OLSON: Yes.

MR. DAVIS: The logic of this is precisely the same logic that the Commission used when it clarified the exemption for irrigation flood control facilities of five numeric standards, and that is that the standards, as Steve pointed out, apply to the ambient water. They do not address the source of the pollutant. They establish the criteria against which ambient water is measured.

That logic, as it applies to the irrigation and flood control facility exemption, is correct. Equally, it would be correct under this circumstance, and that is that these standards are applicable to the water and they do not restrict themselves vis-a-vis the source of the pollutant.

MR. OLSON: Thank you.

I just have two others.

Mr. Pierce, on page 16 of your testimony, you

talked about a logic for not putting in drinking water -- or because of conventional drinking water treatment methods can remove the priority toxic pollutants, the Department doesn't consider those criteria based on the consumption of untreated surface water are necessary to protect public health.

If that's the case, why would we have -- we have some other domestic standards in the table M that we had currently. Is there some conflict with that, with what you're saying there, and the inclusion of those other domestic standards, because those things could be removed by treatment? Should they be in table M?

MR. PIERCE: The statement that conventional treatment could remove those was our way of thinking about whether or not, in a few years when Albuquerque is drinking river, would they be at a higher risk of eating fish and getting that through their drinking water, and the answer was no, based on that, because it would be treated and be removed, but also the water quality standards -- the drinking water standards would apply to Albuquerque.

We were looking to see if there was any significant risk of people who are drinking raw water and eating fish out of the same water, and in that that doesn't seem to be a very widespread situation in the

state; however, if it is determined to be occurring somewhere, then we would be quite willing to come back and propose a different basis for a site-specific standard for someplace where people are consuming the water and eating fish out of that same water.

MR. OLSON: But we do have some standards then for domestic water supply?

MR. PIERCE: That's correct.

These are drinking water standards from the Safe Drinking Water Act that would apply to surface water that people would use after filtration and disinfection.

Since the drinking water standards represent the level that is found to be healthful for people consuming two liters of water over 70 years, the Commission has always adopted those standards in those stretches of water that are recognized to be used directly for people to drink without any treatment beyond filtration or disinfection.

MR. OLSON: So is that the rationale that these ones that are in here wouldn't be removed by the conventional treatment and why there would be a standard, say, for, you know, barium, arsenic?

MR. PIERCE: Those standards do not apply to a municipal water supply. They only apply to a domestic water supply. The assumption under the domestic water

supply is that people use the water, disinfecting it and filtering it, and no other treatment.

MR. OLSON: Okay.

MR. PIERCE: Municipal water supply carries no standards whatsoever at the moment. The municipal water supply designated use carries no standards with it specifically at the moment.

MR. OLSON: Okay.

MR. PIERCE: If there was something that somebody was found not to be able to remove in treatment, then they might request such a site-specific standard for a stream to try to prevent that from going into the water.

Currently, all the items we're looking at now are removed by conventional treatment common in New Mexico.

MR. OLSON: Okay. This is just a question on table M.

Most of the aquatic life calculations that you have here, you have some -- most of them have acute and chronic, but you have a couple that have acute and no chronic criteria calculated.

Why is that? Is there --

MR. PIERCE: Commissioner Olson, these are directly out of the EPA guidelines, so they must have

found some problem with the calculation of a chronic or of acute for certain things.

It may be that some things have an effect over a long period of time -- i.e., the chronic standard can be developed, but the higher level doesn't cause immediate toxicity. So they may have been able to develop a chronic for some things, and it may be that some things that have an acute impact don't have any effect over a long period of time, but if they get it right away, it could kill them.

So I'm surmising there. My straight answer is EPA had no recommended criteria for those particular ones. Beyond that, I think what I'm saying is what I think the reason is.

MR. OLSON: Okay. It just seemed like every one had a -- except for a couple that had an acute standard also had a chronic. That didn't --

MR. PIERCE: For a few of these, they originally had proposed acute and chronic, and due to some problem, they removed one or the other.

For an example of one we had, the Commissioners will remember, we had acute and chronic standards for silver, and it was determined, after further experimentation, that the chronic standards for silver really was not necessary, that there wasn't a chronic

toxicity being shown, so that the Commission dropped its chronic standard and we just have an acute standard for silver.

MR. OLSON: Okay. I think that's all I have. Thank you.

MR. MAGGIORE: Any other cross-examination questions from the Commissioners?

Commissioner Keyes.

MR. KEYES: Mr. Chairman.

Mr. Pierce, I'm curious to know what the history is on the definition of grab sample, and is there a reason that the Commission has not defined that and whether it should be a split grab sample or use the protocol that you all have on the second sample only being used if, in fact, it's an exceedence of the criteria or the standard.

MR. PIERCE: Mr. Chairman, Commissioner Keyes, there is a theory that I've been around since before God, but it's not true. There are people around that have been here a lot longer. In fact, Commissioner Johnson has been on the Commission now for 26 years, so he may have more information.

I'm not aware of why the term was not defined. The protocol we used to determine the assessment were borne out of necessity when all at once the 303(d) list

became a very important document, and in what projects had highest priority, what TMDL developments had to be, and at that time we developed the assessment protocol, which were based on other states' assessment protocols and were based on a more logical look at the overall data.

We still have problems now on large data sets. We may go out and in a single season get 20,000 readings for temperature, and the way the standards read, if one of those 20,000 exceeded, we would consider it at least an exceedence.

So what we've done through the protocol is determined what we would use to determine whether or not the use is actually being nonattained. These are still undergoing tweaking, and I'm sure that they will be proposed to be part of the standards or part of the management plan when they are fully tweaked.

Currently, they are approved as part of our standards by EPA, and they have been tweaked almost yearly, and we're working on several of the large data set protocols, but, no, I do not know why the term grab sample has not been defined, or even if a definition has been kicked around at some point in the past.

MR. KEYES: Mr. Chair, I would like to make a comment off the record, if I may, to Mr. Pierce.

MR. MAGGIORE: Sure. We can go off the record for a minute.

(Off-the-record discussion.)

MR. MAGGIORE: We can go back on the record.

MR. KEYES: That's all I have.

MR. GLASS: I have a follow-up to that, if I might.

The proposed compliance with water quality standards for the protection of human health that shall be determined from the analytical result of a single grab sample, that is your proposed changes, you stated that that never actually really happens, that you don't -- that there is a confirmation, and I think, in fact, that your protocol requires seven samples.

I mean, you've got a couple of them, a second sample, you get an exceedence -- seven samples, I think you said substantiates a violation. Do I remember that right? Is that the QAPD, Q-A-P-D?

MR. DAVIS: Mr. Chairman, Commissioner Glass, let me try to answer that.

As Steve correctly points out, we have a data assessment protocol that the Bureau has developed that addresses a number of these types of issues. A single grab sample is in the standards.

My interpretation, not a definition of it, but

the interpretation that we use practically is that that means there is no averaging or weighting or other kind of statistical manipulation of the result, rather it is the result that derives from a single sample.

However, given that there is uncertainty associated with any analytical result, it is not, in my estimation, prudent to rely on a single number that only occurs -- that you only have one occurrence of. So we sample multiple times to achieve a level of confidence that the number, in fact, is correct, but we do not average cross those multiple samples, we simply use one numeric value to estimate or to determine whether or not a standard has been exceeded.

So, practically, we find ourselves taking multiple samples, but we apply no statistical methodology across those multiple samples, rather we use the result of a single sample, as is specified in the standards.

We simply can't go out and say, "Well, if we have one hit, is that real?" There has to be some repeatability to that, and so we sample multiple times to achieve that repeatability.

Does that help?

MR. GLASS: No, but that sounds very scientifically valid, absolutely, that -- but I guess my concern, or my suggestion is, or my wish is, that that

process could somehow be incorporated here so that we would -- you know, that the dischargers wouldn't be subject or feel subject to just sort of that single instance and then all of a sudden it's $25,000 a day.

MR. DAVIS: Right.

Commissioner Glass, the protocols that I speak of that the Bureau has developed over the last three-and-a-half years or so are currently in the Quality Assurance Project Plan that the Bureau develops every year and submits to EPA. This is a requirement of the federal act -- the various regulations under the federal act.

EPA reviews the procedures that any state is using. We have developed these with both internal and external review, again, to pick up on the -- one of the examples that Steve used is that we have a temperature protocol. We may, in fact, accumulate 20,000 or more temperature readings of a particular segment of stream in the state. We've worked with US Fish & Wildlife Service, New Mexico Department of Game and Fish and EPA to understand what a 15-minute, one-degree Celsius exceedence of the standard might mean, as opposed to a 45-minute, one-and-a-half-degree Celsius exceedence of the standard. Those are different for the biological community.

Accordingly, we developed a protocol that specifies -- I don't have it memorized, but, say, a two-degree Celsius exceedence of the standard for two hours is not acceptable, but a .5-degree Celsius exceedence of the standard for 15 minutes is.

Now, this is something that the Bureau has done to help us understand -- help us interpret the language in the standards that is absolute; where it says, for example, in a high-quality cold-water fishery the temperature is 20-degrees Celsius, shall not exceed.

These protocols are on our website, and they have been -- they are available for review by any interested party. They have been since they were developed. They do undergo routine and ongoing review, or tweaking, as the term of art is, and we're constantly interested in making these things better.

They are not codified anywhere, but we do anticipate, in the rewrite of the CPP, that we will be addressing these protocols through that document, which would then bring into play a review by the Commission. This is -- in any case --

MR. GLASS: But there is no hope, I don't suppose, for these interpretative -- interpretative criteria, if you will, or these methods of interpretation ever to translate themselves into a more -- a

less-limiting compliance scenario for the standards themselves.

I mean, couldn't this sentence say, for instance, compliance with water quality standards can be determined from the analytical results of a single grab sample after confirmation with a second sample?

MR. DAVIS: Mr. Chairman, Commissioner Glass, yes, that kind of thing would be very imaginable.

In fact, some states in the country do precisely that, they place into their standards these interpretative phrases to provide guidance or very clear examples of how the standards apply.

We've not had the opportunity to do that, quite frankly, with the Commission. It would be a very major undertaking in the standards, as you can well imagine, but something like that is, obviously, an option and it would be something we'd be -- we'd be happy to consider.

MR. GLASS: Then are you saying it's your opinion that we couldn't do it with this set of revisions for human health standards because of the potential impact to other parts of the standards?

MR. DAVIS: Mr. Chairman, Commissioner Glass, as a practical matter, no one has proposed it. We do not have any -- we do not have a proposal in front of us to

do that, but as a -- again, speaking, if you will, hypothetically, I see no -- I see no absolute barrier to that at all. I think that approach could be used in the standards.

MR. GLASS: I take it that the Bureau would have no objection to inserting "as confirmed by a second grab sample" in that 20.6.4.11(d)?

Is that a reasonable --

MR. DAVIS: Mr. Chairman, Commissioner Glass, I would ask that we take a careful -- that we give ourselves time to carefully think through the ramifications of it.

Again, as a practical matter, if you're basing -- I mean, I'm speaking simply off the top of my head right now, but if you're basing your estimation of compliance with the standards on a single grab sample that you can take multiple times, do you simply take samples until you find the result that you want, and that would not be appropriate. What would it mean to a permitted discharger?

Again, I don't think that there is any barrier to this approach, hypothetically, but I would like to take the time to think it through carefully.

I do know that I have seen examples of temperature standards in other states where they have

some graduated scale. You know, in discussions with this Commission in other forums, we've recognized this particular problem with the Gila River and San Francisco River Basins in the southwestern portion of the state that are typically exposed to higher ambient temperatures than the mountain streams in the Sangre de Christo Mountains at the border of Colorado.

Accordingly, you might expect a different temperature regime to occur in those waters, yet we have an absolute standard that applies everywhere in the state of 20-degrees Celsius for the designated use of high-quality cold-water or warm-water fishery.

It may in fact be that we need to capture some of that natural variation in the standards, but the way to do that is the difficult part, and so I would -- like I say, I would request that we take our time and think it through very carefully before we do it.

MR. GLASS: Okay. Thanks.

MS. HUGHES: Do you want me to take over?

MS. BRANDVOLD: Are there any more questions from the Commission?

MR. WHIPPLE: One more question.

Mr. Pierce, what is the fish consumption rate under these water quality standards?

MR. PIERCE: The consumption rate used in these

calculations by EPA is six-and-a-half grams of fish a day.

MR. WHIPPLE: Is that like a nationwide average, or is that a considerably high number that EPA has just assumed?

MR. PIERCE: That was developed as a nationwide number on an average of people that eat fish and people that don't eat fish.

Part of the risk level -- EPA has stated that you cannot go below a ten to the minus fourth risk level, and one of the assumptions they have is that you'll have an exposed population that eats a lot more fish.

So our proposal, even somebody who eats a lot of fish, would be protected at least by ten to the minus fourth level -- risk level.

Yes, they used six-and-a-half grams per day per person. There has been some talk of them changing that to 17-and-a-half grams a day, which I feel might be too high for New Mexico, and it might behoove us at that point to try to develop some local guidance to fish consumption.

Right now, we felt the six-and-a-half grams was a valid assumption to start with for New Mexico residents.

MR. WHIPPLE: Thank you.

MR. MAGGIORE: Any other cross-examination from the Commission?

If not, I'll open it up to cross-examination from the public.

If you're cross-examining, please rise and state your name slowly and clearly for the record and then proceed.

Mr. Rose.

MR. ROSE: Thank you, Mr. Chairman.

MR. MAGGIORE: Before you begin, can you estimate how long your cross might be?

MR. ROSE: Depending on the questions, hopefully, not more than ten minutes --

MR. MAGGIORE: Thank you.

MR. ROSE: -- but you never know. It depends on the questions.

For the record, my name is Louis Rose, I'm with Montgomery & Andrews in Santa Fe, and I'm here representing the University of California Board of Regents.

CROSS EXAMINATION BY MR. ROSE

MR. ROSE: It's a question for whoever wants to answer it. It's a toss-up question here.

With respect to -- I'm referring to Section 12.F.2(c) -- I think that's the proposed language that

the Department had in their notice of intent concerning petitioning the Commission for review of the standards.

I was curious, you've chosen 90 days from the final NPDES permit containing the numeric criteria. As I understand it, there would be an interim process where you would be required to certify a number in a proposed NPDES permit.

I wondered why you chose from the date the final permit was issued rather than from the date you certify compliance with the state requirements of the 401 certification?

MR. SAUMS: Mr. Rose, I guess I received the toss-up on that question.

MR. ROSE: I noticed Jim pointed to you.

MR. SAUMS: I think the answer to that is simply that a permit isn't final until it's final, and when EPA makes its final decision, that would be the time to act.

Well, in the case of the Molycorp permit that I referred to in my testimony, while EPA calculated that a number -- that their effluent might cause a water quality -- a human health standard violation, ultimately, a technology-based effluent limit prevailed, and, therefore, the issue of the human health criterion became moot.

So I think in that case it's prudent to wait until a permit is finalized by EPA before we go petitioning the Commission and approaching them with something, that if we were to go earlier than that, we might be premature.

MR. ROSE: In terms of the final number in an individual permit -- but would, for example, the calculation of what was appropriate to be the new -- the narrative standard, would that then be -- would that process be -- could it be replicated later, and in essence, the same analysis be done on a later permit?

Wouldn't it be more prudent to have the Commission review that analysis sooner than later in the process or even in a subsequent permit?

MR. SAUMS: I think that's a suggestion worthy of consideration.

MR. ROSE: When you reference "final NPDES permit," I assume you include storm water permits as well as point source, normal point source discharge permits, do you not?

MR. SAUMS: I think we're referring to all NPDES permits, whether they are individual permits or general permits.

MR. ROSE: Okay. I understand your reference to petition the Commission to be a petition under the

Commission's guidelines for rule-making.

Is that what you understood your testimony to be?

MR. SAUMS: Mr. Rose, I think that we would always adhere to the Commission's guidelines or preferences as they saw fit.

MR. ROSE: While the requirement obligates you to petition the Commission, there is no statement about what happens subsequent to the petition.

I was curious, say, for example, if the Commission were to either not go to hearing on a petition or not accept the number and adopt a different number in the standards, what would be the process?

Would you go back, and if it were a less stringent number, would you be amending or seek to amend the NPDES permit, or what would be the result of this if the Commission were not to agree with analysis of what the appropriate numeric translation of the narrative standard would be?

MR. DAVIS: My turn.

I think at that time, as the Commission deliberated and made its decision known, both to us and to the affected public, we would then probably seek guidance on what the next step should be, and that debate would occur -- the Commission would engage in that debate

and it would occur in the full view of the public.

I don't know that we can anticipate -- I mean, your question is interesting, but it's hypothetical, and I don't know that we can -- that we can speculate in a particularly beneficial manner on what the Commission may or may not do.

MR. ROSE: And I take it that the translation of narrative standards to numeric standards in F.2 is not the only place where that analysis takes place, is it not?

Wouldn't a similar sort of analysis take place under F.3, or could it not, where you translate a narrative into a numeric number? Particularly in F.3 -- I think it's F.3(b) -- or F.3.

Actually, it talks about how you calculate if there is a number in 900, then what you do, and what you apply in sequential order.

MR. AMES: Did you hear the question, Mr. Pierce?

Could you rephrase the question?

MR. PIERCE: I'm sorry, if you could rephrase it.

MR. ROSE: I was curious, as I was reading this -- we've been talking about F.2 and translating a narrative into a numeric standard, and it was my reading

that that's not the only place where that could take place, it could also take place under F.3.

I was curious -- I mean, that's the way I read them, and I wasn't sure if I was correct. I was asking for confirmation of that.

MR. PIERCE: You are correct. It does occur under F.3, which is existing language, and it has occurred at least once since 1995 when the Commission adopted these standards.

MR. ROSE: And I was curious, since you're proposing a process to deal with those narrative standards, which are calculated based on standards under F.2, why the Department did not consider a similar process under F.3 for Commission confirmation of those standards?

MR. DAVIS: That question or that idea was simply not raised. We didn't think of it, and neither did anyone else.

MR. ROSE: Would you object to similar language being interposed as to that process as well?

MR. DAVIS: I don't believe so, but I would prefer to have the opportunity to think about it a little longer.

MR. KEYES: You've got five minutes.

MR. DAVIS: I don't --

MR. MAGGIORE: You can handle that on rebuttal. You could address that, Dr. Davis, on rebuttal if you don't want to --

MR. DAVIS: Yes. That's fine.

MR. AMES: Thank you.

MR. ROSE: That's fine. I have no further questions.

MR. MAGGIORE: Thank you, Mr. Rose.

Any other cross-examination?

Ma'am.

MS. MC CALEB: Yes, Jolene McCaleb on behalf of San Juan Water Commission.

MR. MAGGIORE: Just quickly an estimate on time.

MS. MC CALEB: I'm guessing 45 minutes to an hour.

MR. MAGGIORE: Okay. That's why I asked, I guess.

Let me just ask the members from the public that had indicated they cannot return tomorrow -- there were two folks.

Ma'am, you had indicated earlier and you had already signed in and been sworn in --

MS. GNATKOWSKI: Yes.

MR. MAGGIORE: -- and you had said your

testimony will be relatively brief.

MS. GNATKOWSKI: Yes, it will be very short.

MR. MAGGIORE: Mr. Shields, yourself?

MR. SHIELDS: Yes, it will be very short.

MR. MAGGIORE: Short.

Okay. Commission, what do you want to do? Do you want to hear the public stuff and then call it a night or -- I'm seeing a lot of head shaking.

Okay. Let's go ahead and do that.

If I can ask you two individuals who want to provide some public comment -- ma'am, we will get to you first thing in the morning with cross-examination.

Mr. Shields.

MR. SHIELDS: Mr. Chairman, I had a couple of questions that I have for cross-examination. If I may address those first.

MR. MAGGIORE: I'm sorry?

MS. BRANDVOLD: If he can't come back tomorrow --

MR. MAGGIORE: Yes. Okay. I'm assuming -- I don't mean to inconvenience you, but you have apparently some robust questioning, and you will be back tomorrow; is that right?

MS. MC CALEB: Absolutely.

MR. MAGGIORE: All right.

Having heard that, then, Mr. Shields, why don't you proceed then with cross-examination of the Department, and then we'll move to public comment, and then we'll call it a night.

MR. SHIELDS: Thank you, Mr. Chairman.

MR. MAGGIORE: If you wouldn't mind coming up to the front, Mr. Shields, and stating your name and affiliation clearly for the record.

MR. SHIELDS: My name is Brian Shields. I'm the executive director of Amigos Bravos.

I just had a couple of questions that I wanted to ask.

CROSS EXAMINATION BY MR. SHIELDS

MR. SHIELDS: I guess I'm kind of curious to know how many communities in New Mexico actually use water for domestic purposes at this point. Use surface water, right. Sorry. A little technicality.

MR. MAGGIORE: Hopefully, Mr. Shields, but I think we --

MR. KEYES: Every one of them.

MR. SHIELDS: I was trying to save words. I can just use my voice.

MR. PIERCE: Mr. Chairman, Mr. Shields, right now we don't know -- I don't know that there are any -- any communities that use it. These would be mostly

individuals.

There are houses in Northern New Mexico that run pipes out to a stream for the drinking water. We had at least one of our NMED employees who carries water up from the river and pours it through a sand filter for his household. We know people do take water from the acequias.

I don't think that any communities draw it. If they do, then they would come under the Safe Drinking Water Act as a municipal system, and that's not the same as domestic water supply.

MR. SHIELDS: Okay. I'm aware that there are some -- like the community of Llano, I know that they depend on their water from the acequias, because many people don't have wells there, domestic wells.

So, I was wondering, in terms of that, I noticed that you used the criteria developed for consumption of organisms only, and I assume that the criteria for the consumption of water and organisms would be more protective of human health.

MR. PIERCE: It is a more stringent standard, yes.

MR. SHIELDS: It is a more stringent standard.

Can you tell me how it would relate to, for instance, the arsenic standard?

MR. PIERCE: Under the current recommendations, the arsenic standard for organisms only is 0.14 micrograms per liter. Water plus organisms is 0.018, which is a standard that some of the pueblos have adopted.

It isn't as great a difference in arsenic as it is in some of the highly bioaccumulative organic biocontaminants. So there it's an order of magnitude.

MR. SHIELDS: So I'm wondering, both with this -- using this criteria and also looking at the numbers that were used for risk -- for assessing risk criteria at ten to the minus five, as opposed to ten to the minus six, I'm just wondering, in terms of downstream receiving waters, like the pueblos, for instance, or other states, does -- how that affects what kind of -- what water we're delivering to those people.

MR. PIERCE: Mr. Chairman, Mr. Shields, currently, all of these are at real low levels, so there is probably not a current problem.

There could be a problem, as there could be with a lot of other aspects of water quality standards, because there are so many different sets of standards that apply to different areas of New Mexico.

I believe that the Rio Grande alone goes in and out of eight different jurisdictions and a lot of those

standards are quite different.

These standards were not chosen to be protective of any particular tribal standards. We don't know that they aren't protective, but they are not the same standards as some of the tribes have adopted.

MR. SHIELDS: So do we know, in terms of how many of our neighboring states have used the ten to the minus sixth criteria or -- I mean, I don't know how the pueblo standards are developed, but are they developed in the same manner, so how many pueblos adopted this, the more stringent criteria?

MR. PIERCE: I believe three of the pueblos have adopted human health, the others have not, and those three all adopted at ten to the minus sixth.

There is an exhibit that's being submitted by San Juan Water Commission that shows that Colorado uses ten to the minus sixth, Montana uses the same, Nevada uses the same, Texas is ten to the minus fifth. I can't make it out what it says for Utah. It looks like it's ten to the minus sixth. So they've gone back and forth.

MR. SHIELDS: Okay.

MR. AMES: Point of clarification, this document actually was prepared by the Department; correct?

MR. PIERCE: Originally, it was prepared by the Department in draft form, yes, but we did not introduce it as an exhibit.

MR. AMES: Okay.

MR. SHIELDS: I'm just curious whether adopting ten to the minus five places the state in a situation where they might be liable for not meeting -- not delivering water quality sufficient -- at a sufficient level for those downstream recipients?

MR. DAVIS: Mr. Chairman, Mr. Shields, in the interests of time, in the closing part of my testimony, we were moving quite rapidly, however, I --

MR. AMES: From our perspective.

MR. DAVIS: -- have a protocol for that that we've developed -- no, this is in my written testimony, but I can say it now.

Let me find it. I want to make sure that I say it correctly.

Okay. I say in my written testimony that the Department's proposal is squarely within the range of values authorized by federal law and regulation and would be acceptable to EPA. That's on page four of my written testimony, the last paragraph.

I thought I had a bullet in my notes to that effect, but I can't find it.

So your question of whether or not we would -- the state would be liable, I think -- I think what we're proposing is completely within what EPA would find acceptable, that doesn't go to, you know, hypothetical liability, but I believe it addresses what the federal agency --

MR. SHIELDS: At least it sounds like we don't have to worry about Texas on this one.

Mr. Chairman and Members of the Commission, that brings to a conclusion my cross-examination.

MR. MAGGIORE: Okay. Thank you, Mr. Shields.

Do you want to go straight into your public comment and then we'll have public comment from the Cattle Growers and we'll recess for the evening?

(Oath administered to Brian Shields.)

BRIAN SHIELDS

after having been first duly sworn under oath, was questioned and testified as follows:

DIRECT TESTIMONY

MR. SHIELDS: Mr. Chairman and Members of the Commission, thank you for providing this opportunity for me to make a brief presentation.

As many of you know, Amigos Bravos is a New Mexico river conservation advocacy organization. We have offices in both Taos and in Albuquerque, and we have a

membership of 1,500 members. We have a track record of working on water quality issues, having formally participated in the last triennial review of water quality standards and having helped to secure the NPDES and state water quality permits to control acid mine drainage from the Molycorp Mine in Questa, among other things.

On behalf of our members, who are mainly in New Mexico, we would like to offer support for the Bureau's present petition for the following reasons.

First, many of the priority pollutants in the petition are synthetic, often chlorinated, compounds which do not break down in nature and which, because of their unnaturalness, cause severe problems in natural systems ranging from ecosystems to human bodies. They include many of the worst, most persistent poisons on the planet. Many are known or suspected carcinogens and/or cause human reproduction or nervous system damage.

Second, the Bureau's present effort to prevent toxic bioaccumulations in fish is very valuable. Moreover, there are many other pathways through which these substances can potentially affect the environment and human beings through the use of river water for domestic supplies, for instance, which are being planned for Albuquerque, Santa Fe and other New Mexico cities in

the near future.

We believe that this is a good proactive measure to take at this time.

Third, we're only now finding out exactly where the substances exist in New Mexico surface waters. It seems that the more you look, the more you find. So we think it's important to be looking in order to protect human health.

In conclusion, Amigos Bravos believes that the precautionary principle is highly appropriate for regulating priority pollutants in New Mexico, because of their extreme toxicity, persistence, and uncertain systemic effects. This means that there should be strong efforts to locate and monitor these substances, to determine their extent and sources, and means minimizing the quantities that are allowed to enter the environment, preferably preventing their discharge completely at the source.

We believe that the present petition, as a whole, goes a considerable way towards this by helping to put the monitoring and control of these dangerous substances on a formal, transparent and systematic basis, and for those reasons, Amigos Bravos supports the petition.

Thank you for taking these comments into

consideration.

MR. MAGGIORE: Thank you, Mr. Shields.

Appreciate that.

I believe we have one more.

MS. BRANDVOLD: And cross.

MR. MAGGIORE: I'm sorry, any cross-examination of the witness by the Commission?

Seeing none, any cross-examination from the audience?

MR. AMES: No.

MR. MAGGIORE: None.

Thank you, Mr. Shields. Appreciate that.

(Oath administered to Callie Gnatkowski.)

CALLIE GNATKOWSKI

after having been first duly sworn under oath, was questioned and testified as follows:

DIRECT TESTIMONY

MS. GNATKOWSKI: Mr. Chairman, Members of the Commission, my name is Callie Gnatkowski. I'm here today representing the New Mexico Cattle Growers and the New Mexico Wool Growers Associations.

Caren Cowan, who was here yesterday with the Cattle Growers, wasn't able to come today.

Both organizations would support the San Juan Water Commission's position that the standards, since

they are of this magnitude and could have such impacts, should be considered during the next triennial review process when other standards, such as these, are considered.

Both associations are very interested in issues like this because of the impacts they can have on our membership and would be -- and would like to be involved in the process.

The Wool Growers Association was never notified about the process. I hadn't heard anything about it until I read an article in the New Mexico -- The New Mexican a couple of days ago.

The Cattle Growers were -- Caren asked me to say that the Cattle Growers were contacted by the Department in December about the potential for meeting with them, and she did say that she would like to meet with them, but then never heard back from them again. So that's really all I have to say.

MR. MAGGIORE: Okay. Thank you.

MS. GNATKOWSKI: Thank you.

MR. MAGGIORE: Thank you very much, and thank you for sticking around to share that with us.

Any cross-examination of the witness from the members of the Commission?

Seeing none, any cross-examination of the

witness from the audience?

Seeing none, thank you.

You're excused.

MS. GNATKOWSKI: Thanks.

MR. MAGGIORE: I think we can go off the record now and recess until 8:00 tomorrow morning, where we will pick up with the cross-examination of the Department's witnesses by San Juan.

I will not be able to be here tomorrow, and if it's the Commission's pleasure, I would like to -- since I was voted to be the Hearing Officer for this matter, I would ask the Commission's counsel, Tracy Hughes, to do that.

Is that okay with the fellow Commissioners?

Tracy, is that okay with you?

MS. HUGHES: I will do longer lunches, I promise.

MR. MAGGIORE: I'll give you a lot of work to work with there, Counsel.

(Hearing recessed at 6:54 PM.)

STATE OF NEW MEXICO)
)ss.
COUNTY OF BERNALILLO)

I, Kathy Townsend, the officer before whom the foregoing hearing was taken, do hereby certify that the witnesses whose testimony appears in the foregoing transcript were duly sworn by me; that I personally recorded the testimony by machine shorthand; that said transcript is a true record of the testimony given by said witnesses; that I am neither attorney nor counsel for, nor related to or employed by any of the parties to the action in which this matter is taken, and that I am not a relative or employee of any attorney or counsel employed by the parties hereto or financially interested in the action.

NOTICES

This document provides information to states and tribes authorized to establish water quality standards under the Clean Water Act (CWA), to protect aquatic life from toxic effects of aluminum. Under the CWA, states and tribes are to establish water quality criteria to protect designated uses. State and tribal decision makers retain the discretion to adopt approaches that are scientifically defensible that differ from these criteria to reflect site-specific conditions. While this document contains the Environmental Protection Agency's (EPA) scientific recommendations regarding ambient concentrations of aluminum that protect aquatic life, the Aluminum Criteria Document does not substitute for the CWA or the EPA's regulations; nor is it a regulation itself. Thus, the document does not impose legally binding requirements on the EPA, states, tribes, or the regulated community, and might not apply to a particular situation based upon the circumstances. The EPA may update this document in the future. This document has been approved for publication by the Office of Science and Technology, Office of Water, U.S. Environmental Protection Agency.

Mention of trade names or commercial products does not constitute endorsement or recommendation for use. This document can be downloaded from: https://www.epa.gov/wqc/aquatic-life-criteria-and-methods-toxics.

NMED Exhibit 75

FOREWORD

The Clean Water Act (CWA) Section 304(a)(l) (P.L. 95-217) directs the Administrator of the Environmental Protection Agency (EPA) to publish water quality criteria that accurately reflect the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare that might be expected from the presence of pollutants in any body of water, including groundwater. This document is a final ambient water quality criteria (AWQC) document for the protection of aquatic life based upon consideration of all available information relating to effects of aluminum on aquatic organisms.

The term Water Quality Criteria is used in two sections of the CWA, Section 304(a)(l) and Section 303(c)(2). The term has different meanings in each section. In Section 304, the term represents a non-regulatory, scientific assessment of ecological and human health effects. Criteria presented in this document are such a scientific assessment of ecological effects. In section 303, if water quality criteria associated with specific surface water uses are adopted by a state or the EPA as water quality standards, they become the CWA water quality standards applicable in ambient waters within that state or authorized tribe. Water quality criteria adopted in state water quality standards could have the same numerical values as recommended criteria developed under section 304. However, in some situations states might want to adjust water quality criteria developed under section 304 to reflect local water chemistry or ecological conditions. Alternatively, states and authorized tribes may develop numeric criteria based on other scientifically defensible methods, but the criteria must be protective of designated uses. It is not until their adoption as part of state water quality standards, and subsequent approval by the EPA under section 303(c), that criteria become CWA applicable water quality standards. Guidelines to assist the states and authorized tribes in modifying the criteria presented in this document are contained in the Water Quality Standards Handbook (U.S. EPA 2014).

This document presents recommendations only. It does not establish or affect legal rights or obligations. It does not establish a binding requirement and cannot be finally determinative of the issues addressed. The EPA will make decisions in any particular situation by applying the CWA and the EPA regulations on the basis of specific facts presented and scientific information then available.

NMED Exhibit 75

EXECUTIVE SUMMARY

The U.S. Environmental Protection Agency (EPA) is updating its aquatic life ambient water quality criteria (AWQC) recommendation for aluminum, in accordance with the provisions of section 304(a) directing the EPA to revise AWQC from time to time to reflect the latest scientific knowledge. The recommended aluminum aquatic life AWQC were developed using peer reviewed methods and data that are acceptable for the derivation of criteria, as described in the EPA's 1985 "*Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses*" (Stephan et al. 1985, referred to herein as "1985 Guidelines"). The previous aquatic life AWQC for aluminum were developed in 1988 (EPA 440/5-86-008). These 2018 final recommended aquatic life AWQC for aluminum supersedes the 1988 recommended criteria.

The 2017 draft aquatic life AWQC for aluminum were posted to the Federal Register (Docket ID: EPA-HQ-OW-2017-0260) in late July 2017 for public comment. The public comment period was open for 90 days and closed in late October 2017. Public comments received were incorporated and addressed in these final AWQC, where applicable. The EPA responses to all of the public comments can be found on the website for the aluminum criteria (https://www.epa.gov/wqc/aquatic-life-criteria-aluminum).

Literature searches for laboratory tests published from 1988 to 2017 identified new studies describing the toxicity of aluminum to aquatic life. The EPA supplemented these studies with additional data made available by researchers in late-2017 and 2018. The EPA conducted a full evaluation of available data to determine test acceptability for criteria development. Appendix A of "*Quality Criteria for Water 1986*" (U.S. EPA 1986) provides an in-depth discussion of the minimum requirements for data quality needed to develop AWQC for aquatic life.

This update to the recommended aluminum aquatic life AWQC establishes freshwater criteria magnitude values resulting from the interactions of aluminum and three water chemistry parameters: pH, total hardness, and dissolved organic carbon (DOC). It also expands the toxicity database to include those studies conducted in waters with pH values below 6.5. There were insufficient data to establish an estuarine/marine aluminum criteria.

Multiple linear regression (MLR) models were developed to characterize the bioavailability of aluminum in aquatic systems, based on the effects of pH, total hardness and

NMED Exhibit 75

DOC on aluminum toxicity (DeForest et al. 2018a,b). These authors used a dataset comprised of 22 chronic tests with the fathead minnow (*Pimephales promelas*), and 23 chronic tests with an invertebrate (*Ceriodaphnia dubia*) to evaluate the ability of MLR models to predict chronic toxicity of aluminum as a function of pH, total hardness and DOC water chemistry conditions. These three parameters are considered to be the most influential for aluminum bioavailability and can be used to explain the range of differences in the observed toxicity values. These datasets were supplemented in 2018 with an additional nine *C. dubia* toxicity tests and nine *P. promelas* toxicity tests to expand the range of water chemistry conditions for model development (OSU 2018a,b,d). All of the toxicity test data used in the model were subjected to independent external expert peer review.

Two models, one for invertebrates and one for vertebrates, were used to normalize freshwater aluminum toxicity values. These separate models correspond to effects on invertebrates and vertebrates due to differing effects of pH, total hardness and DOC on aluminum bioavailability and toxicity, and therefore enable the criteria magnitudes to be calculated as a function of the unique chemistry conditions at a given site. The EPA conducted both independent external expert peer review and internal reviews of these models, published by DeForest et al. (2018a,b), to verify the results. The updated aluminum criteria were derived using these MLR models to normalize the freshwater acute and chronic toxicity data. The MLR equations applied to the acute toxicity data were those developed using chronic tests, with the expectation that the effect of water chemistry on bioavailability remains consistent across exposure duration.

Freshwater Criteria Update

The 1988 aluminum freshwater criteria (U.S. EPA 1988) are expressed as total recoverable aluminum. Acid soluble aluminum was considered but not used because the methods were not developed. These updated 2018 criteria are also based on total recoverable aluminum concentrations.

The 1988 criteria did not consider the variable effects of water chemistry on aluminum toxicity, but simply specified that the recommended criteria only applied to a pH range of 6.5 to 9.0. The 2018 final aluminum recommended AWQC take into account the effects of pH, total hardness and DOC on aluminum toxicity.

NMED Exhibit 75

The 1988 freshwater acute criterion was based on data from eight species of invertebrates and seven species of fish for a total of 15 species grouped into 14 genera. This 2018 freshwater acute criterion update is based on data from 13 species of invertebrates, eight species of fish, and one species of frog for a total of 22 species grouped into 20 genera.

The freshwater acute criterion represents the concentration of aluminum at which approximately 95% of genera in a freshwater aquatic ecosystem should be protected if the one-hour average (duration) concentration of total aluminum is not exceeded more than once in three years (frequency). The magnitude of the criterion depends on the water chemistry conditions in the waterbody, using the MLR models to normalize the freshwater acute toxicity data. As a result, the acute criterion will vary with water chemistry conditions. Example acute criteria values for various water chemistry conditions are presented in **Appendix K** (*Recommended Criteria for Various Water Chemistry Conditions*) and can also be calculated with the Aluminum Criteria Calculator V.2.0[1].

The 1988 aluminum freshwater chronic dataset included two species of invertebrates and one fish species grouped into three genera. This 2018 criteria update includes new chronic data for an additional nine species, and consists of eight invertebrate and four fish species grouped into 12 genera. With the addition of one study from **Appendix H** (*Other Data on Effects of Aluminum to Freshwater Aquatic Organisms*), the Minimum Data Requirements (MDRs) for direct calculation (using a sensitivity distribution, as described in the 1985 Guidelines) of the Final Chronic Value (FCV) were fulfilled. This method does not require the use of an acute to chronic ratio (ACR).

Like the acute criterion, the freshwater chronic criterion is also dependent on the water chemistry of the waterbody. Therefore, it is also a function of the MLR models used to normalize the chronic toxicity data. Example chronic criteria (CCC) for various water chemistry conditions are presented in **Appendix K** (*Recommended Criteria for Various Water Chemistry Conditions*) and can also be calculated with the Aluminum Criteria Calculator V.2.0.

The empirical toxicity test data used to develop the MLR models were developed under a range of water chemistry conditions (for more detail, see **Section 4** of this document). The MLRs were then used to normalize all of the toxicity data used in the criteria calculations. MLR models

[1] https://www.epa.gov/wqc/aquatic-life-criteria-aluminum

NMED Exhibit 75

are useful for characterizing trends in data, but should be used with caution when extrapolating beyond the range of data used for model development.

The bounds for pH of the models ranged from 6.0-8.7. The EPA criteria calculator is designed to allow the user to extrapolate beyond the pH values used to generate the MLR models. The criteria calculator can be used to address all waters within a pH range of 5.0 to 10.5. This is reflected in the criteria lookup tables in **Appendix K**. The EPA took this approach so that the recommended criteria can be calculated for, and will be protective of, a broader range of natural waters found in the U.S. Extrapolated criteria values outside of the empirical pH data tend to be more conservative (i.e., lower values) and will be more protective of the aquatic environment in situations where pH plays a critical role in aluminum toxicity. Criteria values generated outside of the range of the pH conditions of the toxicity tests underlying the MLR models are more uncertain than values within the pH conditions of the MLR toxicity tests, and thus should be considered carefully and used with caution.

The bounds for total hardness of the models ranged from 9.8 to 428 mg/L. Since a decrease in total hardness tends to increase aluminum toxicity, the EPA concludes that it is reasonable to extrapolate below the lower bound of the empirical hardness data of 9.8 mg/L to enable generation of more stringent criteria at low hardnesses. This is consistent with existing EPA approaches to address low end hardness values (U.S. EPA 2002). Therefore, hardness input values in the criteria calculator can be entered that are less than 9.8 mg/L down to a limit of 0.01 mg/L. However, hardness input values into the criteria calculator will be bounded at the approximate upper limit of the empirical MLR models' underlying hardness data, at a maximum of 430 mg/L total hardness (as $CaCO_3$). The user can input hardness values greater than 430 mg/L for total hardness into the criteria calculator, but the criteria magnitude will reach its maximum value at 430 mg/L total hardness (as $CaCO_3$), and criteria magnitudes will not increase or decrease by increasing the hardness above 430 mg/L total hardness (as $CaCO_3$). This is also consistent with existing EPA guidance on high end hardness caps (U.S. EPA 2002). This recommendation is reflected in the criteria lookup tables provided in **Appendix K**. The EPA took this approach to ensure that the recommended criteria are protective of a broader range of natural waters found in the U.S. Criteria values generated beyond the lower bound of the hardness conditions of the toxicity tests underlying the MLR models are more uncertain than values within the hardness bounds of the MLR toxicity test data.

NMED Exhibit 75

The bounds for DOC of the models ranged from 0.08 to 12.3 mg/L. Since most natural waters contain some DOC, the lower bound of the empirical toxicity test data (0.08 mg/L) is the lowest value that can be entered into the criteria calculator; thus no extrapolation below the lowest empirical DOC of 0.08 mg/L is provided. Similar to hardness, the criteria values generated will be bounded at the upper limit of the empirical MLR models' underlying DOC data, at a maximum 12.0 mg/L DOC in the criteria calculator. The user can input DOC values greater than 12.0 mg/L into the calculator, but the criteria magnitude will reach its maximum value at 12.0 mg/L DOC, and criteria magnitudes will not increase or decrease by increasing the DOC above 12.0 mg/L. This limitation on the maximum DOC value is also reflected in the criteria lookup tables provided in **Appendix K**. This is consistent with the existing approach for hardness (U.S. EPA 2002) to provide for protection of aquatic organisms through the use of protective, conservative values under water chemistry conditions beyond the upper limits of the empirical toxicity test data.

In addition to **Appendix K** look-up tables, the EPA created a user-friendly **Aluminum Criteria Calculator V.2.0** (Aluminum Criteria Calculator V.2.0.xlsm) that allows users to enter site-specific values for pH, total hardness and DOC to calculate the appropriate recommended freshwater acute and chronic criteria magnitudes for site-specific parameters and will generate criteria magnitude values based on the bounds described above.

2018 Recommended Aluminum Aquatic Life AWQC and the 1988 Criteria[a]

Version	**Freshwater Acute** (1-hour, total aluminum)	**Freshwater Chronic** (4-day, total aluminum)
2018 AWQC (vary as a function of a site's pH, DOC and total hardness)	1-4,800 µg/L[b]	0.63-3,200 µg/L[b]
1988 AWQC (pH 6.5 – 9.0, across all total hardness and DOC ranges)	750 µg/L	87 µg/L

[a] Values are recommended not to be exceeded more than once every three years on average.
[b] Criteria values will be different under differing water chemistry conditions as identified in this document, as described in Appendix K and applied in the Aluminum Criteria Calculator.

Estuarine/Marine Criteria Update

As with the 1988 AWQC for aluminum, there are still insufficient data on estuarine and marine species to fulfill the MDRs as specified in the 1985 Guidelines. As a result, the EPA cannot recommend criteria for estuarine/marine waters at this time. The 1985 Guidelines require

NMED Exhibit 75

that data from a minimum of eight families are needed to calculate an estuarine/marine Final Acute Value (FAV). New acute toxicity data for five families representing five species of estuarine/marine organisms are available for aluminum; no data were previously available. The most sensitive species was the polychaete worm (*Ctenodrilus serratus*) with a Species Mean Acute Value (SMAV) of 97.15 µg/L total aluminum, and the most tolerant species was a copepod (*Nitokra spinipes*) with a SMAV of 10,000 µg/L. No acceptable acute tests on estuarine/marine fish species were available. There are no estuarine/marine chronic toxicity data for fish or other genera that meet the test acceptability and quality assurance and quality control (QA/QC) principles as outlined in the 1985 Guidelines. Thus acute and chronic aluminum toxicity data for estuarine and marine species remain a data gap.

NMED Exhibit 75

1 INTRODUCTION AND BACKGROUND

The United States Environmental Protection Agency (EPA) establishes national recommended Ambient Water Quality Criteria (AWQC) as authorized under section 304(a)(1) of the Clean Water Act (CWA). Section 304(a)(1) aquatic life criteria serve as recommendations to states and authorized tribes by defining ambient water concentrations that will protect against unacceptable adverse ecological effects to aquatic life resulting from exposure to pollutants found in water, consistent with the 1985 Guidelines. Section 304(a) recommended aquatic life criteria are developed to provide for the protection and propagation of fish and shellfish. Once the EPA publishes final section 304(a) recommended water quality criteria, states and authorized tribes may adopt these criteria into their water quality standards to protect designated uses of water bodies. States and authorized tribes may adopt water quality criteria that reflect adjustments to the EPA's recommended section 304(a) criteria to reflect local environmental conditions and human exposure patterns. Alternatively, states and authorized tribes may derive numeric criteria based on other scientifically defensible methods that protect the designated use. After adoption, states and authorized tribes submit new and revised water quality standards (WQS) to the EPA for review and approval or disapproval under CWA section 303(c). When approved by the EPA, the state or authorized tribe's WQS become the applicable WQS for CWA purposes. Such purposes include identification of impaired waters and establishment of Total Maximum Daily Loads (TMDLs) under CWA section 303(d) and derivation of water quality-based effluent limitations in permits issued under the CWA Section 402 National Pollutant Discharge Elimination System (NPDES) permit program.

As required by the CWA, the EPA periodically reviews and revises section 304(a) AWQC to ensure the criteria accurately reflect the latest scientific knowledge. The EPA previously published AWQC recommendations for aluminum in 1988 (EPA-440/5-86-008[2]), and is updating these criteria through its authority under CWA section 304(a). Water quality criteria are developed following the guidance outlined in the EPA's "*Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses*" (Stephan et al. 1985) (herein referred to as the "1985 Guidelines"). This document describes

[2] https://www.epa.gov/wqc/national-recommended-water-quality-criteria-aquatic-life-criteria-table

NMED Exhibit 75

scientifically defensible water quality criteria values for aluminum pursuant to CWA section 304(a), derived utilizing best available data in a manner consistent with the 1985 Guidelines.

2 PROBLEM FORMULATION

Problem formulation provides a strategic framework to develop water quality criteria by providing an overview of a chemical's sources and occurrence, fate and transport in the environment, and toxicological characteristics and factors affecting toxicity. A problem formulation uses this information to develop a conceptual model and identify the most relevant chemical properties and endpoints for evaluation. The structure of this effects assessment for aluminum is consistent with the EPA's *Guidelines for Ecological Risk Assessment* (U.S. EPA 1998a). This ecological effects assessment describes scientifically defensible water quality criteria values for aluminum under CWA section 304(a)(1).

2.1 Overview of Aluminum Sources and Occurrence

This section provides an overview of available reliable information from the peer-reviewed literature that characterizes sources and occurrence of aluminum in the environment. Aluminum is the third most abundant element and the most common metal in the Earth's crust, comprising about eight percent of the lithosphere (CRC 2000). It is typically found in complexation with oxygen (as oxides) and silica (as silicates), but rarely in the elemental state (Greenwood and Earnshaw 1997). Aluminum is found in most rocks, particularly igneous rocks, containing aluminosilicate minerals (Staley and Haupin 1992), and associated with clays and soil/sediments. Different water column forms include monomeric, polymeric, particulate (suspended) and colloidal forms of aluminum. Ions such as chloride, fluoride, nitrate, phosphate and sulfate form soluble complexes with aluminum, as do fulvic and humic acids (U.S. EPA 1988).

Aluminum enters the aquatic environment from both natural and anthropogenic sources, with natural sources typically dominating occurrence (Lantzy and MacKenzie 1979). This is due to the abundance of aluminum in rocks and minerals released by weathering (Lee and Von Lehmden 1973; Sorenson et al. 1974). Other natural aluminum sources include volcanic activity and acidic spring waters (USGS 1993; Varrica et al. 2000).

Anthropogenic releases are primarily associated with industrial processes and include air emissions, wastewater effluent and solid waste (ATSDR 2008). Anthropogenic sources include

NMED Exhibit 75

fossil fuel combustion, aluminum production (mining and smelting) and aluminum present in fertilizers used in agriculture (Lantzy and MacKenzie 1979; Lee and Von Lehmden 1973; Ondov et al. 1982; Que Hee et al. 1982). Alum (potassium aluminum sulfate), used as a coagulant to clarify drinking water and wastewater, can also be a source of aluminum if this water is discharged to aquatic systems (Gidde et al. 2012).

A common source of aluminum in freshwater systems is from the mobilization of aluminum from rocks and soils by acid precipitation, heavy rains, or snow melt (Bjerknes et al. 2003). For estuaries and oceans, the primary source of aluminum is from riverine discharges, with the majority of the introduced aluminum sorbed to the surface of clay particles in estuarine sediments (Hydes and Liss 1977). However, aluminum that is either bound to clays or complexed to dissolved organic carbon can be converted to the reactive species upon mixing with high pH and high salinity ocean waters (Bjerknes et al. 2003; Rosseland et al. 1998; Teien et al. 2006a). The mechanism of this conversion is not well understood.

Aluminum is still actively mined in the U.S. from bauxite, the primary aluminum ore (mainly in Arkansas), with approximately 2 million metric tons produced in 2014. This raw domestic feedstock, plus imported bauxite and recycled aluminum, are currently processed at nine U.S. smelters into refined products (Bray 2015; USGS 2013). Because of aluminum's properties (light weight, resistance to corrosion, electrical conductivity, and durability), it has many diverse uses including: the transportation industry (automobiles, airplanes, trucks, railcars, marine vessels, etc.); packaging (cans, foil, etc.); construction (windows, doors, siding, etc.); consumer durables (appliances, cooking utensils, etc.); electrical transmission lines; and machinery (USGS 2013). Aluminum is also used in wastewater treatment to reduce effluent phosphorus levels (Tchobanoglous et al. 2003) and in the pharmaceutical industry in antacids and as a food additive (Government of Canada 1998).

The Water Quality Data Portal (https://www.waterqualitydata.us/) is an extensive database of environmental measurements available to identify concentrations of chemical contaminants, including aluminum, in surface waters such as rivers and streams. The results are reported in filtered and unfiltered categories. The terms filtered, dissolved, unfiltered, and total and their relationships, as defined by the U.S. Geological Survey (USGS), are presented below. "Dissolved" refers to constituents that exist in chemical solution in a water sample. "Filtered" pertains to constituents in a water sample passed through a filter membrane of specified pore

NMED Exhibit 75

diameter, most commonly 0.45 micrometer or less for inorganic analytes. Therefore, for interpretation, the filtered samples (prior to acidification) will be assumed to be dissolved aluminum. "Total" pertains to the constituents in an unfiltered, representative water-suspended-sediment sample. This term is used only when the analytical procedure includes an acid digestion procedure that ensures measurement of at least 95 percent of the constituent present in both the dissolved and suspended phases of the sample. Therefore, for interpretation, the unfiltered samples are assumed to be total recoverable aluminum.

Aluminum data for freshwater systems were obtained from the Water Quality Data Portal (accessed 2/16/17) for data representing years 1991 to 2017. A total of 7,483 surface water samples were collected (4,991 filtered samples and 2,492 unfiltered samples) in that timeframe and analyzed for dissolved and total aluminum, respectively. The range of concentrations reported for dissolved aluminum was 0.8 µg/L to a maximum concentration reported of 20,600 µg/L. The range of total aluminum concentrations across all sites was a minimum of 0.9 µg/L, with a maximum reported total concentration of 210,000 µg/L. Groundwater concentrations of dissolved aluminum (filtered using a 0.45 micrometer filter) from the USGS National Water Quality Assessment Program (NAWQA) database collected during 1992-2003 are presented in **Figure 1**, and had a 90^{th} percentile concentration of dissolved aluminum concentrations of 11 µg/L.

NMED Exhibit 75

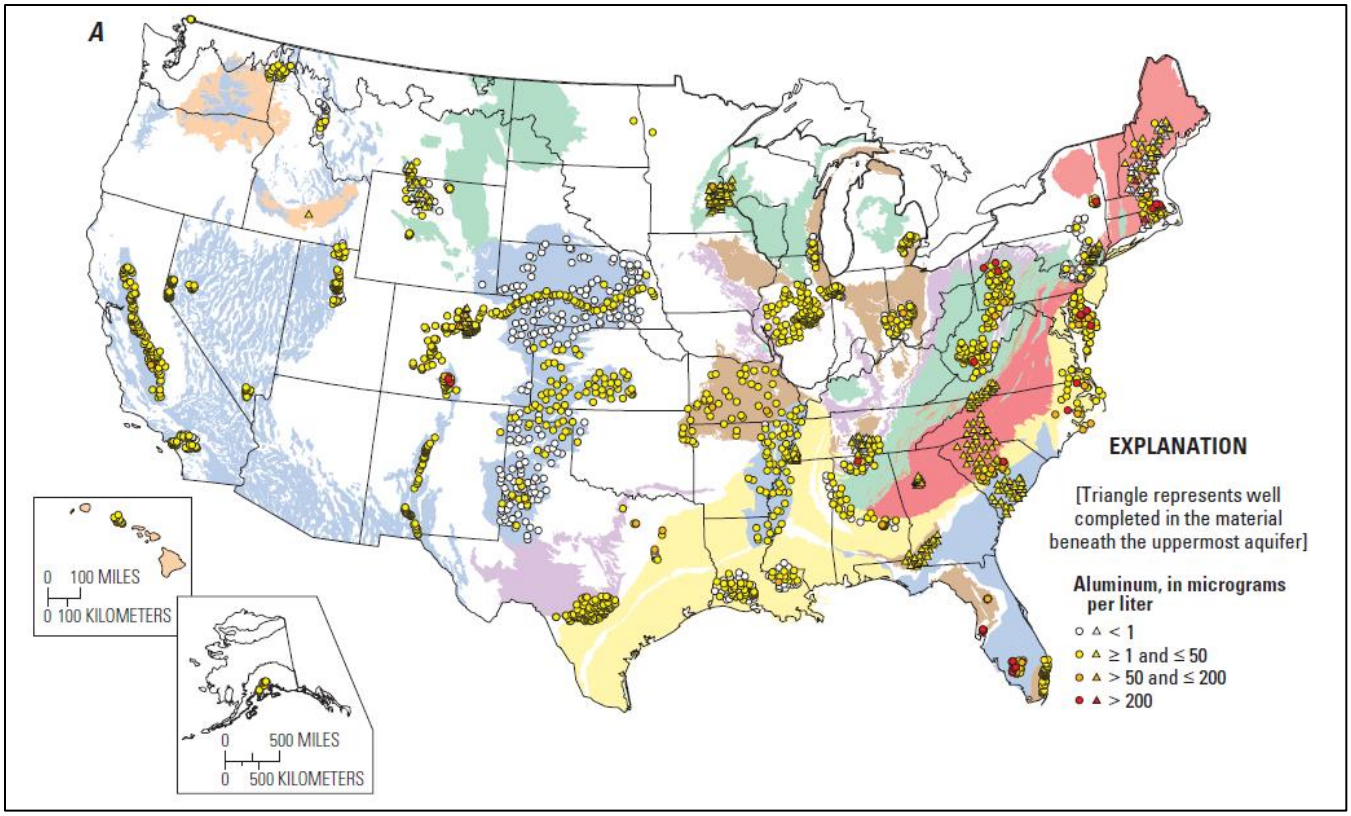

Figure 1. Geographic Distribution of Dissolved Aluminum Concentrations in Groundwater Collected from Wells as Part of the National Water-Quality Assessment Program, 1992–2003.
(Ayotte et al. 2011, used with permission.)

Aluminum concentrations in marine and estuarine waters are generally lower than levels found in freshwater systems, especially compared to acid-impacted areas (Gensemer and Playle 1999). Data for dissolved aluminum in coastal and marine waters were compiled from the scientific literature by Angel et al. (2016) and indicate that concentrations range from 0.5 to 2 µg/L in coastal waters, and from 0.008 to 0.68 µg/L in the open ocean. Other researchers have also reported that values are generally ≤1 µg/L in ocean waters (Brown et al. 2010; Hydes and Liss 1977; Tria et al. 2007). At the typical ocean pH of 8.0-8.3, aluminum forms complexes with hydroxide ion, primarily as $Al(OH)_4$, which precipitates out of solution. This largely explains the low concentrations in marine waters.

Much of the early to mid-1970s metals data in samples from natural waters are considered erroneously high due to contamination from sampling methods or containers. These flaws were corrected with the implementation of clean sampling techniques and guidance provided by U.S. EPA's Method 1669: Sampling Ambient Water for Trace Metals at EPA Water

Quality Criteria Levels (U.S. EPA. 2004). This method was designed to support water quality monitoring programs authorized under the Clean Water Act, specifically created for measuring toxic metals at the low part-per-trillion to low part-per-billion range (U.S. EPA 1996).

Average concentrations of total aluminum in the atmosphere were observed to range from 0.005 to 0.18 μg/m^3 (Hoffman et al. 1969; Potzl 1970; Sorenson et al. 1974). These concentrations are dependent on the location, weather conditions and industrial activity in the area with most of the airborne aluminum present in the form of small suspended particles of soil (dust) (ATSDR 2008). It should be noted that aluminum concentrations in air samples are often dependent upon the aluminum levels of the entrained soil particles, especially if measured as total aluminum. Goncharuk et al. (2012) sampled sea aerosols from the lower portion of the troposphere in the Black Sea (2002-2008), the Caspian Sea (2002-2006), the Baltic Sea (2001-2008), the White, Barents and Kara Seas (2005-2007) and high-altitude arctic regions in the Arctic and South Atlantic Oceans. Air samples were collected by aerosol filters for 3 to 5 hours during headwind conditions in the direction of atmospheric phenomenon. Most reported atmospheric total aluminum concentrations were less than 1 μg/m^3. The authors noted that the lowest concentrations were found at the high-altitude northern arctic regions, with increasing levels observed for the Western Arctic seas, and the highest concentrations reported for the most southerly located Black and Caspian Seas. They suggested that this northern to southern increasing concentration trend could be due to differential anthropogenic loading to the respective water bodies, and also with the increasing emissions of domestic and industrial wastes, wastewater, and emergency discharges of toxicants. Urban and industrial areas can have higher atmospheric total aluminum concentrations with levels reported from 0.4 to 8.0 μg/m^3 (Cooper et al. 1979; Dzubay 1980; Kowalczyk et al. 1982; Lewis and Macias 1980; Moyers et al. 1977; Ondov et al. 1982; Pillay and Thomas 1971; Sorenson et al. 1974; Stevens et al. 1978).

Total aluminum concentrations in North Atlantic precipitation collected in 1988 ranged from 6.1 to 827 μg/L (Lim and Jickells 1990). This is similar to a recent study that collected rainfall from two Mexico locations: a rural forested region 80 km south and downwind of Mexico City and Mexico City itself (Garcia et al. 2009). Average total aluminum precipitation concentrations reported in the rural area (107.2 μg/L, range of 28.8-222.7 μg/L) were higher than observed in the urban area (83.9 μg/L, range 35.8-125.4 μg/L). Samples of wet deposition collected in semi-rural Dexter, Michigan, had an average total aluminum concentration of 57

NMED Exhibit 75

µg/L (Landis and Keeler 1997). Much lower levels of total aluminum were found in rainfall samples collected in Japan during 2000 and 2002 where average concentrations ranged from 2.71 to 6.06 µg/L (Takeda et al. 2000; Vuai and Tokuyama 2011). Atmospheric precipitation (i.e., rain and snow) samples collected in the U.S. have contained up to 1,200 µg/L total aluminum (Dantzman and Breland 1970; DOI 1971; Fisher et al. 1968; USGS 1964). No available information was found reporting concentrations of aluminum in fog.

Due to the abundance of aluminum in the earth's crust, soil concentrations can range widely from approximately 700 mg/kg to over 100,000 mg/kg (Shacklette and Boerngen 1984; Sorenson et al. 1974), averaging 71,000 mg/kg (Frink 1996). These concentrations are generally dependent on local geology and associated vegetation types and can vary within the same area, often strongly correlated with its clay content (Ma et al. 1997). Total aluminum concentrations in 1,903 soil samples collected from the continental U.S., Hawaii, Virgin Islands, Guam and Puerto Rico ranged from 500 to 142,000 mg/kg (Burt et al. 2003). In streambed sediment samples collected from locations in the conterminous U.S. from 1992 to 1996, aluminum concentrations ranged from 1.4 to 14% (by weight) (Rice 1999). Marsh/estuarine sediment samples collected from nine sampling sites within or along Georgia's Cockspur Island and McQueen's Island at Fort Pulaski's National Monument, a salt marsh ecosystem, had aluminum concentrations ranging from 17 to 820 mg/kg dry weight (Kumar et al. 2008).

Aluminum may form a precipitate when aluminum-rich water meets less acidic water. This precipitate mix, referred to as a floc, may include other co-precipitated ions, as well as nutrients, suspended materials and microorganisms. Removal of phosphorus from water has been observed in laboratory studies (Auvraya et al. 2006; Gilmore 2009; Matheson 1975; Minzoni 1984; Peterson et al. 1974; Westholm 2006) and in lake field studies (Knapp and Soltero 1983; Pilgrim and Brezonik 2005; Reitzel et al. 2005). Turbidity due to clay has been removed from pond waters using aluminum sulfate (Boyd 1979). Unz and Davis (1975) hypothesized that aluminum floc might coalesce bacteria and concentrate organic matter in effluents, thus assisting the biological sorption of nutrients. Aluminum sulfate (or alum) has been used to flocculate algae from water (McGarry 1970; Minzoni 1984; Zarini et al. 1983).

2.2 Environmental Fate and Transport of Aluminum in the Aquatic Environment

Aluminum (CAS Number 7429-90-05) is a silver white, malleable, and ductile metal that is odorless, and has a molecular weight of 26.98 g/mole (HSDB 2008). It has a density of 2.70

NMED Exhibit 75

g/cm^3, a melting point of 660°C, a boiling point of 2,327°C, a vapor pressure of 1 mm Hg at 1,284°C, and is insoluble in water (CRC 2000; HSDB 2008). The n-octanol/water partitioning coefficient (K_{ow}), organic-carbon normalized partition coefficient (K_{oc}), and Henry's law constant for aluminum are unknown.

The chemistry of aluminum in surface water is complex because of the following properties: 1) it is amphoteric, meaning it is more soluble in acidic solutions and in basic solutions than in circumneutral solutions; 2) specific ions such as chloride, fluoride, nitrate, phosphate and sulfate form soluble complexes with aluminum; 3) it can form strong complexes with fulvic and humic acids; 4) hydroxide ions can connect aluminum ions to form soluble and insoluble polymers (e.g. gibbsite, corundum); and 5) under at least some conditions, solutions of aluminum in water approach chemical equilibrium rather slowly, with monomeric species of aluminum transforming into insoluble polymers which precipitate out of solution over time (Angel et al. 2016; Campbell et al. 1983; Hem 1968a,b; Hem and Roberson 1967; Hsu 1968; Roberson and Hem 1969; Smith and Hem 1972).

Aluminum exists as inorganic, monomeric species (Al^{3+}, $Al(OH)^{2+}$, $Al(OH)_2^+$, $Al(OH)_3$, and $Al(OH)_4^-$), as amorphous $Al(OH)_3$ leading to gibbsite formation and precipitation, and as polynuclear species such as the tridecameric Al_{13} polynuclear species (Gensemer and Playle 1999). The chemistry of aluminum in aquatic environments is complex, and several comprehensive reviews on its biological effects have been published (e.g., Driscoll and Schecher 1988; Gensemer and Playle 1999; Gostomski 1990; Havas 1986a,b; Havas and Jaworski 1986; Howells et al. 1990; Lewis 1989; Lydersen and Lofgren 2002; Rosseland et al. 1990; Scheuhammer 1991; Sigel and Sigel 1988; Sparling and Lowe 1996a; Sposito 1989, 1996; Wilson 2012; Yokel and Golub 1997). Effects on the aquatic community and considerations for criteria development are addressed below.

Aluminum from both natural and anthropogenic sources is transported by several means. Natural aluminum transport mechanisms include rock and mineral weathering, volcanic activity and acidic spring waters (USGS 1993; Varrica et al. 2000). Anthropogenic releases include air emissions, effluent dischargers and solid waste leaching. Aluminum is transported through the atmosphere as windblown particulate matter and is deposited onto land and water by wet and dry deposition. Atmospheric loading rates of aluminum to Lake Michigan have been estimated at 5

NMED Exhibit 75

million kg/year (Eisenreich 1980), and at 0.1 g/m^2-year on Massachusetts Bay (Golomb et al. 1997).

Factors such as pH, temperature, and presence of complexing ions influence the fate and transport of aluminum in the environment. Of primary importance to understanding aluminum fate and behavior are its interactions with pH (see **Figure 2**). At neutral pH, aluminum is nearly insoluble, but its solubility increases exponentially as the pH reaches either acidic (pH<6) or basic (pH>8) conditions (Gensemer and Playle 1999). At pH values between 6.5 and 9.0 in fresh water, aluminum occurs predominantly in solution as monomeric, dimeric, and polymeric hydroxides and as complexes with fulvic and humic acids, chloride, phosphate, sulfate, and less common anions. The K_{sp} (solubility product) of aluminum hydroxide (gibbsite) ranges from 1.06×10^{-33} (Gayer et al. 1958) to 3.7×10^{-15} at 25°C (CRC 2000). Thus, aluminum hydroxide is insoluble compared to the more soluble salts used to determine aluminum toxic effect levels to aquatic species (aluminum chloride $K_{sp} = 2.04 \times 10^{4}$, aluminum nitrate $K_{sp} = 2.16 \times 10^{3}$, and aluminum sulfate $K_{sp} = 6.92 \times 10^{1}$) (CRC 2000).

NMED Exhibit 75

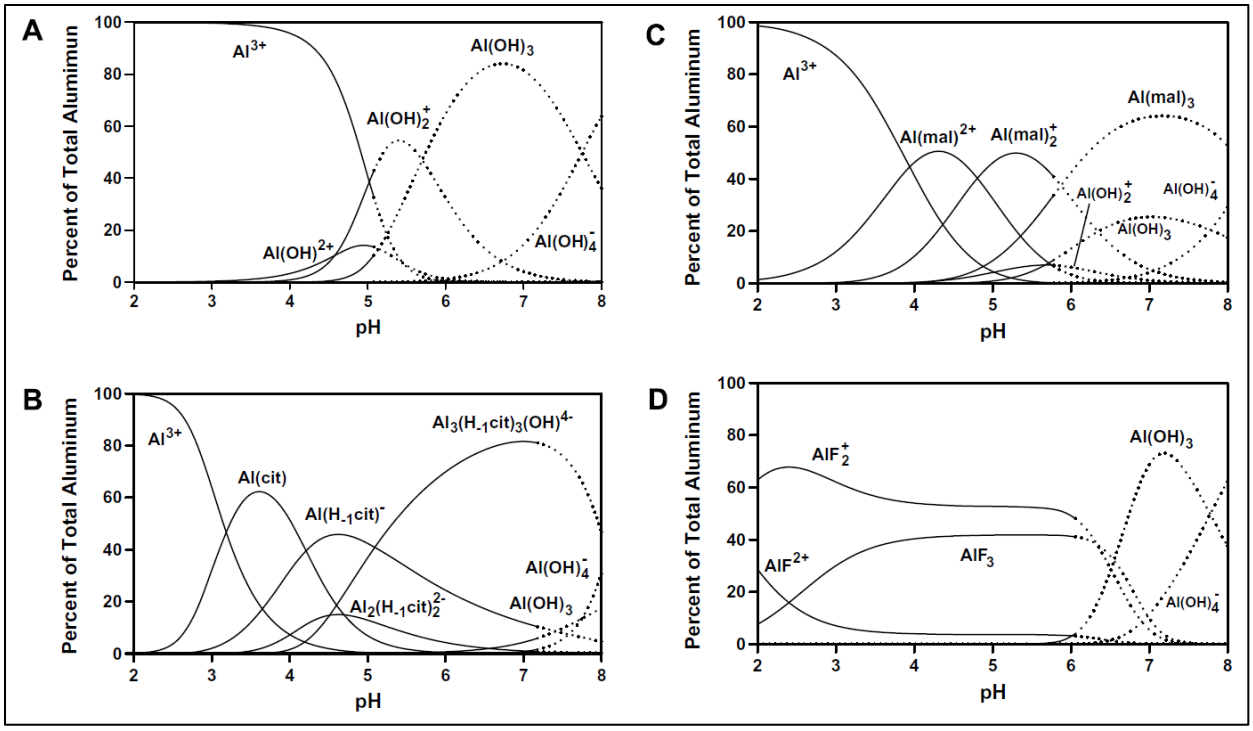

Figure 2. Results of Al Speciation Calculations at a Total of 65 µM Al in the Absence of Ligands (panel A) and in the Presence of Citrate (65 µM) (panel B), Maltolate (195 µM) (panel C), and Fluoride (260 µM) (panel D) in the pH Range 2 to 8.
The dotted lines indicate solutions that would be supersaturated with respect to freshly prepared $Al(OH)_3$. (Zhou et al. 2008, Figure 1, used with permission.)

Aluminum solubility increases at lower temperatures and in the presence of complexing ligands (both inorganic and organic) (ATSDR 2008; Lydersen, 1990; Wilson 2012). These two characteristics are significant because episodic acidic pulses in streams, for example during winter snowmelt, maximize the solubility of aluminum if pH drops to 5.5 or lower (Schofield 1977; Wilson 2012), and therefore may mobilize aluminum.

In the early 1980s the impacts of acid rain and aluminum toxicity were observed in aquatic and terrestrial environments in specific regions of the U.S., most notably in the northeastern part of the country where aquatic systems had limited buffering capacity to prevent pH changes. Researchers observed that aluminum can be a major factor responsible for the demise of biotic communities since the toxicant becomes more soluble and potentially more toxic to aquatic biota at acidic pH (Gensemer and Playle 1999).

2.3 Mode of Action and Toxicity

Aluminum has no biologically important functions or beneficial properties to aquatic life, and is therefore considered a non-essential metal (Eichenberger 1986; Exley 2003; Tchounwou

et al. 2012; Williams 1999; Wood 1984, 1985). It has been identified as the cause of harmful effects on fish and wildlife, but is not a known teratogen, carcinogen or mutagen (Leonard and Gerber 1988). The specific mechanisms of aluminum toxicity to aquatic organisms have been investigated extensively for fish and to a lesser extent for aquatic invertebrates.

For invertebrates, it is postulated that aluminum disrupts concentrations of specific ions, primarily resulting in a loss of sodium (Hornstrom et al. 1984). Elevated levels of aluminum affect ion regulation and the respiratory efficiency of sensitive species (Sparling and Lowe 1996a). Havas (1985) found that aluminum interfered with salt regulation in *Daphnia magna*, which caused a reduction in whole body sodium and chloride concentrations, resulting in death. In addition, aluminum has been shown to increase respiration, and thereby energy demands among mayfly species (Herrmann and Andersson 1986).

For fish, the gill is the primary site of aluminum toxic action, resulting in ionoregulatory, osmoregulatory and respiratory dysfunction. The gill is the primary site of aluminum toxicity under either acidic or alkaline conditions (Wilson 2012). Under acidic conditions, aluminum disrupts the barrier properties of the gill epithelium by binding with functional groups at both the apical gill surface and intracellularly within the lamellar epithelial cells (Exley et al. 1991). At reduced pH (<6.5), aluminum will accumulate on the gill surface resulting in physical damage to the epithelial cells that subsequently causes a loss of plasma ions (Na^+, Cl^-), reduced ion uptake and gas exchange. At alkaline pH (>8), the negatively charged aluminate anion dominates which also disrupts gill function, but to a lesser degree due to the lack of binding of the aluminate anion to the negatively charged gill surface. The subsequent necrosis of the epithelial cells causes a loss of plasma ions (Na^+, Cl^-), reduced osmolality and gas exchange, and if severe enough, the death of the fish (Dietrich 1988; Dietrich and Schlatter 1989a,b; Leivestad et al. 1980; Mallatt 1985; Muniz and Leivestad 1980a,b; Rosseland and Skogheim 1984, 1987). Mitigation of these toxic effects was observed with moderate concentrations of calcium (Brown 1981b), high concentrations of humic acids (Baker and Schofield 1982; Driscoll et al. 1980), and high concentrations of silica (Birchall et al. 1989). Fish in low pH waters with high aluminum concentrations will accumulate aluminum on the gill surface (Rosseland et al. 1990). Bjerknes et al. (2003) observed elevated aluminum concentrations in the gills of dead and "sluggish" Atlantic salmon (*Salmo salar*) associated with ruptured atria, which the authors suggested may have resulted from hypercapnia (abnormally elevated carbon dioxide levels in the blood) caused

NMED Exhibit 75

by circulatory distress from the clogging of gills with aluminum. The specific mechanisms of aluminum toxicity at alkaline pH are not well understood.

In laboratory toxicity tests, organisms are exposed to a mixture of dissolved and particulate aluminum depending on how long the acidic aluminum stock solution has been allowed to equilibrate prior to dosing the organisms (Angel et al. 2016). Over time (minutes) as the aluminum from the stock solution equilibrates with the test water and the pH increases, the monomeric species of aluminum transform to the newly-formed insoluble polymeric hydroxide species, which are more toxic (Cardwell et al. 2018). Thus, soon after test initiation, there is a transformation period of rapid speciation changes from short-lived transient amorphous and colloidal forms of aluminum (from minutes to a few hours) to more stable crystalline forms that can take days to form (Gensemer et al. 2018). Aged stock solutions (aluminum solutions that have been given sufficient time (i.e., hours to days) to form more stable forms of aluminum) have been shown to be less toxic than those that are not aged (Exley et al. 1996; Witters et al. 1996). Unfortunately, many studies included for criteria derivation did not describe stock solution age prior to test initiation, and this variable therefore cannot be factored into the toxicity assessment.

Several investigators have found different trends in the toxicity of aluminum under different pH conditions, and toxicity of aluminum appears to be lowest at neutral pH (approximately 7), with toxicity tending to increase with either increasing or decreasing pH (above and below neutral pH). Freeman and Everhart (1971) found that the lethal time to 50% of the rainbow trout decreased (i.e., was more toxic) as the pH increased from 6.8 to 8.99 when rainbow trout were exposed in flow-through tests to the same nominal (unmeasured) aluminum concentration. They concluded that soluble aluminum was the toxic form. Hunter et al. (1980) observed the same relationship of increasing toxicity with rainbow trout over a pH range of 7.0 to 9.0 in chronic static renewal toxicity studies (also nominal aluminum exposures). Call (1984) conducted measured static acute toxicity studies with fathead minnows at pH of 7.61 and 8.05 and showed a slight increase in toxicity at increased pH. However, in another measured static acute toxicity study with a different species, rainbow trout, Call (1984) found a decrease in toxicity as pH increased for the studies conducted at pH 7.31 and 8.17. Thus, generally, most studies show that aluminum toxicity increases as pH increases in the range of approximately 7.0 to 9.0.

NMED Exhibit 75

Regarding toxicity at low pH, Freeman and Everhart (1971) also observed the greater toxicity at acidic pH 6.52 in static renewal tests with rainbow trout. In a measured static acute toxicity study with rainbow trout by Call (1984), tests were conducted with pH measurements of 6.59, 7.31 and 8.17. The greatest toxicity was observed at the acidic pH of 6.59. The tests conducted by Freeman and Everhart (1971) and Hunter et al. (1980) were static renewal or flow-through and showed the lowest acute values. The flow-through and renewal tests are considered to be a more reliable way to conduct toxicity tests for aluminum because the dosed chemical is more likely to remain in solution at the desired concentration, and less likely to drop below nominal levels due to precipitation and/or adherence to test vessel surfaces. In addition, because the polymerization of aluminum hydroxide is a relatively slow process, the chemical form of aluminum might have differed from test to test due to the amount of time the aluminum was in stock and test solutions.

The influence of pH on aluminum speciation and associated toxicity to aquatic organisms is readily apparent and highlights the importance of pH control during toxicity tests. Depending on the pH at test initiation, the greatest potential for pH drift would be static exposures, followed by static-renewal and finally flow-through studies. All of the studies evaluated for criteria derivation reported pH, and most included the standard deviation of the measurements, thus providing a rough estimate of pH drift during the exposure. Only selected studies, however, described pH drift for individual tests (e.g., ENSR 1992c,d; European Aluminum Association 2009).

Driscoll et al. (1980) tested postlarvae of brook trout and white suckers under slightly acidic conditions and concluded that only inorganic forms of aluminum were toxic to fish. Hunter et al. (1980) reported that the toxicity of test solutions was directly related to the concentration of dissolved aluminum that passed through a 0.45 μm membrane filter.

In dilute aluminum solutions, formation of particles and the large insoluble polynuclear complexes known as floc is primarily a function of the concentration of organic acids and the hydroxide ion. Time for particle formation varies from less than one minute to several days depending upon the source of aluminum (i.e., aluminum chloride, aluminum nitrate), the pH and the presence of electrolytes and organic acids (Snodgrass et al. 1984). When particles form an aggregate large enough to become visible, the floc is white in color, and tends to settle. Mats of aluminum floc have been reported blanketing a stream bed (Hunter et al. 1980). Laboratory

NMED Exhibit 75

studies conducted at alkaline pH levels have reported floc in the exposure chambers (Brooke 1985; Call 1984; Lamb and Bailey 1981; Zarini et al. 1983). The floc did not appear to affect most aquatic species. However, the swimming ability of *Daphnia magna* was impeded by "fibers" of flocculated aluminum trailing from the carapaces. Additionally, the mobility and feeding of midges also was affected, ultimately resulting in death (Lamb and Bailey 1981). Bottom-dwelling organisms may be impacted more by aluminum floc in the field than in the laboratory due to the greater floc layer thickness observed in the field relative to laboratory exposures (U.S. EPA 1988), but this will also depend on the water velocity and mixing in both the field and the laboratory.

Aquatic plant toxicity to aluminum can be dependent on the speciation of aluminum which is controlled by pH. In a study of cell growth rate of the green alga, *Chlorella pyrenoidosa*, to aluminum, Helliwell et al. (1983) found that decreased cell growth occurred in the pH range of 5.8 to 6.2. This is near the pH of minimum solubility of aluminum and maximum concentration of $Al(OH)_2^+$. They found that the toxicity of aluminum decreased as pH increased from 6.2 to 7 or as pH decreased from 5.8 to 4.7, and they hypothesized that the monovalent hydroxide is the most toxic form. Seip et al. (1984) stated that "the simple hydroxides ($Al(OH)^{+2}$ and $Al(OH)_2^+$) are regarded as the most dangerous forms, while organically bound aluminum and polymeric forms are less toxic or essentially harmless." However, one study found algae productivity and biomass were seldom affected if the pH is above 3.0 (Sparling and Lowe 1996a). Aluminum and acid toxicity tend to be additive to some algae when the pH is less than 4.5. Because aluminum binds with inorganic phosphorus, it may reduce the availability of this nutrient thereby reducing productivity (Sparling and Lowe 1996a). As shown in **Appendix E** and **Appendix H**, the effects of aluminum on algae productivity and biomass are dependent on the pH, total hardness and DOC of the exposure solutions.

2.3.1 Water Quality Parameters Affecting Toxicity

Bioavailability of aluminum is affected by water chemistry parameters such as pH, total hardness and DOC, and to a lesser extent fluoride. The pH of waters affects aluminum speciation and solubility. Aluminum can sorb to dissolved organic carbon (DOC), such as humic and fulvic acids, and form organic aluminum complexes. An increase in DOC in waters reduces the bioavailability of aluminum to aquatic organisms as a result of this binding (Wilson 2012). Hardness also has an effect on the toxicity of aluminum, as the cation Al^{+3} competes with other

NMED Exhibit 75

cations present in water such as calcium (Ca^{+2}) for uptake (Gensemer and Playle 1999). The observed effect of total hardness may be due to one or more of a number of usually interrelated ions, such as hydroxide, carbonate, calcium, and magnesium. Acute tests were conducted at four different levels of water total hardness with *Ceriodaphnia dubia* (ENSR 1992d), demonstrating that daphnids were more than 138 times more sensitive to aluminum in soft water than in hard water (**Appendix A** *Acceptable Acute Toxicity Data of Aluminum to Freshwater Aquatic Animals*). Data in **Appendix A** also indicate that aluminum was more toxic to *Daphnia magna*, brook trout, and fathead minnows in soft water than in hard water. In contrast, no apparent total hardness-toxicity relationship was observed for rainbow trout exposed to three different total hardness levels at a controlled pH of 8.3 (Gundersen et al. 1994). This is consistent with data recently published by DeForest et al. (2018a) and Gensemer et al. (2018) demonstrating that there is a reduced effect of total hardness at elevated pH levels.

Development of the Biotic Ligand Model (BLM - formerly the "gill model") and multi-parameter linear regression models in recent years were intended to better account for the water chemistry parameters that most strongly affect the bioavailability, and hence toxicity, of metals to aquatic life. The BLM, a mechanistic model that uses a series of submodels to quantify the capacity of metals to accumulate or bind to active sites on the gills of aquatic organisms, estimates the bioavailable portion of dissolved metals in the water column based on site-specific water quality parameters such as pH, hardness, and DOC (McGeer et al. 2000; Meyer et al. 1999; Pagenkopf 1983; Paquin et al. 1999; U.S. EPA 1999a, 2000). Multiple linear regression (MLR) models are statistical in nature and can also take into account pH, total hardness and DOC. While MLR models are less complex than BLM models, they also estimate the bioavailability of aluminum to aquatic species. The EPA evaluated the use of empirical, non-mechanistic MLR models for aluminum (DeForest et al. 2018a) as a bioavailability-based approach for deriving water quality criteria as well as a BLM model for aluminum (Santore et al. 2018). Note that the aluminum BLM developed by Santore et al. (2018) differs from earlier BLMs for other metals, because the aluminum BLM accounts for the dissolved and precipitated fraction of aluminum. Previous BLMs for other metals only account for the dissolved fraction of the metal.

The EPA decided to use an empirical MLR approach in this aluminum criteria update rather than a BLM model due to: 1) the relative simplicity and transparency of the model, 2) the relative similarity to the available BLM model outputs, and 3) the decreased number of input

NMED Exhibit 75

data on water chemistry needed to derive criteria at different sites. An external peer review of an approach using a pH and total hardness equation-based criteria, an MLR approach, and a BLM approach for aluminum criteria development was conducted in 2015 and peer-reviewers' comments were considered in the selection of the MLR-based criteria approach. The EPA independently examined and verified the quality and fit of the DeForest et al. (2018a,b) MLR models before applying them in this criteria document.

2.4 Conceptual Model

Conceptual models consist of a written description and diagram (U.S. EPA 1998a) that illustrate the relationships between human activities, stressors, and ecological effects on assessment endpoints. The conceptual model links exposure characteristics with the ecological endpoints important for management goals.

2.4.1 Conceptual Diagram

Aluminum can originate from both natural and anthropogenic sources (Lantzy and MacKenzie 1979). The environmental fate properties of aluminum indicate that weathering/erosion, volcanic activity, runoff/leaching, groundwater recharge, spray drift from aluminum-containing pesticides, and atmospheric deposition represent potential transport mechanisms of aluminum to surface water habitats for aquatic organisms (ATSDR 2008). These transport mechanisms are depicted in the conceptual model below for natural (i.e., weathering and erosion, volcanic activity) and anthropogenic sources of aluminum to the environment (i.e., wastewater treatment, resource extraction, smelting/manufacturing operations, agricultural uses and fossil fuel combustion) (**Figure 3**). The model also depicts exposure pathways for biological receptors of concern (e.g., aquatic animals) and the potential attribute changes (i.e., effects such as reduced survival, growth and reproduction) in the receptors due to aluminum exposure. A solid line indicates a major pathway and a dashed line indicates a minor pathway. Aquatic assessments address exposure primarily through anthropogenic releases, runoff and atmospheric deposition.

The conceptual model provides a broad overview of how aquatic organisms can potentially be exposed to aluminum. Derivation of criteria focuses on effects on survival, growth and reproduction of aquatic organisms. However, the pathways, receptors, and attribute changes depicted in **Figure 3** may be helpful for states and authorized tribes as they adopt criteria into standards and need to evaluate potential exposure pathways affecting designated uses.

NMED Exhibit 75

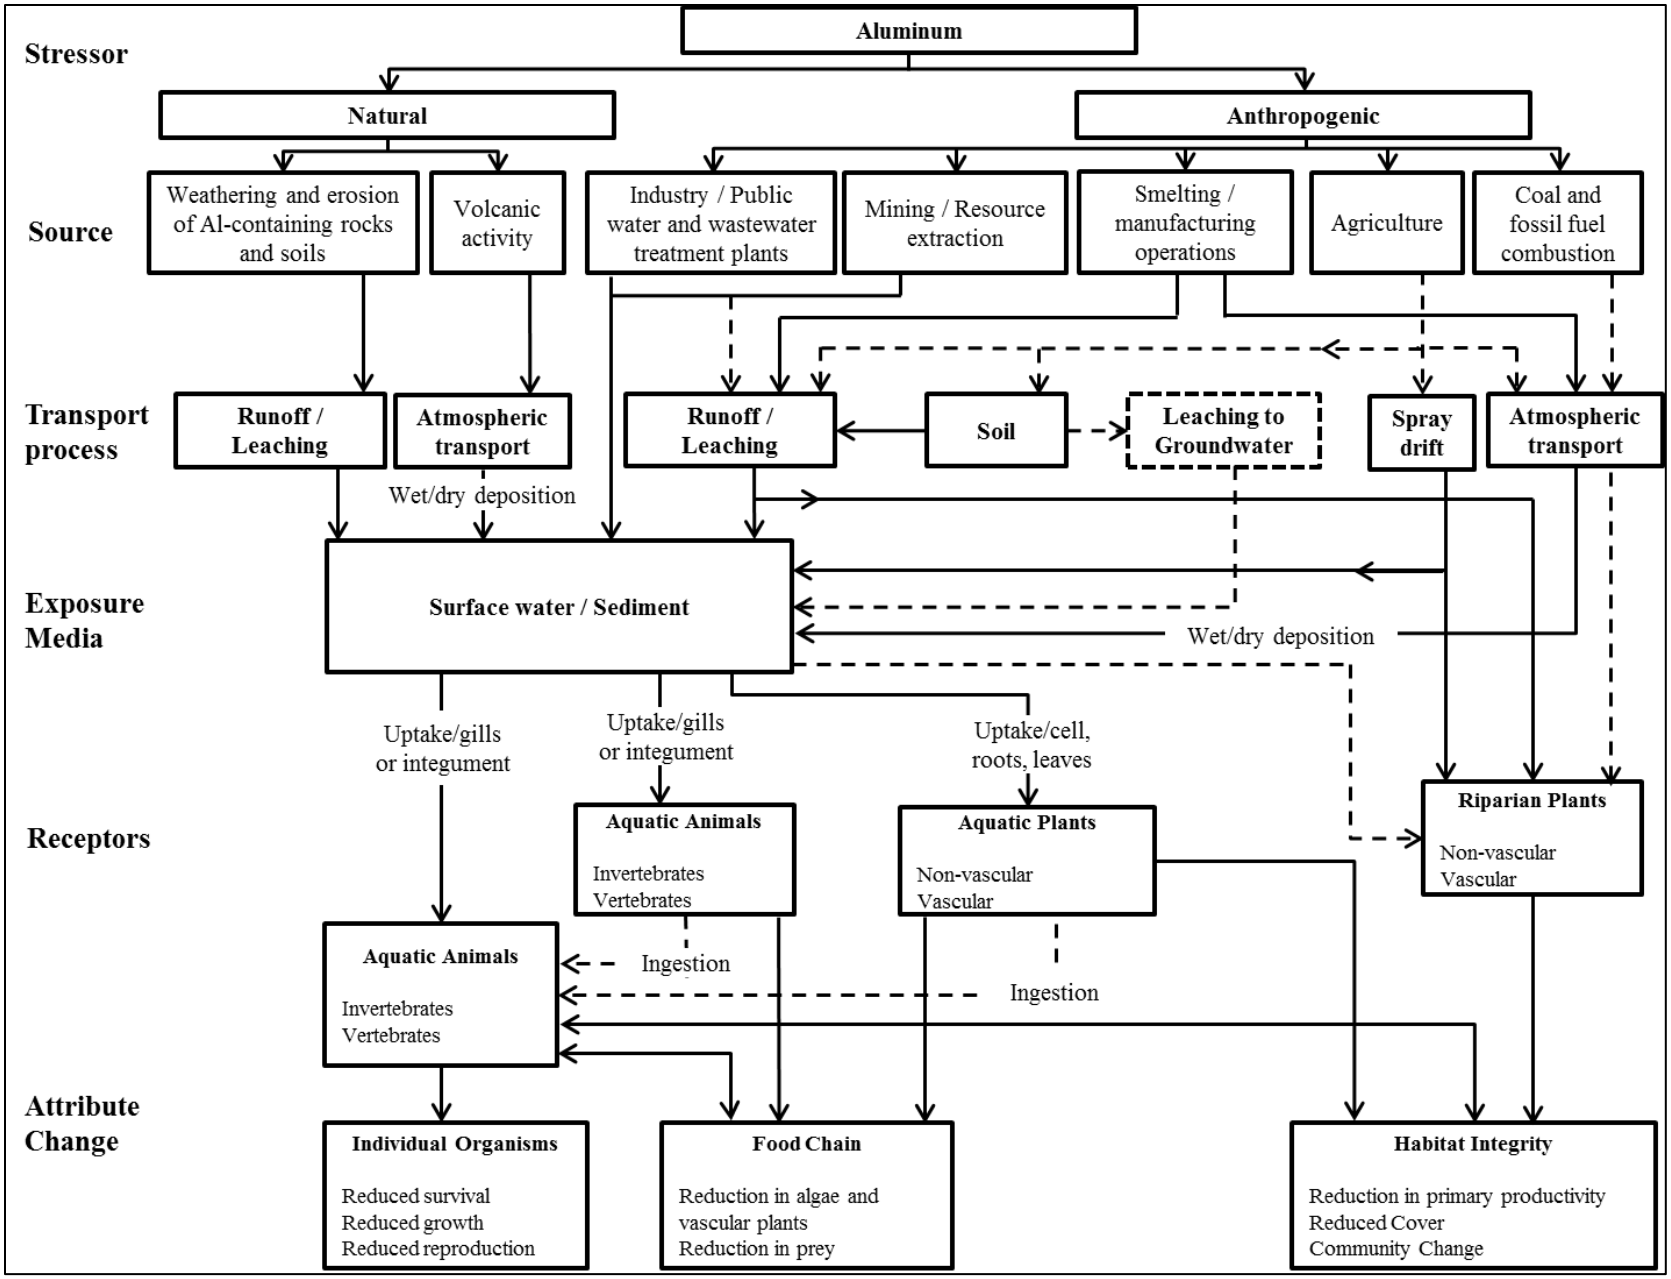

Figure 3. Conceptual Model for Aluminum Effects on Aquatic Organisms.
(Dotted lines indicate exposure pathways that have a lower likelihood of contributing to ecological effects).

NMED Exhibit 75

2.5 Assessment Endpoints

Assessment endpoints are defined as the explicit expressions of the environmental values to be protected and are comprised of both the ecological entity (e.g., a species, community, or other entity) and the attributes or characteristics of the entity to be protected (U.S. EPA 1998a). Assessment endpoints may be identified at any level of organization (e.g., individual, population, community). In the context of the CWA, aquatic life criteria for toxic substances are typically determined based on the results of toxicity tests with aquatic organisms, for which adverse effects on growth, reproduction, or survival are measured. This information is aggregated into a genus sensitivity analysis that characterizes an impact to the aquatic community. Criteria are designed to be protective of the vast majority of aquatic animal taxa in an aquatic community (i.e., approximately the 95^{th} percentile of genera based on tested aquatic animals representing the aquatic community per the 1985 Guidelines recommendations (Stephan et al 1985). Assessment endpoints consistent with the criteria developed in this document are summarized in **Table 1**.

The concept of using laboratory toxicity tests to protect North American bodies of water and resident aquatic species is based on the theory that effects occurring to a species in controlled laboratory tests will generally occur to the same species in comparable field situations. Since aquatic ecosystems are complex and diversified, the 1985 Guidelines require acceptable data be available for at least eight genera with a specified taxonomic diversity (the standard eight-family minimum data requirement, or MDR). The intent of the eight-family MDR is to serve as a typical surrogate sample community representative of the larger and generally much more diverse natural aquatic community, not necessarily the most sensitive species in a given environment. For many aquatic life criteria, enough data are available to describe a sensitivity distribution to represent the distribution of sensitivities in natural ecosystems. In addition, since aquatic ecosystems can tolerate some stress and occasional adverse effects, protection of all species at all times and places is not deemed necessary. The intent is to protect approximately 95 percent of a group of diverse taxa, with special consideration given to any commercially and recreationally important species (Stephan et al 1985). Thus, if properly derived and used, the combination of a freshwater or estuarine/marine acute and chronic aquatic life criteria should provide an appropriate degree of protection of aquatic organisms and their uses from acute and

NMED Exhibit 75

chronic toxicity to animals, toxicity to plants, and bioaccumulation by aquatic organisms (Stephan et al. 1985).

Table 1. Summary of Assessment Endpoints and Measures of Effect Used in Criteria Derivation.

Assessment Endpoints for the Aquatic Community	Measures of Effect
Survival, growth, and reproduction of freshwater fish, other freshwater vertebrates, and invertebrates	For acute effects: LC_{50}, EC_{50} For chronic effects: EC_{20}, MATC (only used when an EC_{20} could not be calculated for the genus), EC_{10} (for bioaccumulative compounds)
Survival, growth, and reproduction of estuarine/marine fish and invertebrates	For acute effects: LC_{50}, EC_{50} For chronic effects: EC_{20}, MATC (only used when an EC_{20} could not be calculated for the genus), EC_{10} (for bioaccumulative compounds)
Maintenance and growth of aquatic plants from standing crop or biomass (freshwater and estuarine/marine)	LOEC, EC_{20}, EC_{50}, IC_{50}, reduced growth rate, cell viability, calculated MATC

MATC = Maximum acceptable toxicant concentration (geometric mean of NOEC and LOEC)
NOEC = No observed effect concentration
LOEC = Lowest observed effect concentration
LC_{50} = Lethal concentration to 50% of the test population
$EC_{50}/EC_{20}/EC_{10}$ = Effect concentration to 50%/20%/10% of the test population
IC_{50} = Concentration of aluminum at which growth is inhibited 50% compared to control organism growth

2.6 Measurement Endpoints

Measurement endpoints (**Table 1**) are the measures of ecological effect used to characterize or quantify changes in the attributes of an assessment endpoint or changes in a surrogate entity or attribute, in this case a response to chemical exposure (U.S. EPA 1998a). Toxicity data are used as measures of direct and indirect effects on representative biological receptors. The selected measures of effects for the development of aquatic life criteria encompass changes in the growth, reproduction, and survival of aquatic organisms (Stephan et al. 1985).

The toxicity data used for the development of aquatic life criteria depend on the availability of applicable toxicity test outcomes, the acceptability of test methodologies, and an in-depth evaluation of the acceptability of each specific test, as performed by the EPA. Measurement endpoints for the development of aquatic life criteria are derived using acute and chronic toxicity studies for representative test species, which are then quantitatively and qualitatively analyzed, as described in the Analysis Plan below. Measurement endpoints

NMED Exhibit 75

considered for each assessment endpoint in this criteria document are summarized in **Table 1**. The following sections discuss toxicity data requirements for the fulfillment of these measurement endpoints.

2.6.1 Overview of Toxicity Data Requirements

The EPA has specific data requirements to assess the potential effects of a stressor on an aquatic ecosystem and develop CWA section 304(a) aquatic life criteria as described in the 1985 Guidelines (Stephan et al 1985). Acute toxicity test data (short term effects on survival) for species from a minimum of eight diverse taxonomic groups are required for the development of acute criteria to ensure the protection of various components of an aquatic ecosystem.

- Acute toxicity test data for species from a minimum of eight diverse taxonomic groups. The diversity of tested species is intended to ensure protection of various components of an aquatic ecosystem.
    - The acute freshwater requirement is fulfilled with the following eight minimum data requirements:
        - the family Salmonidae in the class Osteichthyes
        - a second family in the class Osteichthyes, preferably a commercially or recreationally important warmwater species (e.g., bluegill, channel catfish, etc.)
        - a third family in the phylum Chordata (may be in the class Osteichthyes or may be an amphibian, etc.)
        - a planktonic crustacean (e.g., cladoceran, copepod, etc.)
        - a benthic crustacean (e.g., ostracod, isopod, amphipod, crayfish, etc.)
        - an insect (e.g., mayfly, dragonfly, damselfly, stonefly, caddisfly, mosquito, midge, etc.)
        - a family in a phylum other than Arthropoda or Chordata (e.g., Rotifera, Annelida, Mollusca, etc.)
        - a family in any order of insect or any phylum not already represented
    - The acute estuarine/marine requirement is fulfilled with the following eight minimum data requirements:
        - two families in the phylum Chordata
        - a family in a phylum other than Arthropoda or Chordata
        - either the Mysidae or Penaeidae family
        - three other families not in the phylum Chordata (may include Mysidae or Penaeidae, whichever was not used above)
        - one from any other family
- Chronic toxicity test data (longer-term survival, growth, or reproduction) are required for a minimum of three taxa, with at least one chronic test being from an acutely-sensitive species.

NMED Exhibit 75

- Acute-chronic ratios (ACRs) can be calculated with data from species of aquatic animals from at least three different families if the following data requirements are met:
    - at least one is a fish
    - at least one is an invertebrate
    - for freshwater chronic criterion: at least one is an acutely sensitive freshwater species (the other two may be estuarine/marine species) or for estuarine/marine chronic criterion: at least one is an acutely sensitive estuarine/marine species (the other two may be freshwater species).

The 1985 Guidelines also require at least one acceptable test with a freshwater alga or vascular plant. If plants are among the aquatic organisms most sensitive to the chemical, results of a plant in another phylum should also be available. Data on toxicity to aquatic plants are examined to determine whether plants are likely to be unacceptably affected by concentrations below those expected to cause unacceptable effects on aquatic animals. As discussed in **Section 3.4** and **Section 5.2**, based on available data the relative sensitivity of fresh and estuarine/marine algae and plants to aluminum (**Appendix E** *Acceptable Toxicity Data of Aluminum to Freshwater Aquatic Plants* and **Appendix F** *Acceptable Toxicity Data of Aluminum to Estuarine/Marine Aquatic Plants*) is less than vertebrates and invertebrates, so plant criteria were not developed. This trend was apparent for all conditions, as vertebrate and invertebrate generated criteria values were always less than alga EC_{20}s (DeForest et al. 2018a), except at unrealistically high pH and very high total hardness.

2.6.2 Measures of Effect

The assessment endpoints for aquatic life criteria are based on survival, growth and reproduction of the assessed taxa per the 1985 Guidelines (Stephan et al 1985). The measures of effect are provided by the acute and chronic toxicity data. These toxicity endpoints (expressed as genus mean values) are used in the sensitivity distribution of the aquatic community at the genus level to derive the aquatic life criteria. Endpoints used in this assessment are listed in **Table 1**. Studies that had unacceptable control survival were not used (i.e., studies where acute and chronic control mortality was >10% and >20%, respectively), regardless of test conditions.

Measure of Aluminum Exposure Concentration

Only data from toxicity tests conducted using chloride, nitrate and sulfate salts (either anhydrous or hydrated) are used in this effects assessment. This is consistent with the EPA's

NMED Exhibit 75

previous 1988 aluminum aquatic life AWQC document. This document addresses the toxicity of total aluminum to freshwater organisms in the pH range of 5.0 to 10.5. The 1988 AWQC addressed waters with a pH between 6.5 and 9.0 (U.S. EPA 1988) to be consistent with the recommended aquatic life pH criteria (U.S. EPA 1986). The pH range for freshwater was expanded, in part, because of the complex chemistry of aluminum in surface waters, the available toxicity data demonstrated an increased sensitivity of freshwater aquatic species in low pH (i.e., pH<6.5), and the expanded range represents a fuller range of pH conditions in natural waters. Tests conducted in pH water less than 5 were deemed too low to be used quantitatively due to a mixture effect from the combined stress of both low pH and aluminum on the test organisms, and the inability to discern a particular effect level to either low pH or elevated aluminum concentration.

Aluminum chemistry in surface waters is extremely complex, and so measurement uncertainty can be high if only one form of aluminum is taken into account. A thorough understanding of aluminum toxicity is complicated by the need to distinguish between aqueous and particulate aluminum, and between inorganic and organic forms of aluminum (Driscoll and Postek 1996; Gensemer and Playle 1999). Laboratory dilution waters do not contain suspended solids, clays or particulate matter where aluminum may be bound (unless specifically investigated). Therefore, a distinction needs to be made in how the EPA interprets the measurements of aluminum in water, so that extrapolating laboratory data to natural waters is better understood. There is also a complication as the available measurement methods (i.e., total, total recoverable, acid soluble, pH 4 extractable and dissolved) present different challenges when applied to natural and laboratory waters. In application to natural waters, total, total recoverable, and acid soluble methods may be confounded by measuring aluminum in aluminum silicate (i.e., clay).

Laboratory Exposures

The 1988 AWQC considered using dissolved aluminum concentrations to set aquatic life criteria, however not enough data were available to allow derivation of a criterion based on dissolved aluminum. The EPA also noted at the time that organisms would be exposed to both dissolved and undissolved aluminum from laboratory exposures. The lack of data prevented any definitive analysis.

NMED Exhibit 75

Data are now available to compare toxicity of aluminum using total aluminum (unfiltered test samples that were acidified) and dissolved aluminum (operationally defined as filtered with typically a 0.45 µm filter before acidification). The total aluminum concentrations in laboratory test solutions will contain dissolved monomeric and precipitated forms (e.g., aluminum hydroxides) of aluminum. Dissolved concentrations will not contain these precipitated forms.

In tests with brook trout at low pH and total hardness, toxic effects increased with increasing concentrations of total aluminum even though the corresponding concentration of dissolved aluminum was relatively constant (Cleveland et al. 1989). This phenomenon was also observed in several chronic studies with widely varying test concentrations and conditions (renewal and flow-through exposures) at pH 6 conducted by the Oregon State University (e.g., 2012a,e), where toxic effects increased with increasing total aluminum concentrations, while measured concentrations of dissolved and monomeric aluminum changed very little with increasing total aluminum concentrations.

In filtration studies at pH 8 with the fathead minnow, both acute and chronic toxicity tests indicated no toxicity when the test water was 0.2 µm filtered prior to exposure (Gensemer et al. 2018). Toxicity was only observed when the test solutions were unfiltered. Furthermore, dose-response relationships were only observed using total aluminum; relationships were not observed using measurements of dissolved or monomeric forms (Gensemer et al. 2018). This same effect was observed in 7-day exposures at pH 7 and 8 with the daphnid (*Ceriodaphnia dubia*) where filtered test solutions were less toxic than unfiltered solutions (Gensemer et al. 2018).

Therefore, because measurements of dissolved aluminum do not reflect the full spectrum of forms of aluminum that results in toxicity, all laboratory exposure data used for criteria derivation will be based on measurements of total aluminum. Measurements with methods using lesser degrees of acidification (that is, acid soluble and pH 4 extractable) are generally not available. If aluminum criteria are based on dissolved concentrations, toxicity will be underestimated, because aluminum hydroxide precipitates that contribute to toxicity would not be measured (GEI Consultants, Inc. 2010; U.S. EPA 1988). All concentrations from toxicity tests are expressed as total aluminum in this document (unless otherwise specified).

Natural Waters

Researchers rely on operationally defined procedures to evaluate the concentration and forms of aluminum in natural waters, and the accuracy of these methods is difficult to evaluate,

NMED Exhibit 75

resulting in uncertainty regarding the actual amount of aluminum present in various forms (Driscoll and Postek 1996). Total aluminum concentrations in natural waters are determined using a wide variety of digestion procedures at varied extraction times, resulting in a range of operational methods and uncertainty in measured values (Driscoll and Postek 1996). Furthermore, particulate material comprises a continual size distribution making measurement of dissolved concentrations dependent on the filter-pore size used (Driscoll and Postek 1996).

A major complication for extrapolating total aluminum concentrations measured in laboratory waters to natural waters is the test method used. The 1988 AWQC for aluminum were based on acid-soluble concentrations (operationally defined as the aluminum that passes through a 0.45 µm filter after the sample has been acidified with nitric acid to a pH between 1.5 and 2.0). In the early 1990s, the EPA converted most metals criteria (excluding aluminum) to the dissolved measurement. With the acid-soluble method seldom used and insufficiently different from total, (U.S. EPA 1999c) the EPA expressed the aluminum criterion as total recoverable aluminum, with a caution that a Water-Effect Ratio would often be needed. The EPA uses the terms "total" and "total recoverable" synonymously for effluent guidelines and permitting under NPDES programs (U.S. EPA 1988b). The current EPA Test Method for measuring total recoverable aluminum in ambient water and wastewater uses inductively coupled plasma-atomic emission spectrometry and inductively-coupled plasma-mass spectrometry (U.S. EPA 1994a,b). The methods recommend that the sample first be solubilized by gentle refluxing with nitric and hydrochloric acids (i.e., digestion to pH<2) when an aqueous sample contains undissolved material. After cooling, the sample is made up to volume, then mixed and either centrifuged or allowed to settle overnight prior to analysis. This process dissolves the monomeric and polymeric forms of aluminum, in addition to colloidal, particulate and clay-bound aluminum. Applying the aluminum criteria to total recoverable aluminum is considered conservative because it includes monomeric (both organic and inorganic) forms, polymeric and colloidal forms, as well as particulate forms and aluminum sorbed to clays (Wilson 2012). However, under natural conditions not all of these forms would be biologically available to aquatic species (e.g., clay-bound aluminum).

EPA Methods 200.7 and 200.8 are the only currently approved methods for measuring aluminum in natural waters and wastewater for NPDES permits (U.S. EPA 1994a,b). Research on new analytical methods is ongoing to address concerns with including aluminum bound to

NMED Exhibit 75

particulate matter (i.e., clay) in the total recoverable aluminum concentrations (OSU 2018c). One approach would not acidify the sample to pH less than 2 but rather to pH 4 (pH 4 extracted method) to better capture the bioavailable fraction of aluminum (CIMM 2016, OSU 2018c). In the pH 4 extraction method, sodium acetate buffer is added to the sample to reach the desired pH, followed by sample agitation for a specified period of time, and finally 0.45 µm sample filtration. The sample is then acidified with nitric acid before inductively coupled plasma-optical emission spectrometry analysis.

To further explore this issue, researchers conducted an aluminum analysis of 12 natural freshwater sources throughout the United States with various concentrations of total suspended solids using four different aluminum methods (i.e., total, acid-soluble, pH 4 extracted and dissolved) (OSU 2018c). The total method (consistent with EPA methods 200.7 and 200.8) acidified the sample to pH 2 before analysis; the acid soluble method acidified the sample to pH<2, held the sample for 16 hours and then filtered the sample with a 0.45 µm filter; the pH extraction method acidified the sample to pH 4.0-4.2, held the sample for three hours, and then filtered the sample with a 0.45 µm filter; and lastly, the dissolved method filtered the sample before acidification. As expected, the total method typically had elevated measured aluminum concentrations compared to the levels quantified by the three other test methodologies. This trend was most evident with natural waters that had high total suspended solids. The validation of the pH 4 extraction method is still on-going, with the expectation that this approach will better estimate the bioavailable fraction of aluminum in natural waters.

Acute Measures of Effect

The acute measures of effect on aquatic organisms are the LC_{50}, EC_{50}, and IC_{50}. LC stands for "Lethal Concentration," and a LC_{50} is the concentration of a chemical that is estimated to kill 50 percent of the test organisms. EC stands for "Effect Concentration," and the EC_{50} is the concentration of a chemical that is estimated to produce a specific effect in 50 percent of the test organisms. IC stands for "Inhibitory Concentration," and the IC_{50} is the concentration of a chemical that is estimated to inhibit some biological process (e.g., growth) in 50 percent of the test organisms. Acute data that were determined to have acceptable quality and to be useable in the derivation of water quality criteria as described in the 1985 Guidelines for the derivation of a freshwater and estuarine/marine criteria are presented in **Appendix A** (*Acceptable Acute Toxicity*

NMED Exhibit 75

Data of Aluminum to Freshwater Aquatic Animals) and **Appendix B** (*Acceptable Acute Toxicity Data of Aluminum to Estuarine/Marine Aquatic Animals*), respectively.

Chronic Measures of Effect

The endpoint for chronic exposure for aluminum is the EC_{20}, which represents a 20 percent effect/inhibition concentration. This is in contrast to a concentration that causes a low level of reduction in response, such as an EC_5, which is rarely statistically significantly different from the control treatment. A major reduction, such as 50 percent, is not consistent with the intent of establishing chronic criteria to protect populations from long-term effects. The EPA selected an EC_{20} to estimate a low level of effect for aluminum that would typically be statistically different from control effects, but not severe enough to cause chronic effects at the population level (see U.S. EPA 1999b). Reported NOECs (No Observed Effect Concentrations) and LOECs (Lowest Observed Effect Concentrations) were only used for the derivation of a chronic criterion when an EC_{20} could not be calculated for the genus. A NOEC is the highest test concentration at which none of the observed effects are statistically different from the control. A LOEC is the lowest test concentration at which the observed effects are statistically different from the control. When LOECs and NOECs are used, a Maximum Acceptable Toxicant Concentration (MATC) is calculated, which is the geometric mean of the NOEC and LOEC.

Regression analysis was used to characterize a concentration-effect relationship and to estimate concentrations at which chronic effects are expected to occur. For the calculation of the chronic criterion, point estimates (e.g., EC_{20}s) were selected for use as the measure of effect rather than MATCs, as MATCs are highly dependent on the concentrations tested (as are the NOECs and LOECs from which they are derived). Point estimates also provide additional information that is difficult to determine with an MATC, such as a measure of magnitude of effect across a range of tested concentrations. Author reported EC_{20}s were used when provided, otherwise point estimates were calculated from raw toxicity data using the EPA's Toxicity Relationship Analysis Program (TRAP). Chronic toxicity data that met the test acceptability and quality assurance and quality control (QA/QC) criteria in the 1985 Guidelines for the derivation of freshwater and estuarine/marine criteria are presented in **Appendix C** (*Acceptable Chronic Toxicity Data of Aluminum to Freshwater Aquatic Animals*) and **Appendix D** (*Acceptable Chronic Toxicity Data of Aluminum to Estuarine/Marine Aquatic Animals*), respectively.

NMED Exhibit 75

2.7 Analysis Plan

During CWA section 304(a) criteria development, the EPA reviews and considers all relevant toxicity test data. Information available for all relevant species and genera are reviewed to identify whether: 1) data from acceptable tests meet data quality standards; and 2) the acceptable data meet the minimum data requirements (MDRs) as outlined in the 1985 Guidelines (Stephan et al. 1985; U.S. EPA 1986). The taxa represented by the different MDR groups represent taxa with different ecological, trophic, taxonomic and functional characteristics in aquatic ecosystems, and are intended to be a representative subset of the diversity within a typical aquatic community. In most cases, data on freshwater and estuarine/marine species are grouped separately to develop separate freshwater and estuarine/marine criteria. Thus, where data allow, four criteria are developed (acute freshwater, acute estuarine/marine, chronic freshwater, and chronic estuarine/marine). If plants are more sensitive than vertebrates and invertebrates, plant criteria are developed.

Table 2 provides a summary of the toxicity data used to fulfill the MDRs for calculation of acute and chronic criteria for both freshwater and estuarine/marine organisms. For aluminum, there are acceptable toxicity data for derivation of a freshwater acute criterion with all of the freshwater MDRs being met. The acceptable acute toxicity data encompass four phyla, 14 families, 20 genera and 22 species (**Table 2**). Acceptable estuarine/marine acute toxicity data are only available for three phyla, five families, five genera and five species. Consequently, only five of the eight MDRs are met for the estuarine/marine acute criterion; and no acceptable acute test data on fish species were available. Therefore, the EPA cannot develop an acute estuarine/marine criterion at this time. The chronic toxicity data for direct calculation of the FCV for the freshwater criterion consisted of seven of the eight freshwater MDRs (the missing MDR was the "other chordate"). However, the 1985 Guidelines still allow derivation of a chronic criterion (see **Section 2.6.1**). Because derivation of a chronic freshwater criterion is important for environmental protection, the EPA examined qualitative data for the Chordate MDR from **Appendix H** (*Other Data on Effects of Aluminum to Freshwater Aquatic Organisms*) and selected an amphibian test to fulfill that MDR. The species did not rank in the lowest four normalized Genus Mean Chronic Values (GMCVs) (the numeric-criteria-driving portion of the sensitivity distribution), and thus its use to fulfill the missing MDR is considered justified (U.S. EPA 2008). There are not enough chronic toxicity data for direct calculation of the FCV for the

NMED Exhibit 75

estuarine/marine criteria (no acceptable estuarine/marine chronic studies), thus the EPA did not derive chronic estuarine/marine criterion. Aluminum toxicity data on estuarine/marine species remain a data gap; additional acute and chronic toxicity testing on estuarine/marine taxa would be needed in order to derive estuarine/marine criteria for aluminum.

NMED Exhibit 75

Table 2. Summary of Acceptable Toxicity Data Used to Fulfill the Minimum Data Requirements in the 1985 Guidelines for Aluminum.

Family Minimum Data Requirement (Freshwater)	Acute (Phylum / Family / Genus)	Chronic (Phylum / Family / Genus)
Family Salmonidae in the class Osteichthyes	Chordata / Salmonidae / Oncorhynchus	Chordata / Salmonidae / Salvelinus
Second family in the class Osteichthyes	Chordata / Centrarchidae / Lepomis	Chordata / Cyprinidae / Pimephales
Third family in the phylum Chordata	Chordata / Cyprinidae / Pimephales	Chordata / Ranidae / Rana*
Planktonic Crustacean	Arthropoda / Daphniidae / Ceriodaphnia	Arthropoda / Daphniidae / Ceriodaphnia
Benthic Crustacean	Arthropoda / Crangonyctidae / Crangonyx	Arthropoda / Hyalellidae / Hyalella
Insect	Arthropoda/ Chironomidae/ Chironomus	Arthropoda / Chironomidae / Chironomus
Family in a phylum other than Arthropoda or Chordata	Mollusca / Physidae / Physa	Mollusca / Lymnaeidae / Lymnaea
Family in any order of insect or any phylum not already represented	Annelida / Naididae / Nais	Annelida / Aeolosomatidae / Aeolosoma
Family Minimum Data Requirement (Estuarine/Marine)	**Acute (Phylum / Family / Genus)**	**Chronic (Phylum / Family / Genus)**
Family in the phylum Chordata	No acceptable data	No acceptable data
Family in the phylum Chordata	No acceptable data	No acceptable data
Either the Mysidae or Penaeidae family	No acceptable data	No acceptable data
Family in a phylum other than Arthropoda or Chordata	Mollusca / Ostreidae / Crassostrea	No acceptable data
Family in a phylum other than Chordata	Annelida / Nereididae / Neanthes	No acceptable data
Family in a phylum other than Chordata	Annelida / Capitellidae / Capitella	No acceptable data
Family in a phylum other than Chordata	Annelida / Ctenodrilidae / Ctenodrilus	No acceptable data
Any other family	Arthropoda / Ameiridae / Nitokra	No acceptable data

* Data used qualitatively, see Section 3.2.1.

	Freshwater Acute			Freshwater Chronic			Estuarine/Marine Acute			Estuarine/Marine Chronic		
Phylum	**Families**	**GMAVs**	**SMAVs**	**Families**	**GMCVs**	**SMCVs**	**Families**	**GMAVs**	**SMAVs**	**Families**	**GMCVs**	**SMCVs**

NMED Exhibit 75

2.7.1 pH, Total Hardness and DOC Normalization

Although many factors might affect the results of toxicity tests of aluminum to aquatic organisms (Sprague 1985), water quality criteria can quantitatively take into account only factors for which enough data are available to show that the factor similarly affects the results of tests with a variety of species. A variety of approaches were evaluated for the development of the freshwater aluminum criteria due to aluminum's unique chemistry and geochemical effects on its bioavailability. These included empirical models that directly relate water chemistry conditions to metal bioavailability and include single parameter regression models (e.g., hardness adjustment equations) and a variety of MLRs. The mechanistic models evaluated included an aluminum BLM model and a simplified aluminum BLM model. For further discussion, see **Section 5.3.5**.

A recent publication by Gensemer et al. (2018) summarized short-term aluminum chronic toxicity data across a range of pH, total hardness, and DOC values. Three-day toxicity tests measuring growth with the green alga (*Pseudokirchneriella subcapitata*), 7-day reproduction tests with the cladoceran (*Ceriodaphnia dubia*), and 7-day mean biomass tests with the fathead minnow (*Pimephales promelas*) were compiled to evaluate how the effect of pH, total hardness, and DOC alters aluminum bioavailability. The *P. subcapitata* data consisted of 27 tests with dilution water parameters that ranged from 6.14-8.0 for pH, 22-121 mg/L total hardness and 0.3-4.0 mg/L DOC (DeForest et al. 2018a). The *C. dubia* data consisted of 23 tests with test parameters that ranged from 6.3-8.1 for pH, 9.8-123 mg/L total hardness and 0.1-4 mg/L DOC (DeForest et al. 2018a). The fathead minnow data consisted of 22 tests with test parameters that ranged from 6.0-8.0 for pH, 10.2-127 mg/L total hardness and 0.08-5.0 mg/L DOC (DeForest et al. 2018a). DeForest et al. (2018a) used these data to evaluate the ability of MLR models to predict chronic toxicity of aluminum as a function of multiple combinations of pH, total hardness, and DOC conditions. These three parameters are thought to be the most influential for aluminum bioavailability and can be used to explain the scale of differences in the observed toxicity values (Cardwell et al. 2018; Gensemer et al. 2018). As a result of the public comments on the draft of this document released into the Federal Register, data on an additional nine *C. dubia* and nine *P. promelas toxicity* tests were obtained in order to expand the ranges of water chemistry conditions for model development. The new toxicity data expanded the DOC range up to 12.3 mg/L for *C. dubia* and 11.6 mg/L for *P. promelas* and the hardness range up to 428 mg/L

NMED Exhibit 75

and 422 mg/L, respectively. These new data were subjected to an independent, external expert peer review, and an EPA quality review, prior to their use in the aluminum criteria. The external expert peer review comments on these new data obtained by the EPA in 2018 and the EPA's response to the external expert peer reviews can be found on the EPA website for the aluminum criteria (https://www.epa.gov/wqc/aquatic-life-criteria-aluminum).

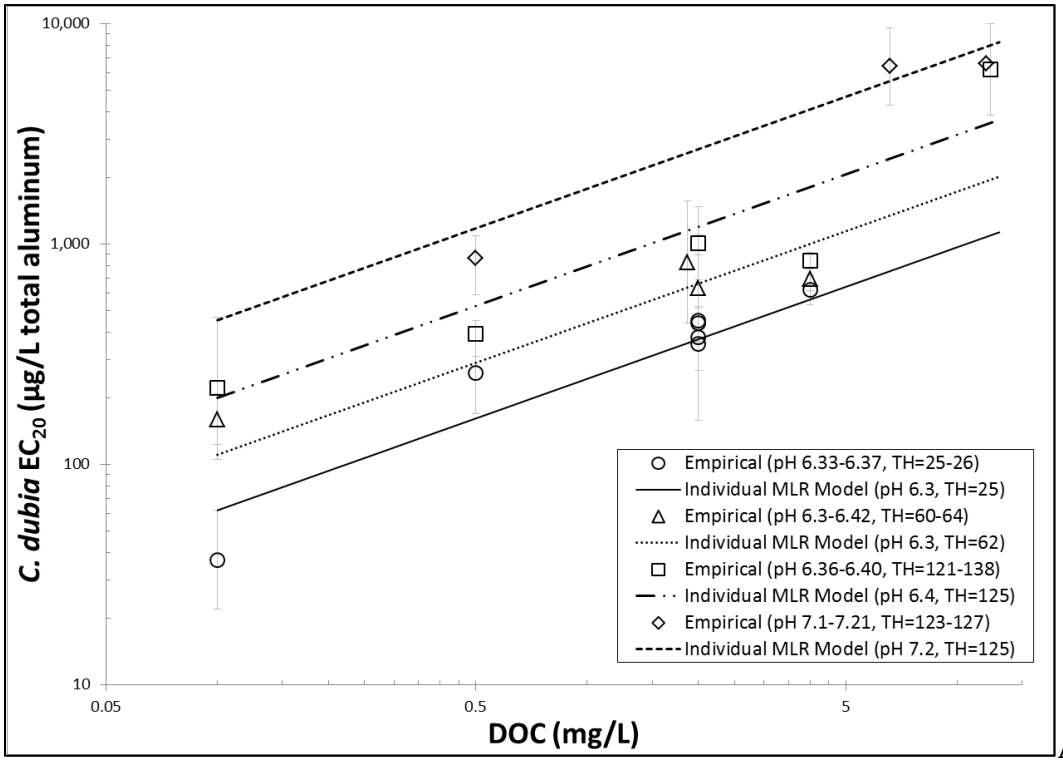
The approach described by DeForest et al. (2018a,b) incorporated pH, total hardness, and DOC into MLR models to determine if the estimation of aluminum bioavailability to animals in freshwater aquatic systems could be applicable in the development of aluminum water quality criteria. The approach resulted in the creation of multiple MLR models that could be used for the development of aluminum water quality criteria following European Union (EU) (ECB 2003) and the EPA methodologies (Stephan et al. 1985). Only the MLR model development for the fathead minnow and *C. dubia* using EC_{20} effects concentrations is described below. Note that while a 7-day survival and growth test for *P. promelas* is not defined as an early-life stage (ELS) test per the 1985 Guidelines, testing demonstrated that it produced sensitivity values for total aluminum comparable to those generated via an acceptable ELS test (DeForest et al. 2018a, Table S1), and therefore, is considered appropriate to use for MLR model development.

MLR models for each species were developed using a multi-step process and the general approach is briefly described below. For more detailed information, figures, tables, and statistical results, please see DeForest et al. (2018a,b) and Brix et al. (2017). The authors first examined if any of the relationships between the dependent variable (total aluminum effect concentrations) and the three main effect terms (pH, total hardness and DOC; all independent variables) were non-linear. Effect concentrations (EC_{20}s) for each species were plotted against each independent variable using data where the other two parameters were held constant. Overall, EC_{20}s increased with each independent variable. However, there was some evidence of a unimodal relationship with pH, with increased EC_{20}s around pH 7 and decreasing EC_{20}s at low and high pH, as well as potential differences regarding the effects of total hardness at low and high pH (DeForest et al. 2018a). To account for these potential nonlinearities, the three potential two-way interactions (i.e., pH:hardness, DOC:hardness and pH:hardness) for each of the three main effect terms were added. Finally, a squared pH term was included in the initial models to account for the potential unimodal relationship between pH and aluminum bioavailability (DeForest et al. 2018a).

NMED Exhibit 75

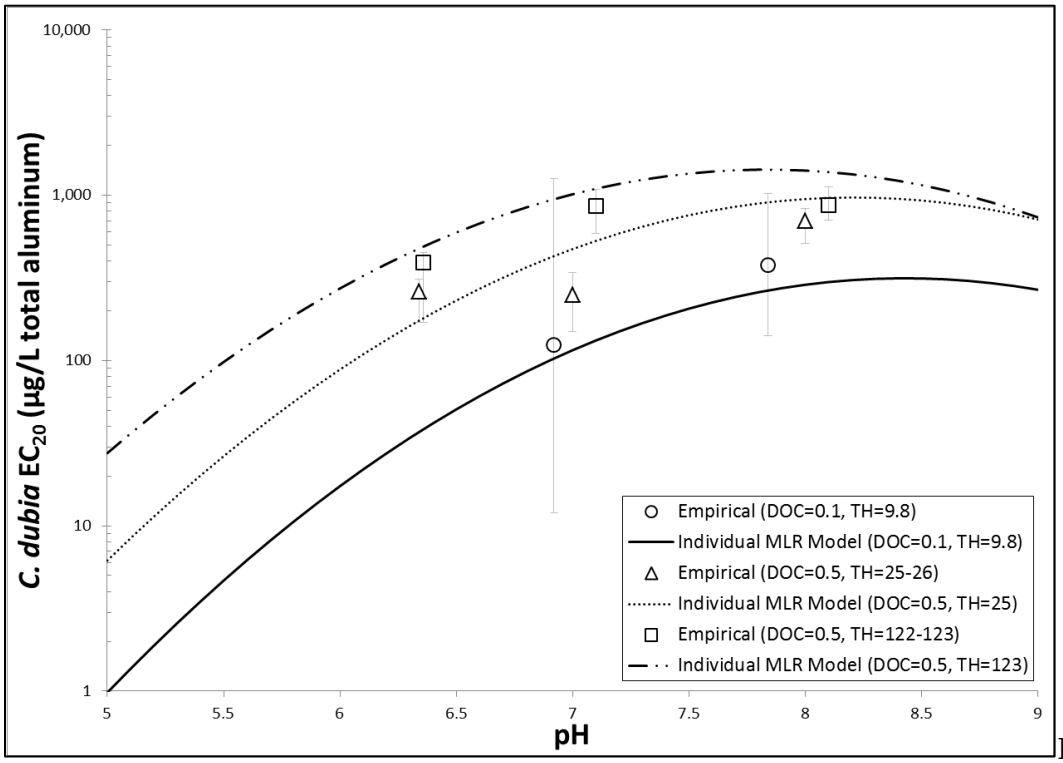
Beginning with a seven-parameter model consisting of the three main effect terms (pH, total hardness and DOC), the three two-way interactions for the main effects, and a squared pH term, a final model was developed for each species using a step-wise procedure. In this procedure, the original model was compared to a series of simpler models by removing one or more of the four "higher-level" terms (i.e., the three interaction terms and the squared pH term), until the most parsimonious model was developed. Each potential model was evaluated using Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC). The overall goodness of fit of a model increases with each additional model term. AIC and BIC penalize a model's goodness-of-fit by a factor related to the number of parameters in the model (DeForest et al. 2018a). AIC and BIC are minimized for the model that best balances overall goodness-of-fit and model complexity, as too many terms in the model may over extrapolate from the dataset making it less useful, whereas too few terms reduces its precision.

DeForest et al. (2018b) re-evaluated the original published models supplemented with the new data and developed a pooled MLR model based on the combined *C. dubia* and *P. promelas* datasets. A pooled model approach is described in Brix et al. (2017) for copper. In a pooled MLR model approach, species-specific intercepts are used to account for the differences in species sensitivity. The same procedures were used to develop a pooled model as was done for the individual species MLR models.



For *C. dubia*, the final individual MLR model, based on AIC and BIC, included both the pH:hardness interaction and the squared pH term (DeForest et al. 2018b). The negative pH^2 term accounts for the fact that aluminum bioavailability decreases from pH 6 to pH 7 and then increases from pH 7 to pH 8, which is expected given the unique solubility chemistry of aluminum (DeForest et al. 2018a). The negative pH:hardness term is reflective of the decreasing effects of total hardness mitigating toxicity as pH increases (DeForest et al. 2018a). The adjusted R^2 for the final model was 0.880, compared to an R^2 of 0.67 for the model consisting of the three main independent variables [pH, ln(total hardness), and ln(DOC)]. In the final MLR model, predicted EC_{20}s were within a factor of two of observed values used to create the model for 97% of the tests (DeForest et al. 2018b). The comparison of MLR predicted versus observed *C. dubia* values where one water chemistry parameter was varied is seen in **Figure 4** and **Figure 5**. No clear pattern was observed in the residuals over a wide range of water chemistry conditions or

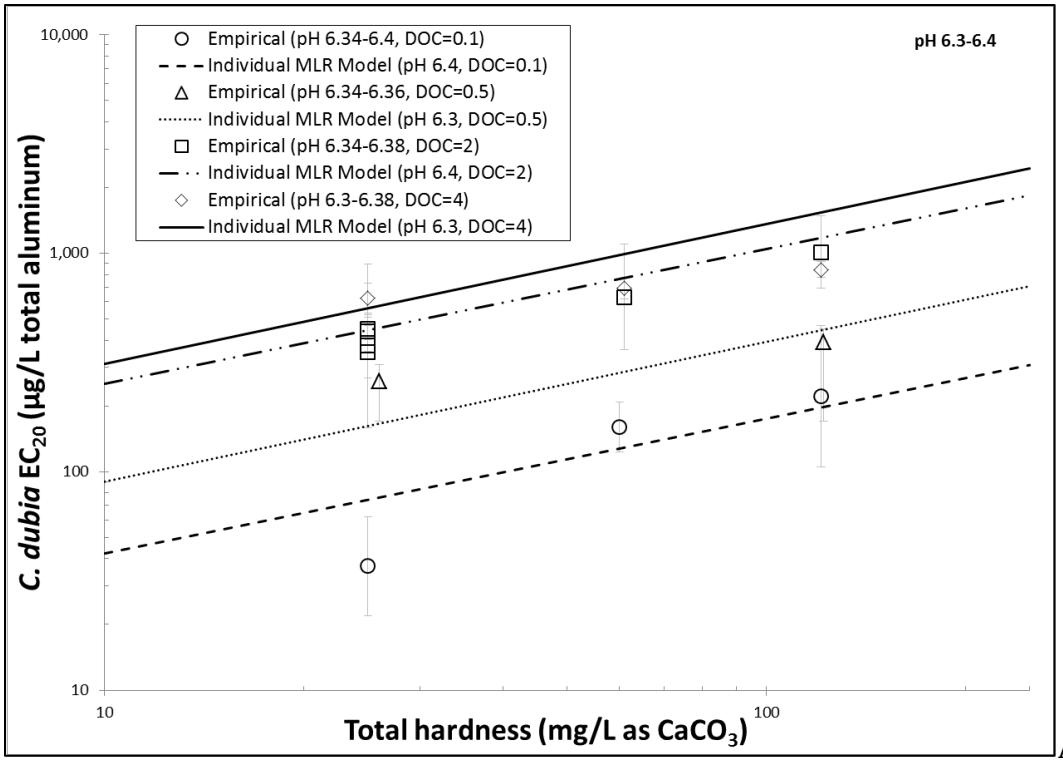
NMED Exhibit 75



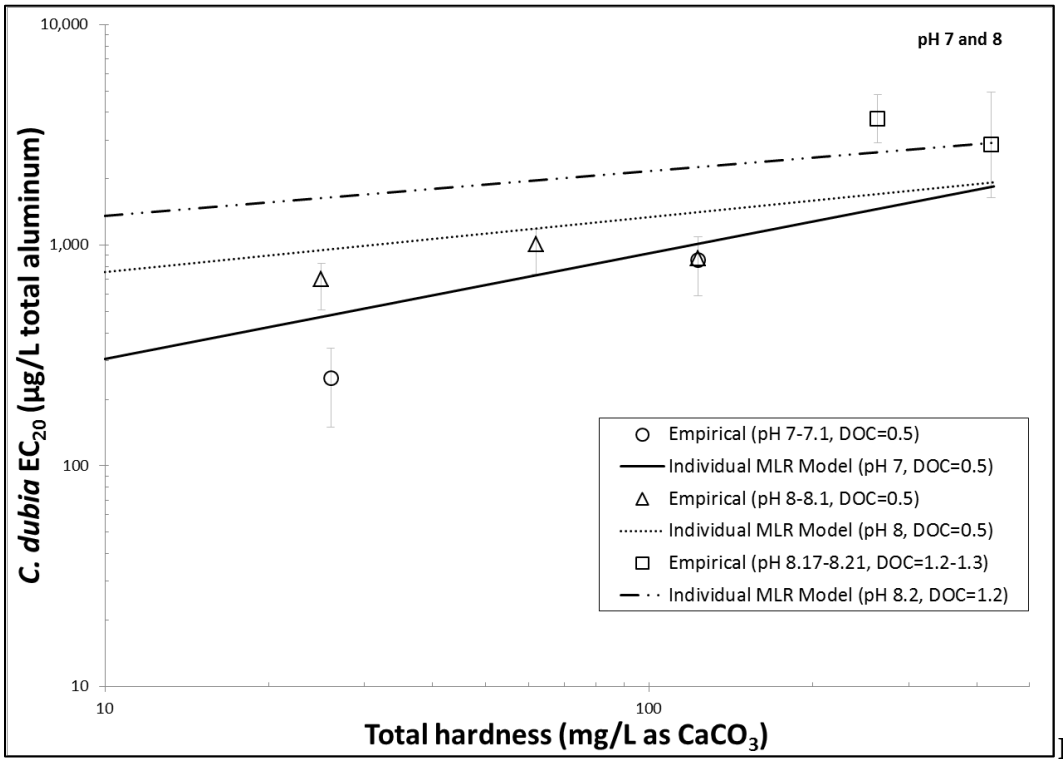
relative to single independent variables (Figure S3-Figure S6, DeForest et al. 2018a). The final individual MLR model for *C. dubia* is:

$$C.dubia\ EC_{20} = e^{\left[-32.523+[0.597\times\ln(DOC)]+[2.089\times\ln(hard)]+(8.802\times pH)-(0.491\times pH^2)-[0.230\times pH:\ln(hard)]\right]}$$

NMED Exhibit 75



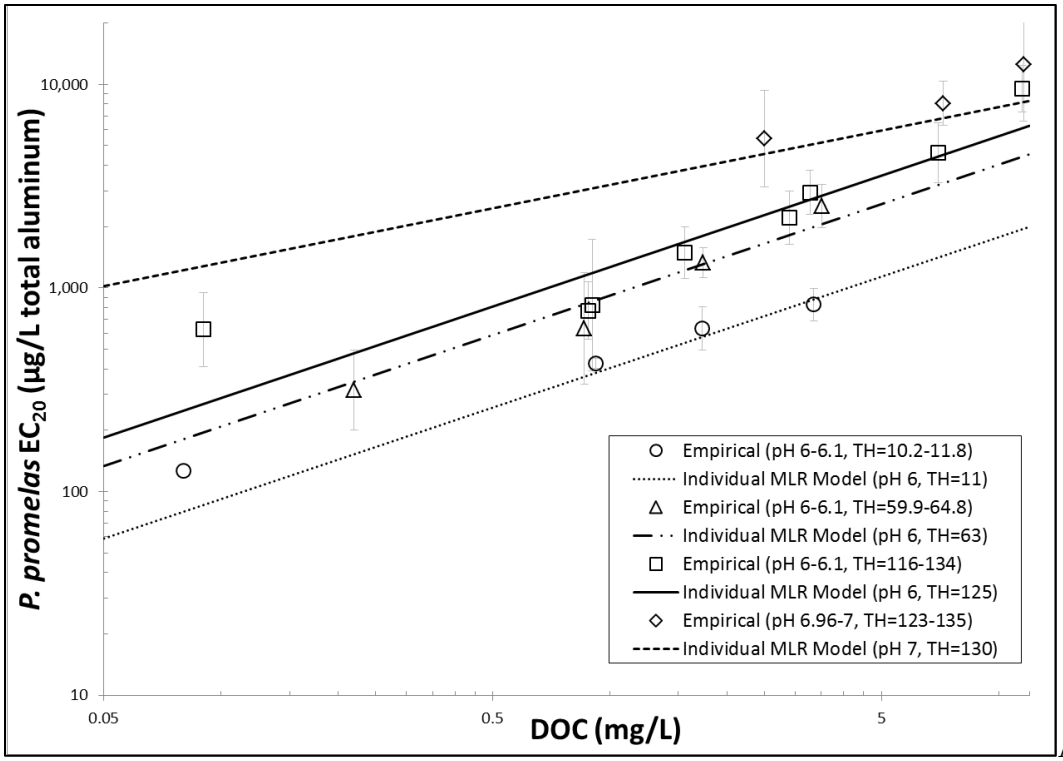
A



B

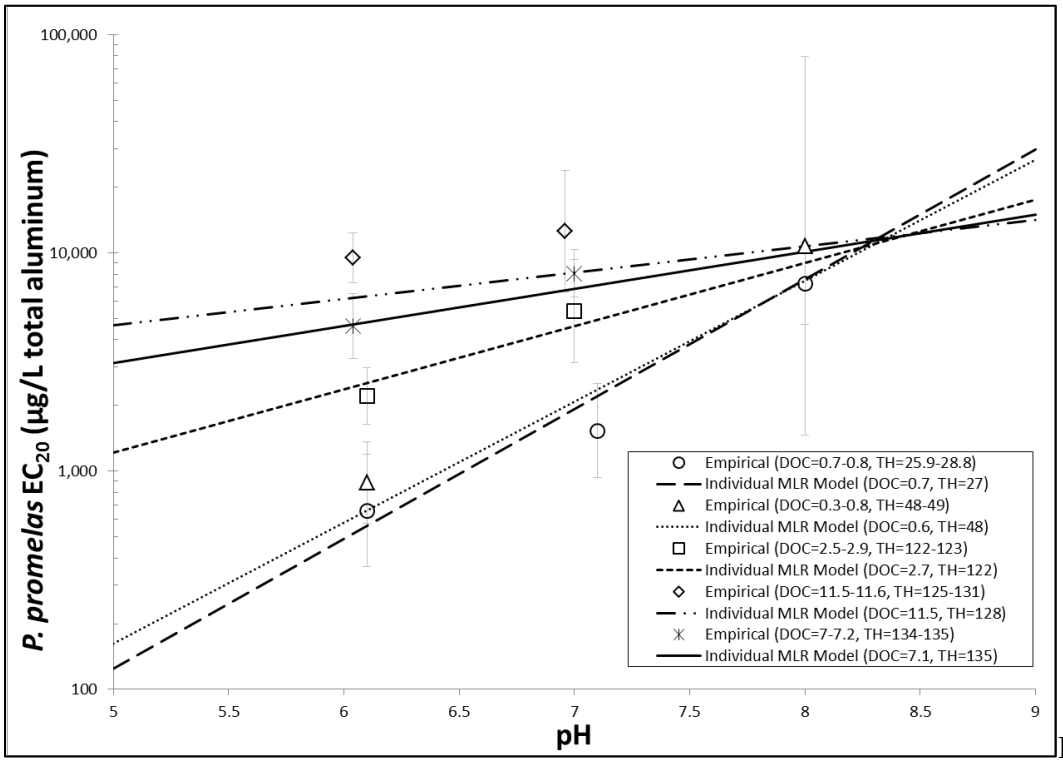
Figure 4. Observed and Individual MLR-Predicted Aluminum EC_{20}s (±95% CLs) for *C. dubia* where DOC or pH was Varied.
(Panel A: DOC is varied; Panel B: pH is varied; Adapted from Figure 2, from DeForest et al. 2018a, used with permission).

A



B

Figure 5. Observed and Individual MLR-Predicted Aluminum EC_{20}s (±95% CLs) for *C. dubia* where Total Hardness was Varied.
(Panel A: pH 6.3-6.4, Panel B: pH 7 and 8; Adapted from Figure 2, from DeForest et al. 2018a, used with permission).



For *P. promelas*, the final individual model, based on AIC and BIC, included the pH:hardness and pH:DOC interaction terms (DeForest et al. 2018b). The pH:hardness interaction term was retained because of the unique chemistry of aluminum where total hardness has less of a mitigating effect on bioavailability at higher pH levels (DeForest et al. 2018a; Gensemer et al. 2018). The adjusted R^2 for the final model was 0.923, compared to an R^2 of 0.85 for the model consisting of the three main independent variables [ln(DOC), pH, and ln(hardness)]. In the final MLR model, predicted EC_{20}s were within a factor of two of observed values used to create the model for 97% of the tests (DeForest et al. 2018b). The comparison of MLR predicted versus observed *P. promelas* values where one water chemistry parameter was varied is provided in **Figure 6** and **Figure 7**. Again, no clear pattern was observed in the residuals over a wide range of water chemistry conditions or relative to single independent variables (Figure S3-Figure S6, DeForest et al. 2018a). The final individual MLR model for *P. promelas* is:

$$P.promelas\ EC_{20} = e^{[-7.371+[2.209\times\ln(DOC)]+[1.862\times\ln(hard)]+(2.041\times pH)-[0.232\times pH:\ln(hard)]-[0.261\times pH:\ln(DOC)]]}$$

Figure 6. Observed and Individual MLR-Predicted Aluminum EC_{20}s (±95% CLs) for *P. promelas* where DOC or pH was Varied.
(Panel A: DOC, Panel B: pH; Adapted from Figure 3, from DeForest et al. 2018a, used with permission).

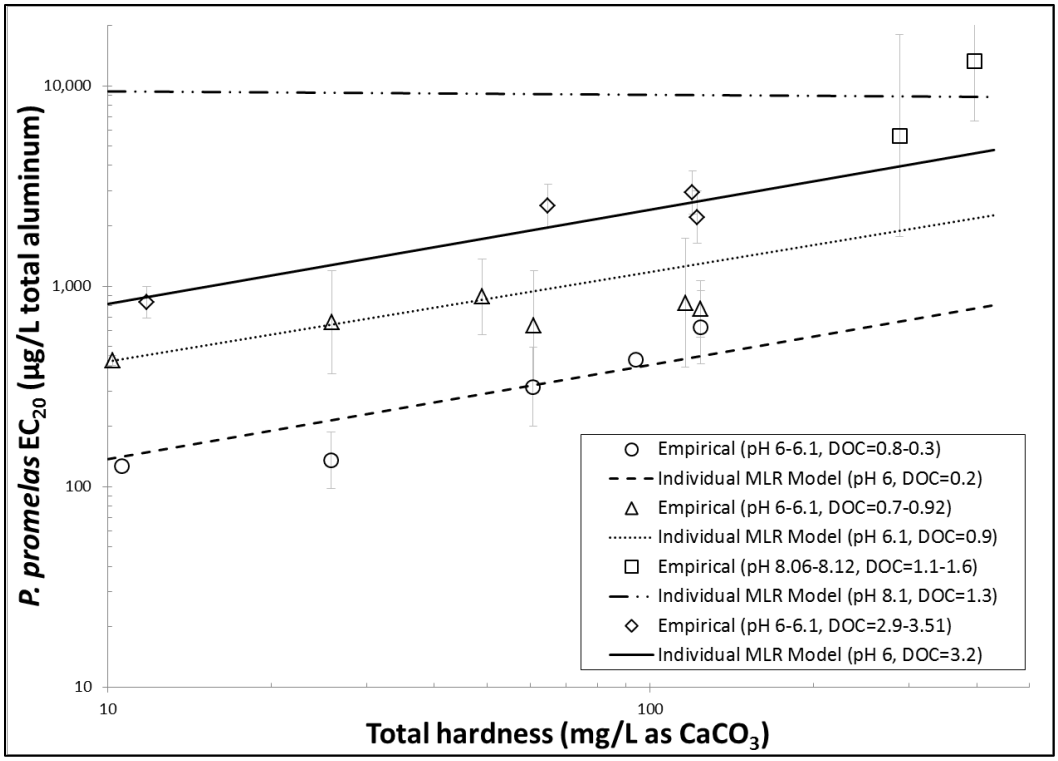

Figure 7. Observed and Individual MLR-Predicted Aluminum EC_{20}s (±95% CLs) for *P. promelas* where Total Hardness was Varied.
(Adapted from Figure 3, from DeForest et al. 2018a, used with permission).

The pooled MLR model performed similarly as the individual (fish and invertebrate) MLR models (DeForest et al. 2018b). The adjusted R^2 value, based on the BIC, was 0.882 and includes the pH:hardness interaction term. The pooled MLR model had a similar to identical level of accuracy as the individual MLR models with 97% of *C. dubia* and 94% of *P. promelas* predicted EC_{20}s within a factor of two of observed values (DeForest et al. 2018b). However, a comparison of the residuals between the observed and predicted values for the two models (individual vs. pooled MLR) showed that the individual models' residuals had smaller standard deviations. Additionally, the pooled model had some patterns in the residuals of the predictions relative to the independent variables (e.g., pH). There were no patterns in the residuals for either the *C. dubia* or *P. promelas* individual MLR models. The EPA elected to use the individual fish and invertebrate models in the final recommended aluminum aquatic life AWQC, instead of a pooled model for the above reasons. This modeling approach is also consistent with the approach in the draft 2017 aluminum criteria document. Additional analysis comparing the performance to the two model approaches (individual vs. pooled MLR) is presented in **Appendix L** (*EPA's MLR Model Comparison of DeForest et al. (2018b) Pooled and Individual-Species Model Options*).

NMED Exhibit 75

The models developed followed the trends seen in the empirical data, 1) at pH 6 predicted effects concentrations increased with both total hardness and DOC concentrations, 2) at pH 7 predicted effect concentrations increased with DOC concentrations, but not total hardness, and 3) at pH 8 predicted effect concentrations increased with DOC concentrations, but predicted effect concentrations decreased with increased total hardness concentrations (DeForest et al. 2018a). The individual species models developed by DeForest et al. (2018b) were used to normalize the freshwater acute and chronic data in **Appendix A** and **Appendix C**, respectively. Invertebrate data were normalized using the individual MLR model for *C. dubia*, and vertebrate data were normalized using the individual MLR model for *P. promelas*. Invertebrate and vertebrate freshwater aluminum toxicity data were normalized with the following equations:

$$Invertebrate\ Normalized\ EC_{20}/LC_{50}$$

$$= e^{\left[\begin{array}{c}(\ln EC_{20,test}/LC_{50,test})-[0.597\times(\ln DOC_{test}-\ln DOC_{target})]-[8.802\times(pH_{test}-pH_{target})]-[2.089\times(\ln hard_{test}-\ln hard_{target})]\\ +[0.491\times(pH_{test}^2-pH_{target}^2)]+[0.230\times[(pH_{test}\times\ln hard_{test})-(pH_{target}\times\ln hard_{target})]]\end{array}\right]}$$

$$Vertebrate\ Normalized\ EC_{20}/LC_{50}$$

$$= e^{\left[\begin{array}{c}\left(\ln\frac{EC_{20,test}}{LC_{50,test}}\right)-[2.209\times(\ln DOC_{test}-\ln DOC_{target})]-[2.041\times(pH_{test}-pH_{target})]-[1.862\times(\ln hard_{test}-\ln hard_{target})]\\ +[0.261\times[(pH_{test}\times\ln DOC_{test})-(pH_{target}\times\ln DOC_{target})]]\\ +[0.232\times[(pH_{test}\times\ln hard_{test})-(pH_{target}\times\ln hard_{target})]]\end{array}\right]}$$

where:

$EC_{20,test}$	=	reported chronic total aluminum effect concentration in µg/L
$LC_{50,test}$	=	reported acute total aluminum effect concentration in µg/L
DOC_{test}	=	reported test DOC concentration in mg/L
pH_{test}	=	reported test pH
$hard_{test}$	=	reported test total hardness concentration in mg/L as $CaCO_3$
DOC_{target}	=	DOC value to normalize to in mg/L
pH_{target}	=	pH value to normalize to
$hard_{target}$	=	total hardness value to normalize to in mg/L as $CaCO_3$

Throughout this document, unless otherwise stated, effect concentrations were normalized to pH 7, total hardness of 100 mg/L and DOC of 1 mg/L. This example scenario is illustrative only and

NMED Exhibit 75

is not meant to represent water quality characteristics typical of U.S. natural waters. Normalized values will be different under differing water chemistry conditions as identified in this document.

2.7.2 Acute Criterion

Acute criteria are derived from the sensitivity distribution of compiled genus mean acute values (GMAVs), calculated from species mean acute values (SMAVs) of acceptable data. SMAVs are calculated using the geometric mean for all acceptable toxicity tests within a given species (e.g., all tests for *Daphnia magna*). If only one test is available, the SMAV is that test value by default. As stated in the 1985 Guidelines, flow-through measured test data are normally given preference over other test exposure types (i.e., renewal, static, unmeasured) for a species, when available. When relationships are apparent between life-stage and sensitivity, only values for the most sensitive life-stage are considered. GMAVs are then calculated using the geometric means of all SMAVs within a given genus (e.g., all SMAVs for genus *Daphnia* - *Daphnia pulex*, *Daphnia magna*). If only one SMAV is available for a genus, then the GMAV is represented by that value. GMAVs are then rank-ordered by sensitivity from most sensitive to least sensitive.

Acute criteria are based on the Final Acute Value (FAV). The FAV is determined by regression analysis based on the four most sensitive genera (reflected as GMAVs) in the data set to interpolate or extrapolate (as appropriate) to the 5^{th} percentile of the sensitivity distribution represented by the tested genera. The intent of the eight MDRs is to serve as a representative sample of the aquatic community. These MDRs represent different ecological, trophic, taxonomic and functional differences observed in the natural aquatic ecosystem. Use of a sensitivity distribution where the criteria values are based on the four most sensitive taxa in a triangular distribution represents a censored statistical approach that improves estimation of the lower tail (where most sensitive taxa are) when the shape of the whole distribution is uncertain, while accounting for the total number of genera within the whole distribution.

The acute criterion, defined as the Criterion Maximum Concentration (CMC), is the FAV divided by two, which is intended to provide an acute criterion protective of nearly all individuals in such a genus. The use of the factor of two to reduce the FAV to the criterion magnitude is based on analysis of 219 acute toxicity tests on a range of chemicals, as described in the *Federal Register* on May 18, 1978 (43 FR 21506-18). For each of these tests, mortality data were used to determine the highest test concentration that did not cause mortality greater than that observed in the control for that particular test (which would be between 0 and 10% for

NMED Exhibit 75

an acceptable acute test). Thus, dividing the LC_{50}-based FAV by two decreases potential acute effects to a level comparable to control mortality levels. Therefore, the acute criterion is expected to protect 95% of species in a representative aquatic community from acute effects.

2.7.3 Chronic Criterion

The chronic criterion, defined as the Criterion Continuous Concentration (CCC), may be determined by one of two methods. If all eight MDRs are met with acceptable chronic test data, then the chronic criterion is derived using the same method used for the acute criterion, employing chronic values (e.g., EC_{20}) estimated from acceptable toxicity tests. In cases where fewer chronic data are available (i.e., must have at least three chronic tests from taxa that also have appropriate acute toxicity data), the chronic criterion can be derived by determining an appropriate acute-chronic ratio (ACR).

The criteria presented are the EPA's estimate of maximum concentrations of aluminum to protect most aquatic organisms from any unacceptable short- or long-term effects. Results of such intermediate calculations such as Species Mean Acute Values (**Appendix A** and **Appendix B**) and chronic values (**Appendix C** and **Appendix D**) are specified to four significant figures to prevent round-off error in subsequent calculations; the number of places beyond the decimal point does not reflect the precision of the value. The acute and chronic criteria are rounded to two significant figures.

3 EFFECTS ANALYSES

Data for aluminum were obtained from studies published in the open literature and identified in a literature search using the ECOTOXicology database (ECOTOX) as meeting data quality standards. ECOTOX is a source of high quality toxicity data for aquatic life, terrestrial plants, and wildlife. The database was created and is maintained by the EPA, Office of Research and Development, and the National Health and Environmental Effects Research Laboratory's Mid-Continent Ecology Division. The latest comprehensive literature search for this document via ECOTOX was conducted in 2017 and supplemented by additional data researchers made available to the EPA in 2018.

A further evaluation of the quality of the available data was performed by the EPA to determine test acceptability for criteria development. Appendix A of *Quality Criteria for Water*

NMED Exhibit 75

1986 (U.S. EPA 1986) provides an in-depth discussion of the minimum data requirements and data quality requirements for aquatic life criteria development.

3.1 Acute Toxicity to Aquatic Animals

All available reliable data relating to the acute effects of total aluminum on aquatic animals were considered in deriving the aluminum criteria. Data suitable (in terms of test acceptability and quality in a manner consistent with the 1985 Guidelines) for the derivation of a freshwater and an estuarine/marine FAV are presented in **Appendix A** (*Acceptable Acute Toxicity Data of Aluminum to Freshwater Aquatic Animals*) and **Appendix B** (*Acceptable Acute Toxicity Data of Aluminum to Estuarine/Marine Aquatic Animals*), respectively. Most fish and invertebrate data are LC_{50} measures from acute toxicity tests that were 96 hours in duration, except the tests for cladocerans, midges, mysids and certain embryos and larvae of specific estuarine/marine groups, which were 48 hours in duration and typically EC_{50} endpoints (per the 1985 Guidelines).

3.1.1 Freshwater

Twenty-two freshwater species encompassing 20 genera are represented in the dataset of acceptable data for acute toxicity to aluminum. The water quality conditions for these 118 toxicity tests ranged from 5.0-8.3 for pH, 2-220 mg/L as $CaCO_3$ for total hardness, and 0.48-4.0 mg/L for DOC. Since these three parameters affect the bioavailability, and hence toxicity of aluminum, all of the acceptable acute toxicity data presented in **Appendix A** were normalized to standardized water quality conditions using the MLR equations described in the Analysis Plan (**Section 2.7.1**). However, the dilution water DOC concentration was not reported for a number of acute studies presented in **Appendix A**. In this situation, where only the DOC was lacking, default values were used for several different dilution waters using a methodology documented in the 2007 freshwater copper AWQC document (see Appendix C, U.S. EPA 2007b). Specifically, the default DOC value for: 1) laboratory prepared reconstituted water is 0.5 mg/L, 2) Lake Superior water is 1.1 mg/L, 3) city tap and well water is 1.6 mg/L, and 4) Liberty Lake, Washington water is 2.8 mg/L. These values were determined from empirical data obtained for each source water.

Once normalized, the toxicity data were compiled (i.e., based on the geometric mean for each species and genus) and ranked by GMAV into a sensitivity distribution. Normalizing the toxicity data to the same pH, total hardness and DOC levels allows comparisons to be made

NMED Exhibit 75

because the MLR derived equations address the differences seen in the magnitude of effects when comparing across conditions. However, because the 118 toxicity tests were each conducted at different water quality conditions, the MLR derived equations may have either a minor or major effect on the magnitude of the observed reported effects depending on the set of conditions to which the tests are normalized. Thus, the relative sensitivity rankings can change depending on what pH, hardness and DOC concentrations are selected for normalization (see **Appendix K** for examples).

All values reported in this section are normalized to pH 7, total hardness of 100 mg/L as $CaCO_3$, and DOC of 1.0 mg/L (see **Section 2.7.1** for more information). Several species tested were not exposed to aluminum concentrations high enough or low enough to allow calculation of an LC_{50} (i.e., the LC_{50} is a "greater than" or "less than" value). The decision rule for using these non-definitive LC_{50}s to calculate SMAVs is consistent with methods used previously in criteria development. The freshwater ammonia AWQC document explains how chronic values (e.g., EC_{20}s) can be evaluated for potential use in deriving SMCVs (U.S. EPA 2013). The methodology is based on the finding that "greater than" values for concentrations of low magnitude, and "less than" values for concentrations of high magnitude do not generally add significant information to the toxicity analysis. The decision rule was applied as follows: "greater than" (>) low chronic values and "less than" (<) high chronic values were not used in the calculation of the SMCV; but "less than" (<) low chronic values and a "greater than" (>) high chronic values were included in the SMCV (U.S. EPA 2013). This approach was also followed for acute SMAV calculations.

While non-definitive SMAVs were ranked in **Table 3** according to the highest concentration used in the test, the value does not necessarily imply a accurate ranking of sensitivities. Again, in this section and below, the relative rankings are presented for comparative purposes and only apply when the set of chemistry conditions are pH 7, total hardness of 100 mg/L and DOC of 1.0 mg/L. SMAVs ranged from 1,836 µg/L for the cladoceran, *Daphnia pulex*, to 119,427 µg/L for the snail, *Melanoides tuberculata*. There is no apparent trend between freshwater taxon and acute sensitivity to aluminum (**Table 3**). The smallmouth bass, *Micropterus dolomieu*, represents the second most sensitive genus; cladocerans represent the first and fourth most sensitive genera; fish genera rank second, third, sixth and seventh in the sensitivity distribution; and an ostracod (*Stenocypris*) ranks fifth.

NMED Exhibit 75

Other fish species were less sensitive with SMAVs of 18,913 µg/L for the brook trout, *Salvelinus fontinalis*, greater than 22,095 µg/L for the fathead minnow, *Pimephales promelas*, greater than 31,087 µg/L for the green sunfish, *Lepomis cyanellus*, and greater than 21,779 µg/L for the Rio Grande silvery minnow, *Hybognathus amarus.* The midge (*Chironomus plumosus*, SMAV = 25,216 µg/L), the aquatic air-breathing snail (*Physa sp.*, SMAV = 41,858 µg/L), and the freshwater juvenile mussel (*Lampsilis siliquoidea*, SMAV = >29,492 µg/L) were comparatively insensitive to aluminum.

Summary of Studies Used in Acute Freshwater Determination

The taxa used in calculating the acute criterion (the lowest four ranked GMAVs) depends on the set of water quality conditions for which the criterion is being derived. Based on the analysis in **Appendix K** (*Recommended Criteria for Various Water Chemistry Conditions*), a combination of several genera will rank in the lowest four. Those acute studies used to calculate the GMAVs are summarized below. The normalized values mentioned below are for pH of 7, total hardness of 100 mg/L as $CaCO_3$ and DOC of 1.0 mg/L.

Invertebrates

Cladoceran, *Daphnia*

The pH/total hardness/DOC-normalized GMAV of 2,325 µg/L aluminum for *Daphnia* is based on the SMAVs for two cladoceran species, *Daphnia magna* and *D. pulex*. The *D. magna* normalized SMAV (2,944 µg/L) is based on the geometric mean of five 48-hr EC_{50}s (ranged from 713.2 to 15,625 µg/L aluminum) as reported by Biesinger and Christensen (1972), European Aluminum Association (2009), Kimball (1978) and Shephard (1983). All tests were static that exposed <24-hr old neonates, and only the Kimball (1978) test measured aluminum concentrations and did not use nominal concentrations. The *D. pulex* normalized SMAV (1,836 µg/L) is based on only one static-renewal unmeasured toxicity test conducted by Griffitt et al. (2008).

Cladoceran, *Ceriodaphnia*

Two species of *Ceriodaphnia, C. dubia* and *C. reticulata,* are used to derive the pH/total hardness/DOC-normalized GMAV of 7,771 µg/L aluminum. The *C. dubia* SMAV of 5,863 µg/L aluminum is calculated from 52 normalized EC_{50} values that ranged from 322.4 to greater than 88,933 µg/L aluminum (ENSR 1992d; European Aluminum Association 2009, 2010; Fort and Stover 1995; Gensemer et al. 2018; Griffitt et al. 2008; McCauley et al. 1986; Soucek et al.

NMED Exhibit 75

2001). The tests were a mix of static or renewal exposures with either measured or unmeasured aluminum concentrations. The *C. reticulata* normalized SMAV of 10,299 µg/L aluminum is based on the two flow-through measured test results reported by Shephard (1983).

Ostracod, *Stenocypris major*

Shuhaimi-Othman et al. (2011a, 2013) reported a 96-hr LC_{50} of 3,102 µg/L aluminum for the ostracod, *S. major*, which equates to a pH/total hardness/DOC-normalized LC_{50}/SMAV/GMAV of 8,000 µg/L total aluminum. The adult organisms were exposed to static-renewal conditions and the test solutions were measured.

Worm, *Nais elinguis*

Shuhaimi-Othman et al. (2012a, 2013) reported a 96-hr LC_{50} of 3,874 µg/L aluminum for the worm, *Nais elinguis* which equates to a pH/total hardness/DOC-normalized LC_{50}/SMAV/GMAV of 9,224 µg/L total aluminum. Adult worms were exposed to aluminum sulfate under static-renewal conditions and the test solutions were measured.

Vertebrates

Rainbow trout, *Oncorhynchus mykiss*

Eight acute toxicity tests for the rainbow trout (*O. mykiss*) were used to calculate the pH/total hardness/DOC-normalized SMAV of 3,312 µg/L aluminum reported by Gundersen et al. (1994). The eight flow-through measured normalized LC_{50}s ranged from 1,680 to 7,216 µg/L aluminum.

Atlantic salmon, *Salmo salar*

Two acceptable acute values reported by Hamilton and Haines (1995) were used to calculate the SMAV/GMAV for the Atlantic salmon, *S. salar*. The sac fry were exposed in static, unmeasured chambers at a total hardness of 6.8 mg/L (as $CaCO_3$) and two different pH levels. The 96-hr LC_{50} values were 584 and 599 µg/L total aluminum conducted at pH levels of 5.5 and 6.5, respectively. The corresponding pH/total hardness/DOC-normalized values are 20,749 and 3,599 and the resulting normalized SMAV/GMAV for the species is 8,642 µg/L total aluminum.

Smallmouth bass, *Micropterus dolomieu*

Three acceptable acute values from one study (reported in both Kane 1984; Kane and Rabeni 1987) are available for the smallmouth bass, *M. dolomieu*. The 48-hr post hatch larva were exposed in static, measured concentration chambers at a total hardness of ~12 mg/L (as $CaCO_3$) and three different pH levels. The LC_{50} values were 130, greater than 978.4 and greater

NMED Exhibit 75

than 216.8 µg/L total aluminum conducted at pH levels of 5.05, 6.25 and 7.5, respectively. The corresponding pH/total hardness/DOC-normalized values are 2,442, greater than 3,655 and greater than 153.4 µg/L. The SMAV/GMAV of 2,988 µg/L for the species/genus is based on the geometric mean of the normalized LC_{50} of 2,442 and greater than 3,655 µg/L total aluminum since the other value (greater than 153.4) is unbounded (i.e., greater than value), and is considered a "greater than" (>) low acute value.

GMAVs for 20 freshwater genera are provided in **Table 3**, and the four most sensitive genera were within a factor of 3.3 of each other. The freshwater FAV (the 5^{th} percentile of the genus sensitivity distribution, intended to protect 95 percent of the genera) for aluminum normalized to a pH 7, total hardness of 100 mg/L and DOC of 1.0 mg/L is 1,961 µg/L, calculated using the procedures described in the 1985 Guidelines. The FAV is an estimate of the concentration of aluminum corresponding to a cumulative probability of 0.05 in the acute toxicity values for the genera with which acceptable acute tests have been conducted (**Table 4**). The FAV is lower than all of the GMAVs for the tested species. The FAV is then divided by two for reasons described above (see **Section 2.7.2**). Based on the above, the FAV/2, which is the freshwater continuous maximum concentration (CMC), for aluminum normalized to a pH 7, total hardness of 100 mg/L and DOC of 1.0 mg/L is 980 µg/L total aluminum (rounded to two significant figures) and is expected to be protective of 95% of freshwater genera potentially exposed to aluminum under short-term conditions (**Figure 8**). However, the freshwater acute toxicity data are normalized using MLR equations that predict the bioavailability and hence toxicity of aluminum under different water chemistry conditions. Thus, the value of the criterion for a given site will depend on the specific pH, total hardness, and DOC concentrations at the site (see **Appendix K** *Recommended Criteria for Various Water Chemistry Conditions* for additional criteria values and four most sensitive genera for each set of conditions).

NMED Exhibit 75

Table 3. Ranked Freshwater Genus Mean Acute Values at pH 7, Total Hardness of 100 mg/L, and DOC of 1.0 mg/L.

(Note: Values will be different under differing water chemistry conditions as identified in this document).

Rank[a]	GMAV (µg/L total Al)	Genus	Species	SMAV[b] (µg/L total Al)
20	119,427	Melanoides	Snail, *Melanoides tuberculata*	119,427
19	>70,647	Paratanytarsus	Midge, *Paratanytarsus dissimilis*	>70,647
18	41,858	Physa	Snail, *Physa sp.*	41,858
17	>31,087	Lepomis	Green sunfish, *Lepomis cyanellus*	>31,087
16	>29,492	Lampsilis	Fatmucket, *Lampsilis siliquoidea*	>29,492

L = 6.334 **L = X-axis intercept**

A = 7.581 **A = lnFAV**

P = cumulative probability

FAV = 1,961 µg/L total aluminum

CMC (acute criterion) = 980 µg/L total aluminum (rounded to two significant figures)

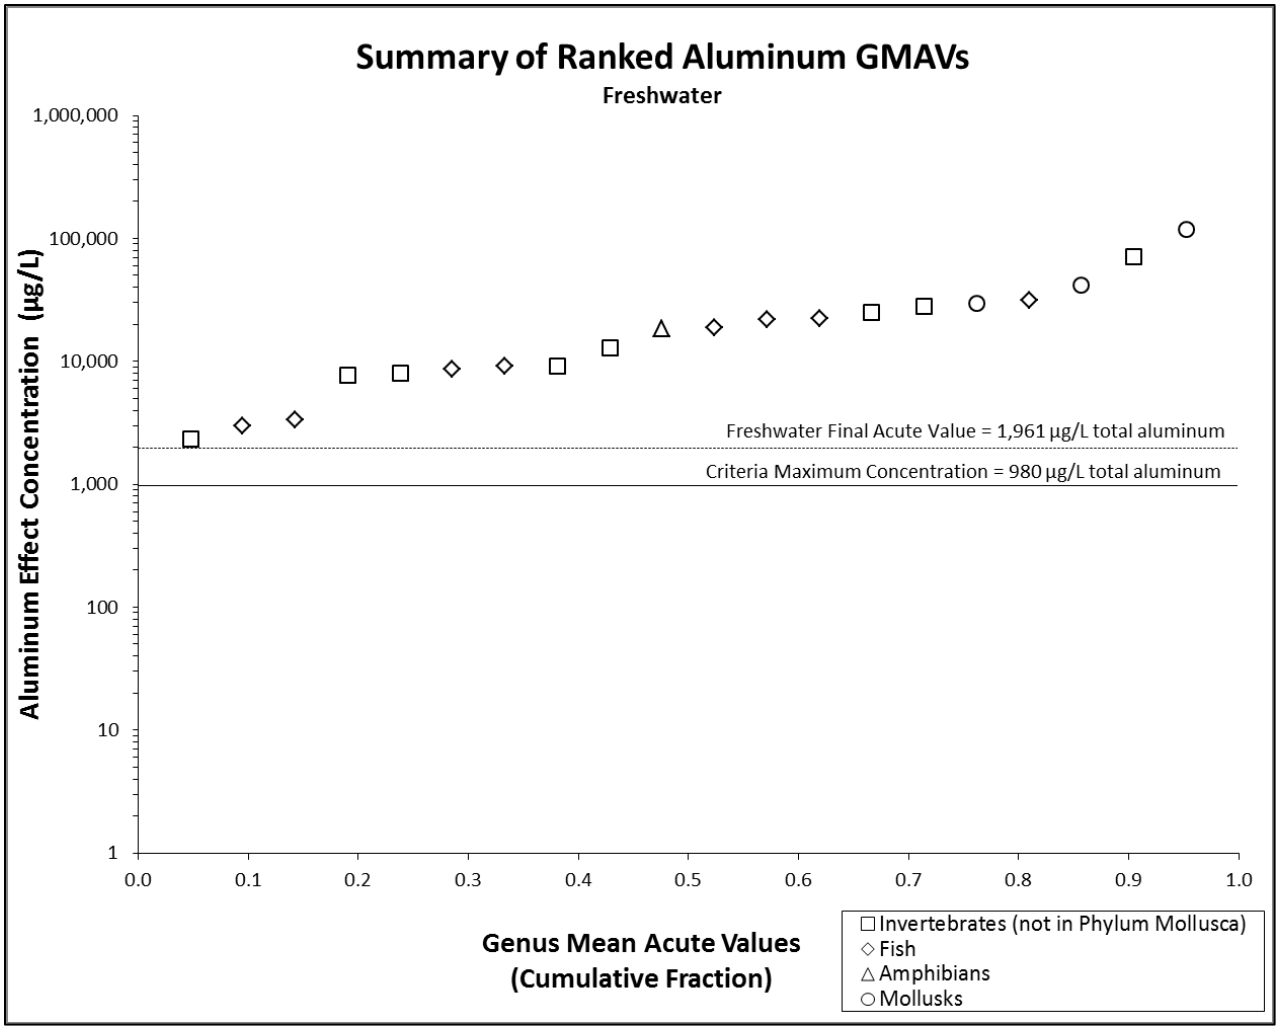

Figure 8. Ranked Summary of Total Aluminum Genus Mean Acute Values (GMAVs) - Freshwater at pH 7, Total Hardness of 100 mg/L, and DOC of 1.0 mg/L.

3.1.2 Estuarine/Marine

The 1985 Guidelines require that data from a minimum of eight families are needed to calculate an estuarine/marine FAV. Notably, no acceptable test data on fish species were available (**Figure 9**). Since data are available for only five families, an estuarine/marine FAV (and consequently the EPA cannot derive an estuarine/marine acute criterion).

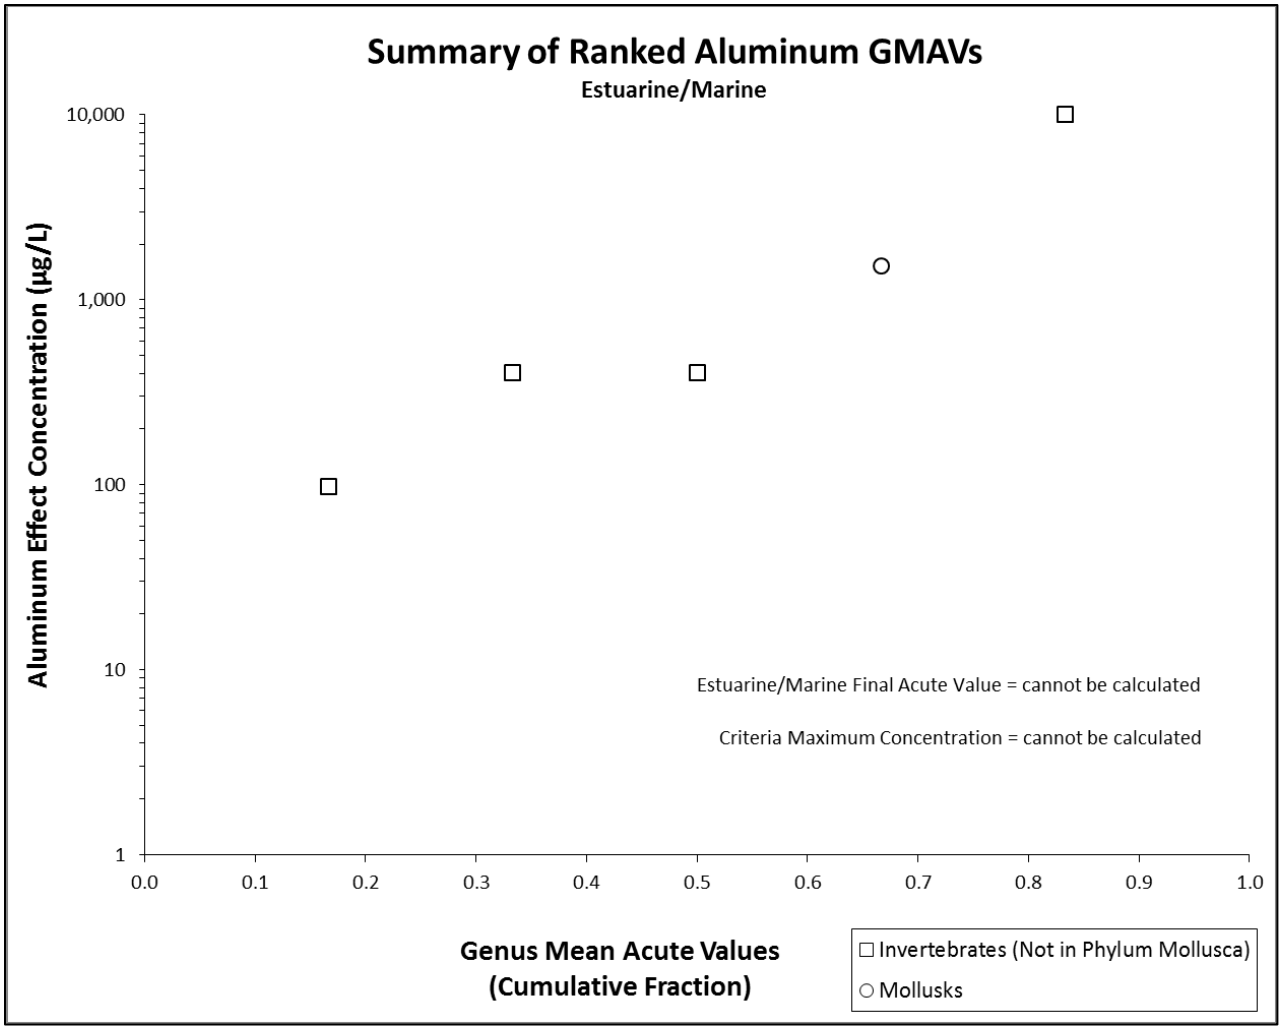

Figure 9. Ranked Summary of Total Aluminum Genus Mean Acute Values (GMAVs) - Estuarine/Marine.

3.2 Chronic Toxicity to Aquatic Animals

3.2.1 Freshwater

Freshwater chronic toxicity data that meet the test acceptability and quality assurance/control criteria (in a manner consistent with the 1985 Guidelines) are presented in **Appendix C** (*Acceptable Chronic Toxicity Data of Aluminum to Freshwater Aquatic Animals*). All tests were conducted with measured concentrations of total aluminum and measurement endpoints are EC_{20}s for all but one test where an EC_{20} could not be calculated. Details on chronic tests are described below. As with the freshwater acute SMAVs/GMAVs, the relative SMCV/GMCV rankings will change depending on the specific pH, total hardness and DOC values selected for data normalization. And as also described for the acute studies, the same

NMED Exhibit 75

DOC default values were used for select chronic tests where the DOC concentration was lacking for specific dilution waters as provided by U.S. EPA (2007b). In addition, the DOC value reported by Cleveland et al. (1989) was applied to the studies by McKee et al. (1989), Palawski et al. (1989) and Buckler et al. (1995). All four studies used the same dilution water preparation, a mixture of well water and reverse osmosis-treated well water to obtain a low hardness (~13 mg/L as $CaCO_3$), and all four studies reported using the same dilution water preparation from Cleveland et al. (1986).

Aluminum chronic toxicity data are available for twelve species of freshwater organisms: two mollusks (a freshwater mussel and a snail), five other invertebrate species (a rotifer, two cladocerans, a midge, an oligochaete and an amphipod) and four fish species (fathead minnow, zebrafish, Atlantic salmon and brook trout). The water quality conditions for these 59 toxicity tests ranged from 5.1-8.7 for pH, 11.8-428 mg/L as $CaCO_3$ for total hardness, and 0.33-12.3 mg/L for DOC. All chronic values were normalized using the same MLR derived equations as the acute data (see **Section 2.7.1**). If aluminum reduced survival and growth, the product of these variables (biomass) was analyzed (when possible), rather than analyzing them separately (U.S. EPA 2013).

In this section and below, the relative rankings only apply when the set of chemistry conditions are pH 7, total hardness of 100 mg/L and DOC of 1.0 mg/L. Ranked GMCVs are provided in **Table 5**. The fish genus *Salmo*, represented by Atlantic salmon, was the most sensitive genus, and the least sensitive genus was represented by an oligochaete. There is no apparent trend between freshwater taxon and chronic sensitivity to aluminum.

Invertebrates

The chronic toxicity of aluminum to the freshwater unionid mussel, *Lampsilis siliquoidea*, was evaluated by Wang et al. (2016, 2018). Six-week old juvenile mussels were exposed under flow-through measured conditions for 28 days to five aluminum nitrate concentrations and dilution water control composed of a well water/deionized water mix adjusted to a nominal pH of 6.0 and total hardness of 100 mg/L as $CaCO_3$. The calculated biomass EC_{20} of 169 µg/L was reported in the study, with a corresponding normalized EC_{20} of 1,026 µg/L (normalized to pH 7, total hardness = 100 mg/L as $CaCO_3$ and DOC = 1.0 mg/L).

Several chronic aluminum studies were conducted in separate laboratories with the cladoceran, *Ceriodaphnia dubia* (CECM 2014; ENSR 1992b; European Al Association 2010;

NMED Exhibit 75

Gensemer et al. 2018; McCauley et al. 1986; OSU 2018a). Aluminum chloride was evaluated by McCauley et al. (1986) at the University of Wisconsin-Superior using life cycle studies (*C. dubia* neonates, ≤16-hr old) in Lake Superior water (both raw and treated dechlorinated city water) to determine ACRs at near neutral pH. Five test concentrations plus a dilution water control were renewed three times over seven days, and the number of young per surviving adult was found to be significantly inhibited at 2,600 and 2,400 µg total aluminum/L in each respective dilution water. The EC_{20} and MATC were estimated to be 1,780 and <1,100 µg/L, respectively, or 2,031 and <925.5 µg/L after normalization. Poor dose response in the treated dechlorinated city water exposure prevented calculation of an EC_{20}.

Three-brood, 6-day static-renewal toxicity tests were conducted with aluminum chloride at four hardness levels using <24-hr old *C. dubia* neonates (ENSR 1992b). Reconstituted dilution water was prepared at nominal 25, 50, 100 and 200 mg/L total hardness as $CaCO_3$ and pH of 7.65, 7.7, 8.2 and 8.45, respectively. The mean number of young produced per female was the most sensitive endpoint with normalized (to pH 7, total hardness = 100 mg/L as $CaCO_3$ and DOC = 1.0 mg/L) EC_{20}s of 2,602, 1,077, 708.8 and 746.8 µg/L, respectively (**Appendix C**).

The Center for the Ecotoxicology and Chemistry of Metals (CECM 2014) and the European Al Association (2010) also evaluated the effect of aluminum on the survival and reproduction of *C. dubia* at different pH and total hardness levels. Less than 24-hr old neonates were exposed to aluminum nitrate for seven days using reconstituted laboratory water established at different nominal total hardness (25, 60 or 120 mg/L as $CaCO_3$), DOC (0.5, 2 or 4 mg/L) and pH (6.3, 7.0 or 8.0) levels. Test solutions were renewed daily and the pH was maintained with synthetic buffers (as summarized in Gensemer et al. 2018). Reproduction was the most sensitive endpoint, with EC_{20}s ranging from 36.6 to 1,011.6 µg/L aluminum, and corresponding normalized (to pH 7, total hardness = 100 mg/L as $CaCO_3$ and DOC = 1.0 mg/L) EC_{20}s ranging from 291.7 to 2,072 µg/L (**Appendix C**). A similar experiment was run with another cladoceran, *Daphnia magna*, except water chemistry parameters were not varied (European Al Association 2010; Gensemer et al. 2018). Less than 24-hr old neonates were exposed to aluminum nitrate for 21 days at a total hardness of 140 mg/L as $CaCO_3$, pH 6.3 and DOC of 2 mg/L. Again, reproduction (young per female) was the most sensitive endpoint with a reported EC_{20} of 791.0 µg/L total aluminum. The normalized SMCV/GMCV for the species is 985.3 µg/L.

NMED Exhibit 75

Oregon State University researchers conducted nine additional aluminum toxicity studies with *Ceriodaphnia dubia* in 2018. The results of these tests allowed the EPA to expand on the bounds of the MLR model. Less than 24-hr old neonates were exposed to one of five aluminum nitrate concentrations for seven days using reconstituted laboratory water established at different nominal total hardness (60-400 mg/L as $CaCO_3$), DOC (1.0-14.0 mg/L) and pH (6.3-8.8) levels (OSU 2018a). Reproduction was the most sensitive endpoint with effect concentrations ranging from 828.6 to 6,612 µg/L total aluminum (1,170 to 2,308 µg/L when normalized using the MLR equation).

Two acceptable *Hyalella azteca* chronic studies are available for aluminum based on recently recommended culture and control conditions (Mount and Hockett 2015; U.S. EPA 2012). Researchers at Oregon State University exposed 7-9 day old juvenile amphipods to five aluminum nitrate concentrations diluted with a well water/reverse osmosis water mix for 42 days under flow-through conditions and a nominal pH of 6 (Cardwell et al. 2018; OSU 2012h). A small amount of artificially-formulated sediment was provided as substrate during the test. Biomass was the most sensitive endpoint, with a 28-day EC_{20} of 199.3 µg/L and a normalized EC_{20} of 665.9 µg/L aluminum (the 28-day results were used since the 79 percent control survival after 42 days was slightly below the 80 percent minimum requirement).

Wang et al. (2016, 2018) also conducted a *H. azteca* chronic test where 7-day old juvenile amphipods were exposed under flow-through measured conditions for 28 days to five aluminum nitrate concentrations and dilution water control composed of a well water/deionized water mix adjusted to a nominal pH of 6.0 and total hardness of 100 mg/L as $CaCO_3$. Silica sand was provided as a substrate. The calculated biomass EC_{20} was 425 µg/L, with a corresponding normalized EC_{20} of 2,890 µg/L (normalized to pH 7, total hardness = 100 mg/L as $CaCO_3$ and DOC = 1.0 mg/L).

Oregon State University (2012f) conducted a 28-day life cycle test with the midge, *Chironomus riparius*, in a mixture of well water and reverse osmosis water (pH range of 6.3-6.9). The authors reported an EC_{20} for the number of eggs per case to be 3,387 µg/L, or 8,181 µg total aluminum/L when normalized to pH 7, total hardness of 100 mg/L as $CaCO_3$ and DOC of 1.0 mg/L. Palawski et al. (1989) also exposed *C. riparius*, but for 30 days at two pH levels (5.6 and 5.0). Larval midge (<24-hr) were exposed to five aluminum sulfate concentrations with a control under flow-through conditions. Adult midge emergence was significantly inhibited at

NMED Exhibit 75

61.4 and 235.2 µg/L aluminum, at pH 5.6 and 5.0, with calculated EC_{20}s of 29.55 and 84.42 µg/L and normalized EC_{20}s of 1,075 and 15,069 µg/L, respectively. The resultant normalized SMCV of 5,099 µg/L is calculated from all three test results.

Oregon State University also conducted chronic studies for three invertebrate species: an oligochaete, *Aeolosoma sp.*; a rotifer, *Brachionus calyciflorus*; and the great pond snail, *Lymnaea stagnalis* (Cardwell et al. 2018; OSU 2012b,c,e). All tests were conducted with aluminum nitrate, and at a nominal pH of 6.0. The normalized EC_{20}s from the aforementioned studies are 20,514 (oligochaete 17-day population count), 1,845 (48-hr rotifer population count) and 5,945 (pond snail 30-day biomass) µg/L, respectively (**Appendix C**). The researchers also conducted a series of validation studies in 2018 with the rotifer and great pond snail at nominal pH 6.3, with various hardness and DOC levels (OSU 2018e,f). The normalized EC_{20}s ranged from 2,132 to 6,653 µg/L for *Brachionus calyciflorus* and 1,812 to 3,902 µg/L for *Lymnaea stagnalis*.

Vertebrates

Kimball (1978) conducted an early life stage test using fathead minnow (*Pimephales. promelas*) fertilized eggs (16 to 40-hr old) in flowing hard well water. Six treatments of aluminum sulfate plus control replicated four times were used to expose fish for 28 days post-hatch, and aluminum concentrations were measured three times per week during the study. Biomass was more sensitive to the aluminum exposures than percent hatchability, growth and survival, with a resulting EC_{20} of 6,194 µg/L, or 2,690 µg/L when normalized.

The chronic toxicity of aluminum to fathead minnows and zebrafish (*Danio rerio*) was also evaluated by OSU (2012g, 2013) and summarized in Cardwell et al. (2018). Fish were exposed under flow-through conditions in the same dilution water and pH as described above for the amphipod and midge tests (OSU 2012f,h). Less than 24-hr old fertilized fathead minnow eggs and less than 36-hr post fertilization zebrafish were exposed to aluminum nitrate for 33 days. Fathead minnow fry survival was the most sensitive endpoint with a calculated EC_{20} of 428.6 µg/L, and normalized EC_{20} of 2,154 µg/L. Zebrafish biomass was the most sensitive endpoint with a calculated EC_{20} of 234.4 µg/L (1,342 µg/L when normalized).

An early life cycle test was also conducted with brook trout (*Salvelinus fontinalis*). Brook trout eyed eggs were exposed to four aluminum sulfate concentrations at pH 5.7 and 6.5 for 60 days (Cleveland et al. 1989). Both exposures were conducted using flow-through conditions and soft water (total hardness = 12.5 mg/L as $CaCO_3$). The survival and hatching of eyed eggs and

NMED Exhibit 75

the survival, growth, behavioral and biochemical responses of the resultant larvae and juveniles were measured during the exposure. The incomplete hatch endpoint reported in the study was not used after further analysis and communication with the authors because the incomplete hatch endpoint may or may not be a transient effect. The incompletely hatched larvae (based on chorion attachment) were removed daily from the study and not fully evaluated further for survivability. In addition, exposure to acidic waters increased the percentage of incomplete hatched larvae (Cleveland et al. 1986; Ingersoll et al. 1990c), and therefore it is difficult to distinguish between the effects of pH versus aluminum. Therefore, the lack of information and uncertainty with the endpoint led to the decision to not use the data from the study to develop the criteria document. The biomass EC_{20} for the test conducted at pH 5.7 was 143.5 µg/L, and at pH 6.5 the biomass EC_{20} was 164.4 µg/L. The normalized EC_{20}s at pH 5.7 and 6.5 were 1,076 µg/L and 378.7 µg/L, respectively.

Atlantic salmon eyed eggs were exposed to flow-through conditions for 60 days at pH 5.7 and a total hardness of 12.7 mg/L as $CaCO_3$ in reconstituted water (McKee et al. 1989). Salmon weight and survival NOEC and LOEC were 71 and 124 µg aluminum/L, respectively. The calculated biomass EC_{20} for the study was 61.56 µg/L (**Appendix C**). Buckler et al. (1995) also reported a chronic *Salmo salar* study initiated with eyed eggs in reconstituted water (total hardness of 12.7 mg/L as $CaCO_3$) that continued for 60 days post-hatch under flow-through exposure conditions. Time to hatch was not significantly affected at pH 5.7 and 264 µg/L, the highest test concentration evaluated. Survival at 60 days post hatch was reduced at 124 µg/L, with an estimated EC_{20} of 154.2 µg/L (normalized EC_{20} = 1,088 µg/L).

When calculating the Atlantic salmon EC_{20}s for the two studies (Buckler et al. 1995 and McKee et al. 1989), it was observed that the studies listed the same test concentrations and similar dose response for the same test measurements, but reported different endpoints between the two studies. It appears that the Buckler et al. (1995) study was a republication of the previous study performed by McKee et al. (1989), and therefore, only the most sensitive EC_{20} was used in the calculation of the SMCV. The most sensitive EC_{20} of 61.56 µg/L (or 434.4 µg/L when normalized to pH 7, total hardness of 100 mg/L as $CaCO_3$ and DOC of 1.0 mg/L), was based on a 60-day reduction in fish biomass.

Only seven of the eight MDRs are met for direct calculation of the FCV, with the third family in the phylum Chordata missing. Because derivation of a chronic freshwater criterion is

NMED Exhibit 75

important for environmental protection, the EPA examined qualitative data in **Appendix H** (*Other Data on Effects of Aluminum to Freshwater Aquatic Organisms*) to determine if any "Other Data" can be used to fulfill the missing MDR group, and selected an amphibian test to fulfill that MDR.

The MDR for the third family in the phylum Chordata was fulfilled using results of an abbreviated life cycle test initiated with wood frog (*Rana sylvatica*) larvae (Gosner stage 25) and continued through metamorphosis (Peles 2013). The NOEC for survival and growth normalized to a pH 7, total hardness of 100 mg/L and DOC of 1.0 mg/L was 10,684 µg/L, with a chronic value of greater than 10,684 µg/L. The study was not included in **Appendix C** because the test pH (4.68-4.70) was lower than 5. If not for the marginally lower pH (Peles 2013), this study would have been an acceptable chronic test for criterion derivation. The addition of this other chronic test does not directly affect the calculation of the FCV as the species does not rank in the lowest four GMCVs (the numeric-criteria-driving portion of the sensitivity distribution). The species was the most sensitive value from the qualitative data that could be used to fulfill the MDR and the test had a minor deviation in pH. After adding this additional study, the chronic dataset consists of 13 freshwater species representing 13 freshwater genera (**Table 5**).

The four most sensitive GMCVs are from the core quantitative chronic dataset and represent taxa which have been determined to be the most sensitive to aluminum. Based on these rankings, the resultant chronic criterion is 380 µg/L total aluminum at pH 7, total hardness of 100 mg/L (as $CaCO_3$) and DOC of 1.0 mg/L (**Table 6**). The chronic toxicity data are normalized using the MLR equations described in the Analysis Plan that account for the effects of pH, total hardness, and DOC on bioavailability and hence toxicity of aluminum. Thus, the value of the criterion for a given site will depend on the specific pH, total hardness, and DOC concentrations at the site (see **Appendix K** *Recommended Criteria for Various Water Chemistry Conditions* for additional criteria values and four most sensitive genera for each set of conditions). The EPA is confident that the criteria values generated using the MLR models are protective of approximately 95% of freshwater genera in an ecosystem that are potentially exposed to aluminum under long-term conditions (**Figure 10**).

NMED Exhibit 75

Table 5. Ranked Genus Mean Chronic Values at pH 7, Total Hardness of 100 mg/L, and DOC of 1.0 mg/L.

(Note: Values will be different under differing water chemistry conditions as identified in this document).

Rank[a]	GMCV (µg/L total Al)	Genus	Species	SMCV[b] (µg/L total Al)
13	20,514	Aeolosoma	Oligochaete, *Aeolosoma sp.*	20,514
12	>10,684	Rana	Wood frog,[c] *Rana sylvatica*	>10,684
11	5,099	Chironomus	Midge, *Chironomus riparius*	5,099
10	3,539	Brachionus	Rotifer, *Brachionus calyciflorus*	3,539
9	3,119	Lymnaea	Great pond snail, *Lymnaea stagnalis*	3,119
8	2,407	Pimephales	Fathead minnow, *Pimephales promelas*	2,407
7	1,387	Hyalella	Amphipod, *Hyalella azteca*	1,387
6	1,342	Danio	Zebrafish, *Danio rerio*	1,342
5	1,181	Ceriodaphnia	Cladoceran, *Ceriodaphnia dubia*	1,181
4	1,026	Lampsilis	Fatmucket, *Lampsilis siliquoidea*	1,026
3	985.3	Daphnia	Cladoceran, *Daphnia magna*	985.3
2	638.2	Salvelinus	Brook trout, *Salvelinus fontinalis*	638.2
1	434.4	Salmo	Atlantic salmon, *Salmo salar*	434.4

NMED Exhibit 75

Table 6. Freshwater Final Chronic Value and Criterion Continuous Concentration (normalized to pH 7, total hardness of 100 mg/L and DOC of 1.0 mg/L).

(See Appendix K for chronic criterion under different water chemistry conditions).

Calculated Freshwater FCV based on 4 lowest values: Total Number of GMCVs in Data Set = 13

Rank	Genus	GMCV (µg/L)	lnGMCV	$(lnGMCV)^2$	P=R/(n+1)	SQRT(P)
4	Lampsilis	1,026	6.93	48.07	0.286	0.535
3	Daphnia	985.3	6.89	47.51	0.214	0.463
2	Salvelinus	638.2	6.46	41.71	0.143	0.378
1	Salmo	434.4	6.07	36.89	0.071	0.267
		Σ (Sum):	**26.36**	**174.2**	**0.714**	**1.64**

S^2 =	12.423	**S = slope**
L =	5.142	**L = X-axis intercept**
A =	5.930	**A = lnFCV**
		P = cumulative probability

FCV = 376.3 µg/L total aluminum

CCC (chronic criterion) = 380 µg/L total aluminum (rounded to two significant figures)

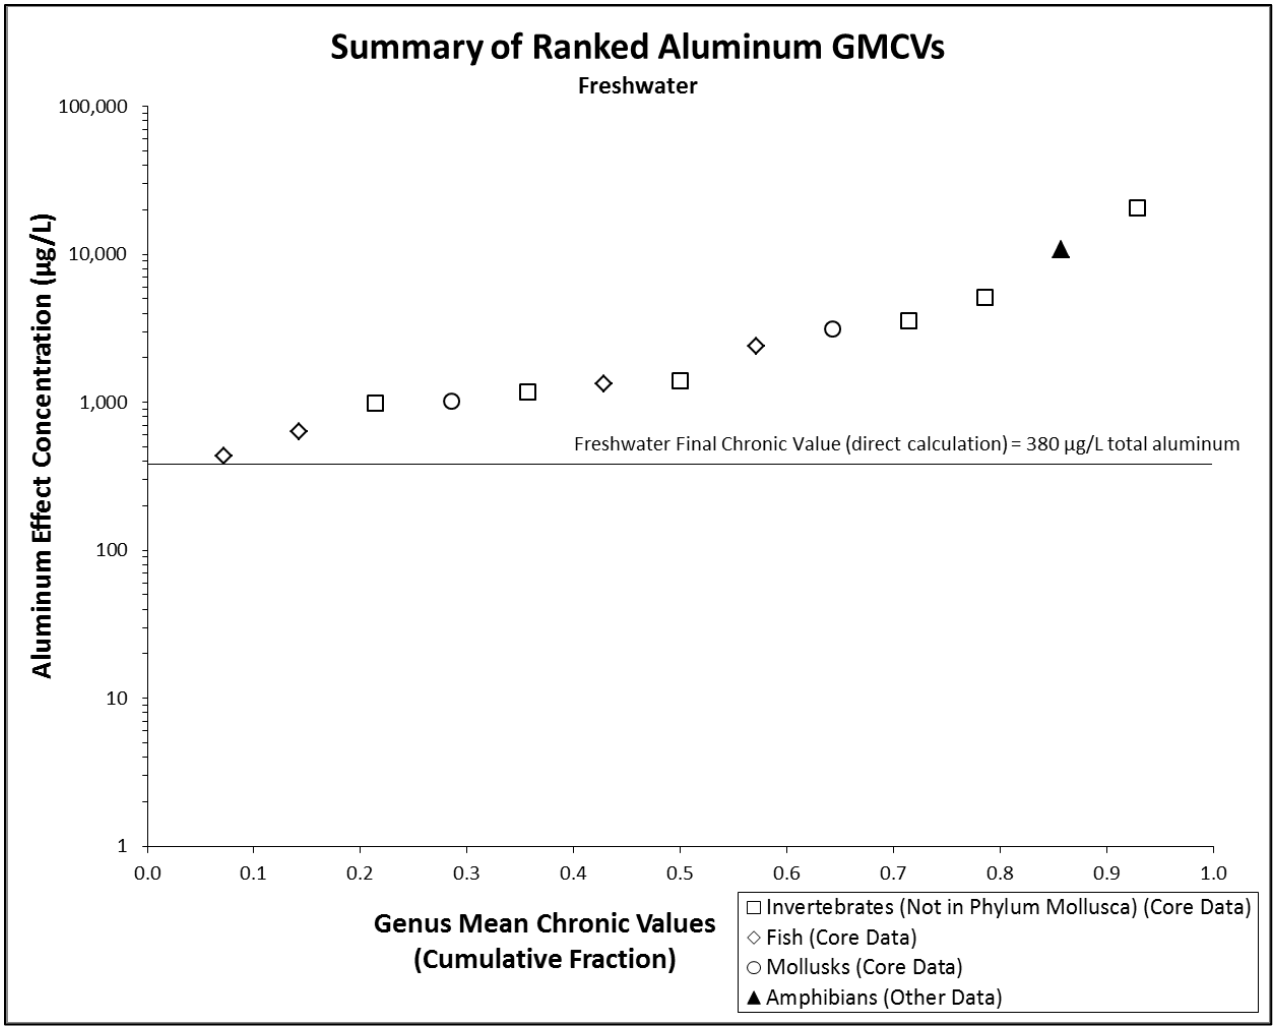

Figure 10. Ranked Summary of Total Aluminum Genus Mean Chronic Values (GMCVs) – Freshwater Supplemented with Other Data to Fulfill Missing MDRs at pH 7, Total Hardness of 100 mg/L, and DOC of 1.0 mg/L.

3.2.2 Estuarine/Marine

There are no estuarine/marine chronic toxicity data that meet the test acceptability and quality assurance/control criteria in a manner consistent with the 1985 Guidelines in **Appendix D** (*Acceptable Chronic Toxicity Data of Aluminum to Estuarine/Marine Aquatic Animals*).

3.3 Bioaccumulation

Aluminum bioaccumulates in aquatic organisms, although increased accumulation through trophic levels in aquatic food chains (i.e., biomagnification) is not usually observed (Suedel et al. 1994, U.S. EPA 2007a). Total uptake generally depends on the environmental aluminum concentration, exposure route and the duration of exposure (McGeer et al. 2003).

NMED Exhibit 75

Desouky et al. (2002) reported that the bioavailability of aluminum to a grazing invertebrate is influenced by both oligomeric silica and humic acid, and that aluminum bound to humic acid may still be bioavailable via grazing. Bioconcentration Factors (BCFs) and bioaccumulation factors (BAFs) typically vary with the bioavailable concentration of metals in water, with higher BCFs occurring at lower metal concentrations (McGeer et al. 2003). In marine sediments, metal bioavailability is altered by increased acid volatile sulfide (AVS) content (Casas and Crecelius 1994), and ligand concentration (Skrabal et al. 2000). Bioaccumulation and toxicity via the diet are considered unlikely relative to direct waterborne aluminum toxicity (Handy 1993; Poston 1991). This conclusion is also supported by the lack of any biomagnification within freshwater invertebrates that are likely to be prey of fish in acidic, aluminum-rich rivers (Herrmann and Frick 1995; Otto and Svensson 1983; Wren and Stephenson 1991). The opposite phenomena, trophic dilution up the food chain, has been suggested (King et al. 1992). A more detailed discussion of bioaccumulation factors is provided in the Effects Characterization section (**Section 5.1.6**).

No U.S. Food and Drug Administration (FDA) action level or other maximum acceptable concentration in tissue, as defined in the 1985 Guidelines, is available for aluminum. Therefore, a Final Residue Value cannot be calculated for fish tissue.

3.4 Toxicity to Aquatic Plants

No aluminum toxicity tests with important aquatic plant species in which the concentrations of test material were measured and the endpoint was biologically important are available in the literature. Therefore, the EPA could not determine a Final Plant Value. However, analysis of plant data provides evidence that criteria magnitudes that are protective of aquatic animals will also be protective of aquatic plants. Effects on aquatic plants are discussed qualitatively in the Effects Characterization section (**Section 5.2**).

4 SUMMARY OF NATIONAL CRITERIA

4.1 Freshwater

The 2018 final aluminum criteria are derived using multiple linear regression (MLR) models that incorporate pH, total hardness, and DOC as input parameters to normalize the acute and chronic toxicity data to a set of predetermined water quality conditions. The MLR equations account for the effects of pH, total hardness and DOC on the bioavailability, and hence toxicity

NMED Exhibit 75

of aluminum. The numeric magnitude of the criteria (acute or chronic criterion) for a given set of conditions, therefore, will depend on the specific pH, total hardness and DOC concentrations used for normalization. The relative GMAVs/GMCVs rankings and subsequent four most sensitive genera used to calculate the criteria will depend on the data normalization conditions selected. The acute and chronic criteria for a given set of input conditions (pH, total hardness and DOC) are numeric magnitude values that are protective for that set of input conditions. The recommended criteria for aluminum can be calculated in two different ways: 1) use the lookup tables provided (see **Appendix K** *Recommended Criteria for Various Water Chemistry Conditions*) to find the numeric aluminum acute and chronic criteria corresponding to the pH, total hardness and DOC conditions of interest, or 2) use the Aluminum Criteria Calculator V.2.0 (*Aluminum Criteria Calculator V.2.0.xlsm*) to enter the pH, total hardness and DOC conditions of interest.

For the purposes of illustration, the following criteria magnitude values are provided at pH 7, total hardness 100 mg/L and DOC of 1.0 mg/L. The resulting numeric values represent the concentrations at which freshwater aquatic organisms would have an appropriate level of protection if the one-hour average concentration of total aluminum does not exceed (in µg/L):

Criterion Maximum Concentration (CMC) =
980 µg/L total aluminum at a pH 7, total hardness of 100 mg/L as $CaCO_3$ and DOC of 1.0 mg/L;

and if the four-day average concentration of total aluminum does not exceed (in µg/L):

Criterion Continuous Concentration (CCC) =
380 µg/L total aluminum at pH 7, total hardness of 100 mg/L as $CaCO_3$ and DOC of 1.0 mg/L.

The criteria value for the specific water chemistry conditions of interest are recommended not to be exceeded more than once every three years on average.

The above illustrative criteria values would vary under other water chemistry conditions for the three water quality parameters (pH, total hardness and DOC) that affect the expression of aluminum toxicity (see **Appendix K** *Recommended Criteria for Various Water Chemistry Conditions*). **Table 7** provides a detailed break-down of the freshwater acute (CMC) and chronic

NMED Exhibit 75

(CCC) criteria across different pH and total hardness levels when the DOC = 1.0 mg/L. **Appendix K** provides additional criteria values across pH and total hardness levels when DOC = 0.1, 0.5, 2.5, 5, 10 and 12 mg/L, and provides the four most sensitive genera for both the acute and chronic criteria. The empirical toxicity test data that the EPA used to develop the MLR models were developed under a specific range of water chemistry conditions as described below.

The pH of toxicity test waters ranged from 6.0-8.7. Specifically, *Ceriodaphnia dubia* toxicity test data ranged 6.3-8.7 for pH (only one *C. dubia* toxicity test was conducted at pH 8.7; the majority of tests were conducted at pH less than 8.3); *Pimephales promelas* toxicity test data ranged 6.0-8.12 for pH. The EPA has determined that for pH it is reasonable to allow the user to extrapolate beyond these values for criteria derivations. The criteria calculator can be used to address all waters within a pH range of 5.0 to 10.5. Thus, criteria values for pH input values beyond the range of the underlying empirical pH data used for model development (pH 6.0 to 8.2) can be generated using the criteria calculator. This is also reflected in the criteria lookup tables in **Appendix K**. The EPA took this approach for pH so that the recommended criteria can be provided for, and thus are protective of, a broader range of U.S. natural waters. Extrapolated criteria values outside of the empirical pH data tend to be more protective of the aquatic environment (i.e., lower criteria values) in situations where pH plays a critical role in aluminum toxicity. However, criteria values generated outside of the range of the pH conditions of the toxicity tests underlying the MLR models are more uncertain than values within the pH conditions of the MLR toxicity tests, and thus should be considered carefully and used with caution. Although the EPA has provided model predictions of criteria values outside the empirical range for pH, these values may warrant further exploration and consideration for site-specific criteria. Additional information regarding the uncertainty associated with the MLR models is provided in **Section 5.3.6** and **Appendix L**.

The total hardness of toxicity test waters ranged from 9.8 to 428 mg/L. More specifically, total hardness (as $CaCO_3$) ranged from 9.8-428 mg/L for *Ceriodaphnia dubia* toxicity tests and from 10.2-422 mg/L for *Pimephales promelas* toxicity tests. Since a decrease in total hardness tends to increase aluminum toxicity, the EPA has determined it is reasonable to extrapolate on the lower bound of the hardness data to enable generation of more stringent criteria at low hardnesses beyond the limit of the empirical data. Thus, hardness input values in the criteria calculator can be entered that are less than 9.8 mg/L down to a limit of 0.01 mg/L. This is

NMED Exhibit 75

consistent with existing EPA approaches to low end hardness (U.S. EPA 2002). However, criteria values are bounded at the approximate upper limit of the empirical MLR models' underlying hardness data, at a maximum of 430 mg/L total hardness (as $CaCO_3$). The user can input hardness values into the criteria calculator that are greater than 430 mg/L for total hardness, but the criteria magnitude will reach its maximum value at 430 mg/L total hardness (as $CaCO_3$), and criteria magnitudes will not increase or decrease by increasing the hardness above 430 mg/L total hardness (as $CaCO_3$). This is also consistent with existing EPA guidance on high end hardness "caps" (U.S. EPA 2002). These total hardness bound approaches are also reflected in the criteria lookup tables in **Appendix K**. The EPA took this approach so that the recommended criteria can be provided for, and will be protective of, a broader range of natural waters found in the U.S. Criteria values generated beyond the lower bound of the hardness conditions of the toxicity tests underlying the MLR models are more uncertain than values within the hardness bounds of the MLR toxicity test data.

The DOC of toxicity test waters ranged from 0.08 to 12.3 mg/L. More specifically DOC ranged from 0.1-12.3 mg/L for *Ceriodaphnia dubia* toxicity tests and 0.08-11.6 mg/L for *Pimephales promelas* toxicity tests. Since most natural waters contain some DOC, the lower bound of the empirical toxicity test data (0.08 mg/L) is the lowest value that can be entered into the criteria calculator; thus no extrapolation below the lowest empirical DOC of 0.08 mg/L is provided. The criteria values generated with the criteria calculator are bounded at the upper limit of the empirical MLR models' underlying DOC data, at a maximum 12.0 mg/L DOC. The user can input DOC values greater than 12.0 mg/L into the calculator, but the criteria magnitude will reach its maximum value at 12.0 mg/L DOC, and criteria magnitudes will not increase or decrease by increasing the DOC above 12.0 mg/L. This is also reflected in the criteria lookup tables in **Appendix K**. This is consistent with the existing approach for hardness (U.S. EPA 2002) to provide for protection of aquatic organisms through the use of protective, conservative values when water chemistry conditions are beyond the upper limits of the empirical toxicity test data.

The EPA created the Aluminum Criteria Calculator V.2.0 (*Aluminum Criteria Calculator V.2.0.xlsm*) that allows users to enter the pH, total hardness and DOC based on water sampling and automatically calculates freshwater criteria for these site-specific parameters based on the bounds described above. Existing data on these water chemistry parameters may be helpful in

NMED Exhibit 75

determining criteria calculator input values. The criteria calculator gives a warning when any of the water quality parameters entered are "outside MLR model inputs," to alert end users. As noted above, total hardness and DOC concentrations entered into the calculator that are greater than the bounds recommended will automatically default to a maximum limit; pH values that are outside the bounds recommended (i.e., pH<6, pH>8.2) can be used, but should be considered carefully and used with caution. As displayed in **Table 7** and **Appendix K**, total hardness and DOC are bounded at a maximum of 430 mg/L as $CaCO_3$ and 12.0 mg/L, respectively. **Table 7** shows example freshwater acute (CMC) and chronic (CCC) criteria at DOC of 1.0 mg/L and various water total hardness levels and pH, with additional tables for other DOC values are provided in **Appendix K**.

NMED Exhibit 75

Table 7. Freshwater Acute and Chronic Criteria at Example Conditions of DOC of 1.0 mg/L and Various Water Total Hardness Levels and pH.

(Italicized and underlined values are outside the pH limits of the empirical data used to generate the MLR models and should be used with caution).

4.2 Estuarine/Marine

Insufficient data are available to fulfill the MDRs for estuarine/marine criteria development, therefore no criteria are recommended at this time.

NMED Exhibit 75

5 EFFECTS CHARACTERIZATION

This section characterizes the potential effects of aluminum on aquatic life based on available test data and describes additional lines of evidence not used directly in the criteria calculations, but which support the 2018 criteria values. This section also provides a summary of the uncertainties and assumptions associated with the criteria derivation and explanations for the decisions the EPA made regarding data acceptability and usage in the effects assessment. Finally, this section describes substantive differences between the 1988 aluminum AWQC and the 2018 update.

5.1 Effects on Aquatic Animals

5.1.1 Freshwater Acute Toxicity

The EPA identifies several acute studies that did not meet data quality screening guidelines for inclusion in criterion calculations (**Appendix H** *Other Data on Effects of Aluminum to Freshwater Aquatic Organisms*), but showed similar ranges of toxicity and are presented here to provide additional supporting evidence of the observed toxicity of aluminum to aquatic organisms.

Among Mollusca studies where the pH was greater than or equal to 5, Harry and Aldrich (1963) observed adverse 24-hr effects to the snail *Taphius glabratus* exposed to aluminum at concentrations between 1,000-5,000 µg/L in distilled water (**Appendix J** *List of Aluminum Studies Not Used in Document Along with Reasons*). In contrast, the 24-hr LC_{50} of 130,500 µg/L (65,415 µg/L when normalized to conditions in **Appendix A**) for the zebra mussel *Dreissena polymorpha* (Mackie and Kilgour 1995) was insensitive, similar to the mollusk *Physa sp.* (**Appendix A**). In a series of 96-hr tests conducted at low pH and total hardness (15.3 mg/L as $CaCO_3$) levels, Mackie (1989) found that *Pisidium casertanum* and *Pisidium compressum* did not reach 50% mortality at 1,000 µg/L when pH was 3.5, and 400 µg/L when pH was 4.0 and 4.5; the highest concentrations tested. When these concentrations are normalized to the conditions in **Appendix A**, LC_{50}s for the species would be greater than 412,645 to greater than 72,075,634 µg/L.

Among cladocerans, Call et al. (1984) observed an unidentified *Ceriodaphnia* species to be similarly acutely sensitive to identified *Ceriodaphnia* species in acceptable tests, with pH/total hardness/DOC-normalized 48-hr LC_{50} values of 2,277 µg/L and 3,083 µg/L. Also

NMED Exhibit 75

similar to results observed among acceptable tests and supporting studies, *Daphnia sp.* was more acutely sensitive than *Ceriodaphnia sp.* For example, Havas and Likens (1985b) observed reduced survival in *Daphnia catawba* for a test with a non-standard test duration (72 hours) at a pH/total hardness/DOC-normalized concentration of 4,341 µg/L; Khangarot and Ray (1989) observed a normalized 48-hr LC_{50} of 23,665 µg/L for *Daphnia magna* exposed to an unacceptable form of aluminum (aluminum ammonium sulfate); and Havas (1985) observed a normalized 48-hr LOEC based on survival of 1,343 µg/L in *Daphnia magna* using lake water as dilution water.

Although no data from benthic crustaceans were used to calculate the freshwater acute criterion (not one of the four most sensitive genera), evidence suggests they are somewhat acutely sensitive to aluminum. The isopod *Asellus aquaticus* was found to be somewhat sensitive to aluminum, with a pH/total hardness/DOC-normalized 72-hr LC_{50} of 12,284 µg/L that was not included because of the test duration (Martin and Holdich 1986). The isopod values would fall 8th out of 20 in relative acute sensitivity to aluminum, despite the decreased length of the acute test over standard acute invertebrate test durations. Both Borgmann et al. (2005) and Mackie (1989) conducted acute toxicity tests with the amphipod *Hyalella azteca*. Seven-day LC_{50}s from the two Borgmann et al. (2005) studies comparing soft reconstituted water and dechlorinated tap water were 212.7 and greater than 2,978 µg/L, respectively (values normalized to **Appendix A** conditions), but these data were not included because of both test length and unacceptable control mortality. Three (pH/total hardness/DOC) adjusted unbounded *H. azteca* LC_{50} values reported by Mackie (1989) ranged from greater than 4,455 to greater than 178,365 µg/L, the highest concentrations tested. The lowest of these values would rank this taxon 4th in the acute genus sensitivity. These data were included in **Appendix H** because of uncertainty regarding whether bromide and chloride concentrations in dilution water met the recently established testing requirements for *H. azteca* (Mount and Hockett 2015; U.S. EPA 2012). The author was not able to provide details regarding bromide and chloride water concentrations, but noted that there was 100% survival in the experiment, suggesting that conditions were met (Gerry Mackie, personal communication, March 2013). In addition, no substrate was provided for the test organisms. Although some substrate is recommended for water only tests with *H. azteca*, the absence of substrate does not invalidate a test result (Mount and Hockett 2015; U.S. EPA 2012). Because the value is unbounded (i.e., a greater than value), the study most likely overestimates

NMED Exhibit 75

the toxicity of aluminum to this species, since the test failed to reach 50% mortality at the highest concentrations tested.

Studies by Vuori (1996) (caddisfly), Mackie (1989) (damselfly) and Rockwood et al. (1990) (dragonfly) suggest some insects may be acutely sensitive to aluminum, but these tests were either conducted at pH<5 (Mackie 1989), or used an atypical endpoint for acute exposures (Rockwood et al. 1990; Vuori 1996). However, when the concentrations are normalized to the conditions in **Appendix A**, LC_{50}s for the damselfly would be greater than 412,645 to greater than 72,075,634 µg/L. (Note: Rockwood et al. and Vuori did not report test hardness so values could not be normalized).

Consistent with data used to calculate the freshwater acute criterion, vertebrates were no more or less sensitive overall to aluminum than invertebrates. Also consistent with vertebrate data from **Appendix H**, acute toxicity data for fish, while variable, provide additional evidence that freshwater fish are acutely sensitive to aluminum. DeLonay et al. (1993) observed reduced 7-day survival of *Oncorhynchus aguabonita* alevin and swim-up larvae exposed to 18,359 µg/L aluminum (pH/total hardness/DOC-normalized). Cutthroat trout (*O. clarkii*) alevin and swim-up larvae also exposed at pH 5 for seven days exhibited reduced survival at 482.0 µg/L (60% reduction) and 340.8 µg/L (~50% reduction) (pH/total hardness/DOC-normalized), respectively (Woodward et al. 1989). Both studies were excluded from acute criteria calculations because of the atypical acute test duration.

In two studies examining the effects of aluminum on rainbow trout survival, pH/total hardness/DOC-normalized *O. mykiss* LC_{50}s after 6 and 7-12 days, respectively, were 2,837 and 460.0 µg/L (Birge et al. 2000; Orr et al. 1986). In two tests with embryo/larva rainbow trout at pH 6.5 and 7.2, Holtze (1983) observed no reduction in survival after an 8-day exposure to 2,544 and 1,023 µg/L aluminum, respectively, when normalized. While these studies demonstrated the sensitivity of rainbow trout survival to aluminum, they were excluded from acute criteria calculations because of atypical acute test durations. In contrast, Hunter et al. (1980) observed 40% mortality at pH/total hardness/DOC-normalized concentration of 18,009 µg/L for rainbow trout, suggesting that rainbow trout could possibly be more tolerant to aluminum than reported by the previous studies. However, this study had only one treatment concentration, did not provide information regarding replicates or the number of fish per replicate, and the fish were fed

NMED Exhibit 75

during the study, precluding it from consideration as a reliable toxicity prediction and for criteria derivation.

Unlike the observed results of the acceptable acute studies, other data for the Family Salmonidae appears to be acutely insensitive to aluminum. In a series of eight 4- and 5-day tests with juvenile Atlantic salmon (*Salmo salar)* conducted at pH 4.42-5.26, Roy and Campbell (1995, 1997) observed pH/total hardness/DOC-normalized LC_{50}s ranging from 2,170-47,329 µg/L. Similarly, Wilkinson et al. (1990) observed a 7-day LC_{50} at pH 4.5 of 88 µg/L (or 13,060 µg/L when normalized to **Appendix A** conditions) for juvenile Atlantic salmon. These studies were not included in the acute criteria calculations because of either a non-standard duration, exposure at pH<5, or both.

Among warm water fishes, goldfish embryos (*Carassius auratus*) were highly sensitive to aluminum, with a 7- to 12-day pH/total hardness/DOC-normalized LC_{50} of 271.1 µg/L (Birge et al. 2000). While this value is below the acute criterion at the same normalized conditions (980 µg/L), the study provided little exposure details and exceeded the duration for an acceptable acute exposure toxicity test, therefore, it is likely overestimating the acute toxicity of aluminum to the species. Fathead minnow (*Pimephales promelas*) sensitivity, however, was variable across studies. In two tests that were excluded because test fish were fed, pH/total hardness/DOC-normalized 96-hr and 8-day LC_{50}s were 19,324 and 12,702 µg/L, respectively (Kimball 1978). In a 96-hour test that was excluded because measured total dissolved aluminum concentrations were greater than reported nominal total aluminum concentrations for all but the highest two treatment concentrations, suggesting total aluminum exposures were greater than reported, the pH/total hardness/DOC-normalized 96-hour LC_{50} was greater than 572.8 µg/L (Palmer et al. 1989). In contrast, Buhl (2002) observed a pH/total hardness/DOC-normalized 96-hr EC_{50} for death and immobility of greater than 21,779 µg/L for this species. Birge et al. (1978) and Birge et al. (2000) found largemouth bass (*Micropterus salmoides*) to be sensitive to aluminum, with 8-day and 7- to 12-day pH/total hardness/DOC-normalized LC_{50}s of 124.6 and 156.1 µg/L, respectively. In contrast, Sanborn (1945) observed no mortality in juvenile *M. salmoides* after a 7-day exposure to a pH/total hardness/DOC-normalized concentration of 45,181 µg/L.

Amphibians appear to be less acutely sensitive to aluminum than fish based on the very limited data available, but their sensitivity is highly variable and appears to depend upon life stage, with embryos being more sensitive than tadpoles. In a series of tests with leopard frogs

NMED Exhibit 75

(*Rana pipiens*) of different tadpole life stages conducted at low (4.2-4.8) pH and low (2.0 mg/L) total hardness, Freda and McDonald (1990) observed pH/total hardness/DOC-normalized 4 to 5-day LC_{50}s ranging from greater than 57,814 to greater than 490,582 µg/L. In two separate studies conducted at pH 4.5 and low total hardness, the pH/total hardness/DOC-normalized 96-hr LC_{50} for American toad (*Bufo americanus*) tadpoles was 358,450 µg/L (Freda et al. 1990); and the pH/total hardness/DOC-normalized 96-hr LC_{50} for the green tree frog (*Hyla cinerea*) was 200,373 µg/L (Jung and Jagoe 1995). In contrast, when *R. pipiens* embryos were exposed to aluminum for 10-11 days at a higher pH range (7.0-7.8), Birge et al. (2000) observed a normalized LC_{50} of 73.94 µg/L. Birge et al. (2000) also found embryonic spring peepers (*Pseudacris crucifer*) and embryonic Fowler's toads (*Bufo fowleri*) to be highly sensitive to aluminum, with a 7-day normalized LC_{50} of 73.94 and 230.0 µg/L, respectively. These values exceed the typical duration for an acute exposure for the species and therefore overestimate the toxicity of aluminum when comparing them to the acute criterion. However, aluminum sensitivity among amphibian embryos was not always greater than tadpole life stages, as the pH/total hardness/DOC-normalized 96-hr LC_{50} for *R. pipiens* embryos at pH 4.8 was 74,782 µg/L (Freda et al. 1990), similar to the LC_{50}s of *R. pipiens* tadpoles (Freda and McDonald 1990).

5.1.2 Freshwater Chronic Toxicity

Several chronic studies were identified as not meeting quality screening guidelines for inclusion in criterion calculations (**Appendix H** *Other Data on Effects of Aluminum to Freshwater Aquatic Organisms*), but showed similar ranges of toxicity and are presented here to provide additional supporting evidence of the potential toxicity of aluminum to aquatic organisms.

In two unmeasured lifecycle (3-brood) tests, IC_{25}s based on reproduction for *Ceriodaphnia dubia* were 566 and 641 µg/L (pH not reported so values could not be normalized), were within the range of observed acceptable chronic values for this species (Zuiderveen and Birge 1997). In three unmeasured 21-day *Daphnia magna* tests, LC_{50} and reproductive EC_{16} and EC_{50} pH/total hardness/DOC-normalized endpoints were 1,162, 265.6 and 564.3 µg/L, respectively (Biesinger and Christensen 1972). These values are within the range of acceptable chronic data reported for the cladoceran *C. dubia* (**Appendix C**).

Among fish species, the pH/total hardness/DOC-normalized 28-day EC_{50} (death and deformity) for *O. mykiss* of 457.4 µg/L (Birge 1978; Birge et al. 1978) was similar to chronic

NMED Exhibit 75

values for acceptable tests with other cold water test species. In addition, the 16-day normalized LC_{50}s for rainbow trout at two different test total hardness levels (20.3 and 103 mg/L as $CaCO_3$) observed by Gundersen et al. (1994) were 485.2 and 1,084 µg/L, respectively. However, the 16-day exposures were about one-fourth the duration of an acceptable ELS test for a salmonid (ASTM 2013). In a 28-day test of *S. fontinalis* conducted at pH 4.4, the pH/total hardness/DOC-normalized MATC for survival was 2,523 µg/L (Ingersoll et al. 1990a). Even though the duration of this test was insufficient and the pH was below 5, it provides additional evidence of the sensitivity of brook trout, a commercially and recreationally important species. Several short-term (7-day) chronic tests conducted by Oregon State University (OSU 2012a) with the fathead minnow at pH 6 and across a range of total hardness and DOC concentrations revealed that both an increase in total hardness and DOC reduced the toxicity of aluminum (non-normalized EC_{20}s ranged from 127.2 to 2,938 µg/L or 1,718 to 7,220 µg/L when normalized to the test conditions in **Appendix C**).

5.1.3 Freshwater Field Studies

Field studies have been conducted to measure effects of aluminum additions to control phosphorus concentrations in lakes, to validate parallel laboratory exposures, and to investigate the effects of acid deposition in aquatic systems. Aluminum sulfate was continuously added for 35 days to the Cuyahoga River 500 meters upstream of Lake Rockwell to control phosphorus concentrations in the reservoir. Artificial colonization substrata were placed at five locations along the treatment reach five weeks before the release, sampled on the day of the release, redeployed after collecting invertebrates immediately before the release, and then sampled weekly throughout the 35-day aluminum addition. After one week of treatment, invertebrate densities declined throughout the study reach, and were completely absent from a site 60 meters downstream of the release point. Once treatment was stopped, invertebrate densities recovered and replaced after approximately three weeks by rapidly colonizing oligochaete taxa (Barbiero et al. 1988).

In Little Rock Lake, WI, sulfuric acid was added to half of the lake between 1984-1990, resulting in a decrease in pH from 6.05 to 4.75 and an increase in aqueous aluminum from 7 to 42 µg/L. The other half of the lake served as a control, where aluminum increased from 7 to 14 µg/L and pH decreased from 6.04 to 5.99 during the same time period (Eaton et al. 1992). In parallel laboratory experiments in 1988, eggs of several fish species were exposed to aluminum

NMED Exhibit 75

concentrations ranging from 8.1-86.9 µg/L and pH values ranging from 4.5-5.5 until seven days' post hatch. In both the acidified portion of the lake and in laboratory exposures at comparable aluminum and pH levels, mortality was higher than in controls (Eaton et al. 1992). However, mortality of control fish in both the *in-situ* and laboratory exposures exceeded the minimum 80 percent survival acceptable guideline for tests of this duration.

Additional field studies have evaluated the effects of aluminum and acidification on different trophic level communities. Havens and Decosta (1987) acidified the circumneutral Lake O'Woods (WV) to pH 4.8 and compared phytoplankton and zooplankton assemblages with and without the addition of 300 µg/L aluminum. They observed similar species in all conditions, but the aluminum dosed water exhibited a decrease in chlorophyll *a* concentrations and a drop in zooplankton abundances over the 49-day observation period, while the acidified condition without aluminum addition only exhibited a drop in chlorophyll *a*. The algal biomass decrease was attributed to the initial co-precipitation of phosphorus and/or algal cells with the aluminum hydroxide at circumneutral pH. Bukaveckas (1989) reported similar declines in algal biomass when acidic, aluminum-rich waters are neutralized with lime. In contrast, aluminum addition produced a more pronounced difference in algal community structure and succession when Havens and Heath (1990) gradually acidified (pH 4.5) and dosed East Twin Lake (OH) with 200 µg/L aluminum.

Increased drift of invertebrates (Ephemeroptera, Diptera and Orthocladiinae chironomids) in an acidified (pH~5) stream dosed with 280 µg/L aluminum was observed relative to a non-dosed stream at the same ~5 pH level (Hall et al. 1987). Ormerod et al. (1987), however, found little added effect of 350 µg/L aluminum on stream invertebrates compared with the effects of acidification alone (pH~4.3). In contrast, brown trout and Atlantic salmon showed significantly increased mortalities in the acidified aluminum condition (50 to 87%) relative to the acid-only treatment (7 to 10%). Baldigo and Murdoch (1997) deployed caged brook trout in selected New York Catskill Mountain streams where the pH, aluminum concentration and other stream conditions fluctuated naturally over time. They noted that fish mortality correlated best with high inorganic aluminum concentrations and low water pH (4.4-5.2), with 20 percent mortality observed for brook trout exposed to greater than or equal to 225 µg/L inorganic monomeric aluminum for two days. They also observed, based on regression analysis, that a vast majority (74-99%) of the variability in mortality could be explained by either the mean or median

NMED Exhibit 75

inorganic monomeric aluminum concentration, and that the mortality was highly related to inorganic monomeric aluminum, pH, dissolved organic carbon, calcium and chloride concentrations. Bulger et al. (1993) also reported that water pH and monomeric inorganic aluminum concentrations best predicted brown trout populations of 584 Norwegian lakes. Lakes with 133 µg/L aluminum and a pH of 4.8 were devoid of brown trout (39% of the 584 lakes), whereas lakes with 11 µg/L aluminum and a pH of 6.0 had healthy brown trout populations.

5.1.4 Estuarine/Marine Acute Toxicity

SMAVs for five genera representing five species of estuarine/marine organisms were calculated for aluminum (**Table 8**). SMAVs and GMAVs were equal since there is only one species present per genus. The most sensitive genus was the polychaete worm (*Ctenodrilus serratus*), with a SMAV of 97.15 µg/L, followed by two other polychaete worms (*Capitella capitata* and *Neanthes arenaceodentata*) with SMAVs of 404.8 and greater than 404.8 µg/L, respectively. The most tolerant genus was a copepod (*Nitokra spinipes*) with a SMAV of 10,000 µg/L (**Figure 9**). However, the freshwater acute criterion (980 µg/L total aluminum) is much higher than the most sensitive acute estuarine/marine species LC_{50} (97.15 µg/L total aluminum). Thus, at least some invertebrate estuarine/marine species would not be protected if the freshwater acute aluminum criterion was applied in those systems.

Table 8. Ranked Estuarine/Marine Genus Mean Acute Values.

Rank[a]	GMAV (µg/L total Al)	Species	SMAV (µg/L total Al)[b]
5	10,000	Copepod, *Nitokra spinipes*	10,000
4	>1,518	American oyster, *Crassostrea virginica*	>1,518
3	>404.8	Polychaete worm, *Neanthes arenaceodentata*	>404.8
2	404.8	Polychaete worm, *Capitella capitata*	404.8
1	97.15	Polychaete worm, *Ctenodrilus serratus*	97.15

[a] Ranked from the most resistant to the most sensitive based on Genus Mean Acute Value.
[b] From Appendix B: Acceptable Acute Toxicity Data of Aluminum to Estuarine/Marine Aquatic Animals.

In contrast to freshwater, only a few acute studies were identified as not meeting screening guidelines for inclusion in criterion calculations (**Appendix I** *Other Data on Effects of Aluminum to Estuarine/Marine Aquatic Organisms*), but showed similar ranges of toxicity. As

NMED Exhibit 75

with other non-conforming studies previously described, the results are presented here to provide additional supporting evidence of the potential toxicity of aluminum to estuarine/marine organisms. In one of these studies, a cohort of sea urchin embryos (*Paracentrotus lividus*) exposed to 539.6 µg/L aluminum for 72-hr exhibited increased developmental defects by 69.7% (Caplat et al. 2010). Although this study was not considered acceptable because the control group exhibited 19.3% defects indicative of some health deficiency, the effect level was comparable to the acute effect levels observed in **Appendix B**. In 24-hr exposures to aluminum added as potassium aluminum sulfate, LC_{50}s for the crab species *Eupagurus bernhardus* and *Carcinus maenas*, the snail *Littorina littorea*, and the mussel *Mytilus edulis* were extremely high, ranging from a low of 250,000 µg/L for *E. bernhardus* to greater than 6,400,000 µg/L for the two mollusk species (Robinson and Perkins 1977). Although these studies were unacceptable because of the atypical acute test duration, they suggest that some saltwater taxa are highly tolerant to acute aluminum exposure.

5.1.5 Estuarine/Marine Chronic Toxicity

There are no acceptable saltwater chronic data available for aluminum (**Appendix D**). However, the EPA identified several chronic studies that did not meet screening guidelines for inclusion in criterion calculations, but provided supporting evidence of potential chronic toxicity of aluminum to aquatic organisms in estuarine/marine environments (**Appendix I** *Other Data on Effects of Aluminum to Estuarine/Marine Aquatic Organisms*). Petrich and Reish (1979) observed a 21-day MATC for reproduction in the polychaete *C. serratus* of 28.28 µg/L. Consistent with acceptable acute test results for this species, this chronic test suggests that polychaetes may be chronically sensitive to aluminum. This study was excluded because of the test duration. In a "semi-chronic" 12-day study of the effects of aluminum on daggerblade grass shrimp (*Palaemonetes pugio*) embryos, the LC_{50} was 1,079 µg/L (Rayburn and Aladdin 2003). This study was not included because it was longer than an acceptable 48-hr acute test, and it was not a full life cycle test.

5.1.6 Bioaccumulation

Three acceptable studies examined the effects of waterborne aluminum bioaccumulation in aquatic organisms (**Appendix G** *Acceptable Bioaccumulation Data of Aluminum by Aquatic Organisms*). Cleveland et al. (1991a) exposed 30-day old brook trout to 200 µg/L of aluminum in test waters at three pH levels (5.3, 6.1, and 7.2) for 56 days. After 56 days, trout were

NMED Exhibit 75

transferred to water of the same pH with no aluminum amendments and held for 28 days. Fish were sampled for whole body aluminum on days 3, 7, 14, 28 and 56 of the exposure; and on days 3, 7, 14 and 28 of the depuration period. The estimated time to achieve steady state whole body aluminum concentrations was 1.5 days at pH 5.3, 4.2 days at pH 6.1, and 1.7 days at pH 7.2. Bioconcentration factors (BCF) were inversely related to pH: 142 at pH 5.3, 104 at pH 6.1, and 14.2 at pH 7.2. Mortality was also highest at pH 5.3 and lowest at pH 7.2. In a separate study, Buckler et al. (1995) continuously exposed Atlantic salmon beginning as eyed eggs to four aluminum treatment levels (33, 71, 124, 264 µg/L) at pH 5.5 for 60 days after the median hatch date. Fish were sampled for whole body aluminum after 15, 30, 45, and 60 days post median hatch. After 60 days, average mortality was 15% in the 124 µg/L treatment and 63% in the 264 µg/L treatment. The mortality NOEC and LOEC were 71 and 124 µg/L, respectively. BCFs were directly related to exposure concentration, and were 76, 154, and 190 at treatment levels 33, 71, and 124 µg/L, respectively. A BCF could not be calculated for the 264 µg/L treatment level because there were insufficient surviving fish to analyze. Snails, *Lymnaea stagnalis,* held in neutral pH for 30 days and 242 µg/L total aluminum reached steady with a reported BCF of 4.26 in the digestive gland (Dobranskyte et al. 2004).

As reported in the literature, aquatic organisms can accumulate metals from both aqueous and dietary exposure routes. The relative importance of each, however, is dependent upon the chemical. Aluminum adsorbs rapidly to gill surface from the surrounding water, but cellular uptake from the water is slow, with gradual accumulation by the internal organs over time (Dussault et al. 2001). Bioaccumulation and toxicity via the diet are considered highly unlikely based on studies by Handy (1993) and Poston (1991), and also supported by the lack of any biomagnification within freshwater invertebrates that are likely to be prey of fish in acidic, aluminum-rich rivers (Herrmann and Frick 1995; Otto and Svensson 1983; Wren and Stephenson 1991). The opposite phenomena, trophic dilution up the food chain, has been suggested based on the lowest aluminum accumulation exhibited by fish predators (perch) and highest by the phytoplankton that their zooplankton prey were consuming (King et al. 1992). Thus, the low aluminum BCFs reported in the literature are supported by the slow waterborne uptake and the lack of dietary accumulation.

NMED Exhibit 75

5.2 Effects on Aquatic Plants

Aquatic plant data are not used to derive the criteria for aluminum. However, a summary of available data is presented below. For freshwater algae, aluminum effect concentrations ranged from 50 µg/L to 6,477 µg/L, with most effect levels below 1,000 µg/L (**Appendix E** *Acceptable Toxicity Data of Aluminum to Freshwater Aquatic Plants*). Studies for freshwater macrophytes are limited, but available data suggest freshwater macrophytes are more tolerant to aluminum than freshwater algae. The effect concentration for Eurasian watermilfoil is 2,500 µg/L based on root weight (Stanley 1974), which is near the upper range of freshwater algae sensitivities. Several 3-day tests with the green alga *Pseudokirchneriella subcapitata* at pH 6, 7 and 8 across a range of total hardness and DOC concentrations revealed that both an increase in pH, total hardness and DOC reduced the toxicity of aluminum (European Aluminum Association 2009). DeForest et al. (2018a) used these 27 toxicity tests (as summarized in Gensemer et al. 2018) to develop a MLR model to explain the effects of water chemistry on algal toxicity. The MLR model developed was:

$$P.\,subcapitata\ EC_{20} = e^{\left[-61.952+[1.678\times\ln(DOC)]+[4.007\times\ln(hard)]+(17.019\times pH)-(1.020\times pH^2)-[0.204\times pH{:}\ln(DOC)]-[0.556\times pH{:}\ln(hard)]\right]}$$

The MLR model for *P. subcapitata* was within a factor of two for 100% of the predicted versus observed values (DeForest et al. 2018a). Most of the acceptable toxicity data for freshwater aquatic plants (**Appendix E**) did not report all three water quality parameters (i.e., pH, total hardness and DOC) preventing the use of applying the alga based MLR equation to the data. The EPA contacted authors and in limited cases, the authors were able to provide rough estimates of some of the missing information. Normalized lowest observed effect concentrations (LOECs) for the twenty-one day tests as reported by Pilsbury and Kingston (1990) were 3,482 µg/L, while normalized 4-day EC_{50}s for *P. subcapitata* were 620 and 1,067 µg/L (Call et al. 1984). These values are above the chronic criterion at the same test conditions, suggesting that the criteria developed using aquatic animals will also be protective of aquatic plants. This was also observed when normalizing the 3-day *P. subcapitata* test in **Appendix H** (*Other Data on Effects of Aluminum to Freshwater Aquatic Organisms*) with normalized effect concentrations ranging from 161 to 5,113 µg/L. The geometric mean of these values was 1,653 µg/L (Note:

NMED Exhibit 75

these tests were excluded from the acceptable table due to the insufficient test duration, less than 4 days).

In contrast to other freshwater plants, duckweed is highly tolerant to aluminum, with an effect concentration based on reduced growth of greater than 45,700 µg/L (Call et al. 1984). For the one acceptable study of a saltwater plant (Seagrass, *Halophila stipulacea*), less than 50% mortality of teeth cells was observed at 26.98 µg/L, and more than 50% mortality of teeth cells observed at 269.8 µg/L (Malea and Haritonidis 1996). In a shorter duration study, the saltwater algal species, *Dunaliella tertiolecta*, also exhibited sensitivity to aluminum, but the effect concentration was higher at 18,160 µg/L (**Appendix I** *Other Data on Effects of Aluminum to Estuarine/Marine Aquatic Organisms*). Although aquatic plant data are not normalized using the alga based MLR equation, the effect levels observed are similar to the available animal data, and the recommended criteria should therefore be protective for algae and aquatic plants.

5.3 Identification of Data Gaps and Uncertainties for Aquatic Organisms

Data gaps and uncertainty were identified for the aluminum criteria. A number of uncertainties are associated with calculation of the freshwater Final Acute Value (FAV) as recommended by the 1985 Guidelines, and include use of limited data for a species or genus, acceptability of widely variable data for a genus, application of adjustment factors, extrapolation of laboratory data to field situations, and data normalization with a MLR model.

5.3.1 Acute Criteria

There are a number of cases in the acute database where only one acute test is used to determine the Species Mean Acute Value (SMAV) and subsequently the Genus Mean Acute Value (GMAV) is based on the one acute test. In this situation, there is a level of uncertainty associated with the GMAV based on the one test result since it does not incorporate the range of values that would be available if multiple studies were available. Such a GMAV is still valid, however, in spite of the absence of these additional data because it represents the best available data and to exclude this data would create an unnecessary data gap. Additionally, many of the acute studies did not report a definitive LC_{50} (i.e., yielded greater than values) because the highest concentration used did not cause more than 50% mortality. This adds more uncertainty since the true LC_{50} is unknown.

The acute criterion is set as equal to half of the FAV to represent a low level of effect for the fifth percentile genus, rather than a 50% effect. This adjustment factor was derived from an

NMED Exhibit 75

analysis of 219 acute toxicity tests with a variety of chemicals (see 43 FR 21506-21518 for a complete description) where mortality data were used to determine the highest tested concentration that did not cause mortality greater than that observed in the control (or between 0 and 10%). Application of this adjustment factor is justified because that concentration represents minimal acute toxicity to the species.

5.3.2 Chronic Criteria

The freshwater FCV calculation is also influenced by the limited availability of data and the use of qualitative data to fulfill the one remaining family (Chordata) MDR. The aluminum freshwater chronic database is comprised of 12 species and subsequently 12 genera that provide seven of the eight MDR families as recommended in the 1985 Guidelines. In order to satisfy the eight-family requirement, the dataset included a wood frog (*Rana sylvatica*) chronic study that was relegated to **Appendix H** due to minor methodology issues (pH<5). While this study does not quantitatively affect the criterion value, it was used to fulfill the MDRs per the 1985 Guidelines, thereby allowing direct calculation of the FCV (see **Section 2.7.3**). Additional testing of other species and families in the Phylum Chordata would reduce the uncertainty in the FCV.

5.3.3 Laboratory to Field Exposures

Application of water-only laboratory toxicity tests to develop water quality criteria to protect aquatic species is a basic premise of the 1985 Guidelines, supported by the requirements of a diverse assemblage of eight families and the intended protection goal of 95 percent of all genera. Confirmation has been reported by a number of researchers (Clements and Kiffney 1996; Clements et al. 2002; Mebane 2006; Norberg-King and Mount 1986), thereby indicating that on the whole, extrapolation from the laboratory to the field is a scientifically valid and protective approach for aquatic life criteria development.

The unique chemistry of aluminum (speciation changes and the transient precipitates formed during toxicity testing) and difference between geological aluminum materials suspended in natural water are additional areas of uncertainty (Angel et al. 2016; Cardwell et al. 2018; Gensemer et al. 2018). The use of total aluminum concentrations is justified for laboratory toxicity test data (see **Section 2.6.2**); where the total aluminum concentration is in either a dissolved or precipitated form (Santore et al. 2018). However, natural water samples may also contain other species of aluminum that are not biologically available (i.e., suspended particles, clays and aluminosilicate minerals) (Santore et al. 2018; Wilson 2012). This creates uncertainty

NMED Exhibit 75

because the total recoverable aluminum concentrations measured in natural waters may overestimate the potential risks of toxicity to aquatic organisms.

EPA Methods 200.7 and 200.8 are the only currently approved methods for measuring aluminum in natural waters and wastes for NPDES permits (U.S. EPA 1994a,b). Research on new analytical methods is ongoing to address concerns with including aluminum bound to particulate matter (i.e., clay) in the total recoverable aluminum concentrations (OSU 2018c). One approach would not acidify the sample to pH less than 2 but rather to pH 4 (pH 4 extracted method) to better capture the bioavailable fraction of aluminum (CIMM 2016, OSU 2018c). Thus, this draft pH 4 extracted method under development is expected to reduce the uncertainty regarding bioavailable aluminum measurements in the aquatic environment.

5.3.4 Lack of Toxicity Data for Estuarine/Marine Species and Plants

Since limited acceptable acute and chronic data are available for estuarine/marine species, the EPA could not derive estuarine/marine acute and chronic aluminum criteria at this time. In addition, very few acceptable aquatic vascular plant studies are available.

5.3.5 Bioavailability Models

Aluminum toxicity is strongly affected by water chemistry, through its effects on bioavailability. The understanding of the interactions between aluminum species, water characteristics, and aquatic toxicity data has led to the development of several bioavailability models. There are currently two different approaches that take into account aluminum bioavailability in relation to aquatic toxicity that are considered applicable to the development of aquatic life criteria: empirical models that relate toxicity to water chemistry; and Biotic Ligand Models that encompass both abiotic and biotic mechanistic factors determining toxicity.

Initially in considering the array of approaches for criteria development, the EPA considered using an empirical total hardness adjustment equation for criteria development. However, studies that tested aluminum at pH 6 for a variety of organisms (OSU 2012a, 2012b, 2012c, 2012d, 2012e, 2012f, 2012g, 2012h, 2013) indicated additional water chemistry parameters affected bioavailability, and hence aquatic effects of aluminum. In addition, new data are available that supported the development of MLR models that incorporate pH and total hardness. Also, a mechanistic BLM model for aluminum was recently developed (Santore et al. 2018). Finally, an approach described in DeForest et al. (2018a,b) incorporated pH, total hardness and DOC into empirical MLR models to determine if the estimation of aluminum

NMED Exhibit 75

bioavailability to animals in freshwater aquatic systems could be applicable in the development of aluminum water quality criteria. The approach resulted in the creation of multiple MLR models that could be used for the development of aluminum water quality criteria methodologies. Both MLR models and the BLM model include the same toxicity test data, with the BLM including additional data on the accumulation of aluminum on the gills of Atlantic salmon (Santore et al 2018). The MLR approach empirically curve-fits log-log pH, total hardness and DOC relationships (with interaction terms) to the empirical data. The BLM uses a mechanistic model based on an underlying theory of how water chemistry input parameters affect aluminum toxicity, although it still has empirically derived factors.

An external peer review of the different aluminum aquatic life criteria approaches was conducted in November 2016 to provide a comparison of the several available approaches to generating aluminum criteria that reflect water quality condition impacts on toxicity. Approaches compared included a 10-parameter BLM, a simplified-BLM approach (e.g., pH, total hardness, dissolved organic carbon, temperature), and MLR models to facilitate evaluation of the most appropriate approaches to consider for aluminum toxicity modeling. The EPA conducted three additional external peer reviews in 2018 regarding the new toxicity data and re-fitted MLR models on: 1) the new invertebrate toxicity tests on *C. dubia* (OSU 2018a); 2) the new fish toxicity tests on *P. promelas* (OSU 2012b); and 3) the new individual and pooled MLRs developed by Deforest et al. (2018b). Based on external peer review comments, ease of use, and transparency, the EPA applied the DeForest et al. (2018b) individual species MLR model to normalize the freshwater acute and chronic data (**Appendix A** and **Appendix C**) and derived the aluminum criteria using the criteria development approaches described in the 1985 Guidelines. The EPA independently examined and verified the quality and fit of the DeForest et al. (2018a,b) MLR models before applying them in this final criteria document.

5.3.6 pH, Total Hardness and DOC MLR Models

There are additional uncertainties, beyond those described above, associated with the normalization of aluminum toxicity data using the MLR models developed by DeForest et al. (2018b). The models were developed with chronic toxicity data from two animal species, one invertebrate (*C. dubia*; a sensitive species) and one fish (fathead minnow; a moderately sensitive species). Incorporating additional species in the model development would improve the representativeness of all species and further validate the MLR model use across species. Though

NMED Exhibit 75

the pH, total hardness, and DOC do explain the majority of differences seen in the toxicity data between the two species, there are two MLR models developed (invertebrate *C. dubia* model and vertebrate *P. promelas* model), which better delineate the differences in their uptake of aluminum. Because the arthropod phylum is highly diverse, there is some uncertainty in the application of the *C. dubia* model across other invertebrate taxa. However, among fish (and amphibians), the MLR approach that uses a model optimized solely for those taxa is the best model to use as opposed to a BLM which uses one model to normalize the data for multiple taxa for criteria calculations. Thus, the MLR-based criteria derivation specific to the most sensitive taxa may address additional uncertainty because some of the model differences may be a function of the species physiology in addition to bioavailability, and hence the MLR approach may better capture taxa physiologic differences in sensitivity across different water chemistry conditions. The models are, however, applied across gross taxonomy (vertebrate vs. invertebrate), creating some additional uncertainty. Finally, only chronic data were used in model development, and application to acute toxicity data assumes that the same relationships are present. All of these uncertainties associated with the model are areas where additional research would be helpful.

The models were developed using data that encompass a pH range of 6.0-8.7, DOC range of 0.08-12.3 mg/L and total hardness range of 9.8-428 mg/L (as $CaCO_3$). The authors (DeForest et al. 2018a) noted that the empirical data evaluated support a reduced total hardness effect at higher pH levels (i.e., 8-9), but limited data are available. Additional chronic aluminum toxicity testing at higher pH levels would be useful for further validating the MLR models (i.e., there is a limited amount of data at pH>8). When any of the water quality parameters selected is outside model inputs, the Aluminum Criteria Calculator V.2.0 (*Aluminum Criteria Calculator V.2.0.xlsm*) flags these values and defaults to the maximum bounds for DOC and total hardness. Values generated outside the recommended water quality parameter for pH (6.0-8.2) should be treated with caution because extrapolating beyond the conditions used for model development is highly uncertain. Of particular concern is the quadratic term (pH^2) in the *C. dubia* MLR model which can compound issues with extrapolating. Additional toxicity tests conducted and pH<6.0 and pH> 8.5 would further define behavior of this model.

NMED Exhibit 75

5.4 Protection of Endangered Species

Although the dataset for aluminum is not extensive, it does include some data representing species that are listed as threatened or endangered by the U.S. Fish and Wildlife Service and/or National Oceanic and Atmospheric Administration (NOAA) Fisheries. Summaries are provided here describing the available aluminum toxicity data for listed species indicating that the 2018 aluminum criteria are expected to be protective of these listed species, based on available scientific data.

5.4.1 Key Acute Toxicity Data for Listed Fish Species

Tests relating to effects of aluminum on several threatened and endangered freshwater fish species are available (certain populations threatened, and others endangered): rainbow trout, *Oncorhynchus mykiss* with a normalized SMAV of 3,312 µg/L (Call et al. 1984; Gundersen et al. 1994; Holtze 1983); Rio Grande silvery minnow, *Hybognathus amarus* with a normalized SMAV of greater than 21,779 µg/L (Buhl 2002); and Atlantic salmon, *Salmo salar* with a SMAV of 8,642 µg/L (Hamilton and Haines 1995). For this comparison, all SMAVs are normalized to a pH 7, a total hardness of 100 mg/L as $CaCO_3$ and a DOC of 1.0 mg/L. All of the normalized SMAVs are above the recommended acute criterion (CMC) of 980 µg/L at the same pH, total hardness and DOC levels. There are no acceptable acute toxicity data for endangered or threatened estuarine/marine aquatic fish species.

5.4.2 Key Chronic Toxicity Data for Listed Fish Species

While there are no acceptable chronic toxicity data for estuarine/marine endangered and/or threatened fish species, there is one acceptable early life-stage test conducted with the endangered freshwater fish, Atlantic salmon, *Salmo salar*. The test, conducted at a pH of 5.7, yielded a pH/total hardness/DOC-normalized species mean chronic value (SMCV) of 434.4 µg/L (McKee et al. 1989). This value is greater than the recommended chronic criterion of 380 µg/L at the same total hardness, DOC and pH.

5.4.3 Concerns about Federally Listed Endangered Mussels

Some researchers have expressed concerns that mussels may be more sensitive to the effects of aluminum than other organisms. A study by Kadar et al. (2001) indicated that adult *Anodonta cygnea* mussels may be sensitive to aluminum at concentrations above 250 µg/L, with reductions in mean duration of shell opening of 50% at 500 µg/L aluminum in the water column

NMED Exhibit 75

(at circumneutral pH) when compared to paired controls. This suggests that chronic elevated aluminum concentrations could lead to feeding for shorter durations with potential implications for survival and growth, and possibly even reproduction. Pynnonen (1990) conducted toxicity tests with two freshwater mussels in the Unionidae family (*Anodonta anatina* and *Unio pictorum*). In both species, pH had a significant effect on accumulation of aluminum in the gills. The *Anodonta* mussel species in the two studies described above are not native to the United States and are included in **Appendix J** (*List of Aluminum Studies Not Used in Document Along with Reasons*). While the *Anodonta* mussel species in these two studies are not native, there are species of the *Anodonta* genus present in the United States. Simon (2005) provides an additional line of evidence that indicates mussels may be more sensitive to the effects of aluminum than other organisms. In a 21-day chronic aluminum toxicity test conducted at circumneutral pH with juvenile unionid freshwater mussel *Villosa iris*, growth was significantly reduced at aluminum levels above 337 µg/L.

New data are available for this update on aluminum toxicity to the fatmucket mussel (*Lampsilis siliquoidea*), another freshwater mussel in the family Unionidae. While the 96-hr LC_{50} juvenile test failed to elicit an acute 50% response at the highest concentration tested (6,302 µg/L total aluminum, or 29,492 µg/L when normalized), the 28-day biomass-normalized SMCV ranked as the fourth most sensitive genus in the dataset. The SMCV is greater than the most sensitive species, Atlantic salmon, and the freshwater criterion value. Thus, the chronic criterion is expected to be protective of this and related species. The fatmucket mussel tested is not a threatened and/or endangered species, but the genus *Lampsilis* contains several listed species with a wide distribution across the United States, and is also member of the family Unionidae.

Freshwater mussels in the family Unionidae are known to be sensitive to a number of chemicals, including metals and organic compounds (Wang et al 2018; U.S. EPA 2013). The EPA's 2013 Aquatic Life Ambient Water Quality Criteria for Ammonia in Freshwater indicates many states in the continental U.S. have freshwater unionid mussel fauna in at least some of their waters (Abell et al. 2000; Williams and Neves 1995; Williams et al. 1993). Roughly one-quarter of the approximately 300 freshwater unionid mussel taxa in the United States are Federally-listed as endangered or threatened species. Additional testing on endangered mussel species, or closely related surrogates, would be useful to further examine the potential risk of aluminum exposures to endangered freshwater mussels.

NMED Exhibit 75

5.5 Comparison of 1988 and 2018 Criteria Values

The 1988 aluminum freshwater acute criterion was based on data from eight species of invertebrates and seven species of fish grouped into 14 genera. This 2018 update now includes 13 species of invertebrates, eight species of fish, and one frog species for a total of 22 species grouped into 20 genera. The data in the previous AWQC were not normalized to any water chemistry conditions making it difficult to compare the magnitude of the two criteria.

The 1988 aluminum freshwater chronic criterion was set at 87 µg/L across a pH range 6.5 to 9.0, and across all total hardness and DOC ranges, based on a dataset that included two species of invertebrates and one fish species. This 2018 criteria update includes new data for an additional nine species, and consists of eight invertebrates and four fish species grouped into 12 genera and is a function of pH, total hardness and DOC. Addition of the frog (*Rana sylvatica*) data from **Appendix H** satisfied the MDR for the one missing family (Chordata), thereby allowing for direct calculation of the FCV.

Like the previous AWQC for aluminum, there are still insufficient data to fulfill the estuarine/marine MDRs as per the 1985 Guidelines, therefore the EPA did not derive estuarine/marine criteria at this time. New toxicity data for five genera representing five species of estuarine/marine organisms are presented in this update; no data were available in 1988.

Table 9. Comparison of the 2018 Recommended Aluminum Aquatic Life AWQC and the 1988 Criteria.

Version	Freshwater Acute[a] (1-hour, total aluminum)	Freshwater Chronic[a] (4-day, total aluminum)
2018 AWQC (vary as a function of a site's pH, DOC and total hardness)	1-4,800 µg/L	0.63-3,200 µg/L
1988 AWQC (pH 6.5 – 9.0, across all total hardness and DOC ranges)	750 µg/L	87 µg/L

[a] Values are recommended not to be exceeded more than once every three years on average.
Note: 2018 Criteria values will be different under differing water chemistry conditions as identified in this document, and can be calculated using the Aluminum Criteria Calculator V.2.0 (*Aluminum Criteria Calculator V.2.0.xlsm*) or found in the tables in Appendix K. See Appendix K for specific comparisons of 1988 and 2018 criteria values across water chemistry parameter ranges.

6 UNUSED DATA

For this 2018 criteria update document, the EPA considered and evaluated all available data that could be used to derive the new acute and chronic criteria for aluminum in fresh and

NMED Exhibit 75

estuarine/marine waters. A substantial amount of those data were associated with studies that did not meet the basic QA/QC requirements in a manner consistent with the 1985 Guidelines (see Stephan et al. 1985) and reflecting best professional judgments of toxicological effects. A list of all other studies considered, but removed from consideration for use in deriving the criteria, is provided in **Appendix J** (*List of Aluminum Studies Not Used in Document Along with Reasons*) with rationale indicating the reason(s) for exclusion. Note that unused studies from previous AWQC documents were not re-evaluated.

Appendix A ACCEPTABLE ACUTE TOXICITY DATA OF ALUMINUM TO FRESHWATER AQUATIC ANIMALS

NMED Exhibit 75

Appendix A. Acceptable Acute Toxicity Data of Aluminum to Freshwater Aquatic Animals
(Bold values are used in SMAV calculation).
(Species are organized phylogenetically).

Species	Method[a]	Chemical	Total Hardness (mg/L as $CaCO_3$)	pH	DOC (mg/L)	LC_{50} / EC_{50} (µg/L)	Normalized Acute Value[b] (µg/L)	Species Mean Acute Value (µg/L)	Reference
Worm (adult, 1.0 cm), *Nais elinguis*	R, M, T	Aluminum sulfate	17.89 (±1.74)	6.51 (±0.01)	3.2	3,874	**9,224**	9,224	Shuhaimi-Othman et al. 2012a, 2013
Snail (adult), *Physa sp.*	S, M, T	Aluminum chloride	47.4 (±4.51)	6.59	1.1[d]	>23,400	**>52,593**	-	Call 1984; Call et al. 1984
Snail (adult), *Physa sp.*	S, M, T	Aluminum chloride	47.4 (±4.51)	7.55	1.1[d]	30,600	**27,057**	-	Call 1984; Call et al. 1984
Snail (adult), *Physa sp.*	S, M, T	Aluminum chloride	47.4 (±4.51)	8.17	1.1[d]	>24,700	>19,341[c]	-	Call 1984; Call et al. 1984
Snail (adult), *Physa sp.*	S, M, T	Aluminum chloride	47.4 (±4.51)	7.46	1.1[d] (aged solution)	55,500	**51,539**	41,858	Call 1984; Call et al. 1984
Snail (adult, 1.5-2.0 cm, 22.5 mg), *Melanoides tuberculata*	R, M, T	Aluminum sulfate	18.72 (±1.72)	6.68 (±0.22)	3.2	68,230	**119,427**	119,427	Shuhaimi-Othman et al. 2012b, 2013
Fatmucket (juvenile, 6 d), *Lampsilis siliquoidea*	R, M, T	Aluminum chloride	107 (±6.3)	8.19 (±0.22)	0.5	>54,300	>57,735[f]	-	Ivey et al. 2014
Fatmucket (juvenile, 7-8 d, 0.38 mm), *Lampsilis siliquoidea*	F, M, T	Aluminum nitrate	106 (104-108)	6.12 (6.10-6.13)	0.48	>6,302	**>29,492**	>29,492	Wang et al. 2016, 2018
Cladoceran (<24 hr), *Ceriodaphnia dubia*	S, M, A	Aluminum chloride	50.0	7.42 (±0.02)	1.1[d]	1,900	**1,771**	-	McCauley et al. 1986
Cladoceran (<24 hr), *Ceriodaphnia dubia*	S, M, A	Aluminum chloride	50.5	7.86 (±0.04)	1.1[d]	1,500	**1,170**	-	McCauley et al. 1986
Cladoceran (<24 hr), *Ceriodaphnia dubia*	S, M, A	Aluminum chloride	50.0	8.13 (±0.03)	1.1[d]	2,560	**1,974**	-	McCauley et al. 1986

[a] S=static, F=flow-through, U=unmeasured, M=measured, A=acid exchangeable aluminum, T=total aluminum, D=dissolved aluminum, NR=not reported.

[b] Normalized to pH 7, total hardness of 100 mg/L as $CaCO_3$ and DOC of 1.0 mg/L (see Section 2.7.1). Values in bold are used in SMAV calculations.

[c] Not used to calculate SMAV because either a more definitive value is available or value is considered an outlier.

[d] When definitive DOC values were not reported by the authors: a DOC value of 0.5 mg/L was used when dilution water was reconstituted, 1.1 mg/L when dilution water was Lake Superior, MN water, 2.8 mg/L when dilution water was Liberty Lake, WA water, 1.6 mg/L when dilution water was tap or well water, or half the detection limit when the reported value was less than the detection limit, based on recommendations in the 2007 Freshwater Copper AWQC (U.S. EPA 2007b).

[e] Missing water quality parameters and/or dilution water type needed to estimate water quality parameters, so values cannot be normalized.

[f] Not used to calculate SMAV because flow-through measured test(s) available.

[g] Phosphate in exposure media is providing an ameliorating effect against aluminum.

Appendix B ACCEPTABLE ACUTE TOXICITY DATA OF ALUMINUM TO ESTUARINE/MARINE AQUATIC ANIMALS

NMED Exhibit 75

Appendix B. Acceptable Acute Toxicity Data of Aluminum to Estuarine/Marine Aquatic Animals
(Bold values are used in SMAV calculation).
(Species are organized phylogenetically).

[a] LC=Life cycle, ELS=Early life-stage.
[b] Normalized to pH 7, total hardness of 100 mg/L as $CaCO_3$ and DOC of 1.0 mg/L (see Section 2.7.1). Values in bold are used in SMCV calculations.
[c] When definitive DOC values were not reported by the authors: a DOC value of 0.5 mg/L was used when dilution water was reconstituted, 1.1 mg/L when dilution water was Lake Superior water, 1.6 mg/L when dilution water was tap or well water, or half the detection limit when the reported value was less than the detection limit, based on recommendations in the 2007 Freshwater Copper AWQC (U.S. EPA 2007b).
[d] Buckler et al. (1995) appears to be a republication of McKee et al. (1989), but does not report the most sensitive endpoint and therefore only the most sensitive endpoint used for calculation of the SMCV.
[e] DOC was taken from reported values in Cleveland et al. (1989) for a similar pH; all studies are from the same lab and used the same procedures to make the dilution water (well water plus reverse osmosis water mixture).
[f] Value is a MATC, poor dose response prevented an EC_{20} from being calculated; not used in SMCV calculation.

NMED Exhibit 75

Appendix D ACCEPTABLE CHRONIC TOXICITY DATA OF ALUMINUM TO ESTUARINE/MARINE AQUATIC ANIMALS

NMED Exhibit 75

Appendix D. Acceptable Chronic Toxicity Data of Aluminum to Estuarine/Marine Aquatic Animals

Appendix I OTHER DATA ON EFFECTS OF ALUMINUM TO ESTUARINE/MARINE AQUATIC ORGANISMS

NMED Exhibit 75

Appendix I. Other Data on Effects of Aluminum to Estuarine/Marine Aquatic Organisms

Species	Chemical	Duration	Salinity (g/kg)	pH	Effect	Concentration (µg/L)	Reference	Reason Other Data
Estuarine/Marine Species								
Phytoplankton, *Dunaliella tertiolecta*	Aluminum nitrate	72 hr	-	8.2	IC25 (inhibit growth)	18,160	Sacan et al. 2007	Duration
Phytoplankton, *Dunaliella tertiolecta*	Aluminum nitrate	72 hr	-	8.2	SC20 (stimulate growth)	4,660	Sacan et al. 2007	Duration
Diatom, *Nitzschia closterium*	Aluminum chloride	72 hr	-	8.2	IC50 (growth rate)	190	Harford et al. 2011	Duration
Polychaete worm, *Ctenodrilus serratus*	Aluminum chloride	21 d	-	7.6-8	Reproduction	20-40 (NOEC-LOEC)	Petrich and Reish 1979	Unmeasured chronic exposure
Sea urchin (embryo), *Paracentrotus lividus*	Aluminum sulfate	72 hr	-	-	69.7% developmental effects	539.6	Caplat et al. 2010	Difficult to determine effect concentration
Bay mussel (28.0 mm), *Mytilus edulis*	Alum (potassium)	24 hr	30	4.4-7.3	LC50	>6,400,000	Robinson and Perkins 1977	Duration
Common winkle (13.3 mm), *Littorina littorea*	Alum (potassium)	24 hr	30	4.4-7.3	LC50	>6,400,000	Robinson and Perkins 1977	Duration
European shore crab (12.6 mm), *Carcinus maenas*	Alum (potassium)	24 hr	30	4.4-7.3	LC50	2,500,000	Robinson and Perkins 1977	Duration
Hermit crab (11.4 mm), *Eupagurus bernhardus*	Alum (potassium)	24 hr	30	4.4-7.3	LC50	250,000	Robinson and Perkins 1977	Duration

NMED Exhibit 75

Species	Chemical	Duration	Salinity (g/kg)	pH	Effect	Concentration (µg/L)	Reference	Reason Other Data
Yellow crab (embryo, 4-lobed stage), *Cancer anthonyi*	-	7 d	34	7.8	Survival	<10,000-10,000 (NOEC-LOEC)	MacDonald et al. 1988	Duration, unmeasured chronic exposure
Yellow crab (embryo, 4-lobed stage), *Cancer anthonyi*	-	7 d	34	7.8	Hatching of embryos	<10,000-10,000 (NOEC-LOEC)	MacDonald et al. 1988	Duration, unmeasured chronic exposure
Daggerblade grass shrimp (embryo, 3 d), *Palaemonetes pugio*	-	12 d	20	7.6-8.1	LC50	1,079	Rayburn and Aladdin 2003	Duration

Appendix J LIST OF ALUMINUM STUDIES NOT USED IN DOCUMENT ALONG WITH REASONS

NMED Exhibit 75

Appendix J. List of Aluminum Studies Not Used in Document Along with Reasons

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Aarab et al.	Histopathology alterations and histochemistry measurements in mussel, *Mytilus edulis* collected offshore from an aluminum smelter industry (Norway)	2008	Bay mussel, *Mytilus edulis*	-	Not applicable; no aluminum toxicity data
Abdelhamid and El-Ayouty	Effect of catfish (*Clarias lazera*) composition of ingestion rearing water contaminated with lead or aluminum compounds	1991	Catfish, *Clarias lazera*	6 wk 50,000 0.33 corrected mortality	Not North American species; dilution water not characterized
Abdel-Latif	The influence of calcium and sodium on aluminum toxicity in Nile tilapia (*Oreochromis niloticus*)	2008	Nile tilapia, *Oreochromis niloticus*	96 hr LC50=175.9	Dilution water not characterized; lack of exposure details
Abraham et al.	Quantified elemental changes in *Aspidisca cicada* and *Vorticella convallaria* after exposure to aluminum, copper, and zinc	1997	Protozoa, *Aspidisca cicada* Protozoa, *Vorticella convallaria*	-	Mixture
Adokoh et al.	Statistical evaluation of environmental contamination, distribution and source assessment of heavy metals (aluminum, arsenic, cadmium, and mercury) in some lagoons and an estuary along the coastal belt of Ghana	2011	-	-	Survey
Ahsan et al.	Comparative proteomic study of arsenic-induced differentially expressed proteins in rice roots reveals glutathione plays a central role during As stress	2008	-	-	Not applicable; no aluminum toxicity data
Al-Aarajy and Al-Saadi	Effect of heavy metals on physiological and biochemical features of *Anabaena cylindrica*	1998	Blue-green alga, *Anabaena cylindrica*	-	Only one exposure concentration; lack of exposure details (duration not reported)
Alessa and Oliveira	Aluminum toxicity studies in *Vaucheria longicaulis v*ar. *macounii* (Xanthophyta, Tribophyceae). I. Effects on cytoplasmic organization	2001a	Alga, *Vaucheria longicaulis* var. m*acouni*	10 hr 2,159 growth ceased	Only one exposure concentration
Alessa and Oliveira	Aluminum toxicity studies in *Vaucheria longicaulis* var. *macounii* (Xanthophyta, Tribophyceae). II. Effects on the F-Actin array	2001b	Alga, *Vaucheria longicaulis* var. m*acouni*	-	Lack of exposure details; dilution water not characterized; only one exposure concentration
Allin and Wilson	Behavioural and metabolic effects of chronic exposure to sublethal aluminum in acidic soft water in juvenile rainbow trout (*Oncorhynchus mykiss*)	1999	Rainbow trout, *Oncorhynchus mykiss*	6 wk 29.2 Reduced appetite	Only one exposure concentration

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Allin and Wilson	Effects of pre-acclimation to aluminum on the physiology and swimming behaviour of juvenile rainbow trout (*Oncorhynchus mykiss*) during a pulsed exposure	2000	Rainbow trout, *Oncorhynchus mykiss*	-	Pulsed exposures to pollutant
Alquezar et al.	Metal accumulation in the smooth toadfish, *Tetractenos glaber*, in estuaries around Sydney, Australia	2006	Toadfish, *Tetractenos glaber*	-	Not North American species; exposed to mixture
Alstad et al.	The significance of water ionic strength on aluminum in brown trout (*Salmo trutta* L.)	2005	Brown trout, *Salmo trutta*	650 Survival time =16-34 hr	No acclimation to test water; only one exposure concentration
Amato et al.	Concentrations, sources and geochemistry of airborne participate matter at a major European airport	2010	-	-	Not applicable; no aluminum toxicity data
Amenu	A comparative study of water quality conditions between heavily urbanized and less urbanized watersheds of Los Angeles Basin	2011	-	-	Not applicable; no aluminum toxicity data
Anderson	The apparent thresholds of toxicity to *Daphnia magna* for chlorides of various metals when added to Lake Erie water	1948	Cladoceran, *Daphnia magna*	64 hr 6,700 LOEC (mortality)	Lack of exposure details; control data not reported
Andersson	Toxicity and tolerance of aluminum in vascular plants	1988	-	-	Review
Andren and Rydin	Toxicity of inorganic aluminum at spring snowmelt-in-stream bioassays with brown trout (*Salmo trutta* L.)	2012	Brown trout, *Salmo trutta*	-	Mixture; dilution water is river water
Andren et al.	Effects of pH and aluminum on embryonic and early larval stages of Swedish brown frogs Rana arvalis, R. temporaria and R. dalmatina	1988	Brown frog, *Rana arvalis* Brown frog, *Rana temporaria* Brown frog, *Rana dalmatina*	15 d NOEC (mortality) =800, 800, & <800, respectively	Not North American species
Andrews et al.	Selected metals in sediments and streams in the Oklahoma part of the Tri-State Mining District, 2000-2006	2009	-	-	Survey
Annicchiarico et al.	PCBs, PAHs and metal contamination and quality index in marine sediments of the Taranto Gulf	2011	-	-	Survey; sediment

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Appelberg	Changes in haemolymph ion concentrations of *Astacus astacus* L. and *Pacifastacus leniusclus* (Dana) after exposure to low pH and aluminium	1985	Signal crayfish, *Pacifastacus leniusculus*	14 d 250 Decrease Na^+ haemolymph concentrations	Too few organisms per treatment (4 per treatmen); only 3 exposure concentrations

Exley et al.	Kinetic constraints in acute aluminum toxicity in the rainbow trout (*Oncorhynchus mykiss*)	1996	Rainbow trout, *Oncorhynchus mykiss*	-	Only one exposure concentration; no control group
Exley et al.	Hydroxyaluminosilicates and acute aluminum toxicity to fish	1997	Rainbow trout, *Oncorhynchus mykiss*	-	Mixture; Al and Si
Fageria	Influence of aluminum in nutrient solutions on chemical composition in two rice cultivars at different growth stages	1985	Rice, *Oryza sativa*	-	Bioaccumulation study: exposure concentrations not measured
Famoso et al.	Development of a novel aluminum tolerance phenotyping platform used for comparisons of cereal aluminum tolerance and investigations into rice aluminum tolerance mechanisms	2010	Sorghum, *Sorghum bicolor* Wheat, *Triticum aestivum* Rice, *Oryza sativa*	-	Excessive EDTA in growth media (25 mg/L)
Farag et al. 1993	The effects of low pH and elevated aluminum on yellowstone cutthroat trout (*Oncorhynchus clarki bouvieri*)	1993	Yellowstone cutthroat trout, *Oncorhynchus clarki bouvieri*	7 d No effect on survival at 50	Too few exposure concentrations; poor control survival
Farringer	The determination of the acute toxicity of rotenone and Bayer 73 to selected aquatic organisms	1972	-	-	Not applicable; no aluminum toxicity data
Fernandez-Davila et al.	Aluminum-induced oxidative stress and neurotoxicity in grass carp (Cyprinidae-*Ctenopharingodon idella*)	2012	Grass carp, *Ctenopharingodon idella*	96 hr Increase lipid peroxidation, dopamine levels, SOD activity and decrease CAT activity in brain tissue at 100	Only one exposure concentration
Finn	The physiology and toxicology of salmonid eggs and larvae in relation to water quality criteria	2007	-	-	Review; results of previously published papers
Fischer and Gode	Toxicological studies in natural aluminum silicates as additives to detergents using freshwater organisms	1977	-	-	Text in foreign language
Fivelstad and Leivestad	Aluminum toxicity to Atlantic salmon (*Salmo salar* L.) and brown trout (*Salmo trutta* L.): Mortality and physiological response	1984	Atlantic salmon, *Salmo salar*	LT50=26 hr at 84.18; LT50=41 hr at 84.72; LT50=62 hr at 45.06	Lack of exposure details; dilution water not characterized
Fjellheim et al.	Effect of aluminium at low pH on the mortality of elvers (*Anguilla anguilla* L.), a laboratory experiment	1985	Eel, *Anguilla anguilla*	-	Only two exposure concentrations; dilution water not characterized

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Fok et al.	Determination of 3,5,3"-triiodo-L-thyronine (T3) levels in tissues of rainbow trout (*Salmo gairdneri*) and the effects of low ambient pH and aluminum.	1990	Rainbow trout, *Oncorhynchus mykiss*	-	Inappropriate form of toxicant ($AlKSO_4$); surgically altered test species
Folsom et al.	Comparative study of aluminum and copper transport and toxicity in an acid-tolerant freshwater green alga	1986	Green alga, *Chlorella saccarophila*	-	Lack of details; cannot determine effect concentration
France and Stokes	Influence of manganese, calcium, and aluminum on hydrogen ion toxicity to the amphipod *Hyalella azteca*	1987	Amphipod, *Hyalella azteca*	-	Mixture; Mn, Ca, pH and Al
Freda	The effects of aluminum and other metals on amphibians	1991	-	-	Review; results of previously published papers
Freeman	Recovery of rainbow trout from aluminum poisoning	1973	Rainbow trout, *Oncorhynchus mykiss*	-	Pre-exposure to pollutant
Frick and Herrmann	Aluminum accumulation in a lotic mayfly at low pH - a laboratory study	1990	Mayfly, *Heptagenia sulphurea*	-	Not North American species; lack of exposure details; cannot determine effect concentration
Fuma et al.	Ecological effects of various toxic agents on the aquatic microcosm in comparison with acute ionizing radiation	2003	Bacteria, *Escherichia coli* Protozoa, *Tetrahymena thermophila* Protozoa, *Euglena gracilis*	-	Mixture; radiation and Al
Gagen	Aluminum toxicity and sodium loss in three salmonid species along a pH gradient in a mountain stream	1986	-	-	Exposure concentration not known; field exposure
Gagen et al.	Mortality of brook trout, mottled sculpins, and slimy sculpins during acidic episodes	1993	Brook trout, *Salvelinus fontinalis* Mottled sculpin, *Cottus bairdi* Slimy sculpin, *Cottus cognatus*	-	Mixture; exposure concentration varied over time; dilution water is river water
Galindo et al.	Genotoxic effects of aluminum on the neotropical fish *Prochilodus lineatus*	2010	Neotropical fish, *Prochilodus lineatus*	96 hr Increase COMET score and number of damaged necleoids at 438	Not North American species, only one exposure concentration
Gallon et al.	Hydrophonic study of aluminum accumulation by aquatic plants: effects of fluoride and pH	2004	Five aquatic plants	-	Bioaccumulation: steady state not reached

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Galloway et al.	Water quality and biological characteristics of the Middle Fork of the Saline River, Arkansas, 2003-06	2008	-	-	Not applicable; no aluminum toxicity data
Garcia-Garcia et al.	Impact of chromium and aluminum pollution on the diversity of zooplankton: a case study in the Chimaliapan wetland (Ramsar Site) (Lerma Basin, Mexico)	2012	-	-	Mixture; dilution water is wetland water
Garcia-Medina et al.	Aluminum-induced oxidative stress in lymphocytes of common carp (*Cyprinus carpio*)	2010	Common carp, *Cyprinus carpio*	96 hr Increase lipid peroxidation and decrease SOD activity at 50	Too few exposure concentrations, dilution water not characterized
Garcia-Medina et al.	Genotoxic and cytotoxic effects induced by aluminum in the lymphocytes of the common carp (*Cyprinus carpio*)	2011	Common carp, *Cyprinus carpio*	96 hr DNA damage: T/N index at 50	Too few exposure concentrations, dilution water not characterized
Garcia-Medina et al.	The relationship of cytotoxic and genotoxic damage with blood aluminum levels and oxidative stress induced by this metal in common carp (*Cyprinus carpio*) erythrocytes	2013	Common carp, *Cyprinus carpio*	96 hr LOEC (reduced USOD and NADPH on erythocytes) = 50	Only three exposure concentrations
Gardner and Al-Hamdani	Interactive effects of aluminum and humic substances on Salvinia	1997	-	-	Not applicable; no aluminum toxicity data
Gardner et al.	Towards the establishment of an environmental quality standard for aluminum in surface waters	2008	-	-	Not applicable; no aluminum toxicity data
Gascon et al.	The interaction of pH, calcium and aluminum concentrations on the survival and development of wood frog (*Rana sylvatica*) eggs and tadpoles	1987	Wood frog, *Rana sylvatica*	100% mortality at 200	Only two exposure concentrations; lack of exposure details; duration not reported
Geiger et al.	Acute toxicities of organic chemicals to fathead minnows (*Pimephales promelas*) Volume V	1990	Fathead minnows, *Pimephales promelas*	-	Not applicable; no aluminum toxicity data
Gensemer	Role of aluminum and growth rate on changes in cell size and silica content of silica-limited populations of *Asterionella ralfsii* var. *americana* (Bacillariophyceae).	1990	Diatom, *Asterionella ralfsii* var. *americana*	21 d Decrease mean cell length, total surface area and biovolume at 75.54	Only two exposure concentrations
Gensemer	The effects of pH and aluminum on the growth of the acidophilic diatom *Asterionella ralfsii* var. *americana*	1991a	Diatom, *Asterionella ralfsii* var. *americana*	-	Review of Gensemer 1989 thesis
Gensemer	The effects of aluminum on phosphorus and silica-limited growth in *Asterionella ralfsii* var. *americana*	1991b	Diatom, *Asterionella ralfsii* var. *americana*	-	Growth stimulation study, not toxicity

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Gensemer and Playle	The bioavailability and toxicity of aluminum in aquatic environments	1999	-	-	Review; results of previously published papers
Gensemer et al.	Comparative effects of pH and aluminum on silica-limited growth and nutrient uptake in *Asterionella ralfsii* var. *americana* (Bacillariophyceae)	1993	Diatom, *Asterionella ralfsii* var. *americana*	-	Only one exposure concentration; cannot determine effect concentration
Gensemer et al.	Interactions of pH and aluminum on cell length reduction in *Asterionella ralfsii* var. *americana* Korn	1994	Diatom, *Asterionella ralfsii* var. *americana*	25 d No effect on cell length at 539.6	Only one exposure concentration; dilution water not characterized
Genter	Benthic algal populations respond to aluminum, acid, and aluminum-acid mixture in artificial streams	1995	Green alga, *Cosmarium melanosporum* Blue-green alga, *Schizothrix calcicola* Diatom, *Achnanthes minutissima* Diatom, *Naviculoids*	28 d Increased growth at 200	Only one exposure concentration
Gibbons et al.	Effects of multiphase restoration, particularly aluminum sulfate application, on the zooplankton community of a eutrophic lake in eastern Washington	1984	-	-	Exposure concentration not known; population/ community changes of a lake exposed to Al over a series of years
Gill et al.	Assessment of water-quality conditions in Fivemile Creek in the vicinity of the Fivemile Creek Greenway, Jefferson County, Alabama, 2003-2005	2008	-	-	Not applicable; no aluminum toxicity data
Gladden	The effect of aluminum on cortisol levels in goldfish (*Carassius auratus*)	1987	Goldfish, *Carassius auratus*	-	Surgically altered test species
Goossenaerts et al.	A microanalytical study of the gills of aluminum-exposed rainbow trout (*Salmo gairdneri*)	1988	Rainbow trout, *Oncorhynchus mykiss*	72 hr Increase the Al-content of the gills at 190	Duration too short, only one exposure concentration
Gopalakrishnan et al.	Toxicity of heavy metals on embryogenesis and larvae of the marine sedentary polychaete *Hydroides elegans*	2007	Polychaete, *Hydroides elegans*	-	Pre-exposure to pollutant
Goss and Wood	The effects of acid and acid/aluminum exposure on circulating plasma cortisol levels and other blood parameters in the rainbow trout, *Salmo gairdneri*	1988	Rainbow trout, *Oncorhynchus mykiss*	-	Surgically altered fish
Greger et al.	Aluminum effects on *Scenedesmus obtusiusculus* with different phosphorus status. I. Mineral uptake	1992a	Green alga, *Scenedesmus obtusiusculus*	-	Excessive EDTA in growth media (108 µm Na_2EDTA)

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Greger et al.	Aluminum effects on *Scenedesmus obtusiusculus* with different phosphorus status. II. Growth, photosynthesis and pH	1992b	Green alga, *Scenedesmus obtusiusculus*	-	Excessive EDTA in growth media (108 µm Na_2EDTA)
Gregor et al.	Growth assays with mixed cultures of cyanobacteria and algae assessed by in vivo fluorescence: One step closer to real ecosystems?	2008	Green alga, *Pseudokirchneriella subcapitata* Blue-green alga, *Aphanothece clathrata*	-	Inappropriate form of toxicant (PAX-18)
Guerold et al.	Occurrence of aluminum in chloride cells of *Perla marginata* (Plecoptera) after exposure to low pH and elevated aluminum concentration	1995	Stonefly, *Perla marginata*	-	Not North American species; Bioaccumulation: steady state not reached
Gunn and Keller	Spawning site water chemistry and lake trout (*Salvelinus namaycush*) sac fry survival during spring snow melt	1984	Lake trout, *Salvelinus namaycush*	-	Mixture, Al and low pH
Gunn and Noakes	Latent effects of pulse exposure to aluminum and low pH on size, ionic composition, and feeding efficiency of lake trout (*Salvelinus namaycush*) alevins	1987	Lake trout, *Salvelinus namaycush*	5 d LOEC (growth)=<100	Only two exposure concentrations
Guo et al.	Involvement of antioxidative defense system in rice seedlings exposed to aluminum toxicity and phosphorus deficiency	2012	Rice, *Oryza sativa*	-	Excessive chelator in growth media (5 mg/L Fe-citrate)
Guthrie et al.	Aquatic bacterial populations and heavy metals-II. Influence of chemical content of aquatic environments on bacterial uptake of chemical elements	1977	Bacterial population	-	Exposure concentration not known; field accumulation study
Guzman et al.	Implementing *Lecane quadridentata* acute toxicity tests to assess the toxic effects of selected metals (Al, Fe and Zn)	2010	Rotifer, *Lecane quadridentata*	48 hr LC50=1,572	Not North American species
Hackett	Ecological aspects of the nutrition of *Deschampsia flexuosa* (L.) Trin. III. Investigation of phosphorus requirement and response to aluminium in water culture, and a study of growth in soil	1967	Wavy hair grass, *Deschampsia flexuosa*	-	Not applicable; terrestrial species
Hall et al.	Mortality of striped bass larvae in relation to contaminants and water quality in a Chesapeake Bay tributary	1985	Striped bass, *Morone saxatilis*	-	Exposed to mixture, high control mortality (15-25%); dilution water is river water
Hamilton-Taylor et al.	Depositional fluxes of metals and phytoplankton in Windermere as measured by sediment traps	1984	-	-	Effluent or mixture

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Handy and Eddy	Surface absorption of aluminium by gill tissue and body mucus of rainbow trout, *Salmo gairdneri*, at the onset of episodic exposure	1989	Rainbow trout, *Oncorhynchus mykiss*	1 hr Gill content=50 µg/g at 954	Only one exposure concentration
Hanks	Effect of metallic aluminum particles on oysters and clams	1965	Soft-shell clam, *Mya arenaria* American oyster, *Crassostrea virginica*	-	Dilution water not characterized, inappropriate form of Al
Harper et al.	In vivo biodistribution and toxicity depends on nanomaterial composition, size, surface functionalisation and route of exposure	2008	Zebrafish, *Danio rerio*	-	Inappropriate form of toxicant (Al-oxide)
Harry and Aldrich	The distress syndrome in *Taphtus glabratus* (Say) as a reaction to toxic concentrations of inorganic ions	1963	Snail, *Taphius glabratus*	24 hr LOEC (distress, inability to move)=5,000	Dilution water is distilled water
Havas	Effects of aluminum on aquatic biota	1986a	-	-	Review
Havas and Hutchinson	Aquatic invertebrates from the Smoking Hills, N.W.T.: effect of pH and metals on mortality	1982	-	-	Mixture
Havas and Hutchinson	Effect of low pH on the chemical composition of aquatic invertebrates from tundra ponds at the Smoking Hills, N.W.T., Canada	1983	-	-	Pre-exposure to pollutant
Havens	Aluminum binding to ion exchange sites in acid-sensitive versus acid tolerant cladocerans	1990	Cladoceran, *Daphnia galeata mendotae* Cladoceran, *Daphnia retrocurva* Cladoceran, *Bosmina longirostris*	24 hr 98% mortality at 200; 94% mortality at 200; 6% mortality at 200	Only one exposure concentration
Havens	Littoral zooplankton response to acid and aluminum stress during short-term laboratory bioassays	1991	-	-	Only one exposure concentration; mixture; low pH and Al
Havens	Acid and aluminum effects on sodium homeostasis and survival of acid-sensitive and acid-tolerant cladocera	1992	Cladoceran, *Daphnia galeata mendotae* Cladoceran, *Bosmina longirostris*	24 hr NOEC (survival)=100; NOEC=200	Only two exposure concentrations
Havens	Acid and aluminum effects on the survival of littoral macro-invertebrates during acute bioassays	1993a	-	-	Only one exposure concentration; control survival issues or mixed species exposure

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Havens	Acid and aluminum effects on osmoregulation and survival of the freshwater copepod *Skistodiaptomus oregonensis*	1993b	Copepod, *Skistodiaptomus oregonensis*	48 hr NOEC (survival)=200 at pH=7.5; LOEC=100 at pH=6.0	Only two exposure concentrations
Havens and Decosta	The role of aluminum contamination in determining phytoplankton and zooplankton responses to acidification	1987	-	-	Mixture; exposure concentration varied over time; Dilution water is lake water
Havens and Heath	Acid and aluminum effects on freshwater zooplankton: and in situ mesocosm study	1989	Zooplankton community	-	Mixture (low pH and Al); only one exposure concentration
Havens and Heath	Phytoplankton succession during acidification with and without increasing aluminum levels	1990	Phytoplankton community	-	Mixture (low pH and Al); only one exposure concentration
Heier et al.	Sublethal effects in Atlantic salmon (*Salmo salar*) exposed to mixtures of copper, aluminum and gamma radiation	2012	Atlantic salmon, *Salmo salar*	48 hr No mortality, but increase plasma glucose and decrease plasma sodium at 267	Only one exposure concentration, too few animals per concentration
Helliwell	Speciation and toxicity of aluminum in a model fresh water	1983	-	-	Lack of details; cannot determine effect concentration
Heming and Blumhagen	Plasma acid-base and electrolyte states of rainbow trout exposed to alum (aluminum sulphate) in acidic and alkaline environments	1988	Rainbow trout, *Oncorhynchus mykiss*	-	Surgically altered fish
Herkovits et al.	Identification of aluminum toxicity and aluminum-zinc interaction in amphibian *Bufo arenarum* embryos	1997	Toad, *Bufo arenarum*	96 hr LC50=460	Not North American Species
Herrmann and Andersson	Aluminum impact on respiration of lotic mayflies at low pH	1986	-	-	Mixture; dilution water is stream water
Herrmann and Frick	Do stream invertebrates accumulate aluminum at low pH conditions?	1995	-	-	Survey
Hesse	Phosphorus relationships in a mangrove-swamp mud with particular reference to aluminum toxicity	1963	-	-	Sediment
Hill et al.	Zebrafish as a model vertebrate for investigating chemical toxicity	2005	Zebrafish, *Danio rerio*	-	Review
Hockett and Mount	Use of metal chelating agents to differentiate among sources of acute aquatic toxicity	1996	Cladoceran, *Ceriodaphnia dubia*	-	Mixture; EDTA, thiosulfate and Al
Hofler	Action of aluminum salts on Spirogyra and Zygnema	1958	-	-	Text in foreign language

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Horne and Dunson	Exclusion of the Jefferson salamander, *Ambystoma jeffersonianum*, from some potential breeding ponds in Pennsylvania: effects of pH, temperature, and metals on embryonic development	1994	Jefferson salamander, *Ambystoma jeffersonianum*	-	Lack of details; mixture; low pH and AL; duration not reported
Horne and Dunson	Toxicity of metals and low pH to embryos and larvae of the Jefferson salamander, Ambystoma jeffersonianum	1995a	Jefferson salamander, *Ambystoma jeffersonianum*	No effect values presented	No effect values presented
Horne and Dunson	Effects of low pH, metals, and water hardness on larval amphibians	1995b	Wood frog, *Rana sylvatica* Jefferson salamander, *Ambystoma jeffersonianum*	Percent survival depended on hardness, duration and species	Only one exposure concentration
Hornstrom et al.	Effects of pH and different levels of aluminum on lake plankton in the Swedish west coast area	1984	-	-	Survey; mixture; dilution water is lake water
Howells et al.	Effects of acidity, calcium, and aluminum on fish survival and productivity - a review	1983	-	-	Review; results of previously published papers
Howells et al.	EIFAC water quality criteria for European freshwater fish: Report on aluminum	1990	-	-	Review
Huebner and Pynnonen	Viability of glochidia of two species of *Anodonta* exposed to low pH and selected metals	1992	Swan mussel, *Anodonta cygnea*	24 hr glochidia EC50=18,000 at pH 4.5	Not North American species
Hunn et al.	Influence of pH and aluminum on developing brook trout in a low calcium water	1987	Brook trout, *Salvelinus fontinalis*	45 d Reduced growth and some behaviors at 283	Only one exposure concentration
Husaini and Rai	pH dependent aluminum toxicity to *Nostoc linckia*: Studies on phosphate uptake, alkaline and acid phosphatase activity, ATP content, and photosynthesis and carbon fixation	1992	Blue-green alga, *Nostoc linckia*	14 d Reduce photosynthetic O_2 evolution at 53,336	Only three exposure concentrations
Husaini et al.	Impact of aluminum, fluoride and flouroaluminate on ATPase activity og *Nostoc linckia* and *Chlorella vulgaris*	1996	Blue-green alga, *Nostoc linckia* Green alga, *Chlorella vulgaris*	-	Mixture
Hutchinson and Sprague	Toxicity of trace metal mixtures to American flagfish (*Jordanella floridae*) in soft, acidic water and implications for cultural acidification	1986	American flagfish, *Jordanella floridae*	-	Mixture; heavy metals
Hutchinson et al.	Lethal responses of salmonid early life stages to H+ and Al in dilute waters	1987	-	-	Review
Hwang	Lysosomal responses to environmental contaminants in bivalves	2001	American oyster, *Crassostrea virginica*	-	Exposure concentration not known; field accumulation study

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Hyne and Wilson	Toxicity of acid-sulphate soil leachate and aluminum to the embryos and larvae of Australian bass (*Macquaria novemaculeata*) in estuarine water	1997	Australian bass, *Macquaria novemaculeata*	No effect on survival at 1,000 and pH=1,000; Reduce survival by 63% at 500 and pH=4.0	Not North American species; dilution water not characterized
Ingersoll	The effects of pH, aluminum, and calcium on survival and growth of brook trout (*Salvelinus fontinalis*) early life stages	1986	Brook trout, *Salvelinus fontinalis*	-	Survival problems; low fertility success
Ingersoll et al.	Epidermal response to pH, aluminum, and calcium exposure in brook trout (*Salvelinus fontinalis*) fry	1990b	Brook trout, *Salvelinus fontinalis*	-	Only two exposure concentrations; too few test organisms per concentration
Jagoe and Haines	Changes in gill morphology of Atlantic salmon (*Salmo salar*) smolts due to addition of acid and aluminum to stream water	1997	Atlantic salmon, *Salmo salar*	-	Only one exposure concentration, increasing Al concentration over time
Jain et al.	Acute and chronic toxicity of aluminium fluoride to flora and fauna in a microcosm	2012	Duckweed, *Lemna aequinoctialis* Cladoceran, *Daphnia similis* Western mosquitofish, *Gambusis affinis*	-	Inapporiate form of toxicant (Aluminum floride)
Jan and Matsumoto	Early effects of aluminium on nutrient (K, Ca, and Mg) status of different root zones of two rice cultivars	1999	Rice, *Oryza sativa*	-	No control group; only one exposure concentration
Jan and Pettersson	Effects of low aluminium levels on growth and nutrient relations in three rice cultivars with different tolerances to aluminium	1993	Rice, *Oryza sativa*	-	Bioaccumulation study: exposure concentrations not measured
Jancula et al.	Effects of polyaluminium chloride on the freshwater invertebrate Daphnia magna	2011	-	-	Inappropriate form of toxicant; PAX-18 (9% Al)
Jaworska and Tomasik	Metal-metal interactions in biological systems. Part VI. Effects of some metal ions on mortality, pathogenicity and reproductivity of Steinernema carpocapsae and Heterohabditis bacteriophora entomopathogenic nematodes under laboratory conditions	1999	Nematode, *Steinernema carpocapsae*	-	Distilled water without proper salts added
Jaworska et al.	Effect of metal ions under laboratory conditions on the entomopathogenic Steinernema carpocapsae (Rhabditida: sterinernematidae)	1996	Nematode, *Steinernema carpocapsae*	-	Distilled water without proper salts added; infected test organism

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Jaworska et al.	Effect of metal ions on the entomopathogenic nematode *Heterorhabditis bacteriophora* Poinar (Nematode: Heterohabditidae) under laboratory conditions	1997	Nematode, *Heterorhabditis bacteriophora*	-	Distilled water without proper salts added
Jay and Muncy	Toxicity to channel catfish of wastewater from an Iowa coal beneficiation plant	1979	-	-	Effluent
Jensen and Malte	Acid-base and electrolyte regulation, and haemolymph gas transport in crayfish, *Astacus astacus*, exposed to soft, acid water with and without aluminum	1990	Crayfish, *Astacus astacus*	21 d No effect on haemolymph haemocyanin concentration at 675	Not North American species, only one exposure concentration
Jensen and Weber	Internal hypoxia-hypercapnia in tench exposed to aluminum in acid water: Effects on blood gas transport, acid-base status and electrolyte composition in arterial blood	1987	Tench, *Tinca tinca*	-	Surgically altered test species
Ji et al.	Toxicity of oxide nanoparticles to the green algae *Chlorella sp.*	2011	Green alga, *Chlorella sp.*	-	Inappropriate form of toxicant (aluminum oxide)
Jones	The relation between the electrolytic solution pressures on the metals and their toxicity to the stickleback (*Gasterosteus aculeatus* L.)	1939	Threespine stickleback, *Gasterosteus aculeatus*	-	Lack of details; review
Jones	A further study of the relation between toxicity and solution prssure, with *Polycelis nigra* as test animals	1940	Planarian, *Polycelis nigra*	48 hr Survival time affected at 100,000	Not North American species; distilled water without proper salts
Jones et al.	Comparison of observed and calculated concentrations of dissolved Al and Fe in stream water	1974	-	-	Not applicable; no aluminum toxicity data
Jonsson et al.	Metals and linear alkylbenzene sulphonate as inhibitors of the algae *Pseudokirchneriella subcapitata* acid phosphatase activity	2009	Green alga, *Pseudokirchneriella subcapitata*	7 d Decrease relative acitivity at 53,960	Only two exposure concentrations
Juhel et al.	Alumina nanoparticles enhance growth of Lemna minor	2011	Duckweed, *Lemna minor*	-	Inappropriate form of toxicant; nanoparticles
Kadar et al.	Avoidance responses to aluminum in the freshwater bivalve, *Anodonta cygnea*	2001	Swan mussel, *Anodonta cygnea*	15 d Decrease in duration of shell gape at 516.3	Not North American species
Kadar et al.	Effect of sub-lethal concentrations of aluminum on the filtration activity of the freshwater mussel *Anodonta cygnea* L. At Neutral Ph	2002	Swan mussel, *Anodonta cygnea*	15 d Duration of siphon activity at 241.3	Not North American species, only two exposure concentrations

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Pond et al.	Downstream effects of mountaintop coal mining: comparing biological conditions using family- and genus-level macroinvertebrate bioassessment tools	2008	-	-	Field survey, mixture
Poor	Effect of lake management efforts on the trophic state of a subtropical shallow lake in Lakeland, Florida, USA	2010	-	-	Survey
Poston	Effects of dietary aluminum on growth and composition of young Atlantic salmon	1991	Atlantic salmon, *Salmo salar*	-	Fed pollutant
Prange and Dennison	Physiological responses of five seagrass species to trace metals	2000	Seagrass	-	Exposure concentration not known; field accumulation study
Pribyl et al.	Cytoskeletal alterations in interphase cells of the green alga Spirogyra decimina in response to heavy metals exposure: I. the effect of cadmium	2005	Green alga, *Spirogyra decimina*	-	Not applicable; cadmium study
Pynnonen	Aluminum accumulation and distribution in the freshwater clams (Unionidae)	1990	Mussel, *Anodonta anatina* Mussel, *Unio pictorum*	-	Not North American species; exposure concentrations varied too much over time
Quiroz-Vazquez et al.	Bioavailability and toxicity of aluminum in a model planktonic food chain (*Chlamydomonas-Daphnia*) at neutral pH	2010	-	-	Bioaccumulation: not renewal or flow-through; steady state not reached
Radic et al.	Ecotoxicological effects of aluminum and zinc on growth and antioxidants in *Lemna minor* L.	2010	Duckweed, *Lemna minor*	15 d NOEC (relative growth rate)=4,047; LOEC=8,094	
Rahman et al.	Varietal differences in the growth of rice plants in response to aluminum and silicon	1998	Rice	-	Scientific name not given
Rai et al.	Physiological and biochemical responses of *Nostoc linckia* to combined effects of aluminium, fluoride and acidification	1996	Cyanobacteria, *Nostoc linckia*	15 d pH 7.5 LC50=121.4, pH 6.0 LC50=11.13, pH4.5 LC50=3.643	Only three exposure concentrations
Rajesh	Toxic effect of aluminum in *Oreochromis mossambicus* (Peters)	2010	Mozambique tilapia, *Oreochromis mossambicus*	4 d LC50=8,000	Dilution water not characterized
Ramamoorthy	Effect of pH on speciation and toxicity of aluminum to rainbow trout (*Salmo gairdneri*)	1988	Rainbow trout, *Oncorhynchus mykiss*	-	Mixture
Razo-Estrada et al.	Aluminum-induced oxidative stress and apoptosis in liver of the common carp, *Cyprinus carpio*	2013	Common carp, *Cyprinus carpio*	96 hr Increase lipid peroxidation at 50	Only three exposure concentrations

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Reader and Morris	Effects of aluminium and pH on calcium fluxes, and effects of cadmium and manganese on calcium and sodium fluxes in brown trout (*Salmo trutta* L.)	1988	Brown trout, *Salmo trutta*	-	Only one exposure concentration; too few fish per exposure concentration
Reader et al.	Growth, mineral uptake and skeletal calcium deposition in brown trout, *Salmo trutta* L., yolk-sac fry exposed to aluminum and manganese in soft acid water	1988	Brown trout, *Salmo trutta*	-	Mixture, Al, NH_3, NH_4
Reader et al.	The effects of eight trace metals in acid soft water on survival, mineral uptake and skeletal calcium deposition in yolk-sac fry of brown trout, *Salmo trutta* L.	1989	Brown trout, *Salmo trutta*	30 d 0% survival at 178.1 and pH=4.5; No effect on survival at 170.0 at pH=6.5	Only one exposure concentration
Reader et al.	Episodic exposure to acid and aluminum in soft water: survival and recovery of brown trout, *Salmo trutta* L.	1991	Brown trout, *Salmo trutta*	-	No control group
Reid et al.	Acclimation to sublethal aluminum: modification of metal - gill surface interactions of juvenile rainbow trout (*Oncorhynchus mykiss*)	1991	Rainbow trout, *Oncorhynchus mykiss*	-	Only two exposure concentrations; pre-exposure to pollutant
Reznikoff	Micrurgical studies in cell physiology. II. The action of chlorides of lead, mercury, copper, iron, and aluminum on the protoplasm of Amoeba proteus	1926	-	-	Lack of exposure details; dilution water not characterized
Riseng et al.	The effect of pH, aluminum, and chelator manipulations on the growth of acidic and circumneutral species of *Asterionella*	1991	Diatom, *Asterionella ralfsii* Diatom, *Asterionella formosa*	-	Mixture; EDTA and Al
Rizzo et al.	Removal of THM precursors from a high-alkaline surface water by enhanced coagulation and behaviour of THMFP toxicity on *D. magna*	2005	Cladoceran, *Daphnia magna*	-	Not applicable; no aluminum toxicity data
Robertson and Liber	Bioassays with caged *Hyalella azteca* to determine in situ toxicity downstream of two Saskatchewan, Canada, uranium operations	2007	Amphipod, *Hyalella azteca*	-	Mixture; downstream exposure of uranium mining operation
Robertson et al.	Survival of *Cryptosporidium parvum* oocysts under various environmental pressures	1992	Parasite, *Cryptosporidium parvum*	-	Poor control survival; only two exposure concentrations
Robinson and Deano	The synergistic effects of acidity and aluminum on fish (Golden shiners) in Louisiana	1985	Golden shiner, *Notemigonus crystoleucas*	-	Dilution water not characterized; high control mortality (10-20%)

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Robinson and Deano	Acid rain: the effect of pH, aluminum, and leaf decomposition products on fish survival	1986	Golden shiner, *Notemigonus crystoleucas*	-	Only two exposure concentrations
Rosemond et al.	Comparative analysis of regional water quality in Canada using the water quality index	2009	-	-	Survey; no aluminum toxicity data
Rosseland and Skogheim	Comparative study on salmonid fish species in acid aluminum-rich water II. Physiological stress and mortality of one- and two-year-old fish	1984	-	-	Mixture; dilution water is lake water
Rosseland et al.	Mortality and physiological stress of year-classes of landlocked and migratory Atlantic salmon, brown trout and brook trout in acidic aluminium-rich soft water	1986	Atlantic salmon, *Salmo salar* Brown trout, *Salmo trutta* Brook trout, *Salvelinus fontinalis*	83 hr, pH=5.14, 228 100% mortality; 0% mortality; 0% mortality	Dilution water not characterized; only one exposure concentration
Rosseland et al.	Environmental effects of aluminum	1990	-	-	Review of previously published literature
Rosseland et al.	The mixing zone between limed and acidic river waters: Complex aluminum and extreme toxicity for salmonids	1992	-	-	Mixture; exposure concentration varied over time; dilution water is river water
Roy and Bhadra	Hematoxylin staining of seedling roots is a potential phenotypic index for screening of aluminium tolerance in rice (*Oryza sativa* L.)	2013	Rice, *Oryza sativa*	-	Not applicable, no aluminum toxicity information
Royset et al.	Diffusive gradients in thin films sampler predicts stress in brown trout (*Salmo trutta* L.) exposed to aluminum in acid fresh waters	2005	Brown trout, *Salmo trutta*	-	Mixture; dilution water is river water
Rueter et al.	Indirect aluminum toxicity to the green alga *Scenedesmus* through increased cupric ion activity	1987	Green alga, *Scenedesmus quadricauda*	-	Mixture; Al and Cu
Sacan and Balcioglu	Bioaccumulation of aluminium in *Dunaliella tertiolecta* in natural sewater: Aluminium-metal (Cu, Pb, Se) interactions and influence of pH	2001	Phytoplankton, *Dunaliella tertiolecta*	-	Bioaccumulation, steady state not documented
Sadler and Lynam	Some effects on the growth of brown trout from exposure to aluminum at different pH levels	1987	Brown trout, *Salmo trutta*	7 d NOEC (specific growth rate)=18.87 at pH=5.5; LOEC=30.04 at pH=5.5	Too few exposure concentrations; duration

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Sadler and Lynam	The influence of calcium on aluminum-induced changes in the growth rate and mortality of brown trout, *Salmo trutta* L.	1988	Brown trout, *Salmo trutta*	42 d Increase mortality at 54 and hardness from 3-6 mg/L as $CaCO_3$, but not greater than 9 mg/L	Only one exposure concentration
Salbu et al.	Environmentally relevant mixed exposures to radiation and heavy metals induce measurable stress responses in Atlantic salmon	2008	Atlantic salmon, *Salmo salar*	-	Only one exposure concentration; mixture
Sauer	Heavy metals in fish scales: accumulation and effects on cadmium regulation in the mummichog, *Fundulus heteroclitus* L.	1986	Mummichog, *Fundulus heteroclitus*	-	Not applicable; no aluminum toxicity data
Sayer	Survival and subsequent development of brown trout, *Salmo trutta* L., subjected to episodic exposures of acid, aluminum and copper in soft water during embryonic and larval stages	1991	Brown trout, *Salmo trutta*	-	Only one exposure concentration; mixture; low pH and Al
Sayer et al.	Embryonic and larval development of brown trout, Salmo trutta L.: exposure to aluminum, copper, lead or zinc in soft, acid water	1991a	Brown trout, *Salmo trutta*	700 d 13% mortality at 161.8	Only one exposure concentration
Sayer et al.	Embryonic and larval development of brown trout, *Salmo trutta* L.: exposure to trace metal mixtures in soft water	1991b	Brown trout, *Salmo trutta*	-	Only two exposure concentrations; mixture
Sayer et al.	Effects of six trace metals on calcium fluxes in brown trout (*Salmo trutta* L.) in soft water	1991c	Brown trout, *Salmo trutta*	-	Only two exposure concentrations; mixture
Sayer et al.	Mineral content and blood parameters of dying brown trout (*Salmo trutta* L.) exposed to acid and aluminum in soft water	1991d	Brown trout, *Salmo trutta*	4 d Increase haematocrit and decrease plasma sodium levels and whole body sodium and potassium content at 273.6	Only one exposure concentration; too few organisms per concentration
Schindler and Turner	Biological, chemical and physical responses of lakes to experimental acidification	1982	-	-	Mixture, Al and low pH
Schofield and Trojnar	Aluminum toxicity to brook trout (*Salvelinus fontinalis*) in acidified waters	1980	Brook trout, *Salvelinus fontinalis*	-	Mixture; dilution water not characterized
Schumaker et al.	Zooplankton responses to aluminum sulfate treatment of Newman Lake, Washington	1993	-	-	Exposure concentrations not known
Segner et al.	Growth, aluminum uptake and mucous cell morphometrics of early life stages of brown trout, *Salmo trutta*, in low pH water	1988	Brown trout, *Salmo trutta*	5d Decrease weight and length at 230	Only one exposure concentration

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Senger et al.	Aluminum exposure alters behavioral parameters and increases acetylcholinesterase activity in zebrafish (*Danio rerio*) brain	2011	Zebrafish, *Danio rerio*	4 d Increase AChE activity in brain at 10.12 at pH=5.8 but not pH=6.8	Only one exposure concentration
Shabana et al.	Studies on the effects of some heavy metals on the biological activities of some phytoplankton species. II. The effects of some metallic ions on the growth criteria and morphology of *Anabaena oryzae* and *Aulosira fertilissima*	1986a	-	-	Lack of details; cannot determine effect concentration
Shabana et al.	Studies on the effects of some heavy metals on the biological activities os some phytoplankton species. III. Effects Al3+, Cr3+, Pb2+ and Zn 2+ on heterocyst frequency, nitrogen and phosphorus metabolism of *Anabaena oryzae* and *Aulosira fertilissima*	1986b	-	-	Lack of details; cannot determine effect concentration
Sharma et al.	Protective effect of *Spirulina* and tamarind fruit pulp diet supplement in fish (*Gambusia affinis* Baird & Girard) exposed to sublethal concentration of fluoride, aluminum and aluminum fluoride	2012	Western mosquitofish, *Gambusia affinis*	-	Only one exposure concentration; poor control survival
Shuhaimi-Othman et al.	Toxicity of eight metals to Malaysian freshwater midge larvae *Chironomus javanus* (Diptera, Chironomidae)	2011b	Midge, *Chironomus javanus*	4 d LC50=1,430	Not North American species
Shuhaimi-Othman et al.	Toxicity of metals to tadpoles of the commone Sunda toad, *Duttaphrynus melanostictus*	2012c	Sunda toad, *Duttaphrynus melanostictus*	4 d LC50=1,900	Not North American species
Siebers and Ehlers	Heavy metal action on transintegumentary absorption of glycine in two annelid species	1979	-	-	Not applicable; no aluminum toxicity data
Simon	Sediment and interstitial water toxicity to freshwater mussels and the ecotoxicological recovery of remediated acrid mine drainage streams	2005	-	-	Sediment exposure
Sivakumar and Sivasubramanian	FT-IR study of the effect of aluminum on the muscle tissue of *Cirrhinus mrigala*	2011	Carp hawk, *Cirrhinus mrigala*	4 d LC50=8,200	Not North American species; dilution water not characterized
Skogheim and Rosseland	A comparative study on salmonid fish species in acid aluminum-rich water I. Mortality of eggs and alevins	1984	Trout	-	Mixture; dilution water is lake water
Skogheim and Rosseland	Mortality of smolt of Atlantic salmon, *Salmo salar* L., at low levels of aluminum in acidic softwater	1986	Atlantic salmon, *Salmo salar*	-	Mixture; dilution water is lake water

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Skogheim et al.	Addition of NaOH, limestone slurry and finegrained limestone to acidified lake water and the effects on smolts of Atlantic salmon (*Salmo salar* L.)	1987	Atlantic salmon, *Salmo salar*	-	Prior exposure; stressed organisms
Soleng et al.	Toxicity of aqueous aluminum to the ectoparasitic monogenean *Gyrodactylus salaris*	2005	-	-	Only two exposure concentrations; two species tested with one exposure; not sure how much exposure to the parasite
Sonnichsen	Toxicity of a phosphate-reducing agent (aluminum sulphate) on the zooplankton in the lake Lyngby So	1978	-	-	Not applicable; no aluminum toxicity data
Sparling	Conditioned aversion of aluminum sulfate in black ducks	1990	Black ducks, *Anas rubripes*	-	Dietary exposure
Sparling and Lowe	Environmental hazards of aluminum to plants, invertebrates, fish and wildlife	1996a	-	-	Review; results of previously published papers
Sparling and Lowe	Metal concentrations of tadpoles in experimental ponds	1996b	-	-	Exposed through soil
Sparling and Lowe	Metal concentrations in aquatic macrophytes as influenced by soil and acidification	1998	Macrophytes	-	Exposed through soil
Sparling et al.	Responses of amphibian populations to water and soil factors in experimentally-treated aquatic macrocosms	1995	-	-	Exposed through soil
Sparling et al.	Ecotoxicology of aluminum to fish and wildlife	1997	-	-	Review
Staurnes et al.	Reduced carbonic anhydrase and Na-K-ATPase activity in gills of salmonids exposed to aluminium-containing acid water	1984	-	-	Mixture, Al and low pH
Staurnes et al.	Effects of acid water and aluminum on parr-smolt transformation and seawater tolerance in Atlantic salmon, *Salmo salar*	1993	Atlantic salmon, *Salmo salar*	-	Only one exposure concentration; high control mortality (>40%)
Stearns et al.	Occurrence of cyanide-resistant respiration and of increased concentrations of cytochromes in Tetrahymena cells grown with various metals	1978	-	-	Cannot determine effect concentration
Storey et al.	An appraisal of some effects of simulated acid rain and aluminum ions on *Cyclops viridis* (Crustacea, Copepoda) and *Gammarus pulex* (Crustacea, Amphipoda)	1992	Copepod, *Cyclops viridis* Amphipod, *Gammarus pulex*	168 hr LC50=>26,980; LC50=>26,980	Dilution water not characterized
Strigul et al.	Acute toxicity of boron, titanium dioxide, and aluminum nanoparticles to Daphnia magna and Vibrio fischeri	2009	Cladoceran, *Daphnia magna*	-	Inappropriate form of toxicant, nanoparticles

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Sudo and Aiba	Effect of some metals on the specific growth rate of Ciliata isolated from activated sludge	1975	-	-	Pre-exposure to pollutant; isolated from activated sludge
Tabak and Gibbs	Effects of aluminum, calcium and low pH on egg hatching and nymphal survival of *Cloeon triangulifer* McDunnough (Ephemeroptera: Baetidae)	1991	Mayfly, *Cloeon triangulifer*	No effect on hatch success at 100 and pH=5.5	Only two exposure concentrations
Takano and Shimmen	Effects of aluminum on plasma membrane as revealed by analysis of alkaline band formation in internodal cells of *Chara corallina*	1999	Alga, *Chara corallina*	-	Excised cells
Tanaka and Navasero	Aluminum toxicity of the rice plant under water culture conditions	1966	-	-	Species not given
Taneeva	Toxicity of some heavy metals for hydrobionts	1973	Barnacle, *Balanus eburneus*	LC50=240	Text in foreign language
Taskinen et al.	Effect of pH, iron and aluminum on survival of early life history stages of the endangered freshwater pearl mussel, *Margaritifera margaritifera*	2011	Pearl mussel, *Margaritifera margaritifera*	-	Mixture; dilution water is river water
Tease and Coler	The effect of mineral acids and aluminum from coal leachate on substrate periphyton composition and productivity	1984	-	-	Mixture, Al and low pH
Teien et al.	Sodium silicate as alternative to liming-reduced aluminium toxicity for Atlantic salmon (*Salmo salar* L.) in unstable mixing zones	2006b	Atlantic salmon, *Salmo salar*	-	Only one exposure concentration; dilution water not characterized
Terhaar et al.	Toxicity of photographic processing chemicals to fish	1972	-	-	Mixture; no aluminum toxicity data
Thawornwong and Van Diest	Influences of high acidity and aluminum on the growth of lowland rice	1974	Rice	-	Scientific name not provided
Thomas	Effects of certain metallic salts upon fishes	1915	Mummichog, *Fundulus heteroclitus*	36 hr 100% mortality at 2,208; 120 hr 100% mortality at 1,104	Dilution water not characterized; lack of exposure details
Thompson et al.	Concentration factors of chemical elements in edible aquatic organisms	1972	-	-	Review

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Thomsen et al.	Effect of aluminum and calcium ions on survival and physiology of rainbow trout *Salmo gairdneri* (Richardson) eggs and larvae exposed to acid stress	1988	Rainbow trout, *Oncorhynchus mykiss*	25 d LC50=3,800 (soft water); LC50=71,000 (hard water)	Dilution water not characterized; unmeasured chronic exposure
Thorstad et al.	Reduced marine survival of hatchery-reared Atlantic salmon post-smolts exposed to aluminium and moderate acidification in freshwater	2013	Atlantic salmon, *Salmo salar*	-	Only two exposure concentrations; surgically altered test species (outfitted with acoustic transmitters)
Tietge et al.	Morphometric changes in gill secondary lamellae of brook trout (Salvelinus fontinalis) after long-term exposure to acid and aluminum	1988	Brook trout, *Salvelinus fontinalis*	147 d No effect on survival, but decrease growth at 393	Only one exposure concentration
Tipping et al.	Metal accumulation by stream bryophytes, related to chemical speciation	2008	Bryophytes	-	Exposure concentration not known; field accumulation study
Tomasik et al.	The metal-metal interactions in biological systems. Part III. *Daphnia magna*	1995a	Cladoceran, *Daphnia magna*	24 hr 10% mortality at 7,500	High control mortality (10-20%)
Tomasik et al.	The metal-metal interactions in biological systems. Part IV. Freshwater snail *Bulinus globosus*	1995b	Snail, *Bulinus globosus*	96 hr 100% mortality at 10,000; 1% mortality at 3,000	Not North American species
Troilo et al.	Biochemical responses of *Prochilodus lineatus* after 24-h exposure to aluminum	2007	Sabalo, *Prochilodus lineatus*	24 hr Increase in liver GST and increase in gill CAT at 100	Not North American species; lack of details; exposure methods unknown; abstract only
Truscott et al.	Effect of aluminum and lead on activity in the freshwater pond snail *Lymnaea stagnalis*	1995	Snail, *Lymnaea stagnalis*	45 hr Reduce activity at 500	Only two exposure concentrations
Tunca et al.	Tissue distribution and correlation profiles of heavy-metal accumulation in the freshwater crayfish *Astacus leptodactylus*	2013	Crayfish, *Astacus leptodactylus*	-	Field bioaccumulation study: exposure concentration not know; not North American species
Tyler-Jones et al.	The effects of acid water and aluminium on the embryonic development of the common frog, *Rana temporaria*	1989	Common frog, *Rana temporaria*	-	Not North American species; only three exposure concentrations
Umebese and Motajo	Accumulation, tolerance and impact of aluminium, copper and zinc on growth and nitrate reductase activity of *Ceratophyllum demersum* (Hornwort)	2008	Hornwort, *Ceratophyllum demersum*	15 d Decrease dry biomass at 3,000	Only two exposure concentrations

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Upreti et al.	Toxic effects of aluminium and fluoride on planktonic community of the microcosms	2013	Microcosms	-	Only one exposure concentration; dilution water not characterized
van Coillie and Rousseau	Mineral composition of the scales of *Catostomus commersoni* from two different waters: Studies using electron microprobe analysis	1974	White sucker, *Catostomus commersoni*	-	Exposure concentration not known; field accumulation study
van Dam et al.	Impact of acidification on diatoms and chemistry of Dutch moorland pools	1981	-	-	Mixture, Al and low pH
Van Hoecke et al.	Influence of alumina coating on characteristics and effects of SiO2 nanoparticles in algal growth inhibition assays at various pH and organic matter contents	2011	Alga	-	Inappropriate form of toxicant (nanoparticles)
Vazquez et al.	Effects of water acidity and metal concentrations on accumulation and within-plant distribution of metals in the aquatic bryophyte *Fontinalis antipyretica*	2000	Bryophyte, *Fontinalis antipyretica*	-	Exposure concentration not known; field accumulation study
Velzeboer et al.	Release of geosmin by *Anabaena circinalis* following treatment with aluminium sulphate	1995	Cyanobacteria, *Anabaena circinalis*	-	Only two exposure concentrations; dilution water not characterized
Velzeboer et al.	Aquatic ecotoxicity tests of some nanomaterials	2008	-	-	Inappropriate form of toxicant, nanoparticles
Verbost et al.	The toxic mixing zone of neutral and acidic river water: acute aluminum toxicity in brown trout (*Salmo trutta* L.)	1995	Brown trout, *Salmo trutta*	-	Mixture; dilution water is lake water
Vieira et al.	Effects of aluminum on the energetic substrates in neotropical freshwater *Astyanax bimaculatus* (Teleostei: Characidae) females	2013	Two spot astyanax, *Astyanax bimaculatus*	96 hr Decrease T_4 levels and increase T_3 levels at 600	Not North American species; only one exposure concentration
Vinay et al.	Toxicity and dose determination of quillaja saponin, aluminum hydroxide and squalene in olive flounder (*Paralichthys olivaceus*)	2013	Olive flounder, *Paralichthys olivaceus*	-	Injected toxicant
Vincent et al.	Accumulation of Al, Mn, Fe, Cu, Zn, Cd, and Pb by the bryophyte *Scapania undulata* in three upland waters of different pH	2001	Bryophyte, *Scapania undulata*	-	Exposure concentration not known; field accumulation study
Vuorinen et al.	The sensitivity to acidity and aluminum of newly-hatched perch (*Perca fluviatilis*) originating from strains from four lakes with different degrees	1994a	Perch, *Perca fluviatilis*	7 d LC50=>1,000	Not North American species

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Vuorinen et al.	The sensitivity to acidification of pike (*Esox lucius*), whitefish (*Coregonus lavaretus*) and roach (*Rutilus rutilus*): a comparison of field and laboratory studies	1994b	-	-	Review of Vuorineu et al. 1993
Vuorinen et al.	Reproduction, blood and plasma parameters and gill histology of vendace (*Coregonus albula* L.) in long-term exposure to acidity to aluminum	2003	Vendace, *Coregonus albula*	60 d Decrease growth at 168 and pH=5.25; Decrease growth at 213 and pH=4.75	Not North American species; only one exposure concentration
Wakabayashi et al.	Relative lethal sensitivity of two Daphnia species to chemicals	1988	-	-	Text in foreign language
Walker et al.	Effects of low pH and aluminum on ventilation in the brook trout (*Salvelinus fontinalis*)	1988	Brook trout, *Salvelinus fontinalis*	-	Surgically altered fish; only one exposure concentration
Walker et al.	Effects of long-term preexposure to sublethal concentrations of acid and aluminum on the ventilatory response to aluminum challenge in brook trout (*Salvelinus fontinalis*)	1991	Brook trout, *Salvelinus fontinalis*	-	Pre-exposure to pollutant
Wallen et al.	Toxicity to *Gambusia affinis* of certain pure chemicals in turbid waters	1957	Western mosquitofish, *Gambusia affinis*	96 hr LC50=26,919 ($AlCl_3$); LC50=37,062 ($Al_2(SO_4)_3$	Dilution water not characterized; farm pond with high turbidity and poor fish population
Walton et al.	Tissue accumulation of aluminum is not a predictor of toxicity in the freshwater snail, *Lymnaea stagnalis*	2009	Snail, *Lymnaea stagnalis*	steady state not reached	Lack of details; steady state not reached
Walton et al.	Trophic transfer of aluminium through an aquatic grazer-omnivore food chain	2010a	Snail, *Lymnaea stagnalis* Crayfish, *Pacifasticus leniusculus*	-	Bioaccumulation: steady state not reached
Walton et al.	The suitability of gallium as a substitute for aluminum in tracing experiments	2010b	Snail, *Lymnaea stagnalis*	-	Bioaccumulation: steady state not reached
Wang et al.	Optimising indoor phosphine fumigation of paddy rice bag-stacks under sheeting for control of resistant insects	2006	-	-	Not applicable, no aluminum toxicity information
Wang et al.	Toxicity of nanoparticulate and bulk ZnO, Al2O3 and TiO2 to the nematode *Caenorhabditis elegans*	2009	Nematode, *Caenorhabditis elegans*	-	Inappropriate form of toxicant (nanoparticles)
Wang et al.	Synergistic toxic effect of nano-Al2O3 and As(V) on *Ceriodaphnia dubia*	2011	Cladoceran, *Ceriodaphnia dubia*	-	Inappropriate form of toxicant (nanoparticles)

Wilson	Physiological and metabolic costs of acclimation to chronic sub-lethal acid and aluminum exposure in rainbow trout	1996	-	-	Review

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Wilson and Hyne	Toxicity of acid-sulfate soil leachate and aluminum to embryos of the Sydney Rock Oyster	1997	Sydney rock oyster, *Accostrea commercialis*	48 hr EC50 (development)=222; EC50=227	Not North American species
Wilson and Wood	Swimming performance, whole body ions, and gill A1 accumulation during acclimation to sublethal aluminum in juvenile rainbow trout (*Oncorhynchus mykiss*)	1992	Rainbow trout, *Oncorhynchus mykiss*	22 d No effect on mortality, but decrease weight at 31.4	Only one exposure concentration
Wilson et al.	Metabolic costs and physiological consequences of acclimation to aluminum in juvenile rainbow trout (*Oncorhynchus mykiss*). 1: Acclimation specificity, resting physiology, feeding, and growth	1994a	Rainbow trout, *Oncorhynchus mykiss*	34 d 5.5% mortality at 38.1	Only one exposure concentration
Wilson et al.	Metabolic costs and physiological consequences of acclimation to aluminum in juvenile rainbow trout (*Oncorhynchus mykiss*). 2: Gill morphology, swimming performance, and aerobic scope	1994b	Rainbow trout, *Oncorhynchus mykiss*	34 d Decrease # of mucous cells in gills, oxygen consumption rates, swimming performance at 38	Only one exposure concentration
Wilson et al.	Growth and protein turnover during acclimation to acid and aluminum in juvenile rainbow trout (*Oncorhynchus mykiss*)	1996	Rainbow trout, *Oncorhynchus mykiss*	-	Only one exposure concentration; pre-exposure to pollutant
Winter et al.	Influences of acidic to basic water pH and natural organic matter on aluminum accumulation by gills of rainbow trout (*Oncorhynchus mykiss*)	2005	Rainbow trout, *Oncorhynchus mykiss*	-	Bioaccumulation: not renewal or flow-through exposure; high control mortality
Witters	Acute acid exposure of rainbow trout, S*almo gairdneri* Richardson: effects of aluminum and calcium on ion balance and haematology	1986	Rainbow trout, *Oncorhynchus mykiss*	-	Surgically altered test species; only one exposure concentration
Witters et al.	Interference of aluminum and pH on the Na-influx in an aquatic insect *Corixa punctata* (Illig.)	1984	Waterbug, *Corixa punctata*	-	Mixture; low pH and Al
Witters et al.	Ionoregulatory and haematological responses of rainbow trout *Salmo gairdneri* Richardson to chronic acid and aluminum stress	1987a	Rainbow trout, *Oncorhynchus mykiss*	48 hr ~50% mortality at 200	Only one exposure concentration
Witters et al.	Physiological study on the recovery of rainbow trout (*Salmo gairdneri* Richardson) from acid and Al stress	1987b	Rainbow trout, *Oncorhynchus mykiss*	-	Surgically altered test species; only one exposure concentration
Witters et al.	Haematological disturbances and osmotic shifts in rainbow trout, *Oncorhynchus mykiss* (Walbaum) under acid and aluminum exposure	1990a	Rainbow trout, *Oncorhynchus mykiss*	2.5 d ~53% mortality at 200	Only one exposure concentration

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Witters et al.	The effect of humic substances on the toxicity of aluminum to adult rainbow trout, *Oncorhynchus mykiss* (Walbaum)	1990b	Rainbow trout, *Oncorhynchus mykiss*	-	Surgically altered test species
Witters et al.	Adrenergic response to physiological disturbances in rainbow trout, Oncorhynchus mykiss, exposed to aluminum at acid pH	1991	Rainbow trout, *Oncorhynchus mykiss*	-	Surgically altered test species
Witters et al.	Physicochemical changes of aluminum in mixing zones: Mortality and physiological disturbances in brown trout (*Salmo trutta* L.)	1996	Brown trout, *Salmo trutta*	48 hr 60% mortality at 184.0	Only one exposure concentration
Wold	Some effects of aluminum sulfate and arsenic sulfide on *Daphnia pulex* and *Chironomus tentans*	2001	Cladoceran, *Daphnia pulex* Midge, *Chironomus tentans*	-	Inadequate exposure methods; chronic was a static, unmeasured exposure; pre-exposure to pollutant
Wold et al.	Life-history responses of *Daphnia pulex* with exposure to aluminum sulfate	2005	Cladoceran, *Daphnia pulex*	Increased survivorship in clones that were prior-exposed to alum treated lakes	Only three exposure concentrations; dilution water not characterized
Wood and McDonald	The physiology of acid/aluminum stress in trout	1987	Trout	-	Too few exposure concentrations, cannot determine effect concentration
Wood et al.	Blood gases, acid-base status, ions, and hematology in adult brook trout (*Salvelinus fontinalis*) under acid/aluminum exposure	1988a	Brook trout, *Salvelinus fontinalis*	-	Only one exposure concentration; surgically altered test species
Wood et al.	Physiological evidence of acclimation to acid/aluminum stress in adult brook trout (*Salvelinus fontinalis*). 1. Blood composition and net sodium fluxes	1988b	Brook trout, *Salvelinus fontinalis*	10 wk 28% mortality at 77	Only two exposure concentrations
Wood et al.	Physiological evidence of acclimation to acid/aluminum stress in adult brook trout (*Salvelinus fontinalis*). 2. Blood parameters by cannulation	1988c	Brook trout, *Salvelinus fontinalis*	-	Only one exposure concentration; surgically altered test species
Wood et al.	Whole body ions of brook trout (*Salvelinus fontinalis*) alevins: responses of yolk-sac and swim-up stages to water acidity, calcium, and aluminum, and recovery effects	1990a	Brook trout, *Salvelinus fontinalis*	-	Lack of details; cannot determine effect concentration

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Wood et al.	Effects of water acidity, calcium, and aluminum on whole body ions of brook trout (*Salvelinus fontinalis*) continuously exposed from fertilization to swim-up: a study by instrumental neutron activation analysis	1990b	Brook trout, *Salvelinus fontinalis*	-	Lack of details; cannot determine effect concentration
Woodburn et al.	Accumulation and toxicity of aluminium-contaminated food in the freshwater crayfish, *Pacifastacus leniusculus*	2011	Crayfish, *Pacifastacus leniusculus*	-	Dietary exposure
Wooldridge and Wooldridge	Internal damage in an aquatic beetle exposed to sublethal concentrations of inorganic ions	1969	Aquatic beetle, *Tropistermus lateralis nimbatus*	14 d Change the body fat at 26,981	Only one exposure concentration
Wren et al.	Examination of bioaccumulation and biomagnification of metlas in a Precambrian Shield Lake	1983	-	-	Field exposure, exposure concentrations not measured adequately
Wu et al.	QTLs and epistasis for aluminum tolerance in rice (*Oryza sativa* L.) at different seedling stages	2000	Rice, *Oryza sativa*	-	Only one exposure concentration; difficult to determine effect concentration
Wu et al.	Aluminum nanoparticle exposure in L1 larvae results in more severe lethality toxicity than in L4 larvae or young adults by strengthening the formation of stress response and intestinal lipofuscin accumulation in nematodes	2011	-	-	Inappropriate form of toxicant, nanoparticles
Yang and van den Berg	Metal complexation by humic substances in seawater	2009	-	-	Not applicable; no aluminum toxicity data
Yang et al.	Identification of aluminum-responsive proteins in rice roots by a proteomic approach: Cysteine synthase as a key player in Al response	2007	Rice, *Oryza sativa*	3 d Decreased root length at 53,960	Only two exposure concentrations
Youson and Neville	Deposition of aluminum in the gill epithelium of rainbow trout (*Salmo gairdneri* Richardson) subjected to sublethal concentrations of the metal	1987	Rainbow trout, *Oncorhynchus mykiss*	-	Surgically altered test species
Ytrestoyl et al.	Swimming performance and blood chemistry in Atlantic salmon spawners exposed to acid river water with elevated aluminium concentrations	2001	Atlantic salmon, *Salmo salar*	-	Only one exposure concentrations; dilution water not characterized; no true control group
Zaifnejad et al.	Aluminum and water stress effects on growth and proline of sorghum	1997	Sorghum, *Sorghum bicolor*	-	Inappropriate form of toxicant (aluminum potassium sulfate)
Zaini and Mercado	Calcium-aluminum interaction on the growth of two rice cultivars in culture solution	1984	Rice	-	Scientific name not provided

NMED Exhibit 75

Author	Title	Date	Organism(s)	Concentration (µg/L)	Reason Unused
Zarini et al.	Effects produced by aluminum in freshwater communities studied by "enclosure" method	1983	-	-	Mixed species exposure; no species names provided; dilution water not characterized
Zhou and Yokel	The chemical species of aluminum influences its paracellular flux across and uptake into Caco-2 cells, a model of gastrointestinal absorption	2005	-	-	Excised cells, in vitro
Zhu et al.	Comparative toxicity of several metal oxide nanoparticle aqueous suspensions to Zebrafish (*Danio rerio*) early developmental stage	2008	Zebrafish, *Danio rerio*	-	Inappropriate form of toxicant, nanoparticles
Zhu et al.	Acute toxicities of six manufactured nanomaterial suspensions to *Daphnia magna*	2009	Cladoceran, *Daphnia magna*	-	Inappropriate form of toxicant (nanoparticles)

Appendix L EPA's MLR Model Comparison of DeForest et al. (2018b) Pooled and Individual-Species Model Options

NMED Exhibit 75

Background

The EPA conducted a comparison of the DeForest et al. (2018b) pooled MLRs (fish and invertebrate data pooled) and individual-species MLRs (fish and invertebrates regressed separately) in order to determine which approach would be most appropriate for use in the Final 2018 Aluminum Aquatic Life AWQC. This appendix describes the EPA's analysis.

DeForest et al. (2018b) updated the individual-species MLR models to incorporate new toxicity data, with the addition of nine *Ceriodaphnia dubia* and nine *Pimephales promelas* toxicity tests under water chemistry conditions that were largely not addressed in the 2017 EPA Draft Aluminum AWQC or the DeForest et al. (2018a) publication. These toxicity tests were conducted by Oregon State University (OSU) and provided to the EPA and DeForest et al. as a courtesy in 2018. These new toxicity tests included fish and invertebrate testing under higher DOC concentration, higher hardness, and slightly higher pH conditions that were not included in the original publication and MLR database (DeForest et al. 2018a). DeForest et al. provided the MLR analyses, using both the new and older datasets in an memorandum to the EPA (DeForest et al. 2018b).

In addition to the analyses described in this appendix, the EPA subjected the DeForest et al. (2018b) memorandum to independent, external expert peer review in 2018. Several of the external peer reviewers noticed trends in the data and criteria derived using the pooled model. (See EPA's website for the Aluminum AWQC [https://www.epa.gov/wqc/aquatic-life-criteria-aluminum] for supporting documentation including the external peer review reports and EPA's responses to the external peer reviewer comments).

The conditions addressed in these new toxicity tests expanded the water quality conditions for model development (**Table L-1**). All conditions and effect concentrations for the 32 *Ceriodaphnia dubia* and 31 *Pimephales promelas* tests are presented in **Table L-2**.

Table L-1. Range of Water Quality Conditions Tested for MLR Model Development.

		Number of test	Range of Water Quality Conditions Tested		
			DOC (mg/L)	pH	Total Hardness (mg/L as $CaCO_3$)

DeForest et al. (2018b) developed a pooled MLR model that combined the two datasets, fish and invertebrate, with common slopes for the multiple linear regression test parameters. Deforest et al. (2018b) provided the EPA with a memorandum that presented four new MLR models: 1) a *C. dubia* Individual-species MLR Model; 2) *C. dubia* Pooled MLR Model (*C. dubia* and *P. promelas* data pooled, but using *C. dubia* intercept); 3) *P. promelas* Individual-species MLR Model; and 4) *P. promelas* Pooled MLR Model (*C. dubia* and *P. promelas* data pooled, but using *P. promelas* intercept).

Note: the species-specific intercepts in the pooled model account for the difference in sensitivity of the two test organisms, but slopes for each test parameter are the same. To incorporate these models into AWQC, the EPA evaluated the most appropriate approach to normalize the freshwater aluminum toxicity data by comparing model performance. The DeForest et al. reported models from their 2018 memorandum were:

Invertebrate-focused models

C. dubia Individual-species MLR Model:

$$C.dubia\ EC_{20} = e^{\left[-32.523+[0.597\times\ln(DOC)]+[2.089\times\ln(hard)]+(8.802\times pH)-(0.491\times pH^2)-[0.230\times pH:\ln(hard)]\right]}$$

C. dubia Pooled MLR Model (*C. dubia* and *P. promelas* data pooled, but using *C. dubia* intercept):

$$C.dubia\ EC_{20} = e^{[-8.555+[0.592\times\ln(DOC)]+[2.188\times\ln(hard)]+(1.998\times pH)-[0.268\times pH:\ln(hard)]]}$$

Vertebrate-focused models

P. promelas Individual-species MLR Model:

$$P.promelas\ EC_{20} = e^{[-7.371+[2.209\times\ln(DOC)]+[1.862\times\ln(hard)]+(2.041\times pH)-[0.232\times pH:\ln(hard)]-[0.261\times pH:\ln(DOC)]]}$$

P. promelas Pooled MLR Model (*C. dubia* and *P. promelas* data pooled, but using *P. promelas* intercept):

$$P.promelas\ EC_{20} = e^{[-7.550+[0.592\times\ln(DOC)]+[2.188\times\ln(hard)]+(1.998\times pH)-[0.268\times pH:\ln(hard)]]}$$

The EPA Analysis of the DeForest et al. (2018b) MLR Models

The EPA analyzed model performance to determine if it was more appropriate to normalize the freshwater toxicity data using the two individual models applied to vertebrate and invertebrates separately or to use the common pooled slope model to normalize all the data regardless of taxonomy. As DeForest et al. (2018b) suggested in the memorandum, both the pooled model and the individual models performed similarly when comparing observed versus predicted values, with predicted values within a factor of two being a benchmark to determine performance. **Figure L-1** show that 31/32 (97%) of the predicted values for the *C. dubia* tests for both MLR models were within a factor of two (DeForest et al. 2018b). The individual model for *P. promelas* had a similar level of performance with 30/31 (97%) of the tests within a factor of two, while the pooled model was only slightly less with 29/31 (94%) of the predicted values within a factor of two of the observed values (**Figure L-2**) (DeForest et al. 2018b).

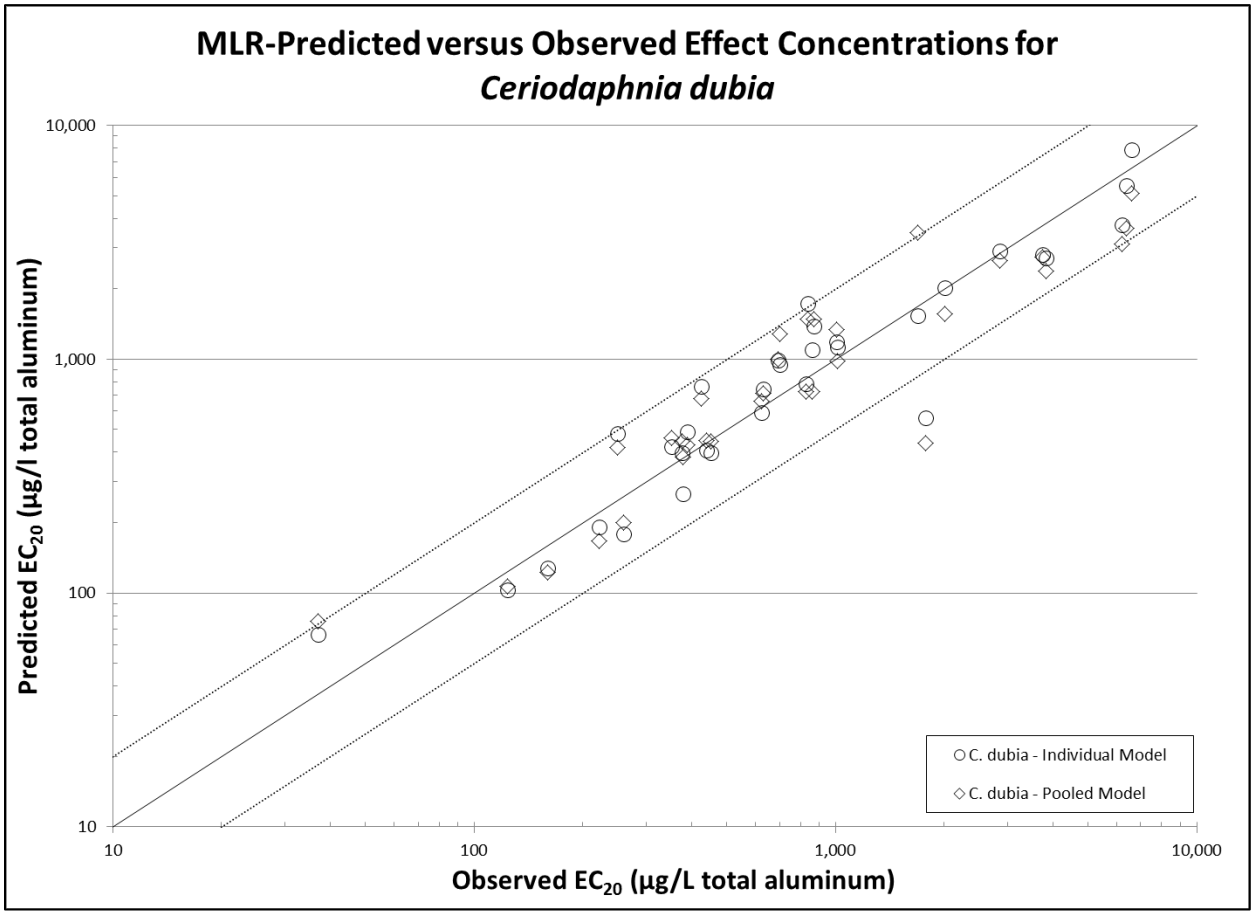

Figure L-1. Predicted versus Observed Values for the *C. dubia* MLR models.
(The solid diagonal line represents a 1:1 relationship while the dotted diagonal lines represent a factor of two).

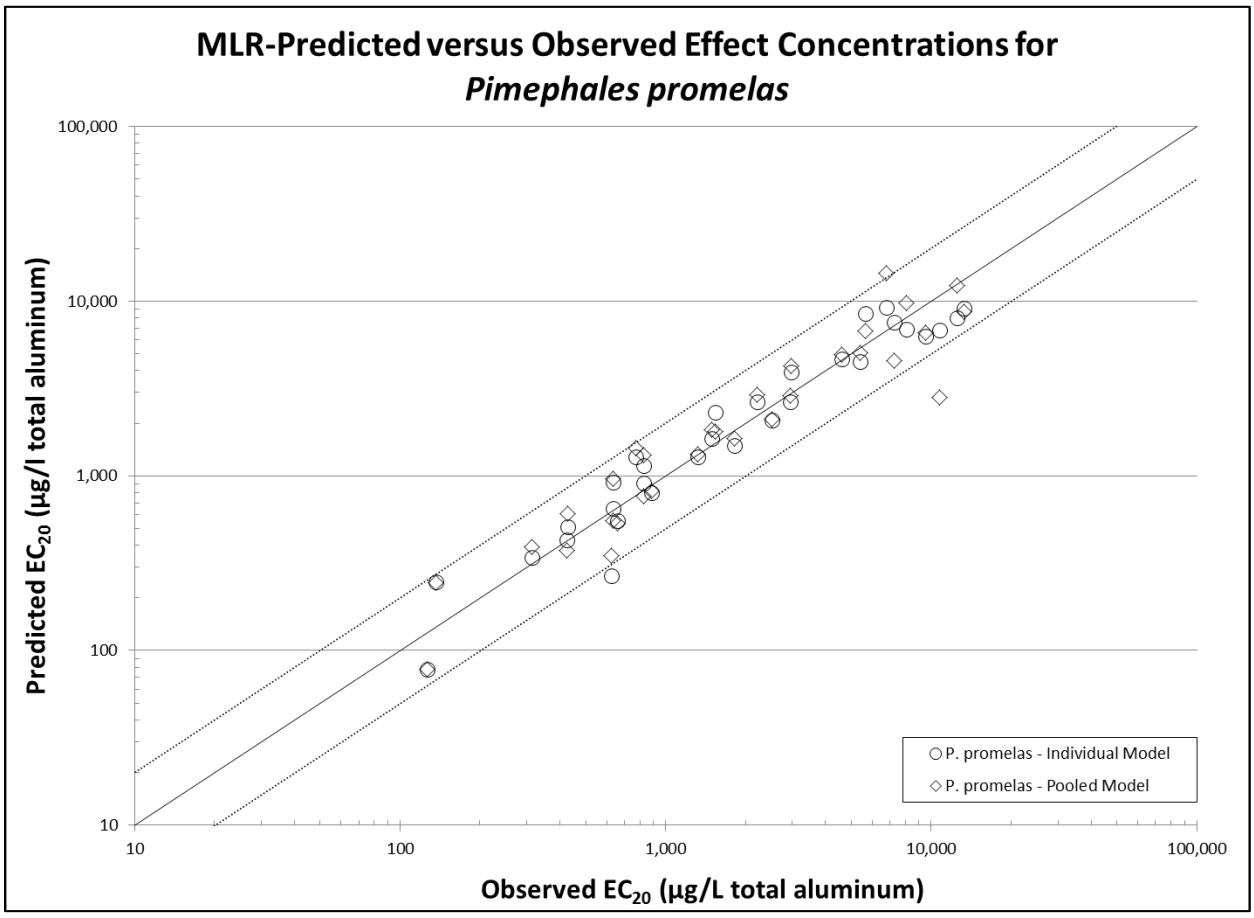

Figure L-2. Predicted versus Observed Values for the *P. promelas* MLR models.
(The solid diagonal line represents a 1:1 relationship while the dotted diagonal lines represent a factor of two).

In order to refine the analysis, the EPA looked at the residuals (observed value minus the predicted value) to determine if one model fit the data better. This analysis is similar to the approach in DeForest et al. (2018a). The residuals were plotted against each individual water quality parameter (pH, total hardness and DOC) to determine if either model generated a biased predicted value. All parameters were natural log transformed for clarity of presentation except pH.

The results of these plots revealed that the *C. dubia* pooled MLR model was over predicting test concentrations (higher predicted EC_{20}s than observed values) as pH increased, and under predicting test concentrations as DOC and total hardness increased (lower predicted EC_{20}s than observed values) (**Figure L-3**, **Figure L-4** and **Figure L-5**). Conversely, the *C. dubia* individual-species MLR model showed no trends in the residuals over any of the test parameters.

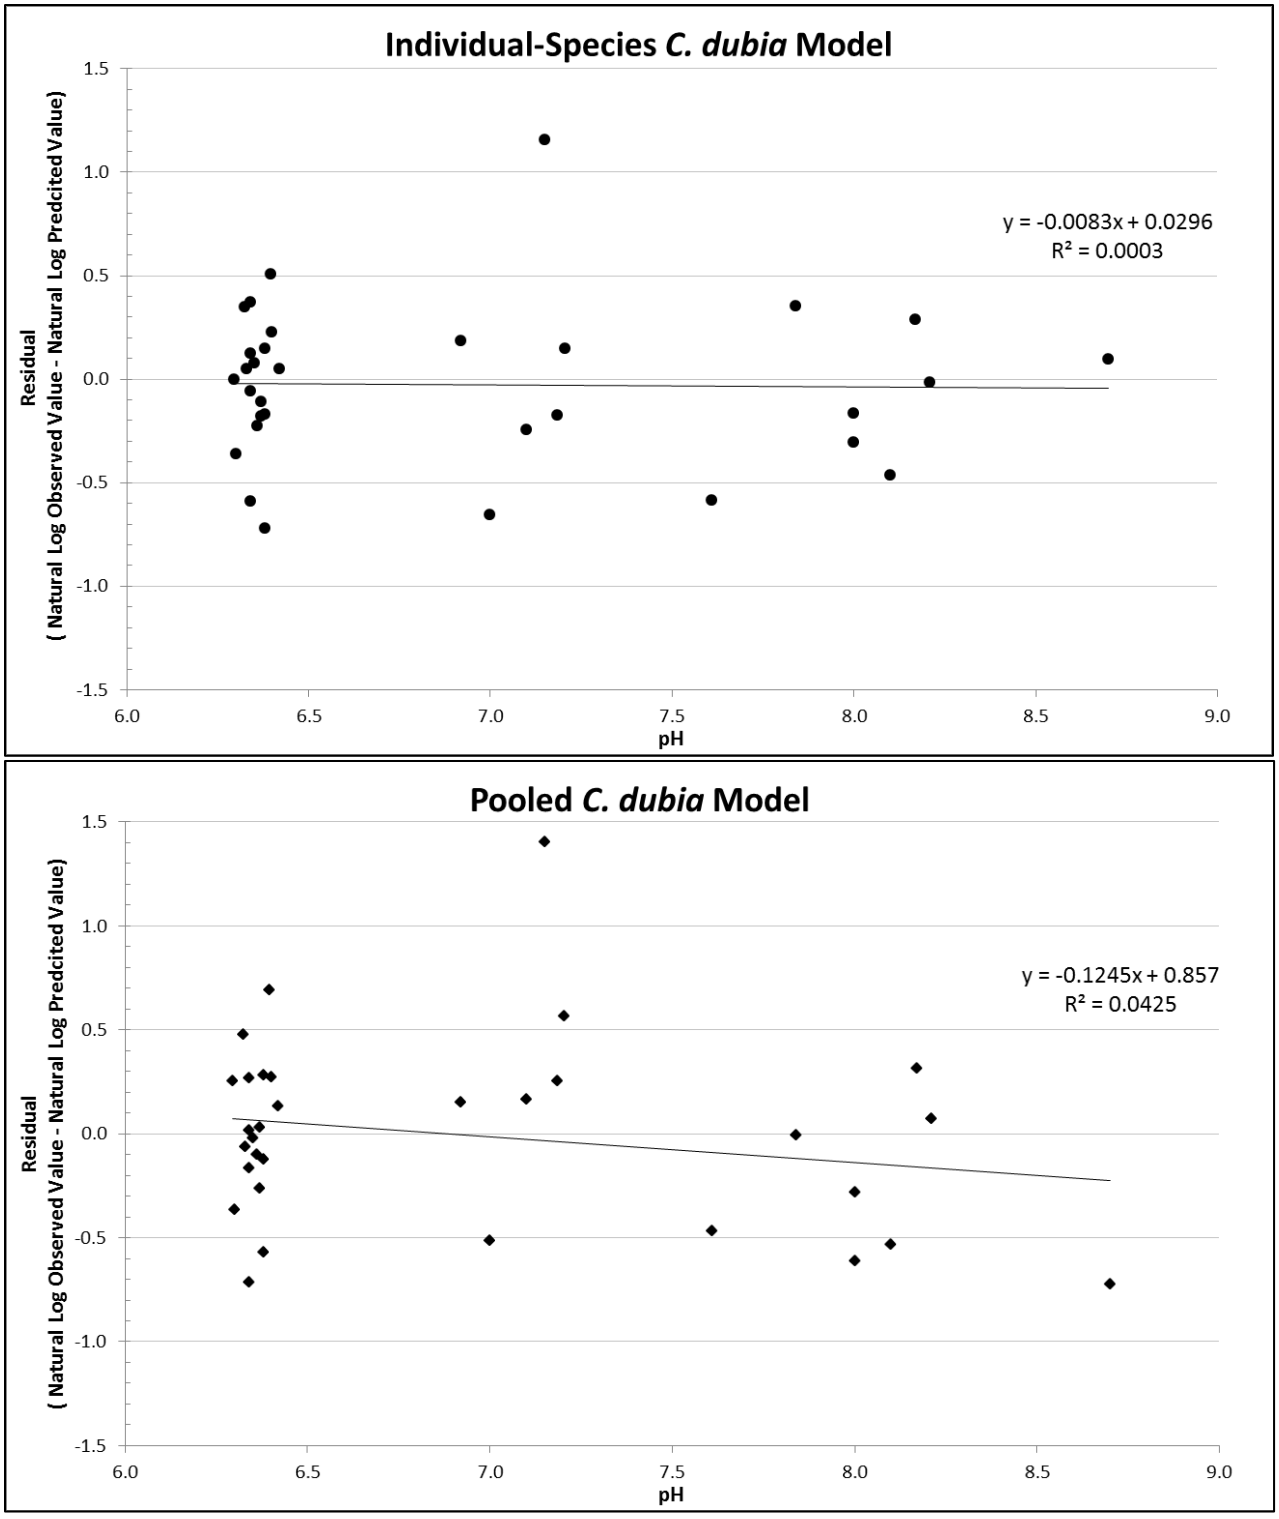

Figure L-3. Residual Plots for the *Ceriodaphnia dubia* models versus pH.

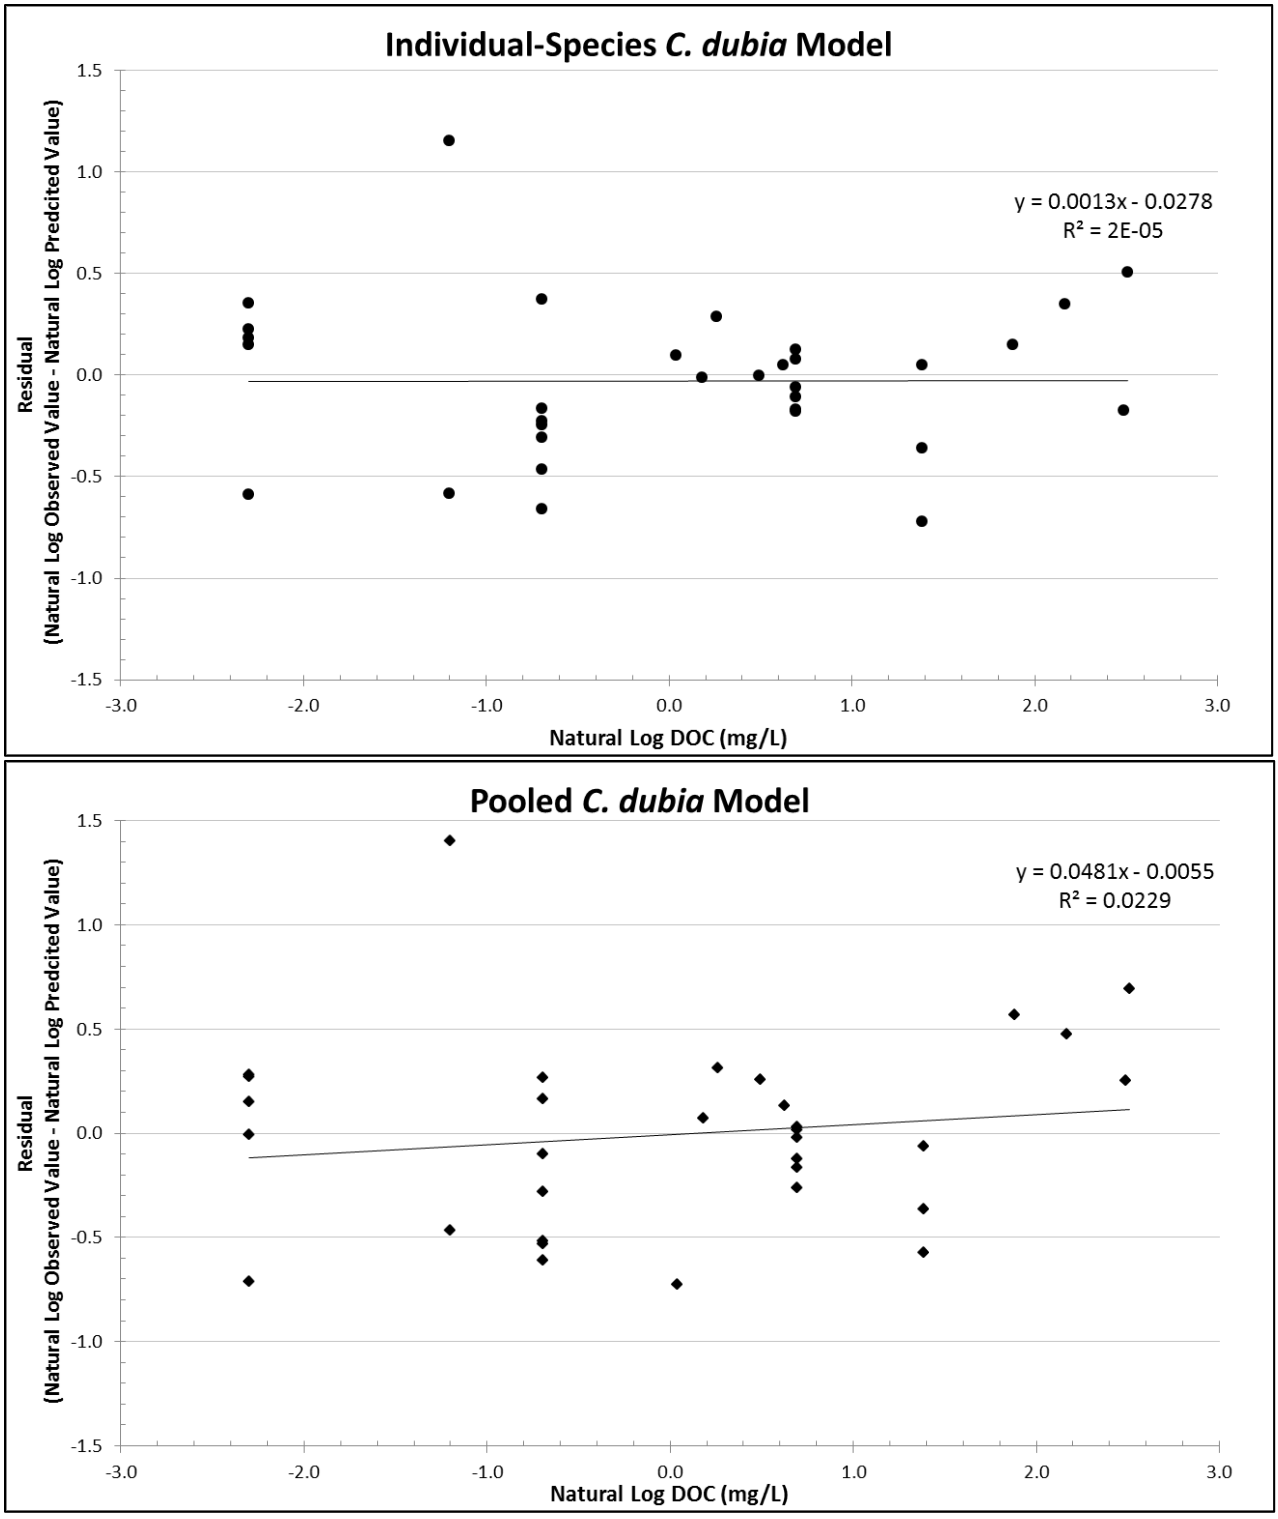

Figure L-4. Residual Plots for the *Ceriodaphnia dubia* models versus DOC

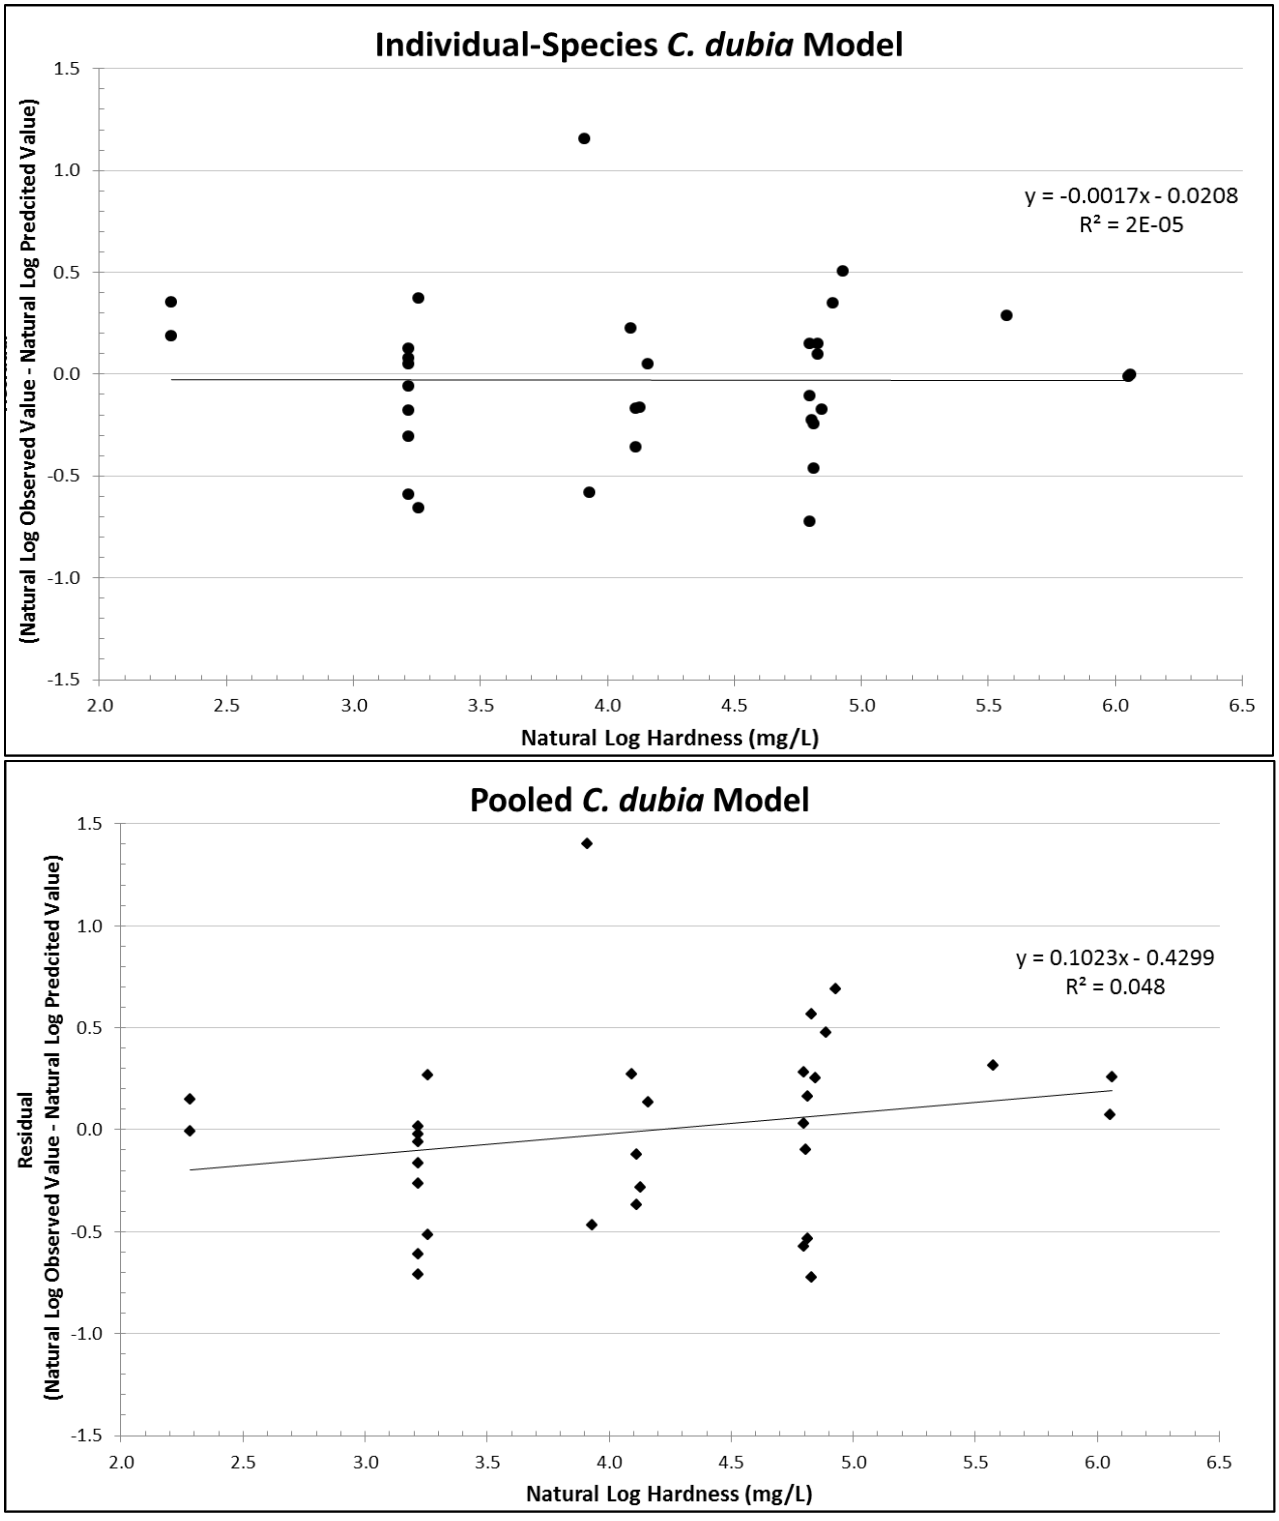

Figure L-5. Residual Plots for the *Ceriodaphnia dubia* models versus Total Hardness.

Similarly, a comparison of the residuals plots for the individual-species *P. promelas* showed no trends in the residuals over any of the test parameters (**Figure L-6**, **Figure L-7** and

Figure L-8). Likewise, there were also trends in the residuals for the pooled *P. promelas* MLR model. The predicted values were over predicting (higher predicted EC_{20}s than observed) as total hardness and DOC increased and under predicting (lower predicted EC_{20}s than observed) as pH increased.

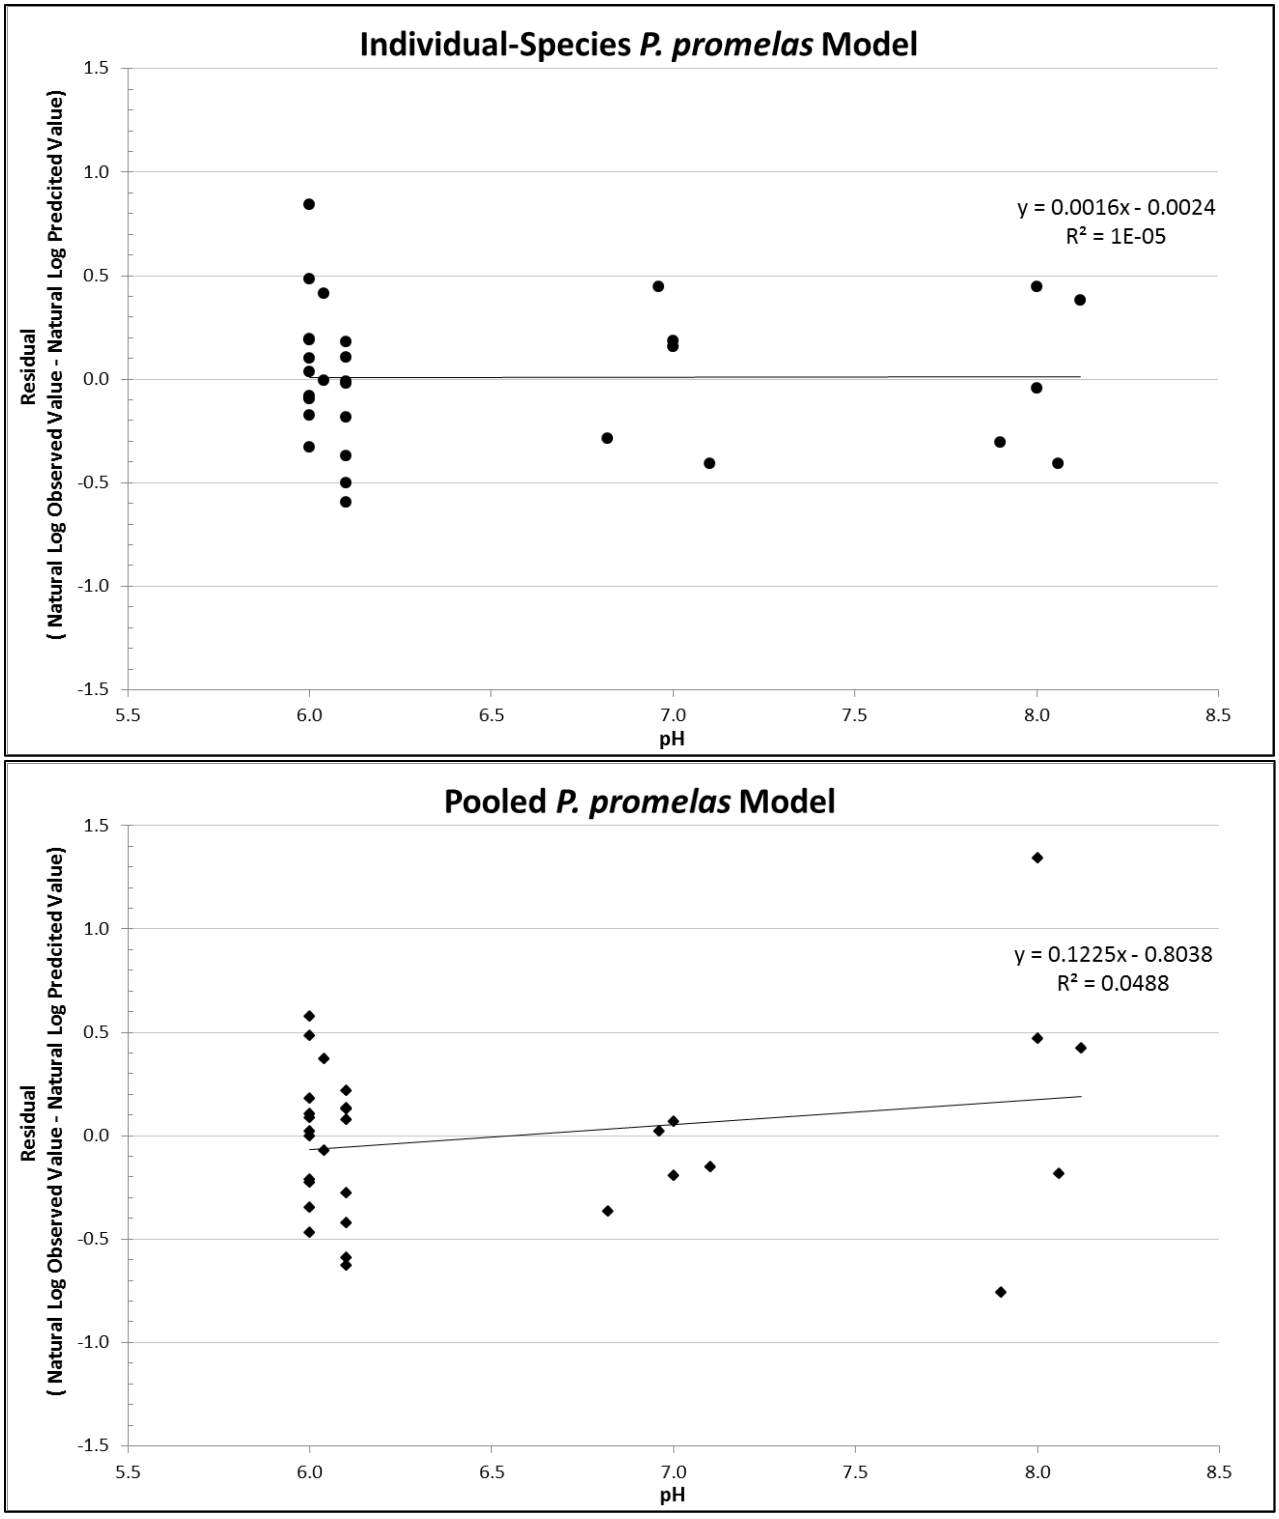

Figure L-6. Residual Plots for the *Pimephales promelas* models versus pH.

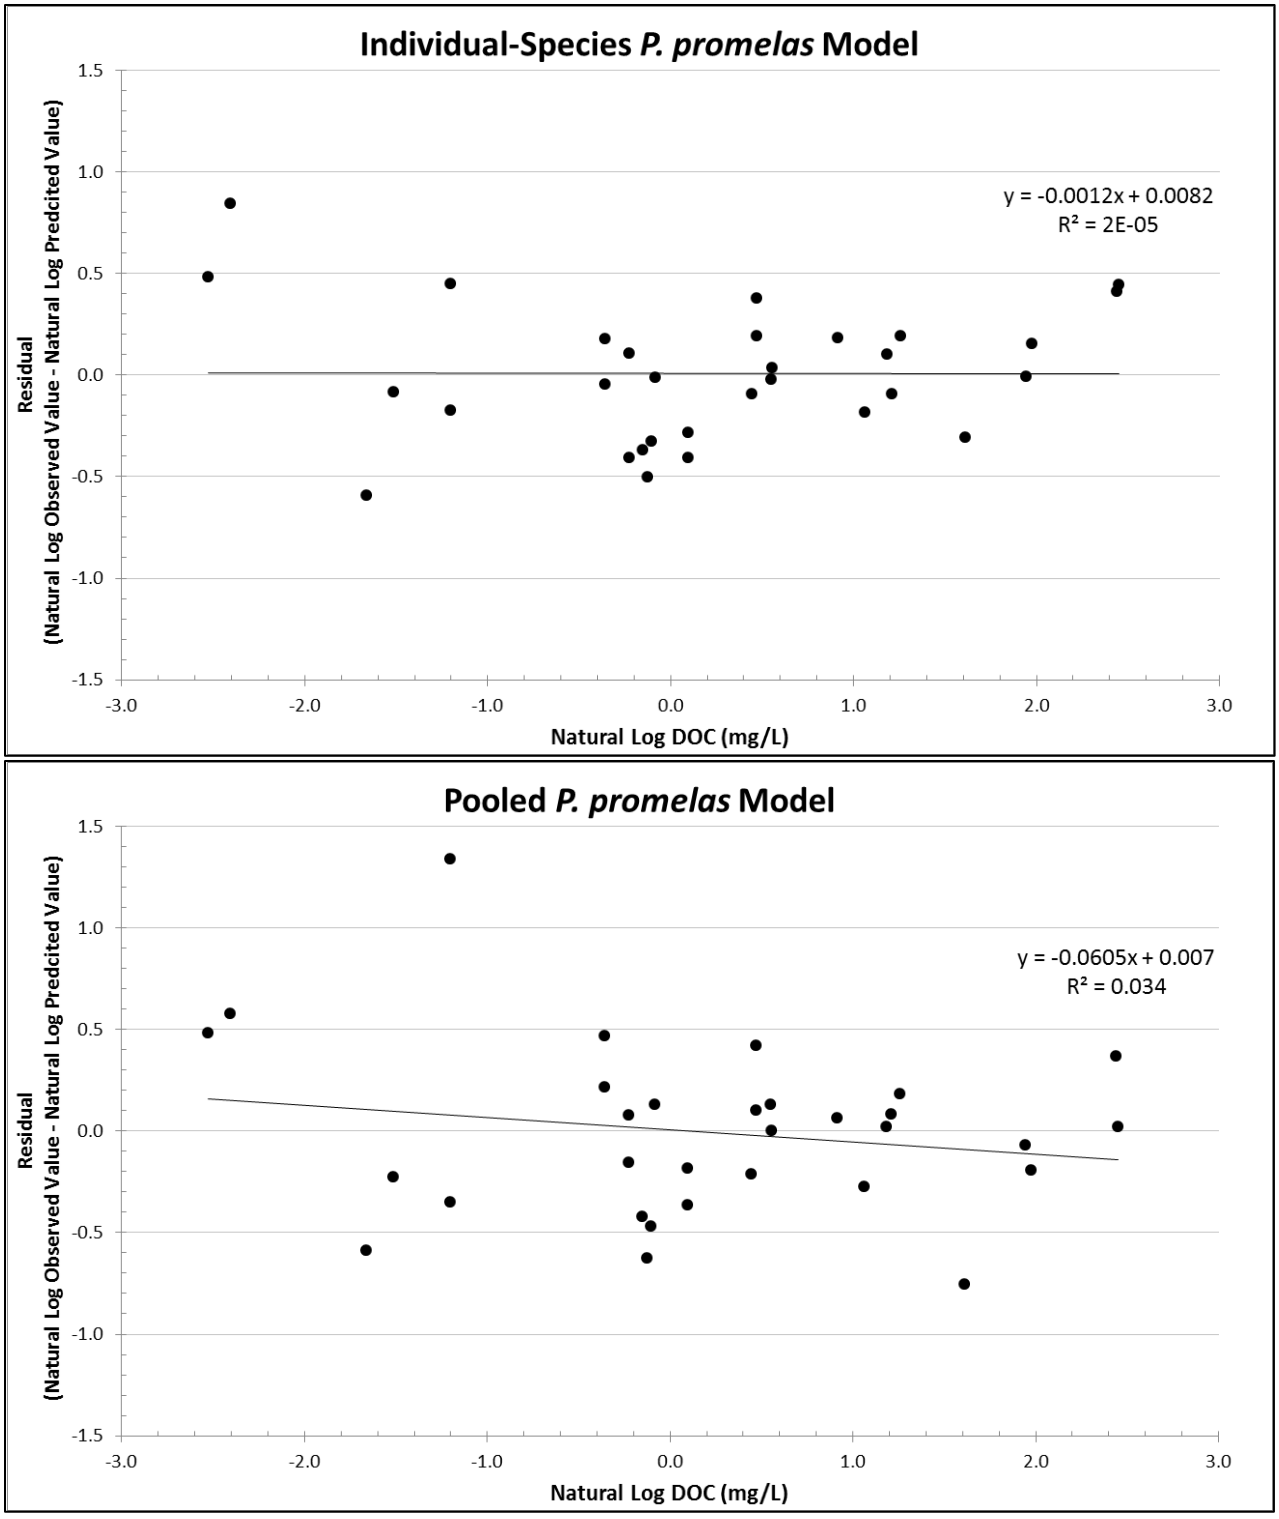

Figure L-7. Residual Plots for the *Pimephales promelas* models versus DOC.

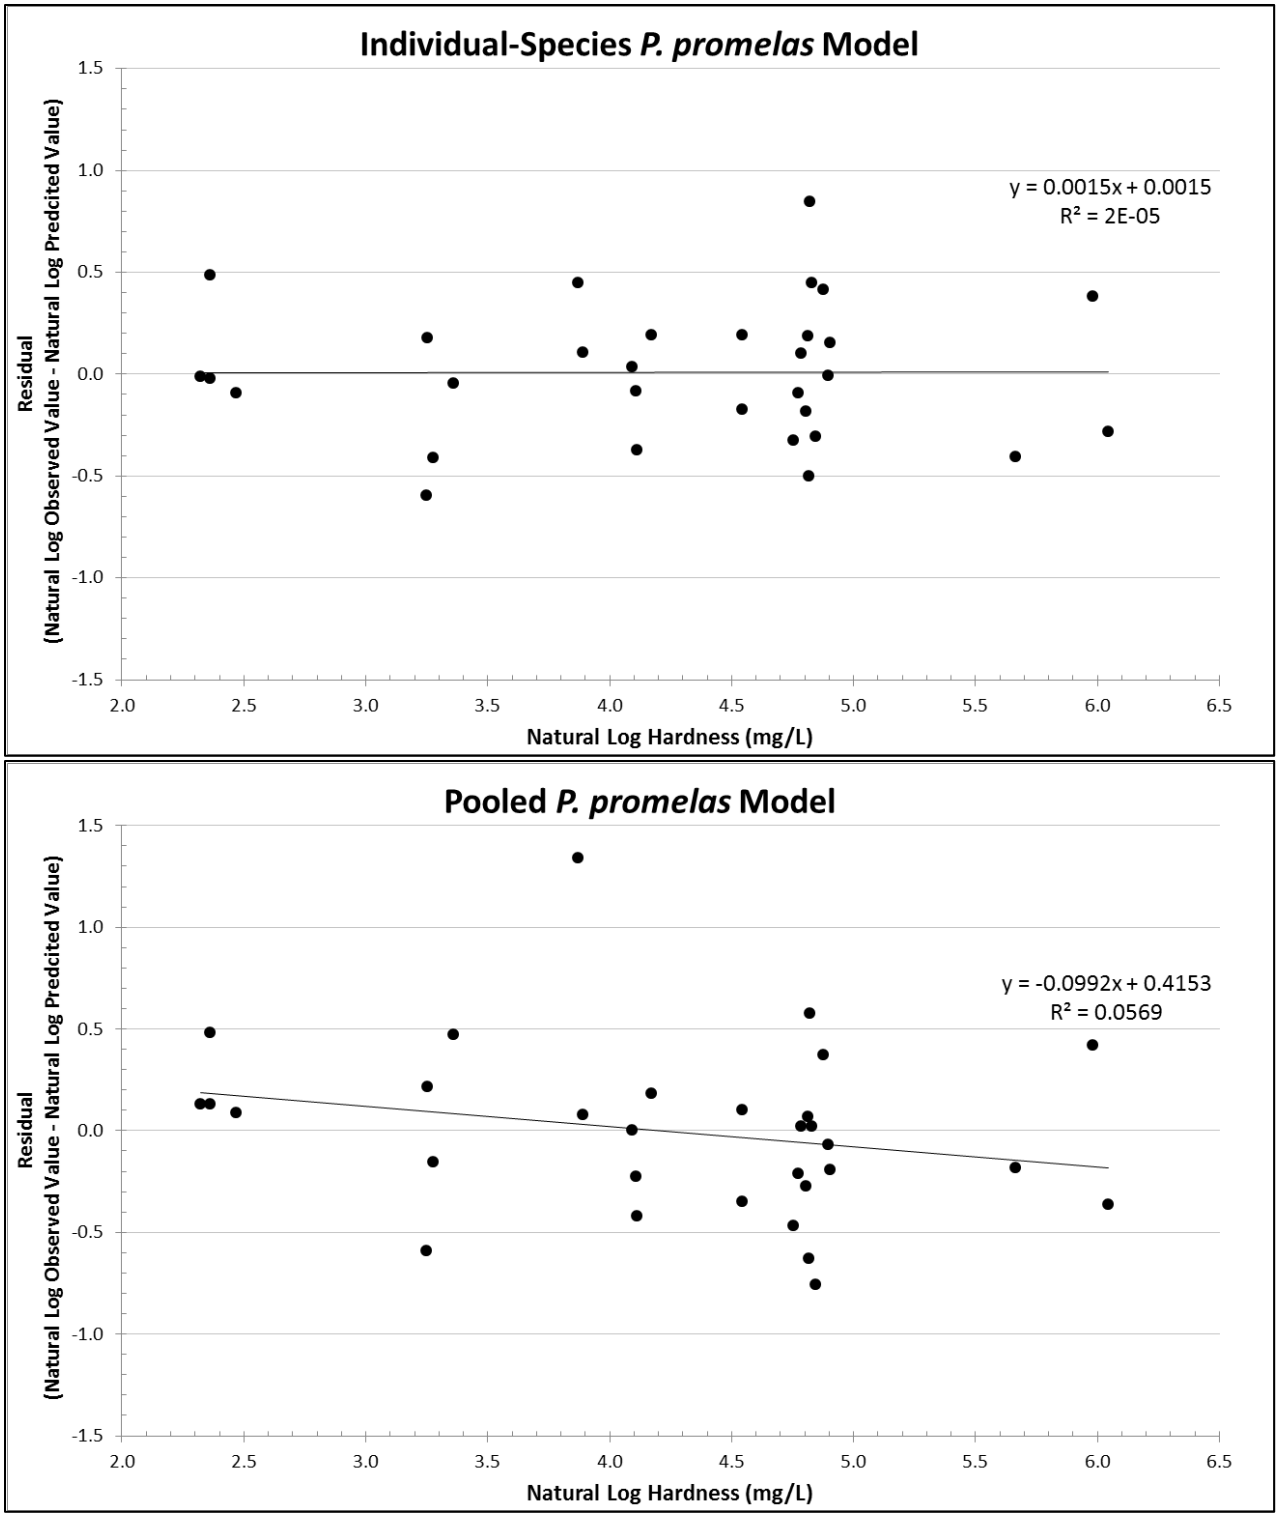

Figure L-8. Residual Plots for the *Pimephales promelas* models versus Total Hardness.

In addition to these residual trends for the pooled model, a poorer fit for the pooled model is indicated by higher standard deviations of the residuals than for the individual-species models.

For the natural logarithm transformed observed and predicted EC_{20}s, the residual standard deviation for the *C. dubia* dataset was 0.45 for the pooled model versus 0.38 for the individual-species model (18% higher). For *P. promelas*, the difference was 0.41 versus 0.32 (27% higher). The statistical significance of this poorer fit was evaluated using an F-test on the merged data across both species. The residual sum-of-squares for the pooled models (SS=11.618, df=57) was reduced 33% by applying the individual-species models (SS=7.814, df=51). For the null hypothesis of no improvement from applying the individual-species models, this translates into a F statistic of 4.14 with 6 and 51 degrees of freedom, rejecting the null hypothesis at $p<0.002$.

Based on these analyses, the EPA decided to use the updated individual-species MLR models presented in DeForest et al. (2018b) to normalize the freshwater aluminum toxicity data in developing the Final 2018 Aluminum Aquatic Life AWQC.

NMED Exhibit 75

Department is not proposing a change in PCBs criteria; however, the Department proposes moving the criteria to fit alphabetically within organic pollutants in Table 20.6.4.900(J)(1) NMAC.

In addition to the proposed changes to the aquatic life criteria described above, the Department proposes spelling corrections or completion of missing chemical abstract service numbers for several pollutants.

3. Numeric Criteria Not Proposed for Adoption

a. EPA's Recommended Aluminum Criteria

The Department does not propose adopting the EPA's recommended acute and chronic aquatic life criteria for aluminum as a replacement of the current hardness-based water quality standard. In 2018, EPA published updated aquatic life criteria for aluminum, based on a multiple linear regression ("MLR") model that takes into account the effects of ambient water quality on the bioavailability of aluminum to freshwater aquatic life (**EXHIBIT 42**). The MLR is based on the observed interactions of aluminum, pH, hardness, and dissolved organic carbon ("DOC") in a compilation of toxicity tests consisting of *P. promelas* and *C. dubia.* The EPA found these three parameters have the most significant influence on the toxicity of aluminum. Development of the MLR model included a range of water quality conditions to capture the variability of ambient conditions: pH (6.0-8.7), hardness (9.8 to 428 mg/L), and DOC (0.08 to 12.3 mg/L). The EPA extrapolated the model to expand its applicability but cautions against using the MLR model for conditions outside the range of empirical testing, for pH in particular. The Department has concerns regarding EPA's linear regression extension of the model for pH ranges 5.0 to 6.0 and 8.7 to 10.5. Also of concern, the EPA MLR model guidance acknowledges temperature as a factor in aluminum solubility yet does not include temperature in the MLR model or explain why it did not use temperature.

Although the aluminum MLR model represents the best available science for calculating appropriate aluminum instantaneous water quality criteria ("IWQC") for freshwater aquatic life, the Department proposes retaining the current hardness-based standard. The Department cannot implement the MLR model effectively since the Department does not have a way to determine the MLR model input value of DOC with confidence. The New Mexico Department of Health Scientific Laboratory Division ("SLD") does not currently perform DOC analysis. SLD is building capacity for DOC analysis; however, the Department is uncertain of the implementation date. The Department has considered contract labs for DOC analysis but does not have the resources required for collection at every site. Recognizing that not all states or tribes can collect all required input parameters to the MLR model, the EPA implementation guidance (**EXHIBIT 43**) suggests using either default or ecoregional values for missing site-specific parameters. However, EPA cautions that the approach may be too general for areas of complex geology. The Department considers New Mexico geologically diverse. Default or ecoregional DOC values are unlikely to capture variability across the state or at a specific location under different flow conditions. The EPA provides ecoregional DOC values in its Draft Technical Support Document: Recommended Estimates for Missing Water Quality Parameters for Application in EPA's Biotic Ligand Model (Table 18, **EXHIBIT 44**) based on DOC results from EPA's National Rivers and Streams Assessment. However, the dataset for New Mexico consists of single site visits to relatively few waterbodies. For example, the entire eight-digit Hydrologic Unit Code ("HUC") representing the Pecos Headwaters watershed (13060001) contains four data points from 2008-2014 representing two ecoregions. The dataset does not represent many other areas of the state.

The Department compared criteria calculated from the MLR model and New Mexico's current hardness-based criteria (**EXHIBIT 45**). Overall, the MLR model results are more

conservative (criteria are lower) within the range of DOC values expected for New Mexico's surface waters. At very low hardness, approximately 50 mg/L or less, both the chronic and acute hardness-based criteria are lower than those from the MLR model. The Department completed an analysis of the difference between the current hardness-based criteria and the MRL model criteria for total recoverable aluminum results collected during the 2017-2018 Upper Rio Grande watershed survey. The Department divided each total recoverable aluminum result by the IWQC calculated from the required input parameters, resulting in an exceedance ratio for each sample. The Department used a DOC concentration of 0.7 mg/L, the average of the recommended DOC concentrations for Omernik Level III ecoregions 21 and 22, for the MLR model input value. Exceedance ratios greater than one indicate a sampling result higher than the applicable IWQC. **EXHIBIT 46** graphs the difference between the MLR model exceedance ratio and the hardness-based exceedance ratio. Values greater than zero indicate the MLR model criterion is more stringent than the hardness-based criterion. These results confirm that hardness-based criteria are more stringent than those of the MLR model at lower hardness concentrations. The largest exceedance ratio differences between the hardness-based calculation and MLR model also occur at low hardness. This analysis identified 42 acute and 111 chronic exceedances using the hardness-based calculation, and 59 acute and 110 chronic exceedances using the MLR model. Overall, the hardness-based calculation resulted in more exceedances at lower hardness values and the MLR model resulted in more exceedances at higher hardness values (**EXHIBIT 47**).

The implementation of the 2018 EPA aluminum ambient water quality criteria ("AWQC") is further complicated because the guidance does not address the distinction between the bioavailable species of aluminum and those forms that are geologically based and present in natural waters as suspended sediment. The EPA acknowledges this challenge in its Final Aquatic

Life Ambient Water Quality Criteria for Aluminum 2018 guidance (**EXHIBIT 42**): "…natural water samples may also contain other species of aluminum that are not biologically available (i.e., suspended particles, clays, and aluminosilicate minerals)…This creates uncertainty because the total recoverable aluminum concentrations measured in natural waters may overestimate the potential risks of toxicity to aquatic organisms." Further, the EPA states that new analytical methods are needed, and it expects ongoing research to improve accurate measurement of toxic aluminum. For total recoverable aluminum analyses, the Department currently filters high turbidity samples with a 10-micron filter to remove terrestrial sediment. However, the infiltration of clay and some silt can still occur since these particles may pass through the filter. Adopting the MLR model may require refinement of this process to better discriminate bioavailable aluminum to prevent unnecessary, and potentially costly, impairment listings in high turbidity areas.

The Department concludes that it does not have adequate information to implement the 2018 aluminum aquatic life criteria with confidence. The Department will continue to evaluate the adoption of the revised aluminum criteria and expects to begin sampling and analysis of DOC. The Department estimates an annual cost of 8,500 Work-Time Units ("WTUs") per year for DOC, which is approximately 5% of SWQB's fixed annual budget with SLD. This extra cost reduces the amount the Department can allocate to sampling for other pollutants. Costs may also increase for NPDES permittees to account for additional monitoring.

b. EPA Section 304(a) Arsenic Criteria

The Department does not propose the adoption of the 2002 EPA recommended human health criterion for arsenic. The State documented the reasoning behind the current human health-organism only criterion of 9.0 µg/L in the Statement of Reason from the 2005 Triennial Review (**EXHIBIT 48**). The State adopted a New Mexico-specific criterion using arsenic water column

Draft Technical Support Document:

Implementing the 2018 Recommended Aquatic Life Water Quality Criteria for Aluminum

NMED Exhibit 77

Notice: This question and answer (Q&A) document is intended to support states and authorized tribes wishing to adopt and implement the U.S. Environmental Protection Agency's (EPA's) recommended Clean Water Act (CWA) Section 304(a) *Final Aquatic Life Ambient Water Quality Criteria for Aluminum*. Pursuant to 40 CFR 131.11(b), when establishing numeric criteria designed to protect designated uses, states and authorized tribes should base those criteria on (i) 304(a) guidance, (ii) 304(a) guidance modified to reflect site-specific conditions, or (iii) other scientifically defensible methods. States and authorized tribes may also consider other approaches that are not described in this document.

EPA may update this Q&A document as new information becomes available. Also, although this document cites statutes and regulations that contain requirements applicable to water quality standards, it does not impose legally binding requirements on EPA, states, authorized tribes, other regulatory authorities, or the regulated community. EPA, states, authorized tribes, and other decision makers retain the discretion to adopt approaches on a case-by-case basis that differ from those recommended in this document, as appropriate and consistent with statutory and regulatory requirements. In addition to this document, EPA has posted its Response to Comments on the 2017 Draft Aluminum Ambient Water Quality Criteria document and its responses to external peer review reports of the toxicity assessments used to model bioavailability; these documents can be found at the Agency's website for aluminum criteria: https://www.epa.gov/wqc/aquatic-life-criteria-aluminum.

NMED Exhibit 77

Table of Contents

Introduction 6

Section 1: Adopting the 2018 Recommended Aquatic Life Water Quality Criteria for Aluminum into State or Tribal Water Quality Standards 8

1.1. What are EPA's recommended criteria for aluminum? 8
1.2. What flexibility does a state or authorized tribe have when adopting EPA's recommended aluminum criteria into its state or tribal water quality standards, and what are the advantages and potential challenges of each approach? 9
1.3. If a state or authorized tribe adopts a methodology, what additional information should be included in their regulation or implementation documents to support such an approach? 13
1.4. If the recommended aluminum criteria are adopted in the form of the Criteria Calculator, how will the public and entities implementing the criteria know what numeric values represent the site-specific criteria for a given waterbody at a given time? 14
1.5. How does the adoption of the new aluminum criteria affect site-specific criteria developed using previous guidance? 15
1.6. Can a state retain an older version of the state's aluminum criteria while also adopting the new CWA Section 304(a) recommended criteria? 15
1.7. Can states/authorized tribes develop their own regionally informed calculators, or modify the Criteria Calculator to reflect regionally important species or situations, rather than using the CWA Section 304(a) recommended criteria as is? 16
1.8. What methods can be used to derive criteria values that will result in protection of aquatic life at a site, given a range of Criteria Calculator outputs? 17

Section 2: Technical Questions on the Criteria Calculator, Sampling and Laboratory Analysis ... 19

2.1. Do the recommended criteria require data for all input parameters be collected concurrently? 19
2.2. How can data from continuous monitoring be used with the Criteria Calculator? 19
2.3. What are the preferred analytical methods to measure the water quality input parameters required by the Criteria Calculator (pH, total hardness, and DOC)? 20
2.4. What are the preferred analytical test methods to measure aluminum in water? 21
2.5. What should states and authorized tribes do to ensure data quality for use in the Criteria Calculator? 24
2.6. If data are available only for total organic carbon (TOC), can these be converted to dissolved organic carbon (DOC) for use as input to the Criteria Calculator? 24
2.7. What information does a single run of the Criteria Calculator provide, and what are the limitations on the output from one set of inputs (single sample)? 25
2.8. Can the Criteria Calculator still be used when the ambient data are outside the ranges included in the models used to develop the calculator? 25
2.9. How is the multiple linear regression (MLR) technique different from the Biotic Ligand Model (BLM)? 26

Section 3: Characterizing Spatial and Temporal Variability of Input Parameters to Develop Protective Criteria Values 28

NMED Exhibit 77

3.1. How should the *site* be defined for measuring input parameters to calculate protective numeric criteria values? 28
3.2. How does the definition of a site impact sampling design and number of sampling locations needed to characterize the spatial variability of a site? 28
3.3. How can a sampling plan be developed to capture the range of conditions that affect aluminum bioavailability (hence, toxicity) at a site? 29
3.4. If monitoring shows seasonal differences in data, can seasonal data be separated out to generate seasonal criteria values? 31

Section 4: Handling Missing or Insufficient Data When Using the Criteria Calculator 32

4.1. Where can I find additional data to use as inputs to the Criteria Calculator? 32
4.2. Must states and authorized tribes have default input parameters or default criteria values for aluminum? 32
4.3. Would default criteria be overly stringent? 33
4.4. Must states and authorized tribes use EPA ecoregions to develop default criteria values or can they use the state's own approach? 33

Section 5: Implementing the Recommended Aluminum Criteria in National Pollutant Discharge Elimination System (NPDES) Permitting 34

5.1. When using the Criteria Calculator for permitting (i.e., for reasonable potential analysis (RPA) or for developing WQBELs), how will an NPDES permit writer know what inputs to use? 34
5.2. When using the Criteria Calculator to derive criteria values to use for developing NPDES permits, should the inputs be based on upstream ambient waters, the effluent, or a measured or modeled mix of ambient waters and effluent? 34
5.3. If the state or authorized tribe has adopted the Criteria Calculator or lookup tables, how may a permit writer account for both the most appropriate conditions with respect to receiving water chemistry in deriving appropriate criteria values and "critical conditions" used in reasonable potential determinations and calculating a WQBEL? 35
5.4. Would the recommended aluminum criteria be appropriate for deriving criteria values in effluent-dominated streams? 36
5.5. Can the recommended aluminum criteria be implemented in an NPDES permit for a facility that has not yet started discharging? 37
5.6. To the extent input parameters to the Criteria Calculator vary throughout the year (e.g., seasonally), and thus criteria values may vary, should permit limits also vary? 37
5.7. Does EPA have any recommendations on criteria development at the watershed scale, or the potential for shared data collection and implementation at multiple NPDES facilities located in the same general vicinity? 38

Section 6: Implementing the Recommended Aluminum Criteria in Assessments, Listings, and Total Maximum Daily Loads (TMDLs) 39

6.1. How will assessment and listing staff know what numeric values represent "the criteria" when assessing waters with respect to the recommended aluminum criteria? 39
6.2. How should states and authorized tribes prepare to transition to assess waters based on their new Criteria Calculator-based aluminum criteria, particularly for waters for which input parameter data are unavailable? 39
6.3. If the state or authorized tribe only has data on aluminum in the dissolved form (when the

NMED Exhibit 77

criteria are expressed as total recoverable), how does that affect assessment and listing? 39
6.4. How does EPA recommend applying the Criteria Calculator for a water that is impaired with respect to one or more of the input parameters? 40
6.5. When both the water chemistry-dependent criteria and an associated derivation methodology are adopted into WQS which aluminum value should be used to develop TMDLs? 400
6.6. When should states and authorized tribes develop TMDLs based on EPA's recommended aluminum criteria? 41
6.7. Can states and authorized tribes write a TMDL to achieve a presumptive aluminum criteria value that is based on a planned change to one of the input variables? 41

NMED Exhibit 77

Introduction

On December 21, 2018, EPA updated its national Clean Water Act (CWA) Section 304(a) recommendations for freshwater aquatic life criteria for aluminum. The 2018 updated recommended criteria supersede EPA's previous 1988 CWA Section 304(a) aluminum criteria recommendations. The 2018 recommended criteria are water chemistry-dependent; this means that different numeric criteria values may be calculated for different waters that have different water chemistry or even at different times or locations within the same water. To calculate aluminum criteria concentration values, EPA developed the recommended Aluminum Criteria Calculator (Criteria Calculator).[1] The numeric outputs of the Criteria Calculator vary depending on the concurrent values for pH, total hardness, and dissolved organic carbon (DOC) at a given site that are entered as *inputs*. The Criteria Calculator *outputs* for a given set of inputs are the numeric values for the acute and chronic criteria that are protective of freshwater aquatic life uses for that unique set of input conditions.

States and authorized tribes have options for adopting aluminum criteria that may be used singly or in combination:

(1) Adopting by reference to the applicable sections of the CWA Section 304(a) recommended criteria document.

(2) Adopting by reference to the Criteria Calculator [V2.0].

(3) Adopting the criteria value lookup tables; or,

(4) Adopting specific ecoregional, statewide, or localized criteria values for aluminum.

This document is intended to provide additional guidance to states and authorized tribes that are interested in implementing EPA's national CWA Section 304(a) recommended aluminum criteria through a state or tribal water quality standards program.

Section 1 describes some of the flexibilities available to states and authorized tribes if they choose to adopt the recommended criteria (or a modified version of the criteria) into state or tribal water quality standards. This section also recommends additional supporting documentation states or authorized tribes should include in their regulation or implementation documents.

Section 2 responds to technical questions about the Criteria Calculator and includes recommendations on water quality sampling and laboratory analysis.

[1] EPA's CWA Section 304(a) recommended aluminum criteria are based upon multiple linear regression (MLR) models for fish and invertebrate species that use site-specific pH, total hardness, and DOC inputs to quantify the effects of these water chemistry parameters on the toxicity of aluminum to aquatic organisms. The MLR models normalize the available toxicity data to accurately reflect the effects of the site-specific water chemistry on the toxicity of aluminum to tested species. The normalized toxicity test data are then used in the recommended Criteria Calculator to generate protective acute and chronic values for specific ambient water chemistry conditions using EPA's *Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and their Uses*. The Criteria Calculator V2.0 is available in Microsoft Excel and in R on EPA's webpage for the Aquatic Life Criteria for Aluminum in Freshwater: https://www.epa.gov/wqc/aquatic-life-criteria-aluminum#2018.

NMED Exhibit 77

Section 3 provides information to help develop protective criteria values for sites, considering the spatial and temporal variability of input parameters.

Section 4 provides recommendations for when there are insufficient data for pH, total hardness or DOC.

Section 5 provides information for implementing the recommended criteria through National Pollutant Discharge Elimination System (NPDES) permits.

Section 6 provides information for waterbody assessors who will be implementing the recommended criteria in assessing ambient waters, in determining whether to list waters as not attaining their water quality standards, and in developing Total Maximum Daily Loads (TMDLs) for those listed waters.

NMED Exhibit 77

Section 1: Adopting the 2018 Recommended Aquatic Life Water Quality Criteria for Aluminum into State or Tribal Water Quality Standards

1.1. What are EPA's recommended criteria for aluminum?

EPA's recommended freshwater aquatic life criteria for aluminum[2] recognize that the bioavailability[3] (and thus toxicity) of aluminum is dependent on water chemistry. Therefore, the recommended criteria provide the means for states and authorized tribes to develop numeric criteria values at a given site, based on local water chemistry. Specifically, the recommended criteria incorporate a statistical technique, known as multiple linear regression (MLR), to model the relationship between pH, total hardness, and DOC measurements and the toxicity of aluminum based on extensive toxicity testing under different water chemistry conditions.[4] To generate numeric criteria values for a specific set of water-chemistry conditions, users input concurrent data for pH, total hardness, and DOC at a given site into the Criteria Calculator[5] or use lookup tables that provide the same information for those conditions.

Ambient water quality criteria recommendations developed under CWA Section 304(a) are typically expressed in two forms: 1) as *acute criteria* to protect against mortality that occurs due to a short-term exposure to a chemical, and 2) as *chronic criteria* to protect against longer term effects on survival, growth and reproduction that may occur due to a longer-term exposure to a chemical. Both the acute and chronic criteria have three components: concentration (*magnitude*) that is averaged over a given time period (*duration*) that should not be exceeded more than "X" times during a specified time period (*frequency*).

- The *magnitude* component of the recommended aluminum CWA Section 304(a) criteria corresponds to the concentration of aluminum that is protective of the aquatic life designated use under specific conditions of pH, total hardness, and DOC.
- The *duration* term accounts for the limit on exposure timeframe that will protect against adverse effects to aquatic life. Duration is expressed as the time over which a chemical concentration is measured and averaged; that is, as a one-hour average for acute exposures, and a four-day average for chronic exposures for aluminum.

---

[2] Final Aquatic Life Ambient Water Quality Criteria for Aluminum 2018, EPA-822-R-18-001, December 2018, https://www.epa.gov/wqc/2018-final-aquatic-life-criteria-aluminum-freshwater.

[3] Not all forms of aluminum that may be present in ambient waters are biologically available or "bioavailable" to aquatic species. Bioavailable aluminum is the toxicologically relevant fraction(s) of aluminum. Large suspended particles, clays, and aluminosilicate minerals are not generally bioavailable.

[4] Two MLR models, one for invertebrates and one for vertebrates, were used to normalize freshwater aluminum toxicity values. These separate models correspond to effects on invertebrates and vertebrates due to differing effects of pH, total hardness, and DOC on aluminum bioavailability and toxicity, and therefore enable criteria magnitude values to be calculated as a function of the unique chemistry conditions at a given site, at the time at which pH, total hardness, and DOC were measured. Toxicity data show that aluminum toxicity is affected by the concentrations of – and interactions among – these parameters, and EPA's CWA Section 304(a) recommended criteria characterize these relationships.

[5] The Criteria Calculator V2.0 is available in Microsoft Excel and in R Code and Data V.2 on EPA webpage for the Recommended Aquatic Life Criteria for Aluminum in Freshwater: https://www.epa.gov/wqc/aquatic-life-criteria-aluminum#2018.

NMED Exhibit 77

- The *frequency* term defines the maximum allowable number of exceedances of the magnitude and duration combination to ensure protection of aquatic life—once in three years on average for aluminum—consistent with recommendations of the 1985 Guidelines.[6]

Input parameters from ambient water samples will yield outputs that represent the recommended magnitude for acute and chronic criteria concentrations of aluminum that would be protective of aquatic life under those specific ambient water quality conditions (i.e., the desired conditions to protect the aquatic life designated use).

If a state or authorized tribe adopts the recommended criteria into its water quality standards, they would also need to adopt the recommendations for the frequency and durations into their standards, as well. In other words, the acute criterion should be expressed as a one-hour average total recoverable[7] aluminum concentration (in µg/L) and the chronic criterion should be expressed as a four-day average total recoverable aluminum concentration (in µg/L). Additionally, the acute and chronic criteria should be expressed as not to be exceeded more than once every three years to ensure protection of aquatic life.

1.2. What flexibility does a state or authorized tribe have when adopting EPA's recommended aluminum criteria into its state or tribal water quality standards, and what are the advantages and potential challenges of each approach?

The regulation at 40 CFR 131.11(a)(1) specifies that states must adopt water quality criteria that are based on sound scientific rationale and protect the designated use. There are several approaches a state or authorized tribe may take to meet this requirement as it relates to EPA's CWA Section 304(a) recommended aluminum criteria.

Under the regulation at 40 CFR 131.11(b)(1), in adopting water quality criteria, states and authorized tribes should adopt water quality criteria based on: EPA's recommended criteria; modifying the Agency's recommended criteria to reflect site-specific conditions, or other scientifically defensible methods.

The Criteria Calculator in EPA's CWA Section 304(a) recommended aluminum criteria to protect aquatic life in freshwater ecosystems generates criteria values that are dependent on the water chemistry at the site. EPA's CWA Section 304(a) criteria for aluminum are recommendations, and not requirements. As discussed below, there are a number of approaches states and authorized tribes may take in adopting these recommended criteria. States and authorized tribes should consider the advantages and potential challenges of each approach, as well as other approaches that may not be described in this document.

---

[6] EPA. Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses, PB85-227049, 1985. https://www.epa.gov/sites/production/files/2016-02/documents/guidelines-water-quality-criteria.pdf.

[7] As discussed further in Question 2.4, states and authorized tribes may choose to incorporate an analytical method (a variation in the sample preparation procedure) that measures bioavailable aluminum in ambient samples into its implementation efforts; if it chooses to do so, the state or authorized tribe should consider providing a reference to the modified method procedure in its water quality standards or other legally binding documents.

NMED Exhibit 77

When states and authorized tribes choose to adopt both the water chemistry-dependent criteria and an associated derivation methodology; this concept – combining criteria with associated derivation methodology – is referred to as a "performance-based approach." EPA first formalized the concept of a performance-based approach for water quality standards in the preamble of the rule *EPA Review and Approval of State and Tribal Water Quality Standards.*[8] With a performance-based approach, the state or authorized tribe can adopt a process, such as a criteria derivation methodology, rather than a specific outcome, such as a concentration of a pollutant. If a state or authorized tribe adopts a process or methodology that is sufficiently detailed and has suitable safeguards that ensure predictable, repeatable outcomes, EPA can approve that process under CWA Section 303(c), and this initial approval would also serve as the approval of each outcome generated from following that process or method.

If a state or authorized tribe chooses to adopt EPA's recommended aluminum criteria, unchanged, into its water quality standards, EPA recommends choosing one, or a combination,[9] of the following approaches (see Table 1, below):

(5) Adopting by reference to the applicable sections of the CWA Section 304(a) recommended criteria document.

(6) Adopting by reference to the Criteria Calculator [V2.0].

(7) Adopting the criteria value lookup tables[10]; or,

(8) Adopting specific ecoregional, statewide, or localized criteria values for aluminum.

Table 1: Comparison of approaches to adopting the recommended aluminum criteria

Approach to adopting the recommended criteria	**Potential Advantages**	**Potential Challenges**
(1) adopting reference to the CWA Section 304(a) criteria document (which includes the Criteria Calculator and criteria value lookup tables).	This approach may provide the greatest amount of background information and context for the criteria. This approach may also provide the greatest flexibility to states and authorized tribes because it allows multiple ways to calculate criteria values. Statewide adoption of the entire recommended criteria	This approach may be difficult to implement due to individual states' or authorized tribes' legal and administrative requirements (e.g., whether a state's or authorized tribe's regulations allow them to adopt or incorporate by reference). Without additional clarity about aquatic life

[8] *EPA Review and Approval of State and Tribal Water Quality Standards* 65 Fed. Reg. 24641 (Apr. 27, 2000)

[9] For example, approaches (2) and (3) can be adopted together (the Criteria Calculator can be used to derive numeric criteria values (*outputs*) when input parameters (i.e., pH, total hardness, or DOC measures or estimates) are not displayed in the lookup tables). Also, ecoregional criteria default values may be adopted in addition to any of the first three listed approaches. When adopting a combination of approaches, the state or authorized tribe should specify the conditions under which each method would be applied.

[10] If the state or authorized tribe chooses to adopt lookup tables into their water quality standards, they should include information on rounding data when input parameter values for pH, total hardness, or DOC fall between values listed in the lookup tables. Lookup tables are published in Section 4.1, Appendix K of the CWA Section 304(a) criteria document.

NMED Exhibit 77

Approach to adopting the recommended criteria	Potential Advantages	Potential Challenges
	document also provides transparency and regulatory certainty to the public and the regulated community and helps to expedite EPA's review of state or tribal water quality standards, as well as a single consultation on the Endangered Species Act.	protection through implementation, this approach may not provide sufficient regulatory certainty.
(2) adopting the Criteria Calculator [V2.0] (or similar method to calculate outputs based on the underlying MLR models).	This is likely the most adaptable and concise approach.	The Criteria Calculator requires users to input data to generate criteria values and therefore would require some data to exist in order to run. Future versions of the Criteria Calculator may require the state or authorized tribe to update their standards to incorporate the revised Criteria Calculator by reference. States and authorized tribes may choose to incorporate regulatory language to accommodate future software updates where the underlying models and toxicity data are the same.
(3) adopting the criteria value lookup tables.	This may be more transparent than adopting only the Criteria Calculator because the lookup tables do not require access to a computer. The lookup tables also display the full range of possible values that could be generated by the Criteria Calculator and therefore might be more transparent and familiar to some users than simply adopting the Criteria Calculator. The tables are included in Appendix K of the recommended criteria document and may be helpful when communicating to the public about the criteria implemented at a given site.	The state or authorized tribe may need to develop a standard procedure to determine which values for pH, total hardness or DOC to use if measured values are *between* the range of input parameter values provided in the lookup table. For example, a state or authorized tribe may decide to always round to the nearest value in the table for each input parameter or may decide to use the value which would yield the most protective criteria. States and authorized tribes may choose to combine this approach with the Criteria Calculator to address this issue of interpolation.
(4) adopting specific ecoregional[11] or	This would allow states and authorized tribes to apply consistent criteria	This approach may be too general for areas with complex geology. That is, use

[11] For more information on how ecoregions are defined, see https://www.epa.gov/eco-research/ecoregions.

NMED Exhibit 77

Approach to adopting the recommended criteria	Potential Advantages	Potential Challenges
statewide criteria values.	throughout an ecoregion or state. This approach does not require a state to identify site-specific input parameters because the criteria values are the same for all sites within the ecoregion (or state), calculated based on representative water quality parameters for each ecoregion or state. Alternatively, a state or authorized tribe may choose to adopt such criteria as defaults for use in the absence of ambient data. Default criteria may also help to increase transparency of criteria for the public if they are adequately explained. This approach may be used in combination with the Criteria Calculator or lookup tables.	of specific ecoregional or statewide criteria values does not allow for the use of water chemistry data at individual sites for input parameters.

After adopting the aluminum criteria and obtaining EPA's approval, the state or authorized tribe may derive acute and chronic criteria values (i.e., criteria magnitude values) that correspond to a surface water or an entire geographic area with similar conditions for pH, total hardness, and DOC. EPA recommends that states and authorized tribes adopt criteria that will protect aquatic life over the full range of conditions, including when aluminum is most toxic, throughout the year (i.e., account for the variability of pH, total hardness, and DOC over time). Section 3 on characterizing spatial and temporal variability of input parameters provides more information about how to derive criteria values that will protect aquatic life throughout the temporal and spatial range of water chemistry conditions at a site, including those conditions when aluminum is most bioavailable (hence, most toxic to aquatic life). Bioavailable aluminum is the toxicologically relevant fraction(s) of aluminum, rather than dissolved aluminum generally. For more discussion on the relevant fractions of aluminum and appropriate analytical methods to measure them, see Question 2.4.

To promote transparent and repeatable outcomes, EPA recommends that states and authorized tribes consider making publicly available the input parameters, along with the calculations and the resulting values for aluminum criteria. A map showing the extent of the site to which the criteria values apply would also be helpful to communicate those criteria values to the public and to the regulated community. States and authorized tribes may also choose to include detailed methods, for example, in an appendix to their water quality standards or in a Continuing Planning Process document, as described in 40 CFR 130.5(b)(6). This provision of the CFR implements CWA Section 303(e) and requires that states

NMED Exhibit 77

and authorized tribes include, among other things, a process for establishing and assuring implementation for new or revised water quality standards, in continuing planning processes.

In summary, EPA's updated aluminum criteria provide users the flexibility to develop numeric criteria values based on site-specific water chemistry or use default values where water chemistry data are not available. Numeric criteria values can be generated using the Criteria Calculator or by using the lookup tables provided in the appendix. If the criteria were adopted as a statewide methodology, the numeric values at a site could be based on site-specific water chemistry.

1.3. If a state or authorized tribe adopts a methodology, what additional information should be included in their regulation or implementation documents to support such an approach?

When EPA approves a water quality standard in the form of both the water chemistry-dependent criteria and an associated derivation methodology, the state or authorized tribe may use the methodology to derive criteria values that are used for other CWA implementation purposes, without additional EPA review under CWA Section 303(c).[12]

To successfully establish such an approach to deriving aluminum criteria, the state or authorized tribe should demonstrate to EPA that it has a legally binding process or derivation methodology for using the Criteria Calculator (or lookup tables) with enough detail to ensure repeatable, predictable, and protective outcomes. The state or authorized tribe may describe the process in rule, or in a separate implementation document that is incorporated by reference into its water quality standards regulation, and would be legally binding to the extent allowed by state or tribal law. EPA recommends that states and authorized tribes include as part of this process the following, at a minimum, in water quality standards or other legally binding documents:

- A reference to applicable sections of the CWA Section 304(a) recommended criteria document (which includes the Criteria Calculator and criteria value lookup tables) and the Criteria Calculator version to be used;
- A statement of the duration and frequency applicable to the output;
- A statement of, or reference to, data and sampling requirements for Criteria Calculator inputs (i.e., pH, total hardness, and DOC);
- Where appropriate, methods for implementing criteria where sufficient data to run the Criteria Calculator are not available (e.g., default values);
- Where appropriate, information identifying seasons if seasonal criteria are to be used;
- A description of how data inputs will be incorporated into the Criteria Calculator;
- A description of representative sampling methods, how any continuous data will be used, and what standard procedures will be followed if one of the input parameters could not be collected; and

[12] *EPA Review and Approval of State and Tribal Water Quality Standards* 65 Fed. Reg. 24641 (Apr. 27, 2000)

NMED Exhibit 77

- A description of how criteria will be generated from a distribution of Criteria Calculator output values for sites with varying conditions of pH, total hardness, and DOC over time.

EPA encourages states and authorized tribes to supplement the legally binding provisions with additional detail in implementation documents or guidance. For example, states and authorized tribes should consider whether to include additional information about sampling or quality assurance plans defining the spatial extent to which Criteria Calculator-derived criteria values would apply, what the state or authorized tribe considers to be "sufficient" ambient water chemistry data to run the Criteria Calculator, and how output values from the Criteria Calculator may be interpreted. Providing additional guidance will increase transparency and facilitate implementation.

1.4. If the recommended aluminum criteria are adopted in the form of the Criteria Calculator, how will the public and entities implementing the criteria know what numeric values represent the site-specific criteria for a given waterbody at a given time?

Where the Criteria Calculator is adopted as the criteria, states and authorized tribes establish criteria magnitude values to be used for CWA implementation purposes on a site-specific basis. In this scenario, the states and authorized tribes would not adopt static or fixed statewide criteria magnitude values into regulation, but instead would calculate those values using the Criteria Calculator as data are collected.

In this scenario, because the criteria magnitude values are calculated from data collected at a particular moment in time, EPA recommends that states and authorized tribes provide publicly available information about each calculated value, along with the spatial extent (i.e., waterbody segment) to which it applies.[13] Making information available to the public, the regulated community, and other stakeholders is important to ensuring regulatory certainty and clarity, particularly when a state or authorized tribe adopts an accompanying derivation methodology (see Question 1.2 for more information on these approaches). A state or authorized tribe may wish to describe how it derived the criteria values, including the data and data source(s) used. Such information may include (but not be limited to) the following:

- The location(s) from which samples were drawn to determine inputs to the Criteria Calculator or lookup tables;
- The timeframe over which samples were drawn, including the number of samples drawn over that timeframe to account for seasonal or other forms of variability;
- Whether the state or authorized tribe relied on site-specific input data, estimated data, or a combination, when developing the site-specific numeric criteria values (or outputs); and
- The date when the criteria values were developed.

[13] When developing criteria for any given site, consideration should be given to what area is defined as the site. See Section 3 for more information on 'site' definition and characterization.

NMED Exhibit 77

Additionally, a permitting authority may wish to describe in the permit factsheet or statement of basis how it used the numeric criteria values to determine if there was reasonable potential and if there was reasonable potential how it used the criteria to derive water quality-based effluent limits (WQBELs). Likewise, for TMDL programs, states and authorized tribes may wish to describe how they derived the criteria values and used them to determine TMDL targets. States and authorized tribes may also wish to describe how they generated criteria magnitude values for the aluminum criteria used in assessment and listing methodologies and integrated reports for each assessed waterbody.

1.5. How does the adoption of the new aluminum criteria affect site-specific criteria developed using previous guidance?

Adopting the 2018 recommended criteria does not automatically invalidate existing aluminum criteria. However, EPA's 2018 recommended criteria for protecting aquatic life from the toxic effects of aluminum in freshwater systems represents the most current science. Historically, water effect ratios (WERs) have been used to adjust criteria values where ambient water chemistry was suspected to alter the bioavailability (hence, toxicity) of a metal. However, the MLR-based construct of the 2018 recommended criteria is superior to previously recommended criteria, by better reflecting aluminum toxicity based on water chemistry conditions at a particular site. Therefore, where the new recommended aluminum criteria are adopted, using WERs would be unnecessary. EPA recommends that states and authorized tribes replace any previous aluminum aquatic life criteria (whether statewide or site-specific) with statewide or site-specific criteria developed through the use of the Criteria Calculator, the look up tables, or the ecoregional default values in the 2018 CWA Section 304(a) recommended aluminum criteria.

Criteria already approved by EPA under CWA Section 303(c)—including criteria developed using previous guidance and methods—remain effective for CWA purposes until EPA approves a change to those water quality criteria, or until EPA establishes more stringent water quality criteria. States and authorized tribes are required by 40 CFR 131.20(a) to review their water quality standards every three years. As part of this triennial review, states and authorized tribes must update any criteria for which EPA has published a new or updated CWA 304(a) recommendation or must provide an explanation if they decline to update such criteria.[14]

1.6. Can a state retain an older version of the state's aluminum criteria while also adopting the new CWA Section 304(a) recommended criteria?

EPA recommends that states and authorized tribes have only one set of acute and chronic aluminum criteria applicable to each waterbody. This way, it is clear to the public what the criteria are and what

[14] 40 CFR 131.20(a) requires that "if a State does not adopt new or revised criteria for parameters for which EPA has published new or updated CWA Section 304(a) criteria recommendations, then the State shall provide an explanation when it submits the results of its triennial review to the Regional Administrator consistent with CWA Section 303(c)(1) and the requirements of paragraph (c) of this section."

NMED Exhibit 77

criteria will be implemented for all aspects of the CWA programs, including NPDES permitting, CWA Section 303(d) listing, and TMDLs.

A state or authorized tribe, however, may elect to retain its older aluminum criteria statewide while it collects data and adopts new aluminum criteria on a site-specific basis. If a state or authorized tribe chooses this approach, then EPA recommends, in order to provide more clarity to the public, that the state or authorized tribe specify (either in rule or in accompanying implementation procedures) how it will select which set of criteria to be applied to specific waterbodies. Because EPA's national CWA Section 304(a) recommended aluminum criteria represent the most current science regarding aluminum toxicity, EPA recommends that states or authorized tribes apply the new aluminum criteria wherever there are sufficient data to do so. Where states or authorized tribes choose to provide for a transition period to the new criteria, EPA recommends they provide clear information on the length of that period.

1.7. Can states/authorized tribes develop their own regionally informed calculators, or modify the Criteria Calculator to reflect regionally important species or situations, rather than using the CWA Section 304(a) recommended criteria as is?

A state or authorized tribe may develop its own regionally informed calculator or may modify the Criteria Calculator to reflect regional conditions. The water quality standards regulation at 40 CFR 131.11(b)(1)(ii) provides states and authorized tribes with the opportunity to adopt water quality criteria that are "modified to reflect site-specific conditions." As with any criteria, site-specific criteria must protect the designated use, must be based on a sound scientific rationale, and must be approved by EPA. 40 CFR 131.11(a)(1).

One process that can be used to modify criteria to reflect site-specific conditions is the species deletion process (also known as the recalculation procedure).[15] The species deletion process is a process used to modify but retain the taxonomic composition of the toxicity dataset to better match the species assemblage that is known or expected to occur at a particular site, and is not simply removing non-resident species from the Criteria Calculator. This process creates a site-specific toxicity dataset (and corresponding site-specific species sensitivity distribution) that is appropriate for deriving site-specific aquatic life criteria. The species deletion process does this by correcting, adding, or deleting test results based on the resident species of the site. This process is intended to provide flexibility to states and authorized tribes to derive site-specific criteria that best reflect the expected resident species at a site. The species deletion process may result in site-specific criteria that differ from national criteria recommendations when there are demonstrated differences in sensitivity between the expected resident aquatic species and those that were used to derive the national criteria recommendations. In the case of aluminum criteria, a state or authorized tribe could consider generating its own calculator using the same basic datasets and underlying model equations as the national CWA Section 304(a) recommended criteria but adding additional data to account for locally important species and to adjust the species sensitivity distribution. EPA recommends that states and authorized tribes that wish to

[15] USEPA. 2013. Revised Deletion Process for the Site-Specific Recalculation Procedure for Aquatic Life Criteria. EPA-823-R-13-001

NMED Exhibit 77

develop aluminum criteria based on the revised deletion process should engage their EPA regional office early in the state's or authorized tribe's criteria development process.

Critical species should be taken into consideration when using the species deletion process. The 2013 revised deletion process document explains that, "A critical species is a resident species that (a) is commercially or recreationally important at the site, or (b) is listed as threatened or endangered under section 4 of the Endangered Species Act, or (c) is a species for which there is firm evidence that its loss would yield an unacceptable impact on the site's commercially or recreationally important species, endangered species, abundances of a variety of other species, or structure or function. The species deletion process should not be undertaken unless toxicity data are available for at least one species in each class of aquatic plants or animals that contains a critical species."[16]

For the species deletion process, all species that occur at the site should be considered when deciding what species, if any, could be deleted from the dataset. Species not present at the site may be representative surrogates for other species for which there were no available toxicity data in the development of the Criteria Calculator database. Therefore, states and authorized tribes should consider how to demonstrate that a species (or any species for which that sensitive species might be a surrogate) is not present at the site before applying the species deletion process. States and authorized tribes that wish to develop site-specific aluminum criteria based on the revised deletion process should engage their EPA regional office early in the process. The Criteria Calculator or associated look-up table adopted into rule also would need to be revised to accurately reflect the revision.

States and authorized tribes using the species deletion process must also ensure that the resulting water quality standards "provide for the attainment and maintenance of the water quality standards of downstream waters" (40 CFR 131.10(b)). This requirement can be met in several ways, including using a combination of water quality standards and general policies. Additional information about this requirement can be found in *Protection of Downstream Waters in Water Quality Standards: Frequently Asked Questions*.[17]

1.8. What methods can be used to derive criteria values that will result in protection of aquatic life at a site, given a range of Criteria Calculator outputs?

EPA recommends that the criteria for each site be derived in a way that will protect aquatic life throughout the range of seasonal and flow conditions at a site, including those conditions of pH, total hardness, and DOC, when aluminum is most bioavailable (hence, toxic effects are greatest). EPA recommends the following three methods for deriving protective criteria values; states and authorized tribes may choose other scientifically defensible and protective methods, as well. Method 1 entails the greatest amount of input parameter data, and Method 3 involves the least (see below). EPA expects

[16] Ibid, 14.

[17] USEPA. 2014. Protection of Downstream Waters in Water Quality Standards: Frequently Asked Questions. EPA 820-F-14-001. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/sites/default/files/2018-10/documents/protection-downstream-wqs-faqs.pdf

NMED Exhibit 77

states and authorized tribes to clearly describe in their water quality standards or other legally binding document how these methods will be used.

Method 1: Identify protective criteria values by selecting one or more individual Criteria Calculator outputs based upon spatially and temporally representative data for inputs. Method 1 can be used where input datasets are more robust and inputs are measured frequently enough to statistically represent changes in the toxicity of aluminum, including water chemistry conditions under which aluminum is most toxic. In this case, the criteria values could be determined by selecting one or more individual outputs that will be protective of aquatic life under the full range of ambient conditions, including conditions of high aluminum toxicity. Method 1 could be used to also establish criteria values to apply on a seasonal basis where the data are sufficient.

Method 2: Generate protective criteria values from the lowest 10^{th} percentile of the distribution of individual Criteria Calculator outputs, based upon spatially and temporally representative data from a site. Although the 10^{th} percentile of outputs should be sufficiently protective in most cases, certain circumstances may warrant use of a different output (e.g., consideration of threatened or endangered species). Sufficient data to characterize the appropriate distribution of outputs are necessary to derive a protective percentile so that the site is protected under conditions where aluminum is most bioavailable.

Method 3: Select the lowest Criteria Calculator outputs calculated from available input data. This could include assessment of individual data points (sometimes referred to as a "point-by-point" approach). Under this method, the lowest values for the acute and chronic criteria would represent the most toxic conditions known at a site. EPA recommends Method 3 be used where few outputs are available (e.g., ten or fewer), due to the higher probability that a sample from a small dataset does not appropriately represent actual variability.

Either Method 2 or 3 is particularly useful when values of acute and chronic criteria need to be protective of particular site conditions, such as for NPDES permitting actions (as discussed in the Section 5 on NPDES permitting). Whichever method is selected, states and authorized tribes should consider developing written implementation methods and make these documents available to the public to maximize transparency, defensibility, and regulatory certainty. To the same end, EPA recommends states or authorized tribes make publicly available the following on the state's or authorized tribe's website, and, if applicable, referenced in the statement of basis for a draft public notice version NPDES permit, draft public notice Integrated Report, or draft public notice TMDL:

- Site-specific water chemistry data, including the inputs used in the Criteria Calculator and resultant criteria values.
- The geographic extent of each site.

As mentioned in Question 1.2, a state or authorized tribe may choose to adopt default criteria for all or some of the waterbodies within the state or tribal jurisdiction. Where a state or authorized tribe chooses to adopt default criteria values, the state or authorized tribe does not need an additional method for reconciling Criteria Calculator outputs, because the default criteria values should already have integrated the concepts above (i.e., ensuring protectiveness under the full range of ambient

NMED Exhibit 77

conditions, including those under which aluminum is most bioavailable; hence, when toxicity is greatest).

Section 2: Technical Questions on the Criteria Calculator, Sampling and Laboratory Analysis

2.1. Do the recommended criteria require data for all input parameters be collected concurrently?

EPA recommends that samples tested for all of the three input parameters (total hardness, pH, and DOC) to be used in the Criteria Calculator be collected concurrently, when possible. The criteria models incorporate the influence of input parameters, as well as interactions among those parameters and were based mainly on laboratory studies that had a 3x3x3 factorial design where the three parameters were changed for the laboratory tests.[18] However, if concurrent measurements of all three input parameters are not available, default values for DOC may be used.[19] For more information on the use of default input parameters, see Section 4 for more information on handling missing and insufficient data.

2.2. How can data from continuous monitoring be used with the Criteria Calculator?

EPA understands that continuous monitoring for pH is more common than continuous monitoring for total hardness or DOC, and pH is more likely to exhibit greater variability over a short time period when compared to total hardness and DOC. The variable nature of pH, throughout a day, season, or year of data collection, raises questions about how continuously collected pH data should be paired with discrete measurements of total hardness and DOC. For example, how would one know whether the grab samples collected for measurement of total hardness or DOC were taken at a time when pH was in a range that would yield protective criteria?

High-quality continuous monitoring data for pH can provide information on when grab samples for total hardness and DOC should be collected to ensure the inputs to the Criteria Calculator generate protective acute and chronic criteria values. The solubility of aluminum varies with pH. Aluminum is most soluble at low and high pH values, and most bioavailable at low and high pH values; therefore, EPA recommends the full range of observed pH values be used when evaluating the Criteria Calculator outputs.[20] When sufficient data for total hardness and DOC are available to characterize the expected spatial and

[18] DeForest, D.K., K.V. Brix, L.M. Tear and W.J. Adams. 2018. Multiple linear regression models for predicting chronic aluminum toxicity to freshwater aquatic organisms and developing water quality guidelines. *Environ. Toxicol. Chem*. 37(1): 80-90.

[19] EPA is developing a geospatial tool that will help determine appropriate input parameter estimates. This work is expected to be complete in 2021.

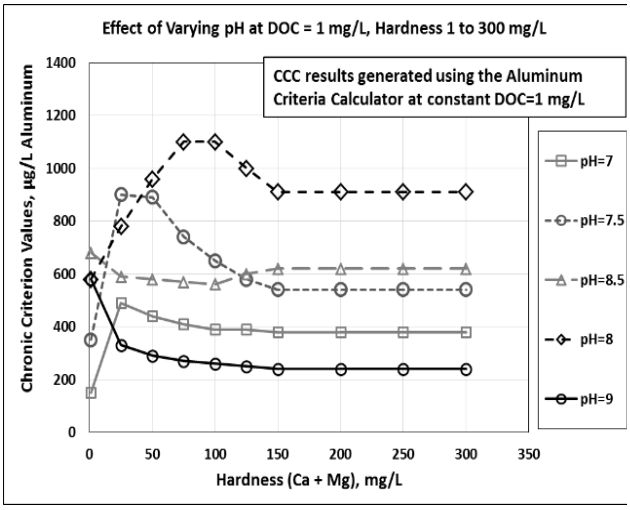
[20] For more information about the Criteria Calculator, please see the Final Aquatic Life Ambient Water Quality Criteria for Aluminum 2018, EPA-822-R-18-001, December 2018, https://www.epa.gov/wqc/2018-final-aquatic-life-criteria-aluminum-freshwater.

NMED Exhibit 77

temporal variability, simultaneously collected pH data should be paired with discrete samples to generate a distribution of criteria values (see Question 1.8).

Selecting a conservative value for pH from the range of observed pH values in a continuous dataset as an input (e.g., low or high pH value depending on the range of pH) and using that value with a conservative total hardness or DOC value may also be acceptable; however, the effects are not linear. In some cases, total hardness can influence the criteria value, such that a higher pH input might produce a lower criteria value with a different hardness concentration (Figure A). In general, a neutral pH produces higher values for the criteria, as do higher concentrations of DOC. However, the precise interaction of the three input parameters can be difficult to predict. For this reason, EPA recommends that a user run a series of input parameters then select the one with the lowest criteria value output by the Criteria Calculator (for n < 10) or a low percentile (e.g., 10%) of the criteria values (for n>10). However, a user might decide to input a conservative DOC value in each calculation that included paired pH and total hardness values because the effect of DOC on criteria values is a monotonic reduction of toxicity (Figure B).

Figure A: Model output at constant DOC



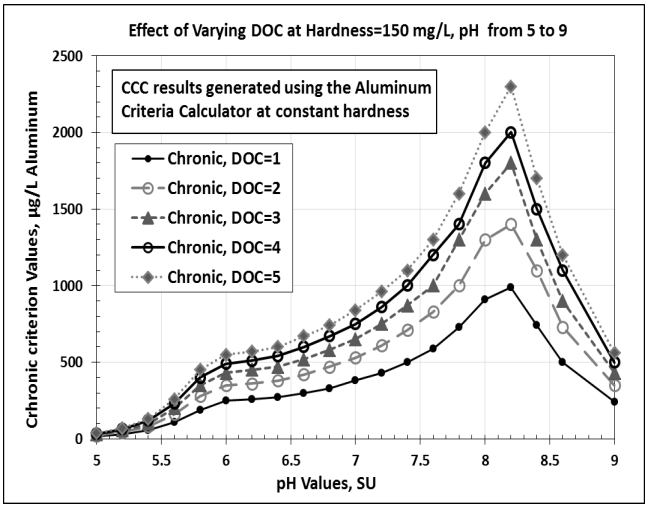


Figure B: Model output at constant hardness

2.3. What are the preferred analytical methods to measure the water quality input parameters required by the Criteria Calculator (pH, total hardness, and DOC)?

For analysis of pH and total hardness, EPA provides "Guidelines Establishing Test Procedures for the Analysis of Pollutants" at 40 CFR Part 136.[21]

[21] Information on these analytical methods is available at https://www.epa.gov/cwa-methods/approved-cwa-chemical-test-methods and https://www.gpo.gov/fdsys/pkg/FR-2017-08-28/pdf/2017-17271.pdf

NMED Exhibit 77

Several well established methods are available for measuring DOC,[22] including EPA Method 415.3[23] and USGS Method O-1122-92. In addition, several well established methods for total organic carbon (TOC) are available, including ASTM D6317-15 and *Standard Methods for the Examination of Water and Wastewater* SM 5310. These methods discuss the stringent sample collection and processing measures that are necessary to minimize sample contamination, especially when the DOC concentrations are expected to be low. For example, the sampling container, filtration apparatus, filters and atmospheric exposure might introduce carbon to the sample and in some situations adsorb DOC. Standard Method 5310A identifies filtration protocols and additional quality control (QC) measures (e.g., filter blanks) that may be considered when using a TOC method (i.e., a method that lacks a filtration step) such as SM 5310B, adapted for DOC. Whichever method is selected, all of the specified QC operations are needed to assess the results of the field sample analyses. Example QC operations can be found at 40 CFR Part 136.7.

2.4. What are the preferred analytical test methods to measure aluminum in water?

EPA's CWA Section 304(a) recommended Criteria Calculator for aluminum is based on data for *total recoverable* aluminum. Therefore, it calculates outputs that can be used to generate criteria values for total recoverable aluminum. The approved test methods for measuring total recoverable aluminum in ambient water and wastewater use a variety of analytical instruments (the most commonly used methods are EPA Methods 200.7 and 200.8). However, recent research has indicated that a less aggressive digestion sample preparation procedure may more accurately reflect aluminum toxicity in ambient waters when using the approved analytical methods.

All of the approved total recoverable methods require that the unfiltered samples be preserved in the field by acidifying to pH<2 and digested in the laboratory with strong acid solution, with a pH of -0.05 to +0.7. This process dissolves the monomeric and polymeric forms of aluminum, in addition to colloidal, particulate, and clay minerals (i.e., aluminosilicate minerals known as phyllosilicates). However, under natural conditions not all of these forms would be biologically available to aquatic species. Over the last three decades, the scientific consensus has been that the total recoverable method for aluminum potentially overestimates the biologically available fraction and that a method that better addresses dissolved aluminum and aluminum bound to particulate matter would be useful and more accurately reflect toxicity under natural instream conditions (e.g., He and Ziemkiewics 2016; Ryan *et al*. 2019).[24] EPA's CWA Section 304(a) recommended criteria document also describes this issue.

Bias in determining aluminum concentrations: Comparison of digestion methods and implications on Al management. *Chemosphere* 159:570–576; Ryan AC, Santore RC, Tobiason S, WoldeGabriel G, and Groffman AR. 2019. Total recoverable aluminum: not totally relevant for water quality standards. *Integrated Environmental Assessment and Management*. 15(6): 974–987.

NMED Exhibit 77

As an example of an approach to better measure the biologically available forms of aluminum, research on new analytical methods was published that addresses concerns with total recoverable aluminum concentrations (Rodriguez *et al.* 2019).[25] Under this approach, the analysis does not digest the sample at pH -0.05 to +0.7 , but rather to pH 4 in order to measure only the bioavailable fraction of aluminum in the sample. The authors concluded that their proposed method is able to characterize and differentiate chronic toxicity effects attributable to bioavailable aluminum from nontoxic forms of aluminum (i.e., aluminum contained in the crystal lattice of aluminosilicate minerals) compared with existing methods for total or total recoverable aluminum. The methods for total or total recoverable aluminum may overestimate instream toxic effects by virtue of the digestion-induced dissolution of aluminum from clay minerals that would not dissolve in most ambient waters under ambient pH conditions.

EPA expects that an adjusted analytical method (referred to as a bioavailable analytical method) that uses a less aggressive initial acid digestion that liberates bioavailable forms of aluminum (including amorphous aluminum hydroxide) yet that minimizes dissolution of mineralized forms of aluminum (such as aluminosilicate minerals associated with suspended sediment particles) will better estimate the bioavailable fraction of aluminum under natural instream conditions.

The forms of aluminum introduced into the laboratory toxicity tests, upon which EPA relied for development of the CWA Section 304(a) recommended criteria, were highly soluble salts of aluminum, rather than clays or other aluminum-containing particulates typically found in natural waters. Aluminum from suspended solids and clays would normally be extracted using total recoverable methods that have a strong acid (pH <2) digestion step but would not be biologically available to aquatic species in natural waters. Empirical laboratory testing indicates that measured concentrations of total recoverable (pH -0.05 to +0.7 digestion) and bioavailable aluminum in laboratory waters are essentially equal up to approximately 1 mg/L of aluminum.[26] Studies are underway at Oregon State University with test solutions with greater than 1 mg/L of aluminum to better understand the relationship above 1 mg/L. Initial studies indicate there is little difference between “total recoverable” and “bioavailable” aluminum above 1 mg/L in laboratory waters.

EPA does not intend to develop or require a conversion or translation factor to compare field measurements using a bioavailable method against the promulgated aluminum total recoverable criteria. This is because both bioavailable and total recoverable analytical methods quantify the toxic fraction of aluminum equivalently in laboratory test waters given that standard toxicity test waters do not include suspended solids or clays per test protocols.

NPDES permit limits for metals must be expressed as “total recoverable” metals with the exception of specific circumstances that would not apply for aluminum. 40 CFR 122.45(c). This regulation exists because chemical differences between the effluent discharge and the receiving water body are expected to result in changes in the partitioning between dissolved and adsorbed or particulate forms of metals. However, for ambient water measurements, analytical methods that measure bioavailable aluminum

[25] Rodriguez PH, Arbildua JJ, Villavicencio G, Urrestarazu P, Opazo M, Cardwell AS, Stubblefield W, Nordheim E, Adams W. 2019. Determination of bioavailable aluminum in natural waters in the presence of suspended solids. *Environmental Toxicology and Chemistry*. 38(8):1668-1681.
[26] *ibid*.

NMED Exhibit 77

should provide more accurate quantification of the toxic fraction of aluminum. EPA acknowledges that for characterizing ambient waters, states and authorized tribes may utilize, as scientifically appropriate and as allowable by state and federal regulations, analytical methods that measure the bioavailable fraction of aluminum. Such methods employ a less aggressive initial acid digestion, such as to a pH of approximately 4 or lower, that includes the measurement of easily dissolved amorphous aluminum hydroxides, yet minimizes the measurement of mineralized forms of aluminum in aluminosilicate minerals, such as clays, which are associated with suspended sediment particles. Use of such a method for bioavailable aluminum would need to comply with other existing requirements in state or authorized tribal water programs, for example, any applicable quality assurance/quality control requirements. For assessment and listing purposes, ambient field measurements analyzed using a bioavailable analytical method may be compared directly to the criteria because that method represents the toxic fraction of aluminum. States and authorized tribes that adopt aluminum criteria should identify which analytical methods they will use to implement the criteria.

In some circumstances, assessing waters using the analytical method for total recoverable aluminum could result in identification of some waters as not attaining water quality standards for aluminum criteria (i.e., being identified as impaired), where the bioavailable analytical method may not indicate impairment. For example, ambient waters with high amounts of total suspended solids may show elevated concentrations of aluminum based on analysis of the total recoverable fraction, yet these concentrations could actually represent only non-toxic forms of aluminum. EPA's existing regulations applicable to implementation of CWA Section 303 programs, which include assessment and listing of waters, do not require use of analytical test methods promulgated at 40 CFR Part 136, nor do the regulations that apply to the determination of the need for a WQBEL. However, EPA's regulations require that states assemble and evaluate all existing and readily available water quality related data and information for use in developing their CWA Section 303(d) lists (40 CFR 130.7(b)(5)); this would include data for total recoverable aluminum. A state or authorized tribe is not required to use all available data and information to make listing decisions, including total recoverable data, where it can provide a technical, science-based rationale for the exclusion of such data and information. 40 CFR 130.7(b)(6)(iii), For example, a state or authorized tribe may be able to demonstrate that total recoverable aluminum samples are not representative of water quality conditions because non-toxic forms of aluminum are leading to an exceedance above the criteria. In such cases, the state or authorized tribe may decline to rely on total recoverable data, or may assign a greater weight to bioavailable data if it is more representative of water quality for listing purposes.

For developing TMDLs and load allocations, aluminum data from bioavailable analytical methods may also be used as the basis for identifying allocations for TMDLs. This includes both wasteload allocations (WLA) for point sources and load allocations (LA) for nonpoint sources. For implementing a WLA, the associated WQBEL must be assessed for NPDES compliance purposes using aluminum data from total recoverable methods, just as would be the case for other NPDES applications consistent with permitting regulations. NPDES permit limits for aluminum concentrations listed in compliance reports must, by regulation, be measured using analytical methods approved by EPA and published at 40 CFR Part 136. Currently the only approved methods at 40 CFR Part 136 are for "total recoverable aluminum."However, states and authorized tribes may use a bioavailable analytical method to measure aluminum

NMED Exhibit 77

concentrations from nonpoint sources (i.e., the LA for surface water runoff) because total suspended solids may include aluminosilicate minerals (e.g., clay minerals) containing aluminum that is not bioavailable under natural conditions.

2.5. What should states and authorized tribes do to ensure data quality for use in the Criteria Calculator?

EPA recommends that states and authorized tribes establish data quality guidelines for data to be input to the Criteria Calculator. Such guidelines would be similar to data quality guidelines used for other water quality criteria. EPA recommends that states develop Quality Assurance Project Plans[27] (QAPPs) for sampling protocols to assure that representative data are collected.

2.6. If data are available only for total organic carbon (TOC), can these be converted to dissolved organic carbon (DOC) for use as input to the Criteria Calculator?

In some cases, states, authorized tribes, or regulated facilities may only have collected data for TOC and not DOC, which is the input parameter for use with the Criteria Calculator. In these situations, a TOC to DOC conversion may be used. Some states have used various methods to convert TOC values to DOC. Data from the U.S. Geological Survey's (USGS) National Water Information System (NWIS) can also provide useful data to supplement state or tribal data when creating translations.[28] It is useful for states and authorized tribes who use a conversion to ensure the details of the conversion are available in the public record for the adoption of the Al criteria or in some other publicly available document.

The following examples demonstrate approaches states have taken to convert TOC data to DOC:

- Kansas uses the TOC to DOC conversion values detailed in EPA-822-R-07-001, *Aquatic Life Ambient Freshwater Quality Criteria – Copper*. See Appendix C-2: Dissolved, Particulate, and Estimated Total Organic Carbon for Streams and Lakes by State.
- Massachusetts uses a TOC to DOC conversion developed by USGS for surface waters in Massachusetts based on a regression of available NWIS data for concurrent measurements of TOC/DOC throughout the state. (See Equation 1)[29] (USGS Untitled Report, *in-prep*).

  Equation 1. TOC to DOC conversion. $$DOC\ (\frac{mg}{L}) = 0.858 * TOC(\frac{mg}{L}) - 0.196$$

- Montana, New Mexico, and Ohio have been collecting both DOC and TOC data at selected sites. These states plan to develop conversion factors based on regression analysis of the TOC and DOC data.

[27] Further information on QAPPs may be found at https://www.epa.gov/quality/guidance-quality-assurance-project-plans-epa-qag-5.
[28] EPA is developing a geospatial tool that will help determine appropriate input parameter estimates. This work is expected to be complete in 2021.
[29] USGS Untitled Report, in-preparation. Publication expected Fall 2021.

NMED Exhibit 77

- Oregon generated a translator to convert TOC data to DOC data for use with the Copper Biotic Ligand Model using a regression approach. A single statewide translator was developed using state and USGS NWIS data.

2.7. What information does a single run of the Criteria Calculator provide, and what are the limitations on the output from one set of inputs (single sample)?

The Criteria Calculator can be run for multiple samples of collected data for pH, total hardness, and DOC (inputs),[30] representing a range of conditions at a site. The samples may be taken from a single site throughout the year or from several different sites within a waterbody (or some combination of data collected over geographical space and time). Each sample would provide one set of input parameters and generate one set of outputs (i.e., the acute and chronic criteria). A single run of the Criteria Calculator could, therefore, provide a distribution of (in the case of the Excel version, up to 500) acute and chronic criteria values (outputs) which would be considered protective for each corresponding input sample. From the distribution of outputs, protective values for acute and chronic criteria may be selected. For more on identifying protective criteria values from a distribution of possible values, see Question 1.8.

As the number of samples of pH, total hardness, and DOC increases, the ability to reliably translate Criteria Calculator outputs to a protective criteria value also increases. A single output of the Criteria Calculator represents one moment in time at a single point and may not adequately characterize the variation in water chemistry for a site throughout the year. The uncertainty associated with a criterion based on only one single set of inputs is not a problem unique to the Criteria Calculator, as other water quality parameters vary spatially and temporally. Running the Criteria Calculator with data from multiple sampling events will yield a distribution of multiple output criteria values, from which a sufficiently protective set of criteria may be selected.

2.8. Can the Criteria Calculator still be used when the ambient data are outside the ranges included in the models used to develop the calculator?

Yes, the Criteria Calculator can be used when the ambient data for the input parameters are outside the ranges included in the MLR models. The Criteria Calculator incorporates a data extrapolation to cover a broader range of inputs for pH, and a slightly broader range for hardness. However, the Criteria Calculator does not process input values far outside of the model range. For input values outside the Criteria Calculator range, it will default to the nearest allowable Criteria Calculator input parameter

[30] The number of samples the Criteria Calculator can run at a time depends on the format: the Excel version can handle up to 500 samples. The Criteria Calculator is also available in R; both versions are available on EPA webpage for the Recommended Aquatic Life Criteria for Aluminum in Freshwater: https://www.epa.gov/wqc/aquatic-life-criteria-aluminum#2018. The R version uses the same formulas and data that are found in the Excel version, but the R code can handle a larger number of parameter inputs and can calculate faster. The R code and data are in an easy-to-download Zip file. They can be found under the "2018 Final Aquatic Life Criteria for Aluminum in Freshwater" header.

NMED Exhibit 77

value. For example, entering a DOC value of 9.5 mg/L is within the range of the Criteria Calculator input values for DOC, therefore the Criteria Calculator will accept an input of 9.5 mg/L without change. However, an input value of 15 mg/L for DOC will default to an input value of 12 mg/L, the maximum allowable DOC value for the Criteria Calculator. The CWA Section 304(a) recommended aluminum criteria document (see pages xiv-xv)[31] explains the decisions the Agency made regarding the bounds of the input parameter ranges in the Criteria Calculator and its corresponding look-up tables.[32] Table 2, below, summarizes the information from the criteria document and compares the range of values used in the MLR models with the corresponding ranges allowable as inputs to the Criteria Calculator for each input parameter. As discussed in Section 4 of the CWA Section 304(a) recommended aluminum criteria document, the ranges incorporated into the Criteria Calculator will be protective across a broad range of ambient waters found in the United States.

Table 2: Comparison of MLR models and Criteria Calculator input parameters

Input parameter	MLR models range	Criteria Calculator range
pH	6.0 – 8.2	5.0 – 10.5
Total hardness (mg/L)	9.8 – 428	0.01 – 430
Dissolved organic carbon (mg/L)	0.08 – 12.3	0.08 – 12.0

2.9. How is the multiple linear regression (MLR) technique different from the Biotic Ligand Model (BLM)?

EPA considered multiple options when developing the national CWA Section 304(a) recommended criteria for aluminum, including the Biotic Ligand Model (BLM).[33] Both the BLM and the multiple linear regression (MLR) models are used to estimate the bioavailability – and resultant toxicity – of metals to aquatic species based on water chemistry at a site, including pH, total hardness, and DOC as inputs. The BLM, however, includes an additional seven inputs.

- The BLM, which is a mechanistic model, uses a series of submodels to estimate the capacity of metals to accumulate or bind to active sites on the gills of aquatic organisms. The submodels are

[31] Final Aquatic Life Ambient Water Quality Criteria for Aluminum 2018, EPA-822-R-18-001, December 2018, https://www.epa.gov/wqc/2018-final-aquatic-life-criteria-aluminum-freshwater.

[32] Two models, one for invertebrates and one for vertebrates, were used to normalize freshwater aluminum toxicity values. These separate models correspond to effects on invertebrates and vertebrates due to differing effects of pH, total hardness, and DOC on aluminum bioavailability and toxicity, and therefore enable the criteria magnitudes to be calculated as a function of the unique chemistry conditions at a given site.

[33] The BLM was formerly referred to as the "gill model." It is a metal bioavailability model that uses metal speciation across water chemistries and associated binding of a metal to fish gills with associated toxicity, receiving waterbody characteristics and monitoring data to develop site-specific water quality criteria. A BLM model was used to develop the 2007 CWA 304(a) aquatic life criteria recommendation for copper.

NMED Exhibit 77

based on an underlying theory of how overall water chemistry, as defined by the ten input parameters, affects the toxicity of metals.

- The MLR approach used to develop the Criteria Calculator empirically curve-fits log-log pH, total hardness, and DOC relationships (with interaction terms) to the empirical data.

EPA evaluated the use of empirical, non-mechanistic MLR models for aluminum as a bioavailability-based approach for deriving water quality criteria as well as a BLM for aluminum. The Criteria Calculator associated with EPA's 2018 CWA Section 304(a) recommended criteria for aluminum uses the MLR approach. Given that the MLR and the BLM approaches performed comparably, EPA decided to use an empirical MLR approach in this aluminum criteria update rather than a BLM due to:

- the relative simplicity and transparency of the MLR model,
- the relative similarity to the available BLM outputs, and
- the decreased number of water chemistry input data parameters needed to derive criteria at different sites.

Under 40 CFR 131.11, states and authorized tribes may use EPA's CWA Section 304(a) recommended criteria with modifications or may use other scientifically defensible methods to develop their own criteria. Regardless of the method used, a state or authorized tribe must submit the criteria to EPA for review and approval. EPA's current recommendation, based on the latest scientific knowledge, employs an MLR model. It is possible to use other modeling approaches, such as the BLM, to predict aluminum toxicity and account for the water chemistry parameters that influence toxicity the most.

If presented with proposed aluminum criteria based on a BLM or different approach, EPA would evaluate its scientific basis and protectiveness of the designated use. For additional information and references, see Section 5.3 of the recommended criteria document available at: https://www.epa.gov/wqc/2018-final-aquatic-life-criteria-aluminum-freshwater.

NMED Exhibit 77

Section 3: Characterizing Spatial and Temporal Variability of Input Parameters to Develop Protective Criteria Values

3.1. How should the *site* be defined for measuring input parameters to calculate protective numeric criteria values?

A *site* may be a state, region, watershed, segment of a waterbody, category of water (e.g., cold-water lakes), etc., but the criteria are to be derived to provide adequate protection for the entire site regardless of how the site is defined. A site could also be a facility mixing zone, an assessment unit, a watershed, or any spatial area that a state or authorized tribe has data to represent.

When defining a site, states and authorized tribes should consider the following:

- How the site definition will facilitate developing criteria values that are protective of the range of conditions expected to occur within the defined site.
- How the site definition will capture significant influences on water chemistry.
- How the size or spatial variability of the site can impact the number of water samples required to adequately characterize the spatial and temporal variability of a site.
- How to communicate a clear definition of the site's area or condition for which the criteria values apply.
- How, if at all, the site definition differs depending on the intended CWA program (e.g., is the receiving water site of a NPDES permit discharge location different from the assessment unit site?).

Regardless of how the "site" is defined, pursuant to 40 CFR 131.10(b), states and authorized tribes must consider downstream water quality standards when establishing protective criteria in upstream waters. For additional information on site-specific water quality criteria, see 40 CFR 131.10(b) and chapter 3 of EPA's *Water Quality Standards Handbook*.[34]

3.2. How does the definition of a site impact sampling design and number of sampling locations needed to characterize the spatial variability of a site?

The number of sampling locations needed to characterize spatial variability at a site will vary with physical and chemical characteristics of the site. Samples should be collected from enough locations so that the resulting dataset captures the expected spatial variability in pH, total hardness, and DOC of the site, based on the observed range of physical and chemical conditions.

When designing a sampling plan to develop inputs for the Criteria Calculator, unique characteristics of a waterbody segment should be considered such as size, flow, and presence of springs, tributaries, and outfalls. States and authorized tribes may also want to consider differences in hydrology, geology, eco-

[34] USEPA. 1994. Water Quality Criteria. Chapter 3 in *Water Quality Standards Handbook*. EPA 823-B-94-005a. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/wqs-tech/water-quality-standards-handbook.

NMED Exhibit 77

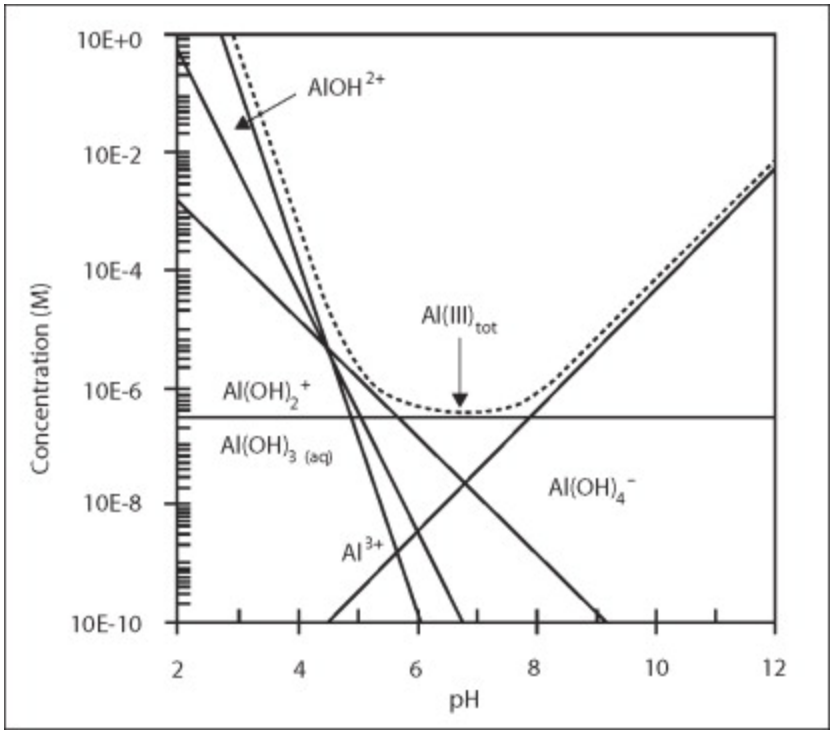
region, watershed land use (e.g., urban, forested, cultivated, wetlands), trophic state (i.e., level of biological activity in the waterbody), and riparian condition within and among sites to inform decisions on the number of sampling locations needed. For example, land use within the watershed, the trophic state, and presence of discharges from a wastewater treatment plant can all influence the variability in concentrations of any of the input parameters.

Generally, relatively large or heterogeneous waterbodies will require more sampling locations to characterize the spatial variability, as compared to the number of sampling locations required to characterize small or homogenous systems. When a wide range of characteristics or water quality conditions is observed in a large waterbody, states and authorized tribes may consider dividing the waterbody into smaller segments or sites for purposes of establishing input values for the Criteria Calculator.

States or authorized tribes considering use of existing or new data for the development of default numeric values over larger geographic scales should evaluate existing data, monitoring strategies and other data sources to evaluate spatial and temporal representativeness of the data so that the variability in pH, total hardness, and DOC is understood. Sampling data from waterbodies with high levels of bioavailable aluminum should be included in the dataset to be representative of the observed site conditions.

See the Section 5 on NPDES permitting for additional considerations for monitoring to characterize waters impacted by point sources.

3.3. How can a sampling plan be developed to capture the range of conditions that affect aluminum bioavailability (hence, toxicity) at a site?



Understanding how aluminum bioavailability changes with increasing or decreasing values of pH, total hardness, and DOC will help when designing sampling plans intended to capture the range of ambient chemistry conditions. A sampling plan should be designed to capture the conditions under which aluminum would be most bioavailable; these conditions have the highest acute toxicity, and also the highest chronic toxicity, with respect to aluminum. However, because the input parameters interact in complex ways, it is not possible to generalize about a universal set of input parameter conditions that would represent conditions of the highest toxicity, with respect to aluminum. Nonetheless, there are some general observations regarding pH, total hardness, and DOC:

- Values of pH in the circumneutral range are associated with lower solubility of aluminum (see Figure C) and conditions of lower bioavailability and toxicity with respect to aluminum (see Figures A and B). Values of pH may vary over several units due to photosynthetic activity in the waterbody (lowest pH at dawn and highest pH in early afternoon coincident with peak photosynthetic activity). Significant diurnal variation in pH values due to photosynthesis and respiration patterns can affect the calculated aluminum criteria values by 1,000 µg/L or more. Therefore, it would be useful to sample during times when pH is expected to be highest or lowest at a particular site, in order to capture conditions under which aluminum would be

NMED Exhibit 77

most bioavailable and toxic. Sampling early in the morning, before photosynthetic activity begins, and mid-afternoon, when photosynthetic activity peaks, may capture the extremes of pH at a site. Alternatively, data loggers could also be used to capture a range of pH values, including times (such as night) when sampling and monitoring is impractical (see Question 2.2 for more information on the use of continuous monitoring data). Effluent discharges to the waterbody that vary over the course of the day or week may also affect pH.

Figure C: Solubility of aluminum hydroxide over a range of pH. Minimum solubility (~0.000001 M) achieved under near-neutral conditions of pH.

Source: Membrane filtration: Managing aluminum in membrane filtration. Filtration + Separation. Volume 51(4):26-28. July-August 2014. https://doi.org/10.1016/S0015-1882(14)70145-4 (p 27)

- Total hardness in flowing waters may be related to stream flow or other factors that alter the concentrations of calcium and magnesium (the components of total hardness). These ions are derived mainly from weathering of rocks and minerals in natural settings and exist in the dissolved phase in most fresh waters.
- DOC can bind aluminum, rendering it less bioavailable (hence, less toxic). In general, DOC and bioavailability of aluminum are inversely correlated. That is, low concentrations of DOC are associated with higher bioavailability of aluminum; hence, yield more stringent (lower) aluminum criteria values. High concentrations of DOC bind aluminum and reduce bioavailability; hence, yield less stringent (i.e., higher) aluminum criteria values. Sampling at times when DOC is low could help capture conditions under which aluminum is more bioavailable (i.e., conditions are more toxic). Seasonal patterns in DOC concentrations at a site may vary depending on soil type, vegetation, upstream inputs, and climate.

NMED Exhibit 77

A sampling plan should also consider other factors, such as precipitation events and snow-melt cycles, particularly for waters that receive stormwater flows. Increased flows may affect the pH and other chemical parameters of the waterbody for up to several hours following a storm event. Wet season and dry season flows may lead to extremes in the conditions that affect aluminum bioavailability. Considering the variety of factors that may affect toxicity over time at a site can help identify strategic times to sample. Strategically timed sampling is more likely to result in development of criteria values for a site that will be protective during more sensitive times (i.e., times when aluminum is most bioavailable). Conditions like time of day, date, and weather should be noted when sampling occurs.

The Criteria Calculator generates both acute and chronic criteria values from the same set of data inputs. The diurnal variability of input parameters may affect acute criteria values more than chronic criteria values, because chronic values are averaged over a four-day period. Capturing the variability of input parameter values on longer time scales (e.g., the average pH over a one- to four-day period) may be informative for chronic criteria values, because understanding that variability will help inform the design of routine sampling plans that include the collection of discrete measurements.

3.4. If monitoring shows seasonal differences in data, can seasonal data be separated out to generate seasonal criteria values?

If enough data are available and those data indicate significant seasonal differences in toxicity with respect to aluminum, it is possible to separate and create criteria values for application on a seasonal basis. For example, if spring snowmelt or heavy seasonal rainfall in the area significantly change the water chemistry parameters that affect aluminum bioavailability (hence, toxicity) during that season, then a state or authorized tribe may consider spring values that differ from values that apply during other seasons. The criteria values should protect the designated uses in all of the seasons. If states or authorized tribes choose to adopt seasonal criteria into their water quality standards, they should clearly define those seasons in their water quality standards.

NMED Exhibit 77

Section 4: Handling Missing or Insufficient Data When Using the Criteria Calculator

4.1. Where can I find additional data to use as inputs to the Criteria Calculator?

The sufficiency of data for pH, total hardness and DOC will depend on the range of variation in the values of those parameters throughout the year. In general, more data are important for waterbodies with characteristics that exhibit a greater range of variability, to achieve an acceptable level of confidence as defined by the user. If a state or authorized tribe has limited data, EPA recommends that the state or authorized tribe consider data from the Water Quality Portal. The Water Quality Portal is a service provided jointly by the EPA, USGS, and the National Water Quality Monitoring Council that uses the EPA's Water Quality Exchange format to share over 380 million water qualtiy data records. It serves data collected by over 900 federal, state, tribal and other partners including the USGS's National Water Information System (NWIS) data (See: https://www.waterqualitydata.us/).[35] Note: Whatever dataset a state or authorized tribe uses, some level of quality assurance is vital, particularly with methods for handling total hardness or DOC, for which the analyst must comply with methodologies and holding times to ensure the resulting data meet state or tribal data quality requirements specified in the respective Quality Assurance Project Plans, or QAPPs.

4.2. Must states and authorized tribes have default input parameters or default criteria values for aluminum?

States and authorized tribes are not required to identify default input parameters or default criteria values for aluminum; however, states and authorized tribes are required to protect the designated uses of waterbodies within their jurisdictions.[36] The protectiveness of a state or authorized tribe's approach to adopting EPA's CWA Section 304(a) recommended criteria will be determined by both the *implementation methods* associated with the criteria and the *input parameter data* (for pH, total hardness, and DOC) used to calculate the criteria values for a given waterbody. See Question 1.2 for more information on approaches to adopting aluminum criteria, including default criteria.

For states and authorized tribes that choose to adopt the criteria in the form of the Criteria Calculator or lookup tables, the adoption of default input values or default criteria values can help to ensure that aquatic life uses will be protected in all waters within their jurisdiction, regardless of data availability for pH, total hardness, or DOC. When considering the establishment of default input parameters, it is especially important to keep in mind the complex (e.g., non-monotonic) relationship between pH and aluminum toxicity as well as the high natural variability of pH. Both issues make it uniquely challenging to establish protective pH default values. See Question 3.3 for more information. Having numeric default criteria values available may also help ensure that anyone implementing the criteria (e.g., a

[35] EPA is developing a geospatial tool that will help determine appropriate input parameter estimates. This work is expected to be complete in 2021.

[36] As provided at 40 CFR 131.11(a), state and tribal water quality criteria must be protective of the designated use based on a sound scientific rationale.

NMED Exhibit 77

permit writer, or someone assessing the water) will have a clear numeric basis for implementation, providing transparency for the public and the regulated community.

4.3. Would default criteria be overly stringent?

Because default criteria are generally applied to a broad geographical area (e.g., ecoregions), it is possible that defaults will result in criteria values that are more or less stringent than the criteria values would be if calculated based on the water chemistry parameters at a given location. The accuracy of an established default value will depend on the method used to group together similar waterbodies that share common physical and chemical characteristics. After grouping similar waterbodies, the state or authorized tribe can derive default values for those waters in each group.

States and authorized tribes have flexibility in the method used to derive default values and may choose whatever grouping method they believe will result in the most accurate defaults, provided that they have sufficient data to support such a method. If states or authorized tribes believe that the default criteria values are more stringent than necessary to protect aquatic life in a specific waterbody, site specific ambient data may be collected and used in the Criteria Calculator to establish site-specific criteria values.

4.4. Must states and authorized tribes use EPA ecoregions to develop default criteria values or can they use the state's own approach?

As described in Question 4.3, states and authorized tribes have discretion on how to establish default criteria values, including how to identify the geographic units to which defaults will be applied, which datasets are used to generate the defaults, and how to generate the default values from those data. A key consideration is grouping waterbodies with similar water chemistry. One option is to group waterbodies based on ecoregions, geographic divisions for which EPA has already processed data and provided DOC estimates. However, states and authorized tribes may elect to use additional data or data divided into different regions. For example, Oregon has "geo-regional" divisions. States and authorized tribes may also choose to define default values by stream order if sufficient data exist to support such a division.

NMED Exhibit 77

Section 5: Implementing the Recommended Aluminum Criteria in National Pollutant Discharge Elimination System (NPDES) Permitting

5.1. When using the Criteria Calculator for permitting (i.e., for reasonable potential analysis (RPA) or for developing WQBELs), how will an NPDES permit writer know what inputs to use?

NPDES permit writers should follow their state's criteria implementation guidance.[37] As stated in EPA's *NPDES Permit Writers' Manual,* [38] the goal of the permit writer is to derive effluent limitations that are enforceable, adequately account for effluent variability, consider available receiving water dilution, protect against acute and chronic impacts, account for compliance monitoring sampling frequency, and assure attainment of water quality standards and any applicable waste load allocation.

As described throughout this document, states and authorized tribes that adopt the recommended aluminum criteria should provide sufficient information and explanation in the criteria itself or in implementing documents so permit writers, the regulated community, and the public understand how the criteria operate to protect designated uses. In some cases, the state or authorized tribe may have adopted numeric criteria values for aluminum (e.g., Criteria Calculator outputs) as its water quality standards or adopted default input parameter values to be used in absence of ambient data. In other cases, the state may have adopted provisions specifying how ambient data, if available, must be used in the Criteria Calculator, and how criteria values must be generated. In the absence of state implementation guidance or other provisions, permit writers may also consider existing practices for similar model-based criteria. Permit writers may also wish to consult the water quality standards experts for the state or authorized tribe and the permitting authority may seek guidance from EPA.

5.2. When using the Criteria Calculator to derive criteria values to use for developing NPDES permits, should the inputs be based on upstream ambient waters, the effluent, or a measured or modeled mix of ambient waters and effluent?

The general principles regarding discharges affecting water chemistry in the context of NPDES permitting for aluminum are similar to permitting for discharges of other metals for which criteria are hardness-based. State water quality standards and permitting policies and procedures should include information on how to select locations for obtaining representative input water chemistry values in a manner that ensures calculated criteria are protective of applicable aquatic life designated uses. If

[37] Additional information on the calculation of design conditions can be found in EPA's *Technical Guidance on Supplementary Stream Design Conditions for Steady State Stream Modeling*. U. S. Environmental Protection Agency, Office of Water, Washington, D.C. EPA-440-48-80-91. December 1988. https://nepis.epa.gov/Exe/ZyPURL.cgi?Dockey=00001JA6.txt

NMED Exhibit 77

obtaining chemistry values is not practicable or possible, model inputs could be calculated as described below.

When a discharge from a point source to a receiving water or tributary is expected to influence the chemistry of the receiving water at the permitted discharge location or a downstream location, ambient sampling locations should include locations representing conditions in the waterbody after complete mixing. The number of sampling locations and the frequency of sampling should be adequate to characterize the spatial and temporal variability of the site (see Question 3.2 and Question 3.3 for more information).

If the boundaries of the mixing zone cannot be determined, or if downstream sampling reflecting conditions after mixing is not practicable, input parameter values representing those conditions may be estimated from concentration and flow values for the point source or tributary and the waterbody. In doing so, a range of observed or expected upstream and effluent/tributary conditions should be evaluated. Care should be taken to consider the buffering capacity (alkalinity) of the waters being mixed when estimating the mixed pH.

In general, effluent water chemistry alone should not be used to determine model input parameters. However, this might be appropriate in an effluent-dominated stream. For more information on effluent-dominated streams, see Question 5.4.

5.3. If the state or authorized tribe has adopted the Criteria Calculator or lookup tables, how may a permit writer account for both the most appropriate conditions with respect to receiving water chemistry in deriving appropriate criteria values and "critical conditions" used in reasonable potential determinations and calculating a WQBEL?

In general, as discussed in EPA's *Technical Support Document for Water Quality-Based Toxics Control* and *NPDES Permit Writers' Manual*, NPDES permit writers seek to represent "critical conditions" in their calculations so that the resulting WQBELs will be set at a level necessary to meet water quality standards under those critical conditions and therefore under other foreseeable conditions.

Deriving applicable water quality criteria values (taking into account the most sensitive water chemistry conditions) is one calculation. Developing WQBELs based on those criteria values and using "critical conditions" is a subsequent calculation. The two steps are described below:

Step 1: If the state has adopted aluminum criteria values as static numeric values for a site, the permit writer would use those values. If not, the permit writer should use the Criteria Calculator as follows:

> The permit writer should run the Criteria Calculator using data that represent the spatial and temporal variability at the site, including the most sensitive conditions. The criteria should protect aquatic life throughout the year, over the range of expected conditions, including conditions under which aluminum would be most bioavailable (hence, most toxic) to aquatic life (see Question 1.2 for more information). The criteria values derived from the distribution of

NMED Exhibit 77

criteria values should protect for the full range of conditions. (See Section 3 on characterizing spatial and temporal variability for more information).

Step 2: Determine the Need for and Derive WQBELs

After applicable criteria values are derived to protect for the range of conditions, the permit writer must determine whether a facility's discharge is causing, has the reasonable potential to cause, or contributes to an excursion of that criteria (also known as "reasonable potential analysis", or RPA). If a WQBEL is needed, then NPDES permit limits should be derived based on the criteria and assuming "critical conditions" to ensure the WQBEL is as stringent as necessary to meet the criteria.[39]

NPDES permit writers often complete RPAs and derive WQBELs based on a set of steady-state conditions, called "critical conditions" in order to ensure that the WQBELs will protect receiving water quality. Commonly, the 7Q10 or 4B3 stream flow is used to determine wasteload allocations based on chronic aquatic life criteria, and the 1Q10 or 1B3 stream flow is used to determine wasteload allocations based on acute aquatic life criteria. The NPDES authority may also use other critical flows as specified in the relevant water quality standards or permitting policies and procedures. Critical low flows represent relatively little available dilution in the receiving water. Permit limits are then based on the wasteload allocation, acute or chronic, whichever is more restrictive. EPA has provided guidance regarding critical low flows for permitting.[40]

The critical low flow used in RPA and WQBEL calculations may not correspond to the flows typically associated with water chemistry conditions under which aluminum would be most bioavailable (hence, most toxic). In order to ensure water quality is protective of the designated use, criteria values that will be protective of the range of conditions, including conditions under which aluminum would be most bioavailable, should be applied in conjunction with the critical conditions used in RPA and WQBEL calculations. This would ensure a protective limit.

EPA recommends that as RP and WQBELs are reevaluated at permit reissuance, permit writers consider potential changes to water chemistry since the last issuance. Conditions that render aluminum more or less bioavailable in receiving waters could change as the result of a newly permitted discharge or modification of an existing discharge, land-use changes, or changes to hydrologic conditions; all of which may affect pH, total hardness, and DOC.

5.4. Would the recommended aluminum criteria be appropriate for deriving criteria values in effluent-dominated streams?

Yes, the Criteria Calculator and lookup tables can be used to derive criteria values in effluent-dominated streams. As in any case, the nature of the discharge in relation to stream conditions should be

[39] For more information on critical conditions, see Chapter 6 of the NPDES Permit Writers' Manual.
[40] For more on critical conditions, see EPA's *Technical Support Document for Water Quality-based Toxics Control* (March 15, 1991). https://www3.epa.gov/npdes/pubs/owm0264.pdf.

NMED Exhibit 77

considered when determining a sampling approach. EPA is aware that in some cases, sampling for inputs to model-based criteria is conducted upstream of the discharge (or the "natural" receiving water, absent any effect of the effluent). However, in other cases sampling for inputs reflects the water chemistry that will exist in the receiving water *after* the receiving water and effluent completely mix (downstream of the discharge). The upstream approach would be more conservative/protective if the discharge itself has characteristics that mitigate aluminum toxicity, such as high concentrations of DOC.

5.5. Can the recommended aluminum criteria be implemented in an NPDES permit for a facility that has not yet started discharging?

Permitting (both determining the need for and deriving a WQBEL) is always a predictive exercise based on critical effluent projections and critical stream conditions that are anticipated during the permit term. The predictive models for both the criteria calculation and for effluent and receiving water mixing are always improved with more refined input values; however, the analyses can be performed using expected ranges of input values even before a discharge occurs.

5.6. To the extent input parameters to the Criteria Calculator vary throughout the year (e.g., seasonally), and thus criteria values may vary, should permit limits also vary?

Seasonal WQBELs can be developed based on calculated seasonal criteria values. As discussed in the response to Question 3.4, the Criteria Calculator may be used to generate seasonal water quality criteria values. The NPDES authority could use the different criteria as the basis for determining reasonable potential and deriving the WQBELs.

Additionally, even in cases where there are not seasonal criteria, NPDES authorities have discretion to provide seasonal or tiered flow limitations in NPDES permits based on seasonal critical conditions, where appropriate, unless the state's water quality standards prohibit this. Where not prohibited, seasonal WQBELs could be based on year-round criteria values but different flow scenarios and background concentrations. To develop seasonal WQBELs, the permit writer would have to model the critical stream flow, background concentrations, and effluent and stream flows during any season in which the criteria were applicable.

EPA recommends that as reasonable potential and WQBELs are reevaluated at permit reissuance, permit writers consider potential changes to water chemistry since the last issuance. Conditions that render aluminum more or less bioavailable in receiving waters could change as the result of a newly permitted discharge or modification of an existing discharge, land-use changes, or changes to hydrologic conditions; all of which may affect pH, total hardness, and DOC. In some cases, additional data and/or monitoring would be required to determine when the various seasonal or tiered flow limits apply.

NMED Exhibit 77

5.7. Does EPA have any recommendations on criteria development at the watershed scale, or the potential for shared data collection and implementation at multiple NPDES facilities located in the same general vicinity?

EPA has not developed specific guidance on watershed scale permitting for toxic metals, though specific TMDLs may provide some examples of how to gather and share data to support use of the Criteria Calculator. A key question for the state to consider is whether the water quality data used as inputs to the Criteria Calculator would be representative of the entire area to which the criteria would apply. For more information regarding site characterization, see Section 3 on characterizing spatial and temporal variability. If a TMDL exists for a particular waterbody or watershed, more information may be available that could be used in considering the appropriate watershed scale. More information on watershed-scale permitting is available at https://www.epa.gov/npdes/watershed-based-permitting.

NMED Exhibit 77

Section 6: Implementing the Recommended Aluminum Criteria in Assessments, Listings, and Total Maximum Daily Loads (TMDLs)

6.1. How will assessment and listing staff know what numeric values represent "the criteria" when assessing waters with respect to the recommended aluminum criteria?

As described throughout this document, states and authorized tribes that adopt some or all of the recommended aluminum criteria should provide sufficient information and explanation in the criteria itself or in implementing documents so permit writers, the regulated community, and the public understand how the criteria operate to protect designated uses. As discussed in Question 1.2 above, states have options for how to adopt EPA's aluminum criteria recommendation. Specifically, states may develop criteria values at different scales (e.g., statewide, ecoregional, site-specific) using EPA's recommended tools (e.g., the Criteria Calculator, look up tables) and submit those values as criteria to EPA for approval under CWA Section 303(c). States may also adopt both the water chemistry-dependent criteria and an associated derivation methodology whereby the same tools are described along with criteria derivation and implementation methods. EPA recommends that criteria derivation and implementation be included in the state's or authorized tribe's water quality standards. As such, states and authorized tribes should be able to determine the applicable water quality criteria for aluminum for completing water quality assessments by consulting EPA-approved aluminum criteria and associated criteria derivation and implementation methods.

6.2. How should states and authorized tribes prepare to transition to assess waters based on their new Criteria Calculator-based aluminum criteria, particularly for waters for which input parameter data are unavailable?

State and authorized tribes should monitor for input parameters and aluminum if they plan to transition to uses of the 2018 recommended criteria. The Criteria Calculator relies on ambient data, so collecting as much data as feasible before running the Criteria Calculator will facilitate assessment of these criteria. During the time of transition to the new criteria, states may maintain aluminum listings on the CWA Section 303(d) list that were based on the state's or authorized tribe's previously applicable aluminum criteria until water quality can be evaluated using the new criteria for aluminum.

6.3. If the state or authorized tribe only has data on aluminum in the dissolved form (when the criteria are expressed as total recoverable), how does that affect assessment and listing?

As described in EPA's CWA Section 304(a) recommended aluminum criteria document, measurements of dissolved aluminum do not sufficiently characterize the full spectrum of forms of aluminum that contribute to toxicity. EPA recommends that if a state or authorized tribe adopts the recommended criteria, it collects data in a form that appropriately characterizes the bioavailability of aluminum.

NMED Exhibit 77

EPA's regulations require that states and authorized tribes assemble and evaluate all existing and readily available water quality-related data and information in developing their CWA Section 303(d) lists (40 CFR 130.7(b)(5)), which would include data and information on the dissolved form of aluminum. However, a state or authorized tribe is not required to use all available data and information to make listing decisions where it can provide a technical, science-based rationale for the exclusion of such data and information. 40 CFR 130.7(b)(6)(iii). For example, a state or authorized tribe may demonstrate that the use of dissolved aluminum measurements in impairment decisions may underestimate the bioavailable aluminum in the waterway and not be representative of the water's impairment status, especially when the levels of aluminum measured as dissolved are below the Criteria Calculator values. However, dissolved aluminum measurements that show concentrations above the criterion would likely indicate that the criterion is exceeded. If a state or authorized tribe decides not to use dissolved aluminum data and information for making listing decisions, particularly measurements that show concentrations above the criterion, it must provide a technical, science-based rationale.

6.4. How does EPA recommend applying the Criteria Calculator for a water that is impaired with respect to one or more of the input parameters?

In some situations, the values for the input parameters would themselves cause impairment of the water (e.g., pH that is outside the range of an approved water quality standard for a state's pH criteria which specify a pH range between 6.5 and 9). If a state or authorized tribe finds that values for input parameters indicate nonattainment of state standards, then the waterbody should be placed on the list of impaired waters for these and any other parameters that are not meeting water quality standards (per 40 CFR 130.7(b)(1)).

The water may or may not be impaired with respect to aluminum, even if one or more of the input parameters causes impairments of other water quality criteria. The Criteria Calculator can be used with a wide range of inputs, regardless of whether those inputs themselves would be considered causes of impairment. For more information about using the Criteria Calculator for values inside and outside the ranges covered by the Criteria Calculator, see Question 2.8.

The Criteria Calculator-derived aluminum criteria are not a substitute for other integrating measures of water quality, such as biological assessments and ambient toxicity tests. When available, the result of these integrative tests should be considered data and information that states and authorized tribes are required to assemble and evaluate for assessment determinations (40 CFR 130.7(b)(5)).

6.5. When both the water chemistry-dependent criteria and an associated derivation methodology are adopted into WQS which aluminum value should be used to develop TMDLs?

States and authorized tribes should develop TMDLs to address the applicable aluminum criteria adopted by the states and authorized tribes and approved by EPA. States and authorized tribes have the option of choosing one, or a combination, of the approaches described in Question 1.2 above.

NMED Exhibit 77

States and authorized tribes that adopt a methodology as part of their criteria should include implementation methods in their water quality standards or other legally binding documents, as described in Question 1.3. Such implementation methods should clearly describe which aluminum criteria value is applicable for TMDL development purposes, particularly for states that adopt a combination of the approaches listed above (e.g., ecoregional default values and criteria values derived from the Criteria Calculator).

6.6. When should states and authorized tribes develop TMDLs based on EPA's recommended aluminum criteria?

CWA Section 303(d) requires states and authorized tribes to develop a TMDL when they identify a waterbody as not meeting applicable water quality standards and place the impairment on their biennial CWA Section 303(d) list. As part of the biennial list, states and authorized tribes are required to prioritize impairments on their CWA Section 303(d) lists for TMDL development, taking into account the severity of the pollution and the uses to be made of such waters, and include a schedule of TMDLs that will be developed over the next two years. See 40 CFR 130.7(b)(4). The opportunity to prioritize impairments for TMDL development provides states and authorized tribes flexibility on scheduling TMDL development for waters not meeting the aluminum water quality standard. Such flexibility may be important to states and authorized tribes that identify impaired waters for inclusion on the 303(d) list using small datasets (such as in method 3 in Question 1.8) because the criteria value may not represent conditions under which aluminum is most bioavailable. In these circumstances, states and authorized tribes can consider scheduling these TMDLs for development once the criteria value for the site is derived in a way that will protect aquatic life throughout the range of seasonal and flow conditions at a site, including those conditions of pH, total hardness, and DOC, when aluminum is most bioavailable.

6.7. Can states and authorized tribes write a TMDL to achieve a presumptive aluminum criteria value that is based on a planned change to one of the input variables?

States and authorized tribes should develop TMDLs for the aluminum criteria value that exists at the time of developing the TMDL rather than a presumptive aluminum criteria value based on a planned increase or decrease to one or more of the input parameters (i.e., pH, total hardness, and DOC). As discussed in Question 1.8, the methods for deriving the recommended criteria value are based on input variable values observed in the field. The methods do not provide for a consideration of presumptive, or potential, input variable values that may be realized in the future after practices are put in place to change the input variables. However, as discussed in the previous question, states and authorized tribes have flexibility on prioritizing and scheduling TMDLs for development. As such, instead of developing a TMDL based on the current aluminum criteria value, a state or authorized tribe may first choose to calculate a new criteria value after measures are taken to change the input variables and those changes are realized in the field.

NMED Exhibit 77

335. The Commission adopts the identical NMED and UC proposals to revise the chronic and acute criteria for mercury to be consistent with EPA's recommended criteria pursuant to 40 CFR §131.11.

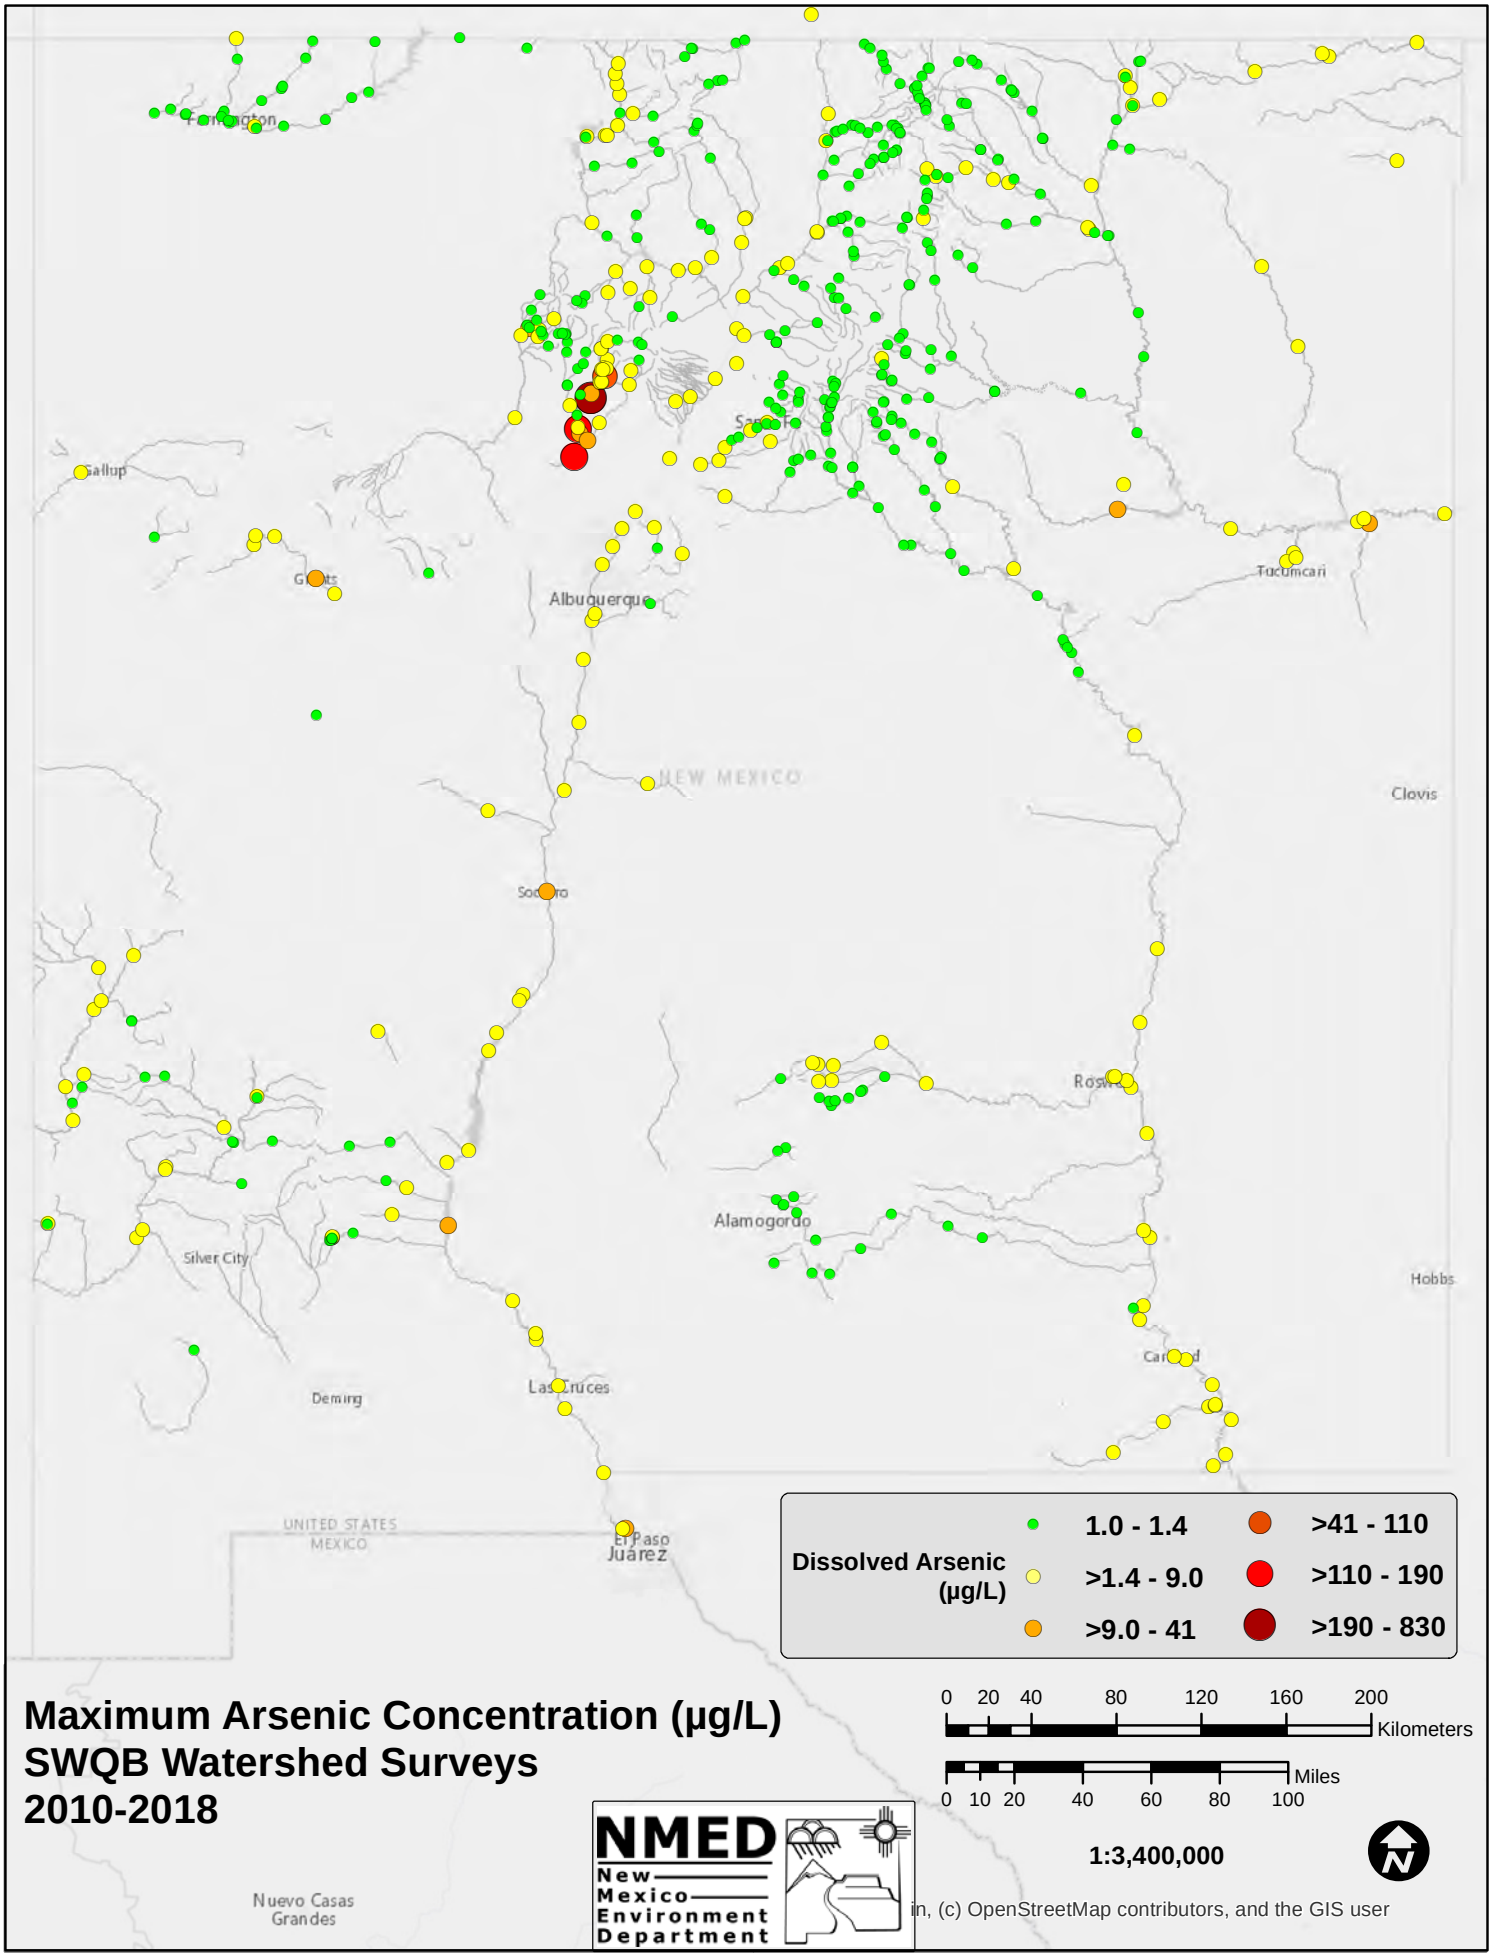
336. The Commission adopts the identical NMED and UC proposals to add a methylmercury criterion of 0.3 mg/kg for protection of human health, as recommended by EPA in 2001.

337. The Commission adopts NMED's proposed revised nitrate criteria based on the research of Dr. Sam Fernald of New Mexico State University, who demonstrated that the revised criteria protect livestock watering.

338. Regarding the "Aquatic Life" criteria the Commission adopts the identical NMED and UC proposals to delete the beryllium criteria because EPA has withdrawn its recommended values. EPA no longer recommends beryllium aquatic life criteria.

339. Regarding the "Human Health" criteria the Commission adopts NMED's proposal to amend the criteria based upon the current EPA recommendations in National Recommended Water Quality Criteria: 2002, EPA-822-R-02-047. The recalculated criteria integrate an updated national default fish consumption rate (17.5 g/day) and, in some cases, relative source contribution values obtained from primary drinking water standards and new cancer potency information from EPA's Integrated Risk Information System.

340. Of these criteria, only the arsenic criterion is New Mexico-specific (e.g., the updated national default fish consumption rate applied to site-specific data collected during a 1997 joint agency study of arsenic in the middle Rio Grande in the vicinity of Albuquerque. The site specific data included: (1) geometric mean of dissolved arsenic concentrations from all river and drain stations of 2.88 mg/L; (2) geometric mean of total arsenic concentrations in eight composited fish-tissue samples from fish collected in the river and drains of 13.13 µg/kg; and (3) risk assumptions, including (a) risk level = 10^{-5}; (b) body weight = 70 kg; (c) cancer potency factor = 1.5; (d) bioaccumulation factor = 4.57 L/kg (geomean tissue 13.13/ geomean H20 2.88); and (e) inorganic As = 65 percent). The recalculation resulted in an arsenic criterion of 9.0 µg/L for consumption of organisms only, and 2.3 µg/L for consumption of water plus organisms. The Commission



expresses its concern to the department that the assumptions of the level of fish consumption from the Rio Grande may be overstated.

341. The Commission rejects AB's proposal to include numeric criteria for perchlorate-domestic water supply- at 1 ug/L for lack of credible scientific data in the record, and because EPA has not recommended a criterion for ambient waters.

342. The Commission rejects AB's proposal to change the criteria for uranium, dissolved- Domestic Water Supply to 7 ug/L for lack of credible scientific data in the record, and because EPA has not recommended a criterion for ambient waters. The Commission is concerned about uranium, and mindful that it recently lowered the ground water standard, but the record in this triennial review simply does not support such a change at this time.

343. The Commission rejects AB's proposed wildlife habitat dissolved aluminum numeric criterion, proposed aquatic life cyanide numeric criteria, and proposed wildlife habitat and aquatic life selenium numeric criteria for lack of credible scientific data in the record.

http://www.epa.gov/waterscience/criteria/aqlife.html

NMED Exhibit 80

FOREWORD

Section 304(a)(l) of the Clean Water Act of 1977 (P.L. 95-217) requires the Administrator of the Environmental Protection Agency to publish water quality criteria that accurately reflect the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare that might be expected from the presence of pollutants in any body of water, including ground water. This document is a revision of criteria based upon consideration of comments received from independent peer reviewers and the public. Criteria contained in this document supplement any previously published EPA aquatic life criteria for the same pollutant(s).

The term "water quality criteria" is used in two sections of the Clean Water Act, section 304(a)(l) and section 303(c)(2). The term has a different program impact in each section. In section 304, the term represents a non-regulatory, scientific assessment of health or ecological effects. Criteria presented in this document are such scientific assessments. If water quality criteria associated with specific waterbody uses are adopted by a state or tribe as water quality standards under section 303, they become enforceable maximum acceptable pollutant concentrations in ambient waters within that state or tribe. Water quality criteria adopted in state or tribal water quality standards could have the same numerical values as criteria developed under section 304. However, in many situations states or tribes might want to adjust water quality criteria developed under section 304 to reflect local environmental conditions. Alternatively, states or tribes may use different data and assumptions than EPA in deriving numeric criteria that are scientifically defensible and protective of designated uses. It is not until their adoption as part of state or tribal water quality standards that criteria become regulatory. Guidelines to assist the states and tribes in modifying the criteria presented in this document are contained in the Water Quality Standards Handbook (U.S. EPA 1994). The handbook and additional guidance on the development of water quality standards and other water-related programs of this agency have been developed by the Office of Water.

This document is guidance only. It does not establish or affect legal rights or obligations. It does not establish a binding norm and cannot be finally determinative of the issues addressed. Agency decisions in any particular situation will be made by applying the Clean Water Act and EPA regulations on the basis of specific facts presented and scientific information then available.

1.0 INTRODUCTION

Copper is an abundant trace element found in the earth's crust and is a naturally occurring element that is generally present in surface waters (Nriagu, 1979). Copper is a micronutrient for both plants and animals at low concentrations and is recognized as essential to virtually all plants and animals (Kapustka et al., 2004). However, it may become toxic to some forms of aquatic life at elevated concentrations. Thus, copper concentrations in natural environments, and its biological availability, are important. Naturally occurring concentrations of copper have been reported from 0.03 to 0.23 µg/L in surface seawaters and from 0.20 to 30 µg/L in freshwater systems (Bowen, 1985). Copper concentrations in locations receiving anthropogenic inputs can vary anywhere from levels that approach natural background to 100 µg/L or more (e.g., Lopez and Lee, 1977; Nriagu, 1979; Hem, 1989) and have in some cases been reported in the 200,000 µg/L range in mining areas (Davis and Ashenberg, 1989; Robins et al., 1997). Mining, leather and leather products, fabricated metal products, and electric equipment are a few of the industries with copper-bearing discharges that contribute to anthropogenic inputs of copper to surface waters (Patterson et al., 1998).

Over the past 20 years, the U.S. Environmental Protection Agency (EPA) has published a number of guidance documents containing aquatic life criteria recommendations for copper (e.g., U.S. EPA 1980, 1985, 1986, 1996). The present document contains EPA's latest criteria recommendations for protection of aquatic life in ambient freshwater from acute and chronic toxic effects from copper. These criteria are based on the latest available scientific information, supplementing EPA's previously published recommendations for copper. This criteria revision incorporated new data on the toxicity of copper and used the biotic ligand model (BLM), a metal bioavailability model, to update the freshwater criteria. With these scientific and technical revisions, the criteria will provide improved guidance on the concentrations of copper that will be protective of aquatic life. The BLM is not used in the saltwater criteria derivation because further development is required before it will be suitable for use to evaluate saltwater data.

This document provides updated guidance to states and authorized tribes to establish water quality standards under the Clean Water Act (CWA) to protect aquatic life from elevated copper exposure. Under the CWA, states and authorized tribes are to establish water quality criteria to protect designated uses. Although this document constitutes EPA's scientific recommendations regarding ambient concentrations of copper, it does not substitute for the CWA or EPA's regulations, nor is it a regulation itself. Thus, it cannot impose legally binding requirements on EPA, states, tribes, or the regulated community, and might not apply to a particular situation based on the circumstances. State and tribal decision makers retain the discretion in adopting approaches, on a case-by-case basis, that differ from this guidance when appropriate. EPA may change this guidance in the future.

Although the BLM has been used in place of the formerly applied hardness-based approach, the updated freshwater criteria derivations in this document are still based on the principles set forth in the *Guidelines for Deriving Numerical Water Quality Criteria for the Protection of Aquatic Life and Their Uses* (Stephan et al. 1985, hereafter referred to as the Guidelines). Section 2 of this document provides an overview of copper bioavailability and the BLM. Additional information on the generalized BLM framework, theoretical background, model calibration, and application for the BLM can be found in the published literature. Section 3 of this document discusses general

NMED Exhibit 80

procedures and requirements for applying the BLM to criteria. Section 4 provides the derivation of criteria Final Acute Value (FAV) and Final Chronic Value (FCV) for freshwater organisms. Section 5 discusses plant data and Section 6 discusses other data not included in the criteria derivation. Sections 7 and 8 provide the final criteria statements and information on implementation. Various supplementary information is provided in several appendices.

2.0 APPROACHES FOR EVALUATING COPPER BIOAVAILABILITY

2.1 *General Aspects of Copper Bioavailability*

The toxicity of a chemical to an aquatic organism requires the transfer of the chemical from the external environment to biochemical receptors on or in the organism at which the toxic effects are elicited. Often, this transfer is not simply proportional to the total chemical concentration in the environment, but varies according to attributes of the organism, chemical, and exposure environment so that the chemical is more or less "bioavailable". Definitions of bioavailability vary markedly (e.g., National Research Council, 2003) and are often specific to certain situations, but a useful generic definition is the relative facility with which a chemical is transferred from the environment to a specified location in an organism of interest.

Of particular importance to bioavailability is that many chemicals exist in a variety of forms (chemical species). Such chemical speciation affects bioavailability because relative uptake rates can differ among chemical species and the relative concentrations of chemical species can differ among exposure conditions. At equilibrium in oxygenated waters, "free" copper exists as cupric ion - Cu(II) weakly associated with water molecules ($Cu{\cdot}nH_2O^{+2}$), but this species is usually a small percentage of the total copper. Most dissolved copper is part of stronger complexes with various ligands (complexing chemicals that interact with metals), including dissolved organic compounds, hydroxides, carbonates, and other inorganic ligands. Substantial amounts of copper can also be adsorbed to or incorporated into suspended particles. More information on copper speciation in freshwater can be found in Kramer et al. (1997), Bryan et al. (2002), and Smith et al. (2002).

Copper toxicity has been reported to vary markedly due to various physicochemical characteristics of the exposure water (e.g., either laboratory or field), including temperature, dissolved organic compounds, suspended particles, pH, and various inorganic cations and anions, including those composing hardness and alkalinity (see reviews by Sprague, 1968; Hunt, 1987; Campbell, 1995; Allen and Hansen, 1996; Paquin et al., 2002). Many of these physicochemical factors affect copper speciation, and their effects on copper toxicity therefore could be due to effects on copper bioavailability. That bioavailability is an important factor is evident from uptake of copper by aquatic organisms being reduced by various organic compounds and inorganic ligands known to complex copper (Muramoto, 1980; Buckley et al., 1984; Playle et al., 1993 a,b; MacRae et al., 1999).

A "ligand" is a complexing chemical (ion, molecule, or molecular group) that interacts with a metal like copper to form a larger complex. A "biotic ligand" is a complexing chemical that is a component of an organism (e.g. chemical site on a fish gill). For certain ligands, some studies have demonstrated that the concentration of free copper associated with a specified level of accumulation or toxicity changes little as the ligand concentration is varied, despite major changes in the

NMED Exhibit 80

proportion of copper bound to the ligand (see review by Campbell, 1995). This suggests that, even at low concentrations, free copper is more important to bioavailability than the ligand-bound copper. This is expected if accumulation and toxicity are dependent on the binding of copper to a biochemical receptor "X" on the surface of the organism, forming a chemical species X-Cu (receptor-bound metal) that is a first limiting step in accumulation and toxicity. By standard chemical equilibrium expressions, the amount of such species and the consequent biological effects would be a function of the activity of just free copper (Morel, 1983 a), a relationship commonly referred to as the free ion activity model (FIAM). Ligand-bound copper (Cu-L) would contribute to copper bioavailability if (a) a species X-Cu-L is formed that is important to copper accumulation/toxicity, (b) the microenvironment near the organism surface is such that Cu-L dissociates and increases the free copper activity interacting with "X", or (c) copper uptake is via mechanisms that do not entail binding to such a receptor and can accommodate different copper species. Some studies have indicated dissolved complexes of copper do contribute to bioavailability (reviews by Sprague, 1968; Hunt, 1987; Campbell, 1995; Allen and Hansen, 1996; Paquin et al., 2002).

The effects of physicochemical factors on copper toxicity are diverse and the specific chemistry of the exposure water will determine whether or not there are appreciable effects on copper speciation and a resulting strong relationship of toxicity to free copper. Usually copper toxicity is reduced by increased water hardness (reviews by Sprague, 1968; Hunt, 1987; Campbell, 1995; Allen and Hansen, 1996; Paquin et al., 2002), which is composed of cations (primarily calcium and magnesium) that do not directly interact with copper in solution so as to reduce bioavailability. In some cases, the apparent effect of hardness on toxicity might be partly due to complexation of copper by higher concentrations of hydroxide and/or carbonate (increased pH and alkalinity) commonly associated with higher hardness. However, significant effects on toxicity often are still present when hardness is increased in association with anions which do not interact strongly with copper (Inglis and Davis, 1972; Chakoumakos et al., 1979; Miller and Mackay, 1980; Erickson et al., 1987). Hardness cations could have some limited effect on copper speciation by competing with copper for the same dissolved ligands, but increased hardness would then increase free copper and thus increase, not decrease, toxicity. Sodium has also been reported to affect copper toxicity (Erickson et al., 1996 b) and pH effects can be partly due to effects of hydrogen ion other than on copper speciation (Peterson et al., 1984).

The effects of hardness cations could be explained by the competing with copper for the biochemical receptor "X", thus reducing copper uptake (Zitko, 1976; Zitko et al., 1976; Pagenkopf, 1983). Reduced metal bioavailability due to increased hardness cations has been experimentally demonstrated (Playle et al., 1992; Meyer et al., 1999, 2002), although this does not specifically establish cation competition as the mechanism. Pagenkopf (1983) provided a mathematical description of a Gill Surface Interaction Model (GSIM) that addressed the effects on metal toxicity of both metal speciation and cations via the interactions of gill surface biochemical receptors with the free toxic metal, other metal species, hardness cations, and hydrogen ion.

The empirical evidence demonstrates that copper toxicity is affected by exposure conditions and that much of these effects is plausibly attributed to effects of ligands and cations on copper bioavailability. However, it should not be presumed that all of the observed effects of the physicochemical factors on copper toxicity reflect effects on bioavailability, or that bioavailability

NMED Exhibit 80

effects are just due to ligand complexation and cation competition. For example, acute copper toxicity in aquatic organisms has been related to disruption of osmoregulation, specifically sodium/potassium exchange (Lauren and MacDonald, 1986; Wood, 1992; Wood et al., 1997; Paquin et al., 2002), which can be affected by calcium other than by competition with copper for the same biochemical receptor. Similarly, reported effects of sodium and potassium on copper toxicity (Erickson et al., 1996 b) might simply reflect favorable or unfavorable ion exchange gradients, rather than any effect on copper bioavailability. Nevertheless, the effects of ligand complexation and cation competition on copper bioavailability provide a reasonable conceptual framework for improved descriptions of how copper toxicity differs across exposure conditions.

2.2 *Existing Approaches*

EPA aquatic life criteria for metals address the reported effects of hardness on metal toxicity using empirical regressions of toxic concentrations versus hardness for available toxicity data across a wide range of hardness (Stephan et al., 1985). Such regressions provided the relative amount by which the criteria change with hardness, but have certain limitations. The regressions were not just of hardness, but of any other factor that was correlated with hardness in the toxicity data set used for the regressions, particularly pH and alkalinity. Although these regressions therefore address more bioavailability issues than hardness alone, they best apply to waters in which the correlations among hardness, pH, and alkalinity are similar to the data used in the regressions. The separate effects of these factors are not addressed for exposure conditions in which these correlations are different. In addition, some physicochemical factors affecting metal toxicity, such as organic carbon, are not addressed at all.

Existing EPA metals criteria also address bioavailability by using dissolved metal as a better approximation for metal bioavailability than total metal (U.S. EPA, 1993). Although this approach accounts for the low bioavailability of metal on suspended particles, it does not address the major effects of various dissolved species on bioavailability. This approach could conceivably be further developed to include just part of the dissolved copper, but this not only requires resolving what species to include, how to weight them, and how to assess their concentrations, but also would not address the effects of cations and other factors that affect toxicity in addition to metal speciation. Such a "bioavailable fraction" approach is not justified, because no fraction of metals species provides a constant measure of toxicity.

To address more completely the modifying effects of water quality than the hardness regressions achieve, EPA issued guidance in the early 1980s on the water-effect ratio (WER) method (Carlson et al., 1984; U.S. EPA, 1983, 1992, 1994). The WER is "a biological method to compare bioavailability and toxicity in receiving waters versus laboratory test waters" (U.S. EPA, 1992). A WER is calculated by dividing the acute LC50 of the metal, determined in water collected from the receiving water of interest, by the LC50 of the metal determined in a standard laboratory water, after adjusting both test waters to the same hardness. The standard laboratory water LC50 is used as the denominator to reflect that this LC50 is measured in test water that has water quality characteristics representative of the test waters used to develop the Water Quality Criteria (WQC) toxicity database, at least as a good approximation. The national hardness-based acute criterion concentration is then multiplied by this ratio (i.e., the WER) to establish a site-specific criterion that reflects the effect of site water characteristics on toxicity. However, a WER accounts only for

NMED Exhibit 80

interactions of water quality parameters and their effects on metal toxicity to the species tested and in the water sample collected at a specific location and at a specific time. There is also significant cost to generate a single WER.

Because of the limitations of these past approaches for addressing bioavailability in metals criteria, there is a need for an approach that (1) explicitly and quantitatively accounts for the effect of individual water quality parameters that modify metal toxicity and (2) can be applied more cost-effectively and easily, and hence more frequently across spatial and temporal scales. An assessment framework that incorporates the bioavailability mechanisms discussed in Section 2.1 was therefore used to address more comprehensively the effects of physicochemical exposure conditions on copper toxicity with lower costs than required by the WER approach.

2.3 *The Biotic Ligand Model and Its Application to Criteria Development*

The interactions of toxic metal species and other exposure water constituents with biological surface receptors described by Zitko (1976), Morel (1983), and Pagenkopf (1983) provided the basic conceptual and mathematical structure for the bioavailability model to be used here (Figure 1). Subsequent experimental work has supported various model tenets by demonstrating the effects of complexing ligands and competing cations on accumulation of toxic metals at fish gills and the relationship of toxic effects to accumulation, and has also provided estimates of various model parameters (Playle et al., 1992, 1993a,b; Janes and Playle, 1995; MacRae et al., 1999, Meyer et al., 1999, 2002; McGeer et al., 2002). Various efforts in metal speciation modeling also have provided the ability to do better speciation calculations, especially regarding complexation of metals by organic matter (e.g., Tipping, 1994). This experimental work has supported further metal toxicity model development (Meyer, 1999; Brown and Markich, 2000; McGeer et al., 2002; Di Toro et al., 2001; Santore et al., 2001; Paquin et al., 2002). This bioavailability modeling approach is now commonly termed "Biotic Ligand Models" to broaden the scope beyond gill surfaces and to acknowledge that the biochemical receptor "X" discussed in Section 2.1 is a metal-binding ligand that is treated similarly to ligands in the exposure water, except that it is on the organism and is the keystone for metal accumulation and toxicity.

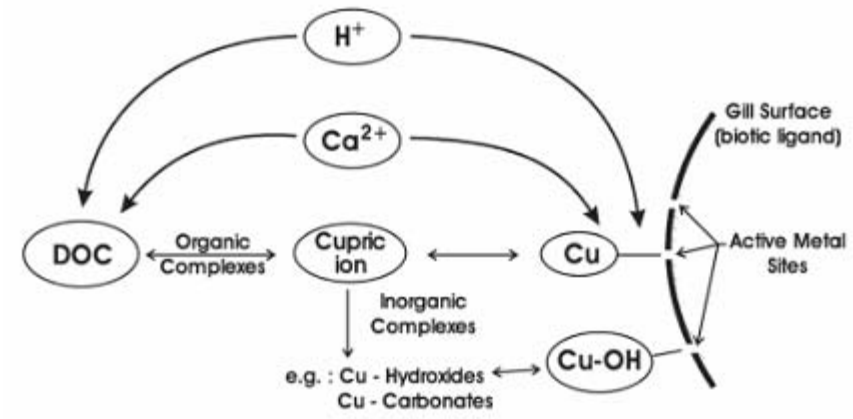

Figure1. Conceptual Diagram of Copper Speciation and Copper-Gill Model (after Pagenkopf, 1983)

NMED Exhibit 80

Briefly, available evidence indicates that both free copper and copper monohydroxide bind to a biotic ligand "Lb" on the organism's surface (Lb-Cu and Lb-CuOH) and that death occurs when a certain amount of the total biotic ligand sites are occupied by copper. This ligand must be at the organism surface because the model describes its interactions with the external exposure water. However, this does not mean that this ligand is the site of toxic action; rather it is only necessary to assume that copper accumulation at the site(s) of toxic action is proportional to binding at the biotic ligand (i.e., the biotic ligand controls bioavailability). Other cations also will bind to the biotic ligand, affecting copper bioavailability because higher concentrations of copper are needed for copper to reach toxic levels. The binding to the biotic ligand is considered to be at equilibrium, with apparent (activity-corrected) equilibrium constants K_{LbCu}, K_{LbCuOH}, and K_{LbCj}, respectively, for free copper, copper hydroxide, and the "jth" competing cation. Chemical speciation in the exposure water is also considered to be at equilibrium, and chemical speciation calculations are conducted to compute the free copper, copper hydroxide, and competing cation activities to which the biotic ligand is exposed. Because binding to the actual biotic ligand cannot be measured, it is expected that accumulation relationships for some measurable variable (e.g., the total metal in gill tissue) provide a reasonable surrogate for the actual biotic ligand. Because criteria deal with concentrations eliciting a certain level of effects on groups of organisms (e.g., LC50s), model calculations are for an organism with characteristics appropriate for such group-wide statistics.

How the BLM is applied to criteria can be best discussed by starting with the following general expression for the BLM:

$$EC = EC_0 \cdot f_C \cdot f_L \qquad \text{Equation 1}$$

where EC is the total dissolved copper concentration eliciting an effect, EC_0 is a baseline EC in the absence of any complexing ligands and competing cations, f_C should be a factor (<1) for how much competing cations increase EC, and f_L should be a factor (<1) for how much complexing ligands increase EC. For the BLM used here:

$$EC_0 = \frac{f_{LbT}}{(1 - f_{LbT}) \cdot K_{LbCu}} \qquad \text{Equation 2}$$

$$f_C = 1 + \sum_j^m \left(K_{CjLb} \cdot [C_j]\right) \qquad \text{Equation 3}$$

$$f_L = \frac{1}{\alpha_{Cu^{+n}} + \frac{K_{LbCuOH}}{K_{LbCu}} \cdot \alpha_{CuOH}} \qquad \text{Equation 4}$$

where f_{LbT} is the fraction of the biotic ligand sites that must be occupied by copper to elicit the toxicity of interest (e.g., a lethal accumulation divided by the accumulation capacity), m is the

NMED Exhibit 80

number of competing cations included in the model, [Cj] is the concentration of the jth competing cation, α_{Cu+2} is the ratio of free copper concentration to total dissolved copper concentration, α_{CuOH} is the ratio for the copper hydroxide complex, and the ratio K_{LbCuOH}/K_{LbCu} specifies the bioavailability of CuOH relative to free copper. Thus, in the absence of complexing ligands and competing cations, the toxic concentration is only a function of the binding strength of free copper and the copper occupied fraction of biotic ligand sites needed to elicit toxicity. The increase in the effect concentration due to competing cations is simply a sum of the products of their concentrations and binding constants. The increase in the effect concentration due to complexing ligands is the inverse of the sum of the products of the relative bioavailabilities and concentration fractions of the species that bind to the biotic ligand (free copper and copper hydroxide).

If toxicity to all the biological species in the criteria (at least the most sensitive ones) were determined based on measured accumulation properties and the relationship of toxicity to accumulation, the above model equations would be directly applied in criteria calculations. However, this is not the case. Although gill accumulation properties and lethal accumulations have been measured for certain species and conditions, and this has been useful in validating BLM assumptions and formulations, the data that must be applied to the criteria consists of water effect concentration (ECs) for biological species for which this accumulation information is generally not available. The BLM therefore is needed, not to make absolute calculations regarding toxic concentrations, but to extrapolate toxic concentrations from one exposure condition to another:

$$EC_A = EC_B \cdot \frac{f_{C,A} \cdot f_{I,A}}{f_{C,B} \cdot f_{I,B}} \qquad \text{Equation 5}$$

where the A and B subscripts refer to different exposure conditions. The general procedure that was followed for criteria development here was to use the above equation to normalize all available toxicity data to a reference exposure condition, calculate criteria values at the reference condition, and again use the above equation to compute criteria at other conditions.

This means that the BLM assumptions and parameters that just pertain to EC_0 are not important to its application to criteria, which actually simplifies model validation and parameterization needs. In particular, there is no need to estimate f_{LbT}, or the lethal accumulations and accumulation capacities that define this fraction. Furthermore, the absolute values of K_{LbCu} and K_{LbCuOH} do not need to be known, only their relative value (and if copper binding to the biotic ligand was dependent only on free copper, the value of K_{LbCu} would not be needed at all). Absolute values are only needed for the binding constants for the competing cations, as well as the various constants needed in speciation calculations to estimate α_{Cu+2} and α_{CuOH}. For BLM application to criteria, the important concern is whether f_C and f_L are suitably formulated and parameterized, and not with issues that relate to lethal accumulations and accumulation capacities.

2.4 *BLM Uncertainties and Performance*

The BLM employed here uses equilibrium reactions of copper and other cations with a single, simple type of surface ligand as the focus for all the effects of physicochemical exposure conditions on toxicity, and thus is a simple, approximate representation for the complex set of chemical

NMED Exhibit 80

reactions and transfers involved with environmental copper concentrations eliciting toxicity. As already noted, cation effects might involve mechanisms other than competition for a surface ligand. The microenvironment at the gill might change copper speciation. Multiple mechanisms that do not react the same to external conditions might be involved in copper bioavailability and toxicity. Accumulation parameters based on bulk gill measurements will likely not be the same as those for the biotic ligand. Nonequilibrium processes might be important, especially regarding the relationship of copper-binding on a surface ligand to toxic action.

However, any model is a simplification of reality and the existence of uncertainties does not preclude a model from being useful and justified. Despite its simplicity, the BLM used here provides a reasonable mechanistic framework for the well-established effects of copper speciation, explicitly addressing the relative bioavailability of different copper species. It also includes a plausible mechanism that allows the effects of cations to be addressed and uses a comprehensive model for calculating the required concentrations of various chemical species. Even if the mechanistic descriptions are incomplete, this model allows the major empirical effects of complexing ligands and competing cations to be described in a more comprehensive and reasonable fashion than other approaches.

Because this model is used in criteria to predict relative effects of physicochemical exposure factors, its utility for criteria can be judged based on how well it predicts the relative effects of these factors in copper toxicity studies. Examples of BLM performance for various exposure factors and studies are provided in the technical support document for this criteria. Figure 2 shows one example from a study on the effects of various exposure conditions on the acute lethality of copper to fathead minnows. This set of exposures consisted of synthetic exposure solutions of various total ion concentrations with fixed ratios of the major cations and anions, at a fixed pH (8.0) and low dissolved organic matter (< 0.5 mg/L). Observed dissolved LC50s (solid circles with uncertainty bars) varied by 24-fold for only a 9-fold change in total ions. These large effects reflect the combined influences of increased alkalinity (copper carbonate complex formation), hardness, and sodium. Considering the wide range of the observed LC50s and that the model was not fitted to these data, BLM-predicted LC50s (open symbols) were rather accurate, ranging from 55 to 87% (average 75%) of the observed value. More importantly for criteria, the predicted relative change across the range of total ion concentration was 20-fold, very close to that observed.

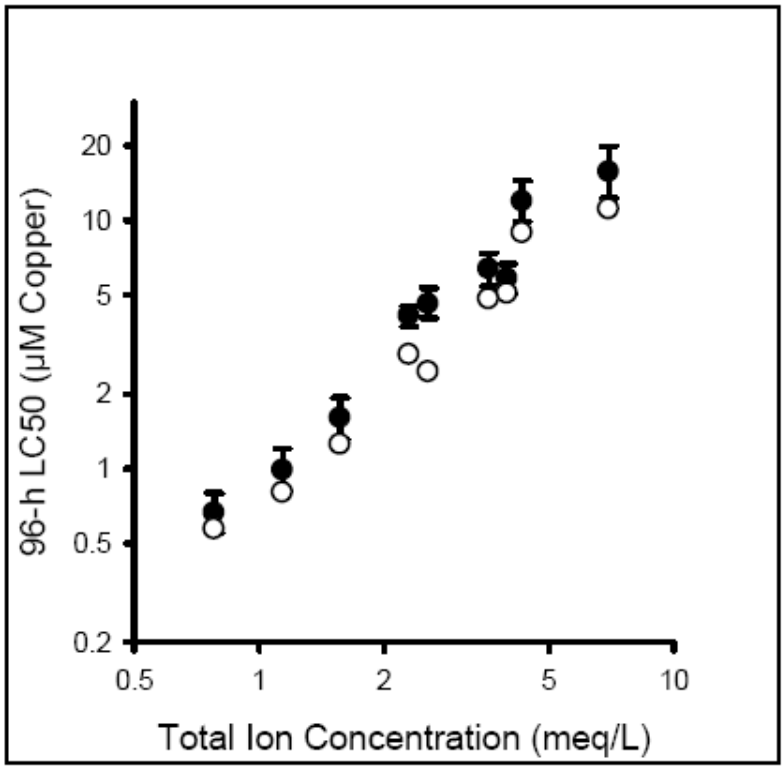

Figure 2. Effects of increasing total ion concentration on the acute lethality of copper to fathead minnows at constant pH=8 and low DOC < 0.5 mg/L. Solid symbols represent observed values, open symbols represent predicted values.

Model performance can also be judged across a variety of factors as in Figure 3, which shows predicted versus observed LC50s for a large number of exposures in the cited study, which varied hardness, alkalinity, sodium, and pH together and separately over a wide range. Observed LC50s varied by about 60-fold, but predicted values deviated from observed values by only 0.12 log units (a factor of 1.3) on average, and at worst only slightly more than a factor of 2. Again, more information on model performance is provided in the Technical Support Document and the figures here just provide some examples demonstrating the utility of this model for use in criteria.

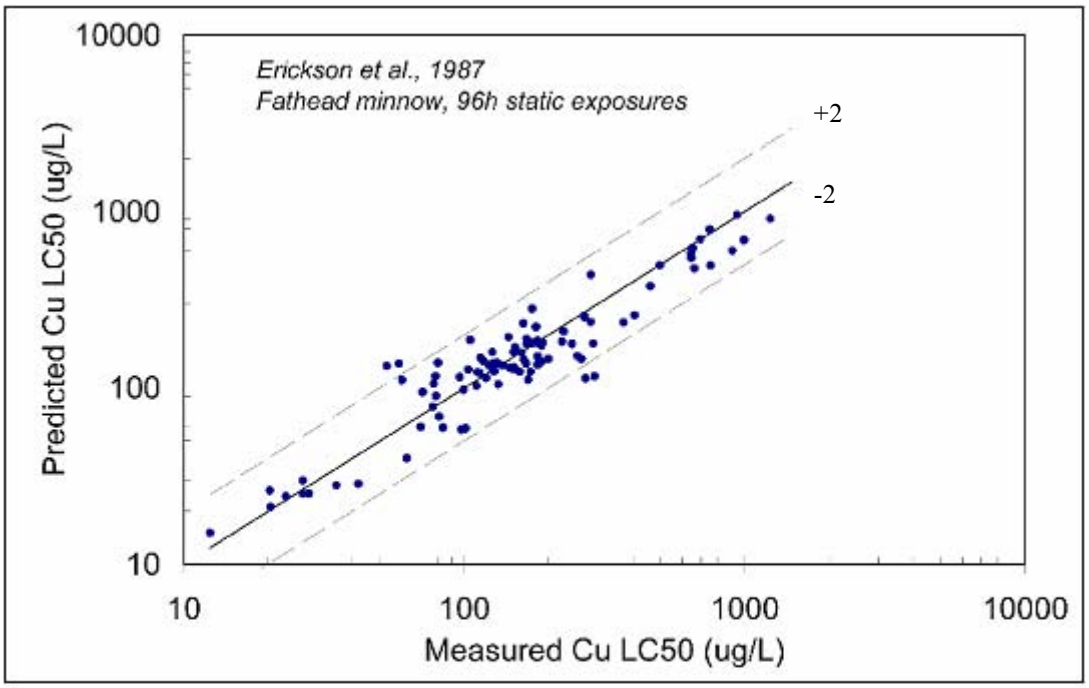

Figure 3. Comparison of Predicted and Measured Acute Copper Toxicity to *P. promelas*.

The use of the BLM to predict the bioavailability and toxicity of copper to aquatic organisms under site-specific conditions is a significant change from the previous Criterion Maximum Concentration (CMC) derivation methodology. Previous aquatic life criteria documents for copper (e.g., U.S. EPA, 1980, 1985, 1996) expressed the CMC as a function of water hardness. Now, EPA chooses to utilize the BLM to update its freshwater acute criterion because the BLM accounts for all important inorganic and organic ligand interactions of copper while also considering competitive interactions that influence binding of copper at the site of toxicity, or the "biotic ligand." The BLM's ability to incorporate metal speciation reactions and organism interactions allows prediction of metal effect levels to a variety of organisms over a wide range of water quality conditions. Accordingly, the BLM is an attractive tool for deriving water quality criteria. Application of the BLM has the potential to substantially reduce the need for site-specific modifications, such as Water Effect Ratio, to account for site-specific chemistry influences on metal toxicity.

The updated BLM-based WQC will in some cases be more stringent and in other cases less stringent than the hardness based WQC. As there is not a single WQC value to use for comparison purposes, it will only be possible to provide illustrative examples of each situation. It is the judgement of the EPA that the BLM-based WQC for Cu will provide an improved framework for evaluating a level of protection (LOP) that is consistent with the LOP that was intended by the 1985 Guidelines (i.e., a 1-in-3 year exceedance frequency that will be protective of 95% of the genera).

While the BLM is currently considered appropriate for use to derive an updated freshwater CMC for the acute WQC, further development is required before it will be suitable for use to

evaluate a saltwater CMC or a Criterion Continuous Concentration (CCC) or chronic value (freshwater or saltwater WQC).

3.0 INCORPORATION OF THE BLM INTO CRITERIA DERIVATIONS PROCEDURES

3.1 *General Final Acute Value (FAV) Procedures*

Application of the acute copper BLM to the derivation of the copper FAV is analogous to procedures already described in the Guidelines for metals criteria using empirical hardness regressions. For these hardness-dependent metals criteria, LC50s at various hardness are normalized to a reference hardness using the regression slopes. The normalized LC50s for each biological species are averaged to derive Species Mean Acute Values (SMAVs) at the reference hardness. The SMAVs within each genus are then averaged to derive Genus Mean Acute Values (GMAVs) at the reference hardness. The Guidelines' procedures for estimating the fifth percentile of the GMAVs are then used to derive the FAV at the reference hardness. FAVs for other hardness can then be derived using the hardness regression slope, and these FAVs are used to calculate the Criterion Maximum Concentration (CMC) by dividing the FAV by 2.0 and the Final Chronic Values (FCV) by dividing the FAV by the Final Acute-Chronic Ratio (FACR). Following the Guidelines, the Criterion Continuous Concentration (CCC) is set to the FCV unless other data justifies a lower value.

Extending this procedure to apply the BLM simply involves normalizing the LC50s to a reference exposure condition that includes all the physicochemical exposure factors important to the BLM, not just hardness. For this normalization, the BLM provides the factors f_C and f_L discussed in Section 2.3, these factors serving the same purpose as the hardness regression slope described above. Each LC50 to be used in criteria derivation would be normalized to the reference exposure conditions by the equation:

$$LC50_R = LC50_A \cdot \frac{f_{C,R} \cdot f_{L,R}}{f_{C,A} \cdot f_{L,A}} \qquad \text{Equation 6}$$

where the subscript A refers to the exposure conditions for the observed LC50 and the subscript R refers to the reference exposure conditions to which the LC50 is being normalized. These normalized LC50s are then used to derive the SMAVs, GMAVs, and FAV at the reference exposure condition as described above for the hardness-corrected criteria. The BLM is then used to derive FAVs at other exposures by the equation:

$$FAV_B = FAV_R \cdot \frac{f_{C,B} \cdot f_{L,B}}{f_{C,R} \cdot f_{L,R}} \qquad \text{Equation 7}$$

NMED Exhibit 80

where the subscript B refers to the exposure conditions for which an FAV is desired. These BLM-derived FAVs are then used to derive CMCs and CCCs following standard Guidelines procedures.

For the criteria in this document, the reference exposure conditions to which LC50s are normalized and at which the reference FAV is calculated are as follows (see also footnote f in Table 1). The water chemistry used in the normalization was based on the EPA formulation for moderately-hard reconstituted water, but any other water chemistry could have been used. In this formulation the parameters included: temperature = 20°C, pH = 7.5, DOC = 0.5 mg/L, Ca = 14.0 mg/L, Mg = 12.1 mg/L, Na = 26.3 mg/L, K = 2.1 mg/L, SO_4 =81.4 mg/L, Cl = 1.90 mg/L, Alkalinity = 65.0 mg/L and S = 0.0003 mg/L.

3.2 *BLM Input Parameters*

For applying an LC50 to criteria derivations and for determining an FAV at exposure conditions of interest, the necessary water quality input parameters for BLM calculations are temperature, pH, dissolved organic carbon, major geochemical cations (calcium, magnesium, sodium, and potassium), dissolved inorganic carbon (DIC, the sum of dissolved carbon dioxide, carbonic acid, bicarbonate, and carbonate), and other major geochemical anions (chloride, sulfate). DIC measurements are typically not made in the environment, and an alternative input parameter is alkalinity, which can be used with pH and temperature to estimate DIC. There is some evidence that other metals such as iron and aluminum can have an effect on copper toxicity to aquatic organisms, which might be due to interactions of these metals with the biotic ligand, effects of these metals on organic carbon complexation of copper, or adsorption of copper to iron and aluminum colloids which are present in filtrates used to measure dissolved copper. These metals are not currently included in routine BLM inputs, but users are encouraged to measure dissolved iron and aluminum as part of monitoring efforts to support possible future criteria applications.

A number of fixed parameters are also used in the BLM but are not required user inputs in criteria derivations. These include the variety of equilibrium constants used in copper speciation calculations, and also the binding constants for copper and various cations to the biotic ligand. The values for these constants were obtained from work by Playle and coworkers (Playle et al., 1992, 1993a,b) and also by inference from the relationship of toxicity to various water quality characteristics. More information about these parameters can be obtained from the technical support document.

3.3 *Data Screening Procedures*

To use a toxicity test in the derivation of BLM-based criteria, information must be available for the various water quality parameters described in Section 3.2. This is in contrast to past metals criteria, for which the only necessary water quality parameter was hardness. Many of these parameters are not routinely measured in toxicity tests and, if measured, are not necessarily reported in the primary literature for the test, especially for older toxicity tests. However, this information might be available from supplemental sources or be estimated based on other information. Therefore, in addition to reviewing the primary sources for relevant information,

NMED Exhibit 80

additional efforts were made to obtain or estimate the necessary water quality parameters for as many of the available LC50s as possible.

A detailed description of these efforts is provided in Appendix C, Estimation of Water Chemistry Parameters for Acute Copper Toxicity Tests, and are summarized as follows. Reports of acute copper toxicity tests identified in literature searches were reviewed to identify LC50s for possible inclusion in the criteria derivation. In addition to test acceptability standards specified in the Guidelines, the current effort also required that the LC50s be based on measured copper concentrations. LC50s based on nominal concentrations have been used in previous criteria, but there are enough measured LC50s for copper that this was considered to be no longer warranted, especially considering the more advanced bioavailability assessments represented by the BLM. For the identified LC50s, the primary reports were reviewed to record all reported information on dilution and test water chemistry. Any additional references specified by the authors were also obtained and reviewed. If test waters were synthetically prepared based on specified formulas, these were used to estimate parameters as appropriate. When critical water chemistry parameters were not available, authors were contacted regarding unpublished information or to measure missing water chemistry parameters in dilution source waters. If primary or corresponding authors could not be contacted, an attempt was made to contact secondary authors or personnel from the laboratories where the studies were conducted. Where actual water chemistry data were unavailable, data from other studies with the same water source were used as surrogate values if appropriate. Absent this, the U.S. Geological Survey's National Stream Quality Accounting Network (NASQAN) and the EPA STOrage and RETrieval (STORET) were used to obtain data for ambient surface waters which were the source of water for a test. In some instances other available sources were contacted to obtained water chemistry data (e.g., city drinking water treatment personnel). The acquired data were scrutinized for representativeness and usefulness for estimating surrogate values to complete the water quality information for the dilution and/or test water that was used in the original studies. When the above sources could not be used, geochemical ion inputs were based on reported hardness measurements and regressions relationships constructed for the relationship of various ions to hardness from NASQAN data.

As with any modeling effort, the reliability of model output depends on the reliability of model inputs. Although the input data have been closely scrutinized, the reliability of the BLM-normalized LC50s are subject to the uncertainties of the estimation procedures described above. Therefore, a ranking system was devised to rank the quality of the chemical characterization of the test water. Studies with a rank of 1 contain all of the necessary parameters for BLM input based on measurements from either the test chambers or the water source. In general, studies in which the BLM input parameters were reported for test chamber samples take precedence over studies in which the parameters were reported only for the source water. A characterization ranking of 2 denotes those studies where not all parameters were measured, but reliable estimates of the requisite concentrations could be made. Similarly, a rank of 3 denotes studies in which all parameters except DOC were measured, but reliable estimates of DOC could be made. For the majority of the tests, a chemical characterization of 4+ was assigned because hardness, alkalinity, and pH were measured, and the ionic composition could be reliably estimated or calculated. A 4- was assigned to those studies conducted using standard reconstituted water in which hardness, alkalinity, or pH was either measured or referenced, and the recipe for the water is known (ASTM, 2000; U.S. EPA, 1993). The chemical characterization rank of 5 was ascribed to studies in which

NMED Exhibit 80

one of the key parameters (DOC, Ca, pH, alkalinity) was not measured, and when it could not be reliably estimated. If two or more key parameters (DOC, Ca, pH, alkalinity) were not measured and could not be reliably estimated, a study was given a chemical characterization rank of 6. Studies receiving a quality rating of greater than 4+ (i.e., higher than 4) were not used in the criteria development procedures because the estimates for some of the key input parameters were not thought to be reliable, all other studies were used.

3.4 *Conversion Factors*

The LC50s used in deriving previous EPA metals criteria were based on total metal concentration (measured or nominal) and the criteria were consequently for total metals concentration. EPA afterwards made the decision that metals criteria should be based on dissolved metal because it was thought to better represent the bioavailable fraction of the metal (U.S. EPA, 1993). It was thus necessary to convert the criteria to a dissolved concentration basis. However, at that time, most toxicity tests reported only total concentration, so that a procedure was necessary to estimate the likely fractions of metals that were dissolved in typical toxicity tests. Studies were therefore conducted to determine these fractions under a variety of test conditions that mimicked the conditions in the tests used to derive the metals criteria (University of Wisconsin-Superior, 1995). These tests demonstrated high fractions of dissolved copper and resulted in a conversion factor (CF) of 0.96 for converting both the CMC and CCC for copper from a total to dissolved basis (Stephan, 1995). The BLM-derived criteria developed here also uses dissolved copper as the basis for criteria, assuming a negligible bioavailability for particulate copper. The conversion factor of 0.96 was also used to convert total to dissolved copper for any toxicity test for which dissolved copper measurements were not available.

3.5 *Final Chronic Value (FCV) Procedures*

Because the minimum eight family data requirements for chronic toxicity data were not met in order to calculate the FCV by the fifth percentile method used for the FAV and because insufficient information was available to develop a chronic BLM, EPA derived the CCC utilizing the Acute to Chronic Ratio (ACR) approach from the Guidelines (Stephan et al., 1985). To calculate the FCV at a specific water chemistry, the FAV at that chemistry is divided by the FACR. This entails the assumption that the acute BLM reasonably approximates the bioavailability relationships for chronic toxicity. Limited data available regarding effects of water chemistry on sublethal effects and chronic lethality do show substantial effects of organic matter, alkalinity, pH, and sodium (Winner, 1985; Erickson et al., 1996 a,b) similar to those in the acute BLM used here. For hardness, apparent effects are limited and uncertain, but the use of the acute BLM does not introduce major uncertainties in this regard because the effects of hardness by itself in the acute BLM are also limited.

4.0 DATA SUMMARY AND CRITERIA CALCULATION

4.1 *Summary of Acute Toxicity to Freshwater Animals and Criteria Calculation*

The screening procedure outlined in Sec. 3.3 (high quality data = 1, low quality data > 4, e.g. 4+) identified approximately 600 acute freshwater toxicity tests with aquatic organisms and copper

NMED Exhibit 80

potentially acceptable for deriving criteria. Of these tests, approximately 100 were eliminated from the criteria derivation process because they did not report measured copper concentrations. Nearly 150 additional tests were eliminated from the calculation of the FAV because they received a quality rating of greater than 4 in the quality rating scheme described in section 3.3 described above.

Data from approximately 350 tests were used to derive normalized LC50 values, including 15 species of invertebrates, 22 species of fish, and 1 amphibian species (Table 1), representing 27 different genera. Species Mean Acute Values (SMAVs) at the reference chemistry were calculated from the normalized LC50s and Genus Mean Acute Values (GMAVs) at the normalization chemistry were calculated from the SMAVs.

SMAVs ranged from 2.37 µg/L for the most sensitive species, *Daphnia pulicaria*, to 107,860 µg/L for the least sensitive species, *Notemigonus crysoleucas*. Cladocerans were among the most sensitive species, with *D. pulicaria, D. magna*, *Ceriodaphnia dubia*, and *Scapholeberis sp.* being four out of the six most sensitive species. Invertebrates in general were more sensitive than fish, representing the 10 lowest SMAVs.

The 27 GMAVs calculated from the above-mentioned SMAVs ranged from 4.05 µg/L for *Daphnia* to 107,860 µg/L for *Notemigonus* (Table 3a). Nine of the 10 most sensitive genera were invertebrates. The salmonid genus *Oncorhynchus* was the most sensitive fish genus, with a GMAV of 31.39 µg/L and an overall GMAV ranking of 10.

The ranked GMAVs are presented in Figure 4. Pursuant to procedures used to calculate the FAV, a FAV of 4.67 µg/L was derived from the four GMAVs with cumulative probabilities closest to the 5th percentile toxicity value for all the tested genera (Table 3b). The presumption is that this

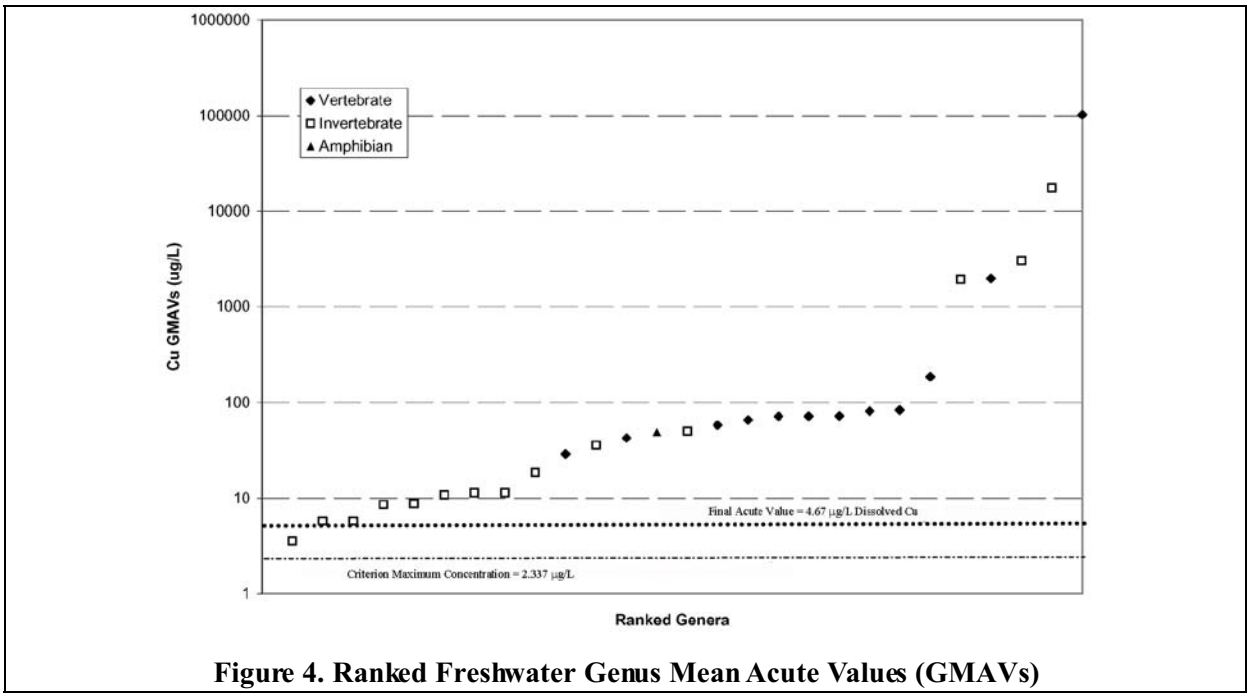

Figure 4. Ranked Freshwater Genus Mean Acute Values (GMAVs)

NMED Exhibit 80

acute toxicity value represents the LC50 for an organism that is sensitive at the 5th percentile of the GMAV distribution. The CMC is the FAV divided by two. Therefore, the freshwater dissolved copper CMC for the reference chemistry presented is 2.337 µg/L.

Site-water chemistry parameters are needed to evaluate a criterion. This is analogous to the situation that previously existed for the hardness-based WQC, where a hardness concentration was necessary in order to derive a criterion. Examples of CMC calculations at various water chemistry conditions are presented in Figure 5 and Appendix G.

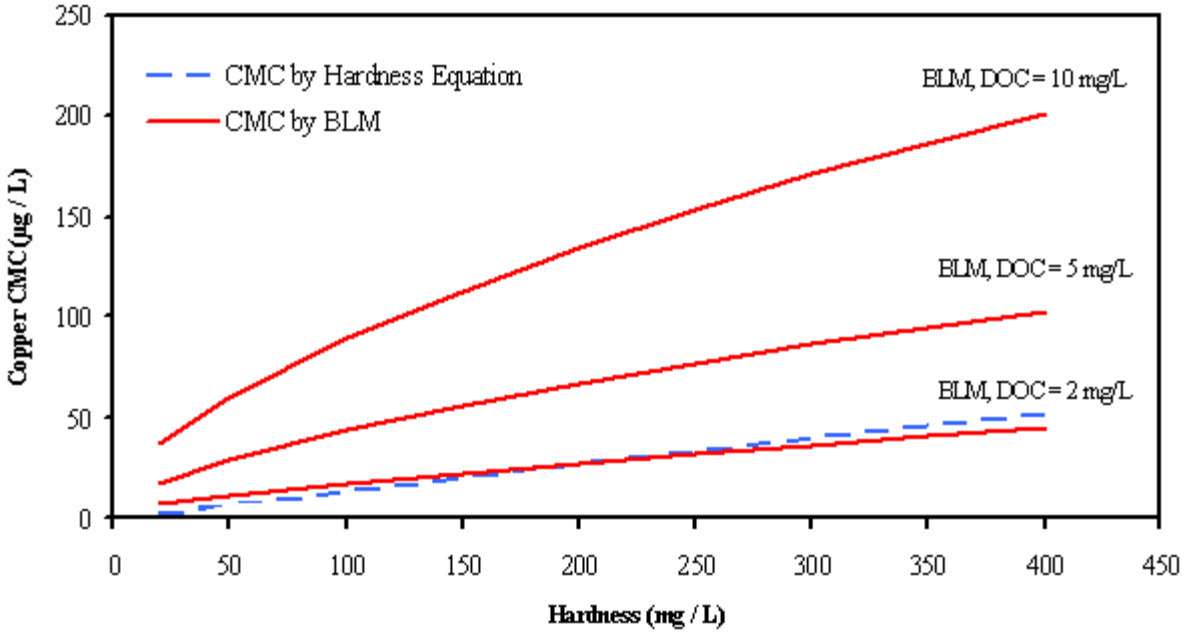

Figure 5. Comparison of CMC calculated by BLM or Hardness Equation Alkalinity (11 - 245 mg CaCO3/L) and pH (7.3 - 8.7) Covary with Hardness

4.1.1 *Comparison With Earlier Hardness-Adjusted Criteria*

EPA's earlier freshwater copper criteria recommendations were hardness-dependent values. One would expect a BLM-based criterion calculation procedure to yield the more appropriate criterion—appropriate in the sense that it accounts for the important water chemistry factors that affect toxicity, including DOC complexation, where the hardness correction does not. Application of the BLM in field situations where DOC is expected to be present at higher concentrations than those observed in laboratory studies would likely improve the performance of the BLM compared with the hardness adjustment. The reason is that the BLM would reasonably account for the typically observed increase in effect levels under such conditions, while the hardness-based approach would not (Figure 5).

As a comparison between the hardness typical of the previous copper criterion and this revised criterion using the BLM, both procedures were used to calculate criterion values for waters with a range in hardness as specified by the standard EPA recipes (U.S. EPA, 1993). The EPA formulations specify the concentration of various salts and reagents to be used in the synthesis of

NMED Exhibit 80

laboratory test waters with specific hardness values (e.g., very soft, soft, moderately hard, hard, or very hard). As the water hardness increases in these recipes, pH and alkalinity also increase. This has implications for the BLM because the bioavailability of copper would be expected to decrease with increasing pH and alkalinity due to the increasing degree of complexation of copper with hydroxides and carbonates and decreasing proton competition with the metal at both DOM and biotic ligand binding sites. The BLM criterion for these waters agrees very well with that calculated by the hardness equation used in previous copper criterion documents (Figure 5). However, alkalinity and pH change as hardness changes in the EPA recipes. The BLM prediction is taking all of these changes in water quality into account.

It is possible to use the BLM to look only at the change in predicted WQC with changes in hardness (e.g., alkalinity and pH remaining constant). The hardness equation is based on waters where changes in hardness are accompanied by changes in pH and alkalinity. However, there are many possible natural waters where changes in hardness are not accompanied by changes in pH and alkalinity (such as water draining a region rich in gypsum). In these cases, the hardness equation based criterion will still assume a response that is characteristic of waters where hardness, alkalinity, and pH co-vary, and will likely be underprotective relative to the level of protection intended by the Guidelines, in high hardness waters. Conversely, in waters where the covariation between hardness, pH, and alkalinity is greater than is typical for data in Table 1, the hardness equation based criteria may be overprotective. Appendix G shows representative water quality criteria values using both the BLM and the hardness equation approaches for waters with a range in pH, hardness, and DOC concentrations. The hardness approach does not consider pH and DOC while the BLM approach takes those water quality parameters into consideration.

4.2 Formulation of the CCC

4.2.1 *Evaluation of Chronic Toxicity Data*

In aquatic toxicity tests, chronic values are usually defined as the geometric mean of the highest concentration of a toxic substance at which no adverse effect is observed (highest no observed adverse effect concentration, or NOAEC) and the lowest concentration of the toxic substance that causes an adverse effect (lowest observed adverse effect concentration, or LOAEC). The significance of the observed effects is determined by statistical tests comparing responses of organisms exposed to low-level and control concentrations of the toxic substance against responses of organisms exposed to elevated concentrations. Analysis of variance is the most common test employed for such comparisons. This approach, however, has the disadvantage of resulting in marked differences between the magnitudes of the effects corresponding to the individual chronic values, because of variation in the power of the statistical tests used, the concentrations tested, and the size and variability of the samples used (Stephan and Rogers, 1985).

An alternative approach to calculating chronic values focuses on the use of point estimates such as from regression analysis to define the dose-response relationship. With a regression equation or probit analysis, which defines the level of adverse effects as a function of increasing concentrations of the toxic substance, it is possible to determine the concentration that causes a specific small effect, such as a 5 to 30 percent reduction in response. To make chronic values reflect a uniform level of effect, regression and probit analyses were used, where possible, both to demonstrate that a significant concentration-effect relationship was present and to estimate chronic

NMED Exhibit 80

values with a consistent level of effect. The most precise estimates of effect concentrations can generally be made for 50 percent reduction (EC50); however, such a major reduction is not necessarily consistent with criteria providing adequate protection. In contrast, a concentration that causes a low level of reduction, such as an EC5 or EC10, might not be statistically significantly different from the control treatment. As a compromise, the EC20 is used here to represent a low level of effect that is generally significantly different from the control treatment across the useful chronic datasets that are available for copper. The EC20 was also viewed as providing a level of protection similar to the geometric mean of the NOEC and LOEC. Since the EC20 is not directly dependent on the tested dilution series, similar EC20s should be expected irrespective of the tested concentrations, provided that the range of tested concentrations is appropriate.

Regression or probit analysis was utilized to evaluate a chronic dataset only in cases where the necessary data were available and the dataset met the following conditions: (1) it contained a control treatment (or low exposure data point) to anchor the curve at the low end, (2) it contained at least three concentrations, and (3) two of the data points had effect variable values below the control and above zero (i.e., "partial effects"). Control concentrations of copper were estimated in cases where no measurements were reported. These analyses were performed using the Toxicity Relationship Analysis Program software (version 1.0; U.S. EPA, Mid-Continental Ecology Division, Duluth, MN, USA). Additional detail regarding the aforementioned statistical procedures is available in the cited program.

When the data from an acceptable chronic test met the conditions for the logistic regression or probit analysis, the EC20 was the preferred chronic value. When data did not meet the conditions the chronic value was usually set to the geometric mean of the NOAEC and the LOAEC. However, when no treatment concentration was an NOAEC, the chronic value is reported as less than the lowest tested concentration.

For life-cycle, partial life-cycle, and early life stage tests, the toxicological variable used in chronic value analyses was survival, reproduction, growth, emergence, or intrinsic growth rate. If copper apparently reduced both survival and growth (weight or length), the product of variables (biomass) was analyzed, rather than analyzing the variables separately. The most sensitive of the toxicological variables was generally selected as the chronic value for the particular study.

A species-by-species discussion of each acceptable chronic test on copper evaluated for this document is presented in Appendix F. Figures that present the data and regression/probability distribution line for each of the acceptable chronic test which contained sufficient acceptable data are also provided in Appendix F.

4.2.2 *Calculation of Freshwater CCC*

Acceptable freshwater chronic toxicity data from early life stage tests, partial life-cycle tests, and full life-cycle tests were available for 29 tests including data for 6 invertebrate species and 10 fish species (Table 2a). The 17 chronic values for invertebrate species range from 2.83 (*D. pulex)* to 34.6 µg/L (*C. dubia*); and the 12 chronic values for the fish species range from <5 (brook trout) to 60.4 µg/L (northern pike). Of the 29 chronic tests, comparable acute values are available for 18 of the tests (Table 2c). The relationship between acute toxicity values and ACRs is presented in Figure 6. The supporting acute and chronic test values for the ACRs and the species mean ACRs are

NMED Exhibit 80

presented in Table 2c. For the 11 tests in Table 2a with chronic values both from a regression EC20 and the geometric mean of the NOAEC and LOAEC, the EC20 averaged 81% of the geometric mean, demonstrating the similar level of protection for the two approaches.

Overall, individual ACRs varied from <1 (0.55) for *C. dubia* (Oris et al., 1991) to 191.6 for the snail, *Campeloma decisum* (Arthur and Leonard, 1970). Species mean acute-chronic ratios ranged from 1.48 in saltwater for the sheepshead minnow (Hughes et al., 1989) to 171.2 in freshwater for the snail, *C. decisum*. Pursuant to the Guidelines (Stephan et al., 1985), consideration was given to calculating the FACR based on all ACRs within a factor of 10, but because there appeared to be a relationship between acute sensitivity and ACRs (Figure 6), the FACR was derived from data for species whose SMAVs were close to the FAV. The FACR of 3.22 was calculated as the geometric mean of the ACRs for sensitive freshwater species, *C. dubia, D. magna, D. pulex, O. tshawytscha*, and *O. mykiss* along with the one saltwater ACR for *C. variegatus* (Table 2b). Based on the normalization water chemistry conditions used for illustrative purposes in the document, the freshwater site specific FAV value is 4.67 µg/L, which divided by the FACR of 3.22 results in a freshwater FCV of 1.45 µg/L dissolved Cu.

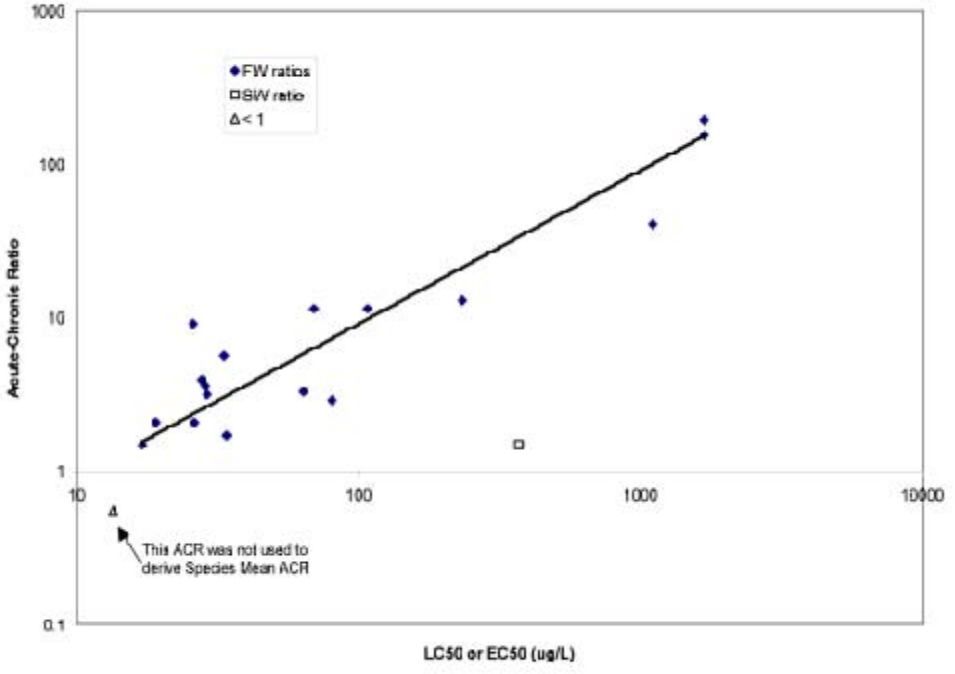

Figure 6. Relationship Between Freshwater Acute Copper Sensitivity (LC50 or EC50) and Acute-Chronic Ratios

5.0 PLANT DATA

Copper has been widely used as an algicide and herbicide for nuisance aquatic plants (McKnight et al., 1983). Although copper is known as an inhibitor of photosynthesis and plant growth, toxicity data on individual species suitable for deriving aquatic life criteria (Table 4) are not numerous.

The relationship of copper toxicity to the complexing capacity of the water or the culture medium is now widely recognized (Gächter et al., 1973; Petersen, 1982), and several studies have used algae to "assay" the copper complexing capacity of both fresh and salt waters (Allen et al., 1983; Lumsden and Florence, 1983; Rueter, 1983). It has also been shown that algae are capable of excreting complexing substances in response to copper stress (McKnight and Morel, 1979; Swallow et al., 1978; van den Berg et al., 1979). Foster (1982) and Stokes and Hutchinson (1976) have identified resistant strains and/or species of algae from copper (or other metal) impacted environments. A portion of this resistance probably results from induction of the chelate-excretion mechanism. Chelate excretion by algae may also serve as a protective mechanism for other aquatic organisms in eutrophic waters; that is, where algae are capable of maintaining free copper activities below harmful concentrations.

Copper concentrations from 1 to 8,000 µg/L have been shown to inhibit growth of various freshwater plant species. Very few of these tests, though, were accompanied by analysis of actual copper exposure concentrations. Notable exceptions are freshwater tests with green alga including *Chlamydomonas reinhardtii* (Schafer et al., 1993; Winner and Owen, 1991b), which is the only flow-through, measured test with an aquatic plant, *Chlorella vulgaris* and *Selenastrum capricornutum* (Blaylock et al., 1985). There is also a measured test with duckweed, *Lemna minor* (Taraldsen and Norberg-King, 1990).

A direct comparison between the freshwater plant data and the BLM derived criteria is difficult to make without a better understanding of the composition of the algal media used for different studies (e.g., DOC, hardness, and pH) because these factors influence the applicable criteria comparison. BLM derived criteria for certain water conditions, such as low to mid-range pH, hardness up to 100 mg/L as $CaCO_3$, and low DOC are in the range of, if not lower than, the lowest reported toxic endpoints for freshwater algal species and would therefore appear protective of plant species. In other water quality conditions BLM-derived criteria may be significantly higher (see Figure 5).

Two publications provide data for the red algae *Champia parvula* that indicate that reproduction of this species is especially sensitive to copper. The methods manual (U.S. EPA 1988) for whole effluent toxicity (WET) testing contains the results of six experiments showing nominal reproduction LOECs from 48-hr exposures to 1.0 to 2.5 µg/L copper (mean 2.0 µg/L); these tests used a mixture of 50 percent sterile seawater and 50 percent GP2 medium copper. The second study by Morrison et al. (1989) evaluated interlaboratory variation of the 48-hr WET test procedure; this six-test study gave growth EC50 values from 0.8 to 1.9 µg/L (mean 1.0 µg/L). Thus, there are actually 12 tests that provide evidence of significant reproductive impairment in *C. parvula* at nominal copper concentrations between 0.8 and 2.5 µg/L. For these studies though, the dilution water source was not identified.

NMED Exhibit 80

One difficulty in assessing these data is the uncertainty of the copper concentration in the test solutions, primarily with respect to any background copper that might be found in the dilution water, especially with solutions compounded from sea salts or reagents. Thus, with a CCC of 1.9 µg/L dissolved copper, the significance of a 1 or 2 µg/L background copper level to a 1 to 3 µg/L nominal effect level can be considerable.

The reproduction of other macroalgae appears to be generally sensitive to copper, but not to the extent of *Champia*. Many of these other macroalgae appear to have greater ecological significance than *Champia*, several forming significant intertidal and subtidal habitats for other saltwater organisms, as well as being a major food source for grazers. Reproductive and growth effects on the other species of macroalgae sometimes appear to occur at copper concentrations between 5 and 10 µg/L (Appendix B, Other Data). Thus, most major macrophyte groups seem to be adequately protected by the CMC and CCC, but appear similar in sensitivity to some of the more sensitive groups of saltwater animals.

6.0 OTHER DATA

Many of the data identified for this effort are listed in Appendix B, Other Data, for various reasons, including exposure durations other than 96 hours with the same species reported in Table 1, and some exposures lasting up to 30 days. Acute values for test durations less than 96 hours are available for several species not shown in Table 1. Still, these species have approximately the same sensitivities to copper as species in the same families listed in Table 1. Reported LC50s at 200 hours for chinook salmon and rainbow trout (Chapman, 1978) differ only slightly from 96-hour LC50s reported for these same species in the same water.

A number of other acute tests in Appendix B were conducted in dilution waters that were not considered appropriate for criteria development. Brungs et al. (1976) and Geckler et al. (1976) conducted tests with many species in stream water that contained a large amount of effluent from a sewage treatment plant. Wallen et al. (1957) tested mosquitofish in a turbid pond water. Until chemical measurements that correlate well with the toxicity of copper in a wide variety of waters are identified and widely used, results of tests in unusual dilution waters, such as those in Appendix B, will not be very useful for deriving water quality criteria.

Appendix B also includes tests based on physiological effects, such as changes in appetite, blood parameters, stamina, etc. These were included in Appendix B because they could not be directly interpreted for derivation of criteria. For the reasons stated in this section above, data in Appendix B was not used for criteria derivation.

A direct comparison of a particular test result to a BLM-derived criterion is not always straightforward, particularly if complete chemical characterization of the test water is not available. Such is the case for a number of studies included in Appendix B. While there are some test results with effect concentrations below the example criteria concentrations presented in this document, these same effect concentrations could be above criteria derived for other normalization chemistries, raising the question as to what is the appropriate comparison to make. For example, Appendix B includes an EC50 for *D. Pulex* of 3.6 µg/L (Koivisto et al., 1992) at an approximate hardness of 25 mg/L (33 mg/L as $CaCO_3$). Yet, example criteria at a hardness of 25 mg/L (as $CaCO_3$) (including those in Figure 6) range from 0.23 µg/L (DOC = 0.1 mg/L) to 4.09 µg/L (DOC = 2.3 mg/L) based

NMED Exhibit 80

on the DOC concentration selected for the synthetic water recipe. The chemical composition for the Koivisto et al. (1992) study would dictate what the appropriate BLM criteria comparison should be.

Based on the expectation that many of the test results presented in Appendix B were conducted in laboratory dilution water with low levels of DOC, the appropriate comparison would be to the criteria derived from low DOC waters. Comparing many of the values in Appendix B to the example criteria presented in this document, it appears that a large proportion of Appendix B values are above these concentration levels. This is a broad generalization though and as stated previously, all important water chemistry variables that affect toxicity of copper to aquatic organisms should be considered before making these types of comparisons.

Studies not considered suitable for criteria development were placed in Appendix G, Unused Data.

7.0 NATIONAL CRITERIA STATEMENT

The available toxicity data, when evaluated using the procedures described in the "Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses" indicate that freshwater aquatic life should be protected if the 24-hour average and four-day average concentrations do not respectively exceed the acute and chronic criteria concentrations calculated by the Biotic Ligand Model.

A return interval of 3 years between exceedances of the criterion continues to be EPA's general recommendation. However, the resilience of ecosystems and their ability to recover differ greatly. Therefore, scientific derivation of alternative frequencies for exceeding criteria may be appropriate.

8.0 IMPLEMENTATION

The use of water quality criteria in designing waste treatment facilities and appropriate effluent limits involves the use of an appropriate wasteload allocation model. Although dynamic models are preferred for application of these criteria, limited data or other factors may make their use impractical, in which case one should rely on a steady-state model. EPA recommends the interim use of 1B3 or 1Q10 for criterion maximum concentration stream design flow and 4B3 or 7Q10 for the criterion continuous concentration design flow in steady-state models. These matters are discussed in more detail in the Technical Support Document for Water Quality-Based Toxics Control (U.S. EPA, 1991).

With regard to BLM-derived freshwater criteria, to develop a site-specific criterion for a stream reach, one is faced with determining what single criterion is appropriate even though a BLM criterion calculated for the event corresponding to the input water chemistry conditions will be time-variable. This is not a new problem unique to the BLM—hardness-dependent metals criteria are also time-variable values. Although the variability of hardness over time can be characterized, EPA has not provided guidance on how to calculate site-specific criteria considering this variability. Multiple input parameters for the BLM could complicate the calculation of site-specific criteria because of their combined effects on variability. Another problem arise from potential scarcity of data from small stream reaches with small dischargers. The EPA is currently exploring two

NMED Exhibit 80

approaches to fill data gaps in such situations. One potential approach is the selection of values based on geography, the second approach is based on correlations between measured parameters and missing parameter measurements. A companion document in the form of Supplementary Training Materials, addressing issues related to data requirements, implementation, permitting, and monitoring will be released via EPA's website following the publication of this criteria document.□□

[a] Species appear in order taxonomically, with invertebrates listed first, fish, and an amphibian listed last. Species within each genus are ordered alphabetically. Within each species, tests are ordered by test method (static, renewal, flow-through) and date.

[b] S = static, R = renewal, F = flow-through, U = unmeasured, M = measured, T = exposure concentrations were measured as total copper, D = exposure concentrations were measured as dissolved copper.

[c] S = copper sulfate, N = copper nitrate, C = copper chloride.

[d] Values in this column are total copper LC50 or EC50 values as reported by the author.

[e] Values in this column are dissolved copper LC50 or EC50 values either reported by the author or if the author did not report a dissolved value then a conversion factor (CF) was applied to the total copper LC50 to estimate dissolved copper values.

[f] Normalization Chemistry

Temp	pH	Diss Cu	DOC	%HA	Ca	Mg	Na	K	SO_4	Cl	Alkalinity	S
Deg C		ug/L	mg/L		mg/L	mg/L	mg/L	mg/L	mg/L	mg/L	mg/L	mg/L
20.00	7.5	1.00	0.5	10.0	14.0	12.1	26.3	2.1	81.4	1.9	65.0	0.0003

g Underlined LC50s or EC50s not used to derive SMAV because considered extreme value.

* Table updated as of March 2, 2007

Table 3b. Freshwater Final Acute Value (FAV) and Criteria Calculations

Calculated Freshwater FAV based on 4 lowest values: Total Number of GMAVs in Data Set = 27					
Rank	**GMAV**	**lnGMAV**	**$(lnGMAV)^2$**	**P = R/(n+1)**	**SQRT(P)**
4	9.600	2.261	5.114	0.143	0.378
3	6.670	1.897	3.599	0.107	0.327
2	5.930	1.780	3.170	0.071	0.267
1	4.050	1.398	1.954	0.036	0.189
Sum:		**7.33671**	**13.83657**	**0.35714**	**1.16153**
S =	4.374				
L =	0.5641				
A =	1.542				
Calculated FAV =	**4.674452**				
Calculated CMC =	**2.337**				

Dissolved Copper Criterion Maximum Concentration (CMC) = 2.337 µg/L (for example normalization chemistry see Table 1, footnote f)
Criteria Lethal Accumulation (LA50) based on example normalization chemistry = 0.03395 nmol/g wet wt
Criterion Continuous Concentration (CCC) = 4.67445/3.22 = 1.4516932 µg/L (for example normalization chemistry see Table 1, footnote f)

S = Scale parameter or slope
L = Location parameter or intercept
P = Cumulative probability
A = lnFAV

* Table updated as of March 2, 2007

Table 4. Toxicity of Copper to Freshwater Plants

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Result[b] (Total µg/L)	Reference
Blue-green alga, *Anabaena flos-aqua*	S,U	Copper sulfate	65.2	96 hr	EC75 (cell density)	200	Young and Lisk 1972
Bllue-green alga, *Anabaena variabilis*	S,U	Copper sulfate	65.2	-	EC85 (wet weight)	100	Young and Lisk 1972

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Bacteria, *Escherichia coli*	S,U	Copper sulfate	-	48 hr	Threshold of inhibited glucose use; measured by pH change in media	80	-	Bringmann and Kuhn 1959a
Bacteria, *Pseudomonas putida*	S,U	Copper sulfate	81.1	16 hr	EC3 (cell numbers)	30	-	Bringmann and Kuhn 1976, 1977a, 1979, 1980a
Protozoan, *Entosiphon sulcatum*	S,U	Copper sulfate	81.9	72 hr	EC5 (cell numbers)	110	-	Bringmann 1978; Bringmann and Kuhn 1979, 1980a,
Protozoan, *Microrega heterostoma*	S,U	Copper sulfate	214	28 hr	Threshold of decreased feeding rate	50	-	Bringmann and Kuhn 1959b
Protozoan, *Chilomonas paramecium*	S,U	Copper sulfate	-	48 hr	Growth threshold	3,200	-	Bringmann and Kuhn 1980b, 1981
Protozoan, *Uronema parduezi*	S,U	Copper sulfate	-	20 hr	Growth threshold	140	-	Bringmann and Kuhn 1980b, 1981
Protozoa, mixed species	-	-	-	7 days	Reduced rate of colonization	167	-	Cairns et al. 1980
Protozoa, mixed species	S,M,T	Copper sulfate	-	15 days	Reduced rate of colonization	100	-	Buikema et al. 1983
Green alga, *Cladophora glomerata*	Dosed stream	Copper sulfate	226-310	10 mo	Decreased abundance from 21% down to 0%	120	-	Weber and McFarland 1981
Green alga, *Chlamydomonas reinhardtii*	-	Copper sulfate	76	72 hr	Deflagellation	6.7	-	Garvey et al. 1991
Green alga, *Chlamydomonas reinhardtii*	-	Copper sulfate	76	72 hr	Deflagellation	6.7	-	Garvey et al. 1991
Green alga, *Chlamydomonas reinhardtii*	-	Copper sulfate	76	72 hr	Deflagellation	16.3	-	Garvey et al. 1991
Green alga, *Chlamydomonas reinhardti*	-	Copper sulfate	76	72 hr	Deflagellation	25.4	-	Garvey et al. 1991
Green alga, *Chlorella* sp.	S,U	Copper nitrate	-	28 hr	Inhibited photosynthesis	6.3	-	Gachter et al. 1973
Green alga, *Chlorella pyrenoidosa*	S,U	-	29.4	72 hr	IC50 (cell division rate)	16	-	Stauber and Florence 1989
Green alga, *Chlorella pyrenoidosa*	S,U	-	14.9	72 hr	IC50 (cell division rate)	24	-	Stauber and Florence 1989
Green alga, *Chlorella pyrenoidosa*	S,U	Copper sulfate	82	4 hr	Disturbed photosystem II	25	-	Vavilin et al. 1995
Green alga, *Eudorina californica*	S,U	Copper sulfate	19.1	-	Decrease in cell density	5,000	-	Young and Lisk 1972
Green alga (flagellate cells), *Haematococcus* sp.	S,U	Copper sulfate	2	24 hr	Inhibited growth during 96 hr recovery period	50	-	Pearlmutter and Buchheim 1983
Green alga, *Scenedesmus quadricauda*	S,U	Copper sulfate	214	96 hr	Threshold of effect on cell numbers	150	-	Bringmann and Kuhn 1959b
Green alga, *Scenedesmus quadricauda*	S,U	Copper sulfate	60	72 hr	EC3 (cell numbers)	1,100	-	Bringmann and Kuhn 1980a
Green alga, *Scenedesmus quadricauda*	S,U	Copper sulfate	34.8	24 hr	EC50 (photosynthesis)	100	-	Starodub et al. 1987

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Green alga, *Scenedesmus quadricauda*	S,U	Copper sulfate	34.8	24 hr	NOEC (growth)	50	-	Starodub et al. 1987
Green alga, *Scenedesmus quadricauda*	S,U	Copper sulfate	34.8	24 hr	NOEC (growth)	50	-	Starodub et al. 1987
Green alga, *Scenedesmus quadricauda*	S,U	Copper sulfate	34.8	24 hr	NOEC (growth)	>200	-	Starodub et al. 1987
Green alga, *Selenastrum capricornutum*	S,U	Copper chloride	14.9	7 days	Growth reduction	50	-	Bartlett et al.1974
Green alga, *Selenastrum capricornutum*	S,U	Copper sulfate	29.3	72 hr	EC50 (cell count)	19	-	Vasseur et al. 1988
Green alga, *Selenastrum capricornutum*	S,U	Copper sulfate	24.2	72 hr	EC50 (cell count)	41	-	Vasseur et al. 1988
Green alga, *Selenastrum capricornutum*	S,U	Copper sulfate	24.2	72 hr	EC50 (cell count)	28	-	Vasseur et al. 1988
Green alga, *Selenastrum capricornutum*	S,U	Copper sulfate	14.9	72 hr	EC50 (cell count)	60	-	Vasseur et al. 1988
Green alga, *Selenastrum capricornutum*	S,U	Copper sulfate	24.2	72 hr	EC50 (cell count)	28.5	-	Benhra et al. 1997
Green alga, *Selenastrum capricornutum*	F,U	Copper sulfate	15	24 hr	EC50 (cell density)	21	-	Chen et al. 1997
Diatom, *Cocconeis placentula*	Dosed stream	Copper sulfate	226-310	10 mo	Decreased abundance from 21% down to <1%	120	-	Weber and McFarland 1981
Phytoplankton, mixed species	S,U	-	-	124 hr	Averaged 39% reduction in primary production	10	-	Cote 1983
Macrophyte, *Elodea canadensis*	S,U	Copper sulfate	-	24 hr	EC50 (photosynthesis)	150	-	Brown and Rattigan 1979
Microcosm	F,M,T,D	Copper sulfate	200	32 wk	LOEC (primary production)	9.3	-	Hedtke 1984
Microcosm	F,M,T,D	Copper sulfate	200	32 wk	NOEC (primary production)	4	-	Hedtke 1984
Microcosm	F,M,T	Copper sulfate	76.7	96 hr	Significant drop in no. of taxa and no. of individuals	15	-	Clements et al. 1988
Microcosm	F,M,T	Copper sulfate	58.5	10 days	Significant drop in no. of individuals	2.5	-	Clements et al. 1989
Microcosm	F,M,T	Copper sulfate	151	10 days	58% drop in no. of individuals	13.5	-	Clements et al. 1989
Microcosm	F,M,T	Copper sulfate	68	10 days	Significant drop in species richness and no. of individuals	11.3	-	Clements et al. 1990
Microcosm	F,M,T	Copper sulfate	80	10 days	Significant drop in species richness and no. of individuals	10.7	-	Clements et al. 1990
Microcosm	S,M,T	Copper sulfate	102	5 wk	14-28% drop in phytoplankton species richness	20	-	Winner and Owen 1991b
Microcosm	F,M,T	-	160	28 days	LOEC (species richness)	19.9	-	Pratt and Rosenberger 1993

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Dosed stream	F,M,D	Copper sulfate	56	1 yr	Shifts in periphyton species abundance	5.208	-	Leland and Carter 1984
Dosed stream	F,M,D	Copper sulfate	56	1 yr	Reduced algal production	5.208	-	Leland and Carter 1985
Sponge, *Ephydatia fluviatilis*	S,U	Copper sulfate	200	10 days	Reduced growth by 33%	6	-	Francis and Harrison 1988
Sponge, *Ephydatia fluviatilis*	S,U	Copper sulfate	200	10 days	Reduced growth by 100%	19	-	Francis and Harrison 1988
Rotifer, *Philodina acuticornis*	S,U	Copper sulfate	45	48 hr	LC50 (5^0 C)	1,300	-	Cairns et al. 1978
Rotifer, *Philodina acuticornis*	S,U	Copper sulfate	45	48 hr	LC50 (10^0 C)	1,200	-	Cairns et al. 1978
Rotifer, *Philodina acuticornis*	S,U	Copper sulfate	45	48 hr	LC50 (15^0 C)	1,130	-	Cairns et al. 1978
Rotifer, *Philodina acuticornis*	S,U	Copper sulfate	45	48 hr	LC50 (20^0 C)	1,000	-	Cairns et al. 1978
Rotifer, *Philodina acuticornis*	S,U	Copper sulfate	45	48 hr	LC50 (25^0 C)	950	-	Cairns et al. 1978
Rotifer, *Brachionus calyciflorus*	S, U	Copper sulfate	39.8	24 hr	EC50 (mobility)	200	-	Couillard et al. 1989
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	Copper sulfate	-	2 hr	LOEC (swimming activity)	12.5	-	Charoy et al. 1995
Rotifer, *Brachionus calyciflorus*	S,U	Copper sulfate	90	24 hr	EC50 (mobility)	76	-	Ferrando et al. 1992
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	Copper sulfate	90	5 hr	EC50 (filtration rate)	34	-	Ferrando et al. 1993a
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	Copper sulfate	90	6 days	LOEC (reproduction decreased 26%)	5	-	Janssen et al. 1993
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	Copper sulfate	90	5 hr	LOEC (reduced swimming speed)	12	-	Janssen et al. 1993
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	Copper sulfate	85	3 days	LOEC (reproduction decreased 27%)	5	-	Janssen et al. 1994
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	Copper sulfate	85	3 days	LOEC (reproduction decreased 29%)	5	-	Janssen et al. 1994
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	Copper sulfate	85	8 days	LOEC (reproduction decreased 47%)	5	-	Janssen et al. 1994
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	Copper chloride	170	35 min	LOEC (food ingestion rate)	100	-	Juchelka and Snell 1994
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	Copper sulfate	63.2	24 hr	EC50 (mobility)	9.4	-	Porta and Ronco 1993
Rotifer (2 hr), *Brachionus calyciflorus*	S,U	-	90	2 days	LOEC (reproduction decreased 100%)	30	-	Snell and Moffat 1992
Rotifer (<2 hr), *Brachionus calyciflorus*	S, U	-	85	24 hr	EC50 (mobility)	26	-	Snell et al. 1991b

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Rotifer (<2 hr), *Brachionus calyciflorus*	S, U	-	85	24 hr	EC50 (mobility; 10^0 C)	18	-	Snell 1991; Snell et al. 1991b
Rotifer (<2 hr), *Brachionus calyciflorus*	S, U	-	85	24 hr	EC50 (mobility; 15^0 C)	31	-	Snell 1991; Snell et al. 1991b
Rotifer (<2 hr), *Brachionus calyciflorus*	S, U	-	85	24 hr	EC50 (mobility; 20^0 C)	31	-	Snell 1991; Snell et al. 1991b
Rotifer (<2 hr), *Brachionus calyciflorus*	S, U	-	85	24 hr	EC50 (mobility; 25^0 C)	26	-	Snell 1991; Snell et al. 1991b
Rotifer (<2 hr), *Brachionus calyciflorus*	S, U	-	85	24 hr	EC50 (mobility; 30^0 C)	25	-	Snell 1991; Snell et al. 1991b
Rotifer (<3 hr), *Brachionus rubens*	S, U	Copper sulfate	90	24 hr	LC50	19	-	Snell and Persoone 1989b
Rotifer, *Keratella cochlearis*	S,U	Copper chloride	-	24 hr	LC50	101	-	Borgman and Ralph 1984
Worm, *Aeolosoma headleyi*	S,U	Copper sulfate	45	48 hr	LC50 (5^0 C)	2,600	-	Cairns et al. 1978
Worm, *Aeolosoma headleyi*	S,U	Copper sulfate	45	48 hr	LC50 (10^0 C)	2,300	-	Cairns et al. 1978
Worm, *Aeolosoma headleyi*	S,U	Copper sulfate	45	48 hr	LC50 (15^0 C)	2,000	-	Cairns et al. 1978
Worm, *Aeolosoma headleyi*	S,U	Copper sulfate	45	48 hr	LC50 (20^0 C)	1,650	-	Cairns et al. 1978
Worm, *Aeolosoma headleyi*	S,U	Copper sulfate	45	48 hr	LC50 (50 C)	1,000	-	Cairns et al. 1978
Worm (adult), *Lumbriculus variegatus*	S,U	Copper sulfate	30		LC50	150		Bailey and Liu, 1980
Worm (7 mg), *Lumbriculus variegatis*	F,M,T	Copper sulfate	45	10 days	LC50	35	-	West et al. 1993
Tubificid worm, *Limnodrilus hoffmeisteri*	S,U	Copper sulfate	100		LC50	102		Wurtz and Bridges 1961
Tubificid worm, *Tubifex tubifex*	R, U	Copper sulfate	245		LC50	158		Khangarot 1991
Snail (11-27 mm), *Campeloma decisum*	F,M,T	Copper sulfate	45	6 wk	LOEC (mortality)	14.8	-	Arthur and Leonard 1970
Snail, *Gyraulus circumstriatus*	S,U	Copper sulfate	100		LC50	108		Wurtz and Bridges 1961
Snail, *Goniobasis livescens*	S,U	Copper sulfate	154	48 hr	LC50	860	-	Cairns et al. 1976
Snail, *Goniobasis livescens*	S,M,D	Copper sulfate	154	96 hr	LC50	-	390	Paulson et al. 1983
Snail, *Nitrocris* sp.	S,U	Copper sulfate	45	48 hr	LC50 (5^0 C)	3,000	-	Cairns et al. 1978
Snail, *Nitrocris* sp.	S,U	Copper sulfate	45	48 hr	LC50 (10^0 C)	2,400	-	Cairns et al. 1978

Freshwater mussel (released glochidia), *Villosa iris*	R,M,T	Copper sulfate	55	24 hr		55		Jacobson et al. 1997
Freshwater mussel (released glochidia), *Villosa iris*	R,M,T	Copper sulfate	55	24 hr		38		Jacobson et al. 1997
Freshwater mussel (released glochidia), *Villosa iris*	R,M,T	Copper sulfate	50	24 hr		71		Jacobson et al. 1997
Freshwater mussel (released glochidia), *Villosa iris*	R,M,T	Copper sulfate	160	24 hr		46		Jacobson et al. 1997
Freshwater mussel (released glochidia), *Villosa iris*	R,M,T	Copper sulfate	170	48 hr		66		Jacobson et al. 1997
Freshwater mussel (released glochidia), *Villosa iris*	R,M,T	Copper sulfate	150	48 hr		46		Jacobson et al. 1997
Zebra mussel (1.6-2.0 cm), *Dreissena polymorpha*	R,M,T	Copper chloride	268	9 wk	EC50 +F106(filtration rate)	43	-	Kraak et al. 1992

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Zebra mussel (1.6-2.0 cm), *Dreissena polymorpha*	R,M,T	Copper chloride	268	10 wk	NOEC (filtration rate)	13	-	Kraak et al. 1993
Asiatic clam (1.0-2.1 cm), *Coprbicula fluminea*	S,M,T	Copper sulfate	64	96 hr (24hr LC50 also reported)	LC50	40	-	Rodgers et al. 1980
Asiatic clam (1.0-2.1 cm), *Coprbicula fluminea*	F,M,T	Copper sulfate	64	96 hr (24 hr LC50 also reported)	LC50	490	-	Rodgers et al. 1980
Asiatic clam (juvenile), *Corbicula fluminea*	F,M,D	Copper sulfate	78	30 days	43.3% mortality	14.48	-	Belanger et al. 1990
Asiatic clam (juvenile), *Corbicula fluminea*	F,M,D	Copper sulfate	78	30 days	Stopped shell growth	8.75	-	Belanger et al. 1990
Asiatic clam (adult), *Corbicula fluminea*	F,M,D	Copper sulfate	78	30 days	13.3% mortality	14.48	-	Belanger et al. 1990
Asiatic clam (adult), *Corbicula fluminea*	F,M,D	Copper sulfate	71	30 days	25% mortality	16.88	-	Belanger et al. 1990
Asiatic clam (adult), *Corbicula fluminea*	F,M,D	Copper sulfate	78	30 days	Inhibited shell growth	8.75	-	Belanger et al. 1990
Asiatic clam (adult), *Corbicula fluminea*	F,M,D	Copper sulfate	-	15-16 days	LC50	-	-	Belanger et al. 1991
Asiatic clam (adult), *Corbicula fluminea*	F,M,D	Copper sulfate	-	19 days	LC100	-	-	Belanger et al. 1991
Asiatic clam (veliger larva), *Corbicula manilensis*	S,M,T	Copper chloride	-	24 hr	34% mortality	10	-	Harrison et al. 1981, 1984
Asiatic clam (juvenile), *Corbicula manilensis*	S,M,T	Copper chloride	17	24 hr	LC50	100	-	Harrison et al. 1984
Asiatic clam (veliger), *Corbicula manilensis*	S,M,T	Copper chloride	17	24 hr	LC50	28	-	Harrison et al. 1984
Asiatic clam (trochophore), *Corbicula manilensis*	S,M,T	Copper chloride	17	8 hr	LC100	7.7	-	Harrison et al. 1984
Asiatic clam (adult), *Corbicula manilensis*	F,M,T	Copper chloride	17	7 days	LC50	3,638	-	Harrison et al. 1981, 1984
Asiatic clam (adult), *Corbicula manilensis*	F,M,T	Copper chloride	17	42 days	LC50	12	-	Harrison et al. 1981, 1984
Asiatic clam (4.3 g adult), *Corbicula manilensis*	F,M,T	Copper chloride	17	30 days	LC50	11	-	Harrison et al. 1984
Cladoceran, *Bosmina longirostrus*	S, U	Copper sulfate	33.8		EC50	1.6		Koivisto et al. 1992
Cladoceran (<24 hr), *Daphnia ambigua*	S,U	Copper sulfate	145	72 hr	LC50	86.5	-	Winner and Farrell 1976
Cladoceran (<24 hr), *Daphnia ambigua*	S,U	Copper sulfate	145	Life span (ca. 5 wk)	Chronic limits (inst. rate of population growth)	50	-	Winner and Farrell 1976
Cladoceran, *Ceriodaphnia dubia*	S,U	Copper sulfate	188		EC50	36.6		Bright 1995

Mayfly, *Ephemerella grandis*	F,M,T	Copper sulfate	50	14 days	LC50	180-200	-	Nehring 1976
Mayfly, *Ephemerella subvaria*	S,M	Copper sulfate	44	48 hr	LC50	320	-	Warnick and Bell 1969
Mayfly (6th-8th instar), *Isonychia bicolor*	S,M,T	-	110	48 hr	LC50	223	-	Dobbs et al. 1994
Stonefly, *Pteronarcys californica*	F,M,T	Copper sulfate	50	14 days	LC50	12,000	-	Nehring 1976
Caddisfly, *Hydropsyche betteni*	S,M,T	Copper sulfate	44	14 days	LC50	32,000	-	Warnick and Bell 1969
Midge (2nd instar), *Chironomus riparius*	S,M,T	-	110	48 hr	LC50	1,170	-	Dobbs et al. 1994
Midge (1st instar), *Chironomus tentans*	S,U	Copper sulfate	42.7			16.7		Gauss et al. 1985
Midge (1st instar), *Chironomus tentans*	S,U	Copper sulfate	109.6			36.5		Gauss et al. 1985
Midge (1st instar), *Chironomus tentans*	S,U	Copper sulfate	172.3			98.2		Gauss et al. 1985
Midge (4th instar), *Chironomus tentans*	S,U	Copper sulfate	42.7			211		Gauss et al. 1985
Midge (4th instar), *Chironomus tentans*	S,U	Copper sulfate	109.6			977		Gauss et al. 1985
Midge (4th instar), *Chironomus tentans*	S,U	Copper sulfate	172.3			1184		Gauss et al. 1985
Midge, *Chironomus tentans*	S,U	Copper sulfate	25			327		Khangarot and Ray 1989
Midge (2nd instar), *Chironomus tentans*	S,M,T	Copper sulfate	8	96 hr	LC50	630	-	Suedel et al. 1996

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Midge (4th instar), *Chironomus tentans*	F,M,T	Copper chloride	36	20 days	LC50	77.5	-	Nebeker et al. 1984b
Midge (embryo), *Tanytarsus dissimilis*	S,M,T	Copper chloride	46.8	10 days	LC50	16.3	-	Anderson et al. 1980
Midge, Unidentified	F,M,T,D	Copper sulfate	200	32 wk	Emergence	30	-	Hedtke 1984
Bryozoan (2-3 day ancestrula), *Lophopodella carteri*	S,U	-	190-220			510		Pardue and Wood 1980
Bryozoan (2-3 day ancestrula), *Pectinatella magnifica*	S,U	-	190-220			140		Pardue and Wood 1980
Bryozoan (2-3 day ancestrula), *Plumatella emarginata*	S,U	-	190-220			140		Pardue and Wood 1980
American eel (5.5 cm glass eel stage), *Anguilla rostrata*	S,U	Copper sulfate	40-48	96 hr	LC50	2,540		Hinton and Eversole 1978
American eel (9.7 cm black eel stage), *Anguilla rostrata*	S,U	Copper sulfate	40-48	96 hr	LC50	3,200		Hinton and Eversole 1979
American eel, *Anguilla rostrata*	S,M,T	Copper nitrate	53	96 hr	LC50	6,400	-	Rehwoldt et al. 1971
American eel, *Anguilla rostrata*	S,M,T	Copper nitrate	55	96 hr	LC50	6,000	-	Rehwoldt et al. 1972
Arctic grayling (larva), *Thymallus arcticus*	S,U	Copper sulfate	41.3	96 hr	LC50	67.5		Buhl and Hamilton 1990
Arctic grayling (larva), *Thymallus arcticus*	S,U	Copper sulfate	41.3	96 hr	LC50	23.9		Buhl and Hamilton 1990
Arctic grayling (larva), *Thymallus arcticus*	S,U	Copper sulfate	41.3	96 hr	LC50	131		Buhl and Hamilton 1990
Arctic grayling (swim-up), *Thymallus arcticus*	S,U	Copper sulfate	41.3	96 hr	LC50	9.6		Buhl and Hamilton 1990
Arctic grayling (0.20 g juvenile), *Thymallus arcticus*	S,U	Copper sulfate	41.3	96 hr	LC50	2.7		Buhl and Hamilton 1990
Arctic grayling (0.34 g juvenile), *Thymallus arcticus*	S,U	Copper sulfate	41.3	96 hr	LC50	2.58		Buhl and Hamilton 1990
Arctic grayling (0.81 g juvenile), *Thymallus arcticus*	S,U	Copper sulfate	41.3	96 hr	LC50	49.3		Buhl and Hamilton 1990
Arctic grayling (0.85 g juvenile), *Thymallus arcticus*	S,U	Copper sulfate	41.3	96 hr	LC50	30		Buhl and Hamilton 1990
Coho salmon (larva), *Oncorhynchus kisutch*	S,U	Copper sulfate	41.3	96 hr	LC50	21		Buhl and Hamilton 1990
Coho salmon (larva), *Oncorhynchus kisutch*	S,U	Copper sulfate	41.3	96 hr	LC50	19.3		Buhl and Hamilton 1990
Coho salmon (0.41 g juvenile), *Oncorhynchus kisutch*	S,U	Copper sulfate	41.3	96 hr	LC50	15.1		Buhl and Hamilton 1990

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Coho salmon (0.47 g juvenile), *Oncorhynchus kisutch*	S,U	Copper sulfate	41.3	96 hr	LC50	23.9		Buhl and Hamilton 1990
Coho salmon (0.87 g juvenile), *Oncorhynchus kisutch*	S,U	Copper sulfate	41.3	96 hr	LC50	31.9		Buhl and Hamilton 1990
Coho salmon (10 cm), *Oncorhynchus kisutch*	S,U	Copper sulfate	-	72 hr	LC50	280	-	Holland et al. 1960
Coho salmon (9.7 cm), *Oncorhynchus kisutch*	S,U	Copper sulfate	-	72 hr	LC50	190	-	Holland et al. 1960
Coho salmon (9.7 cm), *Oncorhynchus kisutch*	S,U	Copper sulfate	-	72 hr	LC50	480	-	Holland et al. 1960
Coho salmon (juvenile), *Oncorhynchus kisutch*	R,M,T,I	-	33	96 hr	LC50 (TOC=7.3 mg/L)	164	-	Buckley 1983
Coho salmon (juvenile), *Oncorhynchus kisutch*	R,M,T,I	-	33	96 hr	LC50	286		Buckley 1983
Coho salmon (6.3 cm), *Oncorhynchus kisutch*	F,U	Copper sulfate	-	30 days	LC50	360	-	Holland et al. 1960
Coho salmon (6.3 cm), *Oncorhynchus kisutch*	F,U	Copper sulfate	-	72 hr	LC50	370	-	Holland et al. 1960
Coho salmon (smolts), *Oncorhynchus kisutch*	F,M,T	Copper chloride	91	144 hr	Decrease in survival upon transfer to 30 ppt seawater	20	-	Lorz and McPherson 1976
Coho salmon (smolts >10 cm), *Oncorhynchus kisutch*	F,M,T	Copper chloride	91	165 days	Decrease in downstream migration after release	5	-	Lorz and McPherson 1976
Coho salmon (7.8 cm), *Oncorhynchus kisutch*	F,M,T	Copper acetate	276	14 wk	15% reduction in growth	70	-	Buckley et al. 1982
Coho salmon (7.8 cm), *Oncorhynchus kisutch*	-	-	276	7 days	LC50	220	-	Buckley et al. 1982
Coho salmon (3-8 g), *Oncorhynchus kisutch*	F,M,T	Copper acetate	280	7 days	LC50	275	-	McCarter and Roch 1983
Coho salmon (3-8 g), *Oncorhynchus kisutch*	F,M,T	Copper acetate	280	7 days	LC50 (acclimated to copper for 2 wk)	383	-	McCarter and Roch 1983
Coho salmon (parr), *Oncorhynchus kisutch*	F,M,T,D,I	-	24.4	61 days	NOEC (growth and survival)	22	-	Mudge et al. 1993
Coho salmon, *Oncorhynchus kisutch*	F,M,T,D,I	-	31.1	60 days	NOEC (growth and survival)	18	-	Mudge et al. 1993
Coho salmon (parr), *Oncorhynchus kisutch*	F,M,T,D,I	-	31	61 days	NOEC (growth and survival)	33	-	Mudge et al. 1993
Rainbow trout (15-40g) *Oncorhynchus mykiss*	F,M,	Copper chloride	--	120 hr	LA50 (50% mortality)	~1.4 ug Cu/g gill	-	MacRae et al. 1999
Sockeye salmon (yeasrling), *Oncorhynchus nerka*	S,U	Copper sulfate	12	1-24 hr	Drastic increase in plasma corticosteroids	64	-	Donaldson and Dye 1975
Sockeye salmon (fry, 0.132 g, 2.95 cm), *Oncorhynchus nerka*	R,M,T	Copper chloride	36-46	96 hr	LC50	220	-	Davis and Shand 1978

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Sockeye salmon (fry, 0.132 g, 2.95 cm), *Oncorhynchus nerka*	R,M,T	Copper chloride	36-46	96 hr	LC50	210	-	Davis and Shand 1978
Sockeye salmon (fry, 0.132 g, 2.95 cm), *Oncorhynchus nerka*	R,M,T	Copper chloride	36-46	96 hr	LC50	240	-	Davis and Shand 1978
Sockeye salmon (fry, 0.132 g, 2.95 cm), *Oncorhynchus nerka*	R,M,T	Copper chloride	36-46	96 hr	LC50	103	-	Davis and Shand 1978
Sockeye salmon (fry, 0.132 g, 2.95 cm), *Oncorhynchus nerka*	R,M,T	Copper chloride	36-46	96 hr	LC50	240	-	Davis and Shand 1978
Chinook salmon (18-21 weeks), *Oncorhynchus tshawytscha*	S,U	Copper sulfate	211	96 hr	LC50	58		Hamilton and Buhl 1990
Chinook salmon (18-21 weeks), *Oncorhynchus tshawytscha*	S,U	Copper sulfate	211	96 hr	LC50	54		Hamilton and Buhl 1990
Chinook salmon (18-21 weeks), *Oncorhynchus tshawytscha*	S,U	Copper sulfate	343	96 hr	LC50	60		Hamilton and Buhl 1990
Chinook salmon (5.2 cm), *Oncorhynchus tshawytscha*	S,U	Copper nitrate	-	5 days	LC50	178	-	Holland et al. 1960
Chinook salmon (eyed embryos) *Oncorhynchus tshawytscha*	F,M,D	Copper sulfate	44	26 days	93% mortality	41.67	-	Hazel and Meith 1970
Chinook salmon (alevin), *Oncorhynchus tshawytscha*	F,M,T	Copper chloride	23	200 hr	LC50	20	-	Chapman 1978
Chinook salmon (alevin), *Oncorhynchus tshawytscha*	F,M,T	Copper chloride	23	200 hr	LC10	15	-	Chapman 1978
Chinook salmon (swimup), *Oncorhynchus tshawytscha*	F,M,T	Copper chloride	23	200 hr	LC50	19	-	Chapman 1978
Chinook salmon (swimup), *Oncorhynchus tshawytscha*	F,M,T	Copper chloride	23	200 hr	LC10	14	-	Chapman 1978
Chinook salmon (parr), *Oncorhynchus tshawytscha*	F,M,T	Copper chloride	23	200 hr	LC50	30	-	Chapman 1978
Chinook salmon (parr), *Oncorhynchus tshawytscha*	F,M,T	Copper chloride	23	200 hr	LC10	17	-	Chapman 1978
Chinook salmon (smolt), *Oncorhynchus tshawytscha*	F,M,T	Copper chloride	23	200 hr	LC50	26	-	Chapman 1978
Chinook salmon (smolt), *Oncorhynchus tshawytscha*	F,M,T	Copper chloride	23	200 hr	LC10	18	-	Chapman 1978
Chinook salmon (3.9-6.8 cm), *Oncorhynchus tshawytscha*	F,M,T	Copper sulfate	20-22	96 hr	LC50	32	-	Finlayson and Verrue 1982
Cutthroat trout (3-5 mo), *Oncorhynchus clarki*	F,M	Copper chloride	50	20 min	avoidance of copper	7.708	-	Woodward et al. 1997

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Rainbow trout, *Oncorhynchus mykiss*	-	-	320	48 hr	LC50	500	-	Brown 1968
Rainbow trout (9-16 cm), *Oncorhynchus mykiss*	In situ	-	21-26	48 hr	LC50	70	-	Calamari and Marchetti 1975
Rainbow trout (0.4 g), *Oncorhynchus mykiss*	S,U	Copper sulfate	-	96 hr	LC50	185	-	Bills et al. 1981
Rainbow trout (larva), *Oncorhynchus mykiss*	S, U	Copper sulfate	41.3	96 hr	LC50	36		Buhl and Hamilton 1990
Rainbow trout (0.60 g juvenile), *Oncorhynchus mykiss*	S, U	Copper sulfate	41.3	96 hr	LC50	13.8		Buhl and Hamilton 1990
Rainbow trout (13-15 cm), *Oncorhynchus mykiss*	S,U	Copper sulfate	250	72 hr	LC50	580	-	Brown et al. 1974
Rainbow trout (13-15 cm), *Oncorhynchus mykiss*	S,U	Copper sulfate	250	72 hr	LC50	960	-	Brown et al. 1974
Rainbow trout (3.2 cm), *Oncorhynchus mykiss*	S,U	Copper sulfate	-	24 hr	LC50	140	-	Shaw and Brown 1974
Rainbow trout (3.2 cm), *Oncorhynchus mykiss*	S,U	Copper sulfate	-	24 hr	LC50	130	-	Shaw and Brown 1974
Rainbow trout (4.0-10.6 cm), *Oncorhynchus mykiss*	S,U	Copper sulfate	45	24 hr	LC50 (5^0 C)	950	-	Cairns et al. 1978
Rainbow trout (4.0-10.6 cm), *Oncorhynchus mykiss*	S,U	Copper sulfate	45	24 hr	LC50 (15^0 C)	430	-	Cairns et al. 1978
Rainbow trout (4.0-10.6 cm), *Oncorhynchus mykiss*	S,U	Copper sulfate	45	24 hr	LC50 (30^0 C)	150	-	Cairns et al. 1978
Rainbow trout (0.52-1.55 g), *Oncorhynchus mykiss*	S,U	Copper sulfate	-	96 hr	LC50 (Silver Cup diet)	23.9	-	Marking et al. 1984
Rainbow trout (0.41-2.03 g), *Oncorhynchus mykiss*	S,U	Copper sulfate	-	96 hr	LC50 (purified H440)	11.3	-	Marking et al. 1984
Rainbow trout (0.0.40-1.68 g), *Oncorhynchus mykiss*	S,U	Copper sulfate	-	96 hr	LC50 (SD-9 diet)	15.9	-	Marking et al. 1984
Rainbow trout (0.0.34-1.52 g), *Oncorhynchus mykiss*	S,U	Copper sulfate	-	96 hr	LC50 (liver diet)	14.3	-	Marking et al. 1984
Rainbow trout (0.0.38-1.30 g), *Oncorhynchus mykiss*	S,U	Copper sulfate	-	96 hr	LC50 (brine shrimp diet)	11.3	-	Marking et al. 1984
Rainbow trout (embryo), *Oncorhynchus mykiss*	S,U	Copper chloride	30	56 hr	LC50	100	-	Rombough 1985
Rainbow trout (6.6 cm), *Oncorhynchus mykiss*	R,U	Copper sulfate	320	72 hr	LC50	1,100	-	Lloyd 1961
Rainbow trout (6.6 cm), *Oncorhynchus mykiss*	R,U	Copper sulfate	17.5	7 days	LC50	44	-	Lloyd 1961
Rainbow trout, *Oncorhynchus mykiss*	R,U	Copper sulfate	320	48 hr	LC50	270	-	Herbert and Vandyke 1964
Rainbow trout (yearling), *Oncorhynchus mykiss*	R,U	Copper sulfate	240	48 hr	LC50	750	-	Brown and Dalton 1970

Rainbow trout (2.88 g), *Oncorhynchus mykiss*	F,M,T	Copper chloride	9.2	168 hr	LC50	36.7	-	Cusimano et al. 1986
Rainbow trout (2.70 g), *Oncorhynchus mykiss*	F,M,T	Copper chloride	9.2	168 hr	LC50	3.1	-	Cusimano et al. 1986
Rainbow trout (2.65 g), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	9.2	168 hr	LC50	2.3	-	Cusimano et al. 1986
Rainbow trout (5 day embryo), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	87.7	48 hr	LC50	8,000	-	Shazili and Pascoe 1986
Rainbow trout (10 day embryo), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	87.7	48 hr	LC50	2,000	-	Shazili and Pascoe 1986
Rainbow trout (15 day embryo), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	87.7	48 hr	LC50	400	-	Shazili and Pascoe 1986
Rainbow trout (22 day embryo), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	87.7	48 hr	LC50	600	-	Shazili and Pascoe 1986
Rainbow trout (29 day embryo), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	87.7	48 hr	LC50	400	-	Shazili and Pascoe 1986
Rainbow trout (36 day embryo), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	87.7	48 hr	LC50	100	-	Shazili and Pascoe 1986
Rainbow trout (2 day larva), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	87.7	48 hr	LC50	100	-	Shazili and Pascoe 1986
Rainbow trout (7 day larva), *Oncorhynchus mykiss*	F,M,T	Copper nitrate	87.7	48 hr	LC50	100	-	Shazili and Pascoe 1986
Rainbow trout (yearling), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	63	15 days	Olfactory receptor degeneration	20	-	Julliard et al. 1993
Rainbow trout (swimup), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	60.9	13-40 wk	Inhibited olfactory discrimination	20	-	Saucier and Astic 1995
Rainbow trout (swimup), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	60.9	40 wk	43% mortality	40	-	Saucier and Astic 1995
Rainbow trout (9.0-11.5 cm, 10.6 g), *Oncorhynchus mykiss*	F,M,T	Copper sulfate	284	96 hr	LC50	650	-	Svecevicius and Vosyliene 1996
Rainbow trout (3.5 cm), *Oncorhynchus mykiss*	F,M,T	Copper chloride	24.2	96 hr	LC50	12.7	-	Marr et al. Manuscript
Rainbow trout (3.5 cm), *Oncorhynchus mykiss*	F,M,T	Copper chloride	24.2	96 hr	LC50	16.6	-	Marr et al. Manuscript
Rainbow trout (3.5 cm), *Oncorhynchus mykiss*	F,M,T	Copper chloride	24.2	96 hr	LC50	21.4	-	Marr et al. Manuscript
Rainbow trout (3.5 cm), *Oncorhynchus mykiss*	F,M,T	Copper chloride	24.2	96 hr	LC50	34.2	-	Marr et al. Manuscript
Rainbow trout (10.0 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	362	144 hr	LC50 (extruded diet)	276	-	Dixon and Hilton 1981
Rainbow trout (10.9 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	362	144 hr	LC50 (steam pelleted diet)	350	-	Dixon and Hilton 1981

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Rainbow trout (12.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	362	144 hr	LC50 (Low carbohydrate diet)	408	-	Dixon and Hilton 1981
Rainbow trout (11.6 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	362	144 hr	LC50 (high carbohydrate diet)	246	-	Dixon and Hilton 1981
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level	329	-	Dixon and Sprague 1981a
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level	333	-	Dixon and Sprague 1981a
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level	311	-	Dixon and Sprague 1981a
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level	274	-	Dixon and Sprague 1981a
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level	371	-	Dixon and Sprague 1981a
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level (acclimated to 30 ug/L)	266	-	Dixon and Sprague 1981a
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level (acclimated to 58 ug/L)	349	-	Dixon and Sprague 1981a
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level (acclimated to 94 ug/L)	515	-	Dixon and Sprague 1981a
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level (acclimated to 13 ug/L)	564	-	Dixon and Sprague 1981a
Rainbow trout (1.7-3.3 g), *Oncorhynchus mykiss*	F,M,D	Copper sulfate	374	21 days	Incipient lethal level (acclimated to 19 ug/L)	708	-	Dixon and Sprague 1981a
Rainbow trout (2.9 g), *Oncorhynchus mykiss*	F,M,D	Copper chloride	30.5	ca. 2 hr	Inhibited avoidance of serine	6.667	-	Rehnberg and Schreck 1986
Rainbow trout (3.2 g), *Oncorhynchus mykiss*	F,M,T,D	Copper sulfate	30	96 hr	LC50	-	19.9	Howarth and Sprague 1978
Rainbow trout (1.4 g), *Oncorhynchus mykiss*	F,M,T,D	Copper sulfate	101	96 hr	LC50	-	176	Howarth and Sprague 1978
Rainbow trout (2.2 g), *Oncorhynchus mykiss*	F,M,T,D	Copper sulfate	370	96 hr	LC50	-	232	Howarth and Sprague 1978
Rainbow trout (smolt), *Oncorhynchus mykiss*	F,M,T,D	Copper sulfate	363	>10 days	LC50	97.92	-	Fogels and Sprague 1977
Rainbow trout (parr), *Oncorhynchus mykiss*	F,M,T,D,I	-	31.0	62 days	NOEC (growth and survival)	90	-	Mudge et al. 1993
Atlantic salmon (2-3 yr parr), *Salmo salar*	S,M,T	-	8-10	96 hr	LC50	125	-	Wilson 1972
Atlantic salmon (6.4-11.7 cm), *Salmo salar*	F,M,T	Copper sulfate	20	7 days	LC50	48	-	Sprague 1964
Atlantic salmon (7.2-10.9 cm), *Salmo salar*	F,M,T	-	14	7 days	LC50	32	-	Sprague and Ramsay 1965
Brown trout (3-6 day larva), *Salmo trutta*	S,M,T	Copper chloride	4	30 days	>90% mortality	80	-	Reader et al. 1989

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Brown trout (larva), *Salmo trutta*	S,M,T	Copper chloride	4	30 days	>90% mortality	20	-	Sayer et al. 1989
Brown trout (larva), *Salmo trutta*	S,M,T	Copper chloride	22	30 days	<10% mortality	80	-	Sayer et al. 1989
Brown trout (larva), *Salmo trutta*	F,M,T	Copper chloride	25	60 days	Inhibited growth	4.6	-	Marr et al. 1996
Brook trout, *Salvelinus fontinalis*	-	-	-	24 hr	Significant change in cough rate	9	-	Drummond et al. 1973
Brook trout (1 g), *Salvelinus fontinalis*	S,M,T	Copper chloride	4	80 hr	75% mortality	25.4	-	Sayer et al. 1991 b, c
Brook trout (8 mo), *Salvelinus fontinalis*	R,M,T	-	20	10 days	IC50 (growth)	187	-	Jop et al. 1995
Brook trout (15-20 cm), *Salvelinus fontinalis*	F,M,T	Copper sulfate	47	21 days	Altered Blood Hct, RBC, Hb, Cl, PGOT, Osmolarity, protein	38.2	-	McKim et al. 1970
Brook trout (13-20 cm), *Salvelinus fontinalis*	F,M,T	Copper sulfate	47	337 days	Altered blood PGOT	17.4	-	McKim et al. 1970
Goldfish (3.8-6.3 cm), *Carassius auratus*	S,U	Copper sulfate	20	96 hr	LC50	36		Pickering and Henderson 1966
Goldfish (10.5 g), *Carassius auratus*	S,M,T	Copper sulfate	34.2	-	LC50	150	-	Hossain et al. 1995
Goldfish (embryo), *Carrassius auratus*	R,U	Copper sulfate	195	7 days	EC50 (death or deformity)	5,200	-	Birge 1978; Birge and Black 1979
Goldfish, *Carassius auratus*	R,U	Copper sulfate	45	24 hr	LC50 (5^0 C)	2,700	-	Cairns et al. 1978
Goldfish, *Carassius auratus*	R,U	Copper sulfate	45	24 hr	LC50 (15^0 C)	2,900	-	Cairns et al. 1978
Goldfish, *Carassius auratus*	R,U	Copper sulfate	45	24 hr	LC50 (30^0 C)	1,510	-	Cairns et al. 1978
Common carp (1.8-2.1 cm), *Cyprinus carpio*	S,U	Copper sulfate	144-188	96 hr	LC50	117.5		Deshmukh and Marathe 1980
Common carp (5.0-6.0 cm), *Cyprinus carpio*	S,U	Copper sulfate	144-188	96 hr	LC50	530		Deshmukh and Marathe 1980
Common carp (embryo), *Cyprinus carpio*	S,U	Copper sulfate	360	-	EC50 (hatch and deformity)	4,775	-	Kapur and Yadav 1982
Common carp (embryo), *Cyprinus carpio*	S,U	Copper acetate	274	96 hr	LC50	140	-	Kaur and Dhawan 1994
Common carp (larva), *Cyprinus carpio*	S,U	Copper acetate	274	96 hr	LC50	4	-	Kaur and Dhawan 1994
Common carp (fry), *Cyprinus carpio*	S,U	Copper acetate	274	96 hr	LC50	63	-	Kaur and Dhawan 1994
Common carp, *Cyprinus carpio*	S,M,T	Copper nitrate	53	-	LC50	110	-	Rehwoldt et al. 1971
Common carp, *Cyprinus carpio*	S,M,T	Copper nitrate	55	-	LC50	800	-	Rehwoldt et al. 1972

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Common carp (4.7-6.2 cm), *Cyprinus carpio*	R,U	Copper sulfate	19	96 hr	LC50	63		Khangarot et al. 1983
Common carp (embryo and larva), *Cyprinus carpio*	R,U	Copper sulfate	50	108 hr	77% deformed	10	-	Wani 1986
Common carp (3.5 cm), *Cyprinus carpio*	R,U	Copper sulfate	-	96 hr	LC50	300	-	Alam and Maughan 1992
Common carp (6.5 cm), *Cyprinus carpio*	R,U	Copper sulfate	-	96 hr	LC50	1,000	-	Alam and Maughan 1992
Common carp (embryo), *Cyprinus carpio*	R,M,T	Copper sulfate	50	72 hr	Prevented hatching	700	-	Hildebrand and Cushman 1978
Common carp (1 mo), *Cyprinus carpio*	R,M,T	Copper nitrate	84.8	1 wk	Raised critical D.O. and altered ammonia excretion	14.0	-	De Boeck et al. 1995a
Common carp (22.9 cm), *Cyprinus carpio*	F,M,T	Copper chloride	17	48 hr	LC50	170	-	Harrison and Rice 1981
Common carp (embryo and larva), *Cyprinus carpio*	F,M,T	Copper chloride	100	168 hr	55% mortality	19	-	Stouthart et al. 1996
Common carp (embryo and larva), *Cyprinus carpio*	F,M,T	Copper chloride	100	168 hr	18% mortality;	50.8	-	Stouthart et al. 1996
Bonytail (larva), *Gila elegans*	S, U	Copper sulfate	199	96 hr	LC50	364		Buhl and Hamilton 1996
Bonytail (100-110 days), *Gila elegans*	S, U	Copper sulfate	199	96 hr	LC50	231		Buhl and Hamilton 1996
Golden shiner (11-13 cm), *Notemigonus crysoleucas*	S,U	Copper sulfate	221	94 hr	Decreased serum osmolality	2,500	-	Lewis and Lewis 1971
Golden shiner, *Notemigonus crysoleucas*	S,U	Copper sulfate	45	24 hr	LC50 (5^0 C)	330	-	Cairns et al. 1978
Golden shiner, *Notemigonus crysoleucas*	S,U	Copper sulfate	45	24 hr	LC50 (15^0 C)	230	-	Cairns et al. 1978
Golden shiner, *Notemigonus crysoleucas*	S,U	Copper sulfate	45	24 hr	LC50 (30^0 C)	270	-	Cairns et al. 1978
Golden shiner, *Notemigonus crysoleucas*	F,M,T	Copper chloride	72.2	15 min	EC50 (avoidance)	26	-	Hartwell et al. 1989
Striped shiner, *Notropis chrysocephalus*	F,M,T,D	Copper sulfate	318	96 hr	LC50	3,400	-	Geckler et al. 1976
Striped shiner (4.7 cm) *Notropis chrysocephalus*	F,M,T,D	Copper sulfate	316	96 hr	LC50	4,000	-	Geckler et al. 1976
Striped shiner (5.0 cm) *Notropis chrysocephalus*	F,M,T,D	Copper sulfate	274	96 hr	LC50	5,000	-	Geckler et al. 1976
Striped shiner, *Notropis chrysocephalus*	F,M,T,D	Copper sulfate	314	96 hr	LC50	8,400	-	Geckler et al. 1976

Fathead minnow, *Pimephales promelas*	S,U	Copper sulfate	400	96 hr	LC50	1,400		Tarzwell and Henderson 1960
Fathead minnow (3.2-4.2 cm), *Pimephales promelas*	S,M	Copper acetate	44	96 hr	LC50	117	-	Curtis et al. 1979; Curtis and Ward 1981
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	294	96 hr	LC50	16,000	-	Brungs et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	120	96 hr	LC50	2,200	-	Brungs et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	298	96 hr	LC50	16,000	-	Brungs et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	280	96 hr	LC50	3,300	-	Brungs et al. 1976; Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), Pimephales promelas	S,M,D	Copper sulfate	244	96 hr	LC50	1,600	-	Brungs et al. 1976; Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	212	96 hr	LC50	2,000	-	Brungs et al. 1976; Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	260	96 hr	LC50	3,500	-	Brungs et al. 1976; Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	224	96 hr	LC50	9,700	-	Brungs et al. 1976; Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	228	96 hr	LC50	5,000	-	Brungs et al. 1976; Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	150	96 hr	LC50	2,800	-	Brungs et al. 1976; Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	310	96 hr	LC50	11,000	-	Brungs et al. 1976; Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	280	96 hr	LC50	12,000	-	Brungs et al. 1976; Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	280	96 hr	LC50	11,000	-	Brungs et al. 1976; Geckler et al. 1976

NMED Exhibit 80

Appendix B. Other Data on Effects of Copper on Freshwater Organisms

Species	Method[a]	Chemical	Hardness (mg/L as $CaCO_3$)	Duration	Effect	Total Concentration (µg/L)[b]	Dissolved Concentration (µg/L)	Reference
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	260	96 hr	LC50	22,200	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	308	96 hr	LC50	4,670	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	206	96 hr	LC50	920	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	262	96 hr	LC50	1,190	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	322	96 hr	LC50	2,830	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	210	96 hr	LC50	1,450	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	260	96 hr	LC50	1,580	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	252	96 hr	LC50	1,000	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	312	96 hr	LC50	5,330	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	276	96 hr	LC50	4,160	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	252	96 hr	LC50	10,550	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	298	96 hr	LC50	22,200	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	282	96 hr	LC50	21,800	-	Geckler et al. 1976
Fathead minnow (2.0-6.9 cm), *Pimephales promelas*	S,M,D	Copper sulfate	284	96 hr	LC50	23,600	-	Geckler et al. 1976
Fathead minnow (<24 h), *Pimephales promelas*	S,M,T	Copper nitrate	290	96 hr	LC50	>200	-	Schubauer-Berigan et al. 1993
Fathead minnow (<24 h), *Pimephales promelas*	S,M,T	Copper sulfate	16.8	96 hr	LC50	36.0	-	Welsh et al. 1993
Fathead minnow (<24 h), *Pimephales promelas*	S,M,T	Copper sulfate	19.0	96 hr	LC50	70.3	-	Welsh et al. 1993
Fathead minnow (<24 h), *Pimephales promelas*	S,M,T	Copper sulfate	19.0	96 hr	LC50	85.6	-	Welsh et al. 1993
Fathead minnow (<24 h), *Pimephales promelas*	S,M,T	Copper sulfate	19.0	96 hr	LC50	182.0	-	Welsh et al. 1993
Fathead minnow (<24 h; 0.68 mg), *Pimephales promelas*	S,M,T	Copper sulfate	17	96 hr	LC50	1.99	-	Welsh et al. 1993

FOREWORD

This report was developed by the Great Lakes Environmental Center. Some minor revisions were made by the U.S. Environmental Protection Agency (EPA). These revisions were primarily editorial. Additional editorial and formatting revisions were made by the CDM Group, Inc.

The purpose of this report is to provide input water chemistry information for a Biotic Ligand Model (BLM) analysis of the acute copper toxicity data in Table 1a of the U.S. Environmental Protection Agency's (EPA) draft 2003 Update of Ambient Water Quality Criteria for Copper. EPA will use these BLM data to derive adjusted aquatic life criteria for copper. Many of the reported Table 1a acute copper toxicity data lack sufficient information on the chemistry of the dilution water to generate BLM-derived critical accumulation values. This compendium contains data from the primary authors of these articles. It also contains recommendations for the use of these data, additional supporting documentation and/or computations, and recommendations for estimating missing parameters.

NMED Exhibit 80

Estimation of Water Chemistry Parameters for Acute Copper Toxicity Tests

To prepare for the possibility of incorporating the Biotic Ligand Model (BLM) (Di Toro et al. 2001) into an updated copper aquatic life criteria document, the U.S. Environmental Protection Agency (EPA) sought to generate a data table summarizing the acute toxicity of copper to freshwater organisms that included the following parameters: alkalinity, dissolved organic carbon (DOC), pH, and the major anions (Cl and SO_4) and cations (Ca, Mg, Na, K) of the test water. Published literature was reviewed and appropriate information tabulated, but measurements for many of the aforementioned parameters were not reported. To resolve the overwhelming number of missing test water chemistry values in the database, certain authors were contacted for additional information and to obtain additional measurements in waters where critical information was either not measured or not reported. EPA also attempted to determine appropriate methods for estimating test water chemistry in the absence of reported values. The information received from the authors and recommended procedures for estimating missing parameters are the subject of this report.

1.0 Data Acquisition

The authors of several studies were contacted for additional information on the chemistry of the water or methods used in their studies. If the primary or corresponding authors could not be contacted, an attempt was made to contact secondary authors or personnel from the laboratories where the studies had been conducted. In a few instances, this initial effort failed to produce the desired information, and censored databases (U.S. Geological Survey's [USGS] National Stream Quality Accounting Network [NASQAN] and EPA's STOrage and RETrieval [STORET] data warehouse) were consulted to obtain the missing data. As a last resort, other available sources of water compositional data (e.g., city drinking water treatment officials) were contacted.

The acquired data were scrutinized for representativeness and usefulness in estimating surrogate values to complete the water quality information in the original studies. Summary tables and figures generated from these data are included in the following pages, which serve as the basis for the addition of values in the spreadsheets. Information used for the tabular and graphical summaries of these data is included in separate appendices.

2.0 Technical Issues and Corresponding Recommendations

2.1 *Estimating Ion Concentrations*

Develop a methodology for estimating Ca, Mg, Na, K, Cl, and SO_4 concentrations in laboratory-reconstituted waters.

Recommendation: The best approach for estimating ion concentrations in standard laboratory-reconstituted water involves scaling default ion concentrations based on measured hardness. The default ion concentrations can be computed from the concentrations of the salts added. The use of calculated ion concentrations as input for the BLM applies only to reconstituted water prepared following the standard recipes reported in guidance documents for conducting acute bioassays with aquatic organisms (ASTM 2000; U.S. EPA 1993) (see Table 1). If similar salts are added in different amounts, then the ion concentrations must be calculated using the recipe reported

NMED Exhibit 80

in the article. Otherwise, specific ion ratios, and more importantly ion concentrations, cannot be calculated.

Table 1. Standard Reconstituted Water Composition and Target Water Quality Characteristics

	Reagent Added (mg/L)				Final Water Quality		
Water Type	$NaHCO_3$	$CaSO_4 \cdot 2H_2O$	$MgSO_4$	KCl	pH[a]	Hardness[a]	Alkalinity[b]
Very Soft	12.0	7.5	7.5	0.5	6.4-6.8	10-13	10-13
Soft	48.0	30.0	30.0	2.0	7.2-7.6	40-48	30-35
Mod. Hard	96.0	60.0	60.0	4.0	7.4-7.8	80-100	60-70
Hard	192.0	120.0	120.0	8.0	7.6-8.0	160-180	110-120
Very Hard	384.0	240.0	240.0	16.0	8.0-8.4	280-320	225-245

[a] Approximate equilibrium pH after 24-hour aeration
[b] Expressed as mg/L $CaCO_3$

When standard laboratory-reconstituted water is cited as the dilution water, and no additional measurements are reported, the recommended approach for estimating ion concentrations is to use the ion concentrations calculated from the amount of salts added for the type of reconstituted water reported in the article. For example, if the range of hardness of the reconstituted water is reported as 80-100 mg/L $CaCO_3$, then the specific ion concentrations calculated from the standard recipe for moderately hard reconstituted water should be used for BLM input (see Table 2 and example calculation in Appendix D-2). The use of ion concentrations calculated from the standard recipes assumes that salts were stored in a manner to prevent hydration and that technician errors in weighing of salts, measurements of dilution water, and measurement of solution volumes were minimal.

Alternatively, if the authors state that moderately hard water was prepared following one of the standard recipes, and they measured the hardness of the water, then the calculated ion concentrations should be adjusted to account for any difference from the mean of the expected range. For example, if the mean measured hardness in a test water prepared using the recipe for moderately hard reconstituted water was 78 mg/L $CaCO_3$, the Ca:Mg ratio would be 0.700 for all reconstituted water types, and the respective Ca and Mg concentrations could be calculated using the following equations:

$$Ca = (0.4008 \times \text{measured hardness}) \div [1 + (1 \div \text{Ca:Mg ratio})] \quad \textbf{Equation 1}$$

$$Mg = (0.2431 \times \text{measured hardness}) \div (1 + \text{Ca:Mg ratio}) \quad \textbf{Equation 2}$$

The remaining ion concentrations are each multiplied by 0.92 (quotient of 78 and 85 mg/L $CaCO_3$, the latter of which is the expected hardness for moderately hard reconstituted water), as in Table 1.

NMED Exhibit 80

Table 3 provides ion concentrations predicted for a standard reconstituted water mix using the hardness adjustment in accordance with the example above.

Note that this same rationale for scaling the default major anions and cations in reconstituted water also applies to a variety of natural surface and well waters. Analysis of St. Louis River, MN, water and Western Fish Toxicology Station (WFTS) well water indicated that a strong linear relationship also exists between water hardness and the major anion (Cl, SO_4) and cation (Ca, Mg, Na) concentrations in these water types (see Sections 2.6, 2.7, and 2.19). The strong relationships are consistent with findings

Table 2. Calculated Ion Concentrations Based on the Standard Salts Added

Water Type (Nominal Hardness Range)	Specific Ions[a] (mg/L)						Ca:Mg[b]	Expected Hardness (mg/L $CaCO_3$)[c]
	Ca	Mg	Na	K	Cl	SO_4		
Very Soft (10-13 mg/L $CaCO_3$)	1.75	1.51	3.28	0.262	0.238	10.2	0.700	11
Soft (40-48 mg/L $CaCO_3$)	6.99	6.06	13.1	1.05	0.951	40.7	0.700	42
Moderately Hard (80-100 mg/L $CaCO_3$)	14.0	12.1	26.3	2.10	1.90	81.4	0.700	85
Hard (160-180 mg/L $CaCO_3$)	27.9	24.2	52.5	4.20	3.80	163	0.700	170
Very Hard (280-320 mg/L $CaCO_3$)	55.9	48.5	105	8.39	7.61	325	0.700	339

[a] Ion concentrations were calculated from standard salt recipes (refer to Table 1 and example calculation for very soft water in Appendix D-1).

[b] Ratio equals quotient of (Ca÷40.08) and (Mg÷24.31), where 40.08 and 24.31 are the molecular weights of Ca and Mg, respectively, in units of mg/mmol.

[c] Hardness calculated according to the concentrations of Ca and Mg given here and the equation given in Appendix D-1.

Table 3. Adjusted Ion Concentrations for a Standard Reconstituted Water Mix Based on Reported Hardness

Moderately Hard Reconstituted Water	Hardness (mg/L $CaCO_3$)	Specific Ions (mg/L)					
		Ca	Mg	Na	K	Cl	SO_4
Nominal	85[a]	14.0	12.1	26.3	2.10	1.90	81.4
Adjusted	78	12.9	11.2	***24.2***	***2.10***	***1.75***	***74.9***

[a] Expected hardness based on the amount of salts added (from Table 1). Calcium and magnesium are calculated using Equations 1 and 2. Other adjusted values (italic and bold) are a result of the product of the ratio of measured hardness (78 mg/L) to expected hardness (85 mg/L) and nominal ion concentrations, e.g., the adjusted sodium ion concentration for a standard laboratory reconstituted water mix based on a reported total hardness of 78 mg/L $CaCO_3$ is: 78÷85=0.92; 0.92*26.3=24.2.

NMED Exhibit 80

presented in an earlier comprehensive report by Erickson (1985). Note, however, that because there is generally poor correlation between K and water hardness in the various ambient surface and ground water types (see Section 2.6), the value calculated for K should not be scaled according to hardness.

2.2 *pH Adjustment with HCl*

Schubauer-Berigan et al. (1993) adjusted pH using HCl but reported only nominal hardness and alkalinity. The tests were conducted at the EPA Office of Research and Development, Mid-Continent Ecology Division, Duluth, MN, using a standard very hard reconstituted water mix. The authors need to be contacted to obtain any additional water chemistry data they might have.

Recommendation: Alkalinity and hardness were not measured in the tests reported in Schubauer-Berigan et al. (1993), and no additional water chemistry data are available from the study (Phil Monson, U.S. EPA-Duluth, personal communication). The HCl required to adjust the pH was assumed to be added in amounts too small to significantly affect any of the other water quality parameters (Gerald Ankley, U.S. EPA-Duluth, personal communication). Based on these remarks, we believe ion concentrations for this particular study should be estimated using methods outlined in Section 2.1.

2.3 *Estimation of DOC*

How should DOC be estimated if only total organic carbon (TOC) was measured in the study? Can DOC be estimated if no measurements of organic carbon were reported in the study?

Recommendation: As a general rule, TOC values can be used directly in place of DOC for dechlorinated and de-ionized city tap water, well water, and oligotrophic lake water (e.g., Lake Superior water). TOC values are not recommended in place of DOC for water from estuaries, wetlands, or higher order streams unless data are included that indicate otherwise. Rather, the proportion of organic carbon expected to be dissolved in surface waters should be estimated and used to scale the measured TOC value. When possible, the DOC:TOC ratio for a surface water should be obtained using the USGS NASQAN dataset. The NASQAN dataset can be reached through the USGS Web site (water.usgs.gov/nasqan/data/finaldata.html). If a representative ratio for a particular body of water cannot be determined, the ratio for the particular water type (lake or stream) should be obtained from the final draft of the Ambient Water Quality Criteria Derivation Methodology Human Health Technical Support Document (U.S. EPA 1998a, Table 2.4.11). A summary of these data, by State, is provided in Appendix D-2. In this appendix, TOC is operationally defined as the sum of DOC and particulate organic carbon (POC). The national mean fraction of organic carbon is 86 percent for streams and 88 percent for lakes. The DOC:TOC ratio can be applied to lakes or streams within a State to obtain an estimate of DOC from values reported for TOC.

Example:

Reference	Water Body	TOC (mg/L)	DOC:TOC	Estimated DOC (mg/L)
Lind et al. manuscript	St. Louis R, MN	32	0.87	28

NMED Exhibit 80

For tests with reconstituted, city tap, or well water, default DOC values can be applied if the author does not report a measured value. The recommended default TOC (DOC) value for laboratory prepared reconstituted water is 0.5 mg carbon/L (note: some newer laboratory water systems can achieve a TOC of less than 0.5 mg/L). For regular city tap and well water, a value of 1.6 mg carbon/L can be assumed. The recommended default value for laboratory-prepared reconstituted water is based on the arithmetic mean of recent measurements of DOC in reconstituted water prepared at two Federal (U.S. EPA Cincinnati, OH, and USGS Yankton, SD) and two consulting (Commonwealth Biomonitoring and GLEC) laboratories (range 0.1 to 1 mg/L). The recommended default value for dechlorinated city tap and well water is based on the arithmetic mean of measurements of DOC in source water from Lake Ontario (Environment Canada, Burlington, ON) and the New River, VA (City of Blacksburg, VA), and well water from Oak Ridge National Laboratory (Oak Ridge, TN) and EPA's WFTS (Corvallis, OR). The DOC values in these waters ranged from 1.1 to 2.5 mg/L.

For tests conducted in surface waters, we do not recommend the use of a default DOC value because of the large variability of DOC observed. Rather, a reliable database such as USGS NASQAN (as described above) should be searched for DOC measurements. If a database such as NASQAN is consulted, only those DOC measurements closest to the time of the study should be considered as surrogate values. In general, these DOC concentrations should not differ by more than a factor of 1.25. If DOC measurements for the surface water cannot be obtained from a reliable source, then the toxicity test should not be included in Table 1 for BLM normalization.

2.4 *DOC in Lake Superior Water*

Lake Superior water has been used in a number of acute and chronic toxicity studies included in the Aquatic Life Criteria for Copper (U.S. EPA 1998b). Dissolved organic matter (DOM) in Lake Superior is assumed to be anywhere from 1 to 3 mg/L (Russ Erickson, U.S. EPA-Duluth, personal communication; McGeer et al. 2000). This value is expected to be at least 90 percent of TOC (or 2 mg/L) (see Spehar and Fiandt 1986). A default value based on recent measurements is needed for DOC in Lake Superior water.

Recommendation: Recent measurements of TOC in Lake Superior dilution water are in Appendix D-3 (Greg Lien, U.S. EPA-Duluth, personal communication). The geometric mean concentration of TOC in Lake Superior dilution water from multiple measurements is 1.27 mg/L. Given the recommendation in Section 2.3, the recommended DOC for Lake Superior dilution water is 1.1 mg/L (1.27 mg/L × 0.88).

2.5 *Applying Water Chemistry Data to Lake Superior Water*

The ionic composition included in the Table 1 spreadsheet for Lake Superior water is based on concentrations converted from values reported in Erickson et al. (1996b): Ca at 0.68 meq/L = 13.6 mg/L; Mg at 0.24 meq/L = 2.9 mg/L; Na at 0.065 meq/L = 1.5 mg/L; K at 0.015 meq/L = 0.59 mg/L; SO_4 at 0.070 meq/L = 3.4 mg/L; Cl at 0.035 meq/L = 1.2 mg/L; and alkalinity at 0.85 meq/L = 43 mg/L. The concentrations for most of these parameters were also reported in Biesinger and Christensen (1972) and approximate those listed above. Should the Erickson et al. (1996b) data be applied to all Lake Superior studies, or is there a stronger rationale for applying the Biesinger and Christensen (1972) data to the older studies?

NMED Exhibit 80

Recommendation: We recommend applying the mean of the Erickson et al. (1996b) citation and Biesinger and Christensen (1972) water chemistry data to all Lake Superior studies prior to 1987, when the results were initially reported. After 1987, we recommend use of the Erickson et al. (1996b) water chemistry data alone (Table 4). For each test, Ca and Mg concentrations should be estimated using Equations 1 and 2, the Ca:Mg ratios given below, and the measured hardness of the test water (Section 2.1). Ions other than K should be scaled according to the measured test hardness, also discussed in Section 2.1.

Table 4. Recommended Spreadsheet Addition for Lake Superior Dilution Water

			Specific Ions (mg/L)						
Applied to:	Hardness (mg/L $CaCO_3$)	Alkalinity (mg/L $CaCO_3$)	Ca	Mg	Ca:Mg	Na	K	Cl	SO_4
Pre-1987[a]	46	42	13.6	3.0	2.75	1.3	0.57	1.2	3.4
Post-1987[b]	46	43	13.6	2.9	2.84	1.5	0.59	1.2	3.4

[a] Mean of the Erickson et al. (1996b) and Biesinger and Christensen (1972) water chemistry data
[b] Erickson et al. (1996b) water chemistry data alone

2.6 *Predicting Ionic Composition of WFTS Well Water*

The following studies seem were conducted at EPA's WFTS using well water: Andros and Garton (1980), Chapman (1975, 1978), Chapman and Stevens (1978), Lorz and McPherson (1976), Nebeker et al. (1984a, 1986a, b), and Seim et al. (1984). Among these studies, however, there is a wide range of hardness values (20-100 mg/L), and the ionic composition of the water was not always reported.

The large variation in WFTS well water hardness, and consequently, ionic composition, is due to seasonal variability (Samuelson 1976). The TOC content of this water has been reported to be 1.1 mg/L (McCrady and Chapman 1979), of which 100 percent is expected to be dissolved. A general strategy is needed to predict the ionic composition of WFTS well water based on measured water hardness.

Recommendation: The well feeding the WFTS is susceptible to influx from ground water during rain events in late fall and winter (November through March or April). During this period the water
hardness can reach measured levels as high as 100 mg/L $CaCO_3$. Over the remaining months (particularly from July to November), hardness stabilizes at around 25 to 40 mg/L $CaCO_3$, as do other water quality parameters (Al Nebeker, U.S. EPA Corvallis, personal communication; Samuelson 1976). It is important to note that the high hardness reported for WFTS well water is sporadic, even in the winter.

The recommended strategy for filling the existing gaps in data reported from studies using this well water is to estimate the ion concentrations on the basis of their relationship to the total hardness measured during a particular test. The acceptability of tests conducted using WFTS water depends on the range of hardness values reported, i.e., if the hardness varies widely over the course of a particular test, then perhaps the test should not be used. Regression analyses were performed using measured hardness and ion data for the WFTS well water reported in Samuelson (1976), April 1972

NMED Exhibit 80

to April 1974, and supplemented with additional data from Gary Chapman, personal communication (only those data from May 1974 to April 1978; see Appendix D-4). These relationships and the corresponding regression equations are presented in Figures 1 through 6 (found at the end of this report). Major ion concentrations for WFTS well water were predicted using the regression equations over a wide range of water hardness (10 to 80 mg/L $CaCO_3$) to determine the accuracy of the procedure (Table 5). The error between predicted and measured ion concentrations is generally within 10 percent for all ions except K, where a default value of 0.7 mg/L was chosen for all hardness levels (actual range is 0.1 to 1.1 mg/L, with the majority of data falling between 0.5 and 0.9 mg/L). The correlation coefficient (R^2) for the relationship between K and water hardness in WFTS well water was only 0.124. Note: BLM predictions of copper gill accumulation and toxicity are relatively insensitive to the concentration of K, so errors in its estimation should not appreciably affect model predictions. The following regression equations were used to generate the example data provided in Table 5:

$$[Ca] = 0.3085 + (\text{measured hardness} * 0.2738)$$
$$[Mg] = 0.5429 + (\text{measured hardness} * 0.0573)$$
$$[Na] = 3.3029 + (\text{measured hardness} * 0.0713)$$
$$[Cl] = 2.7842 + (\text{measured hardness} * 0.1278)$$
$$[SO_4] = -3.043 + (\text{measured hardness} * 0.2816)$$

Lorz and McPherson (1976) and the Seim et al. (1984) tests were not run in WFTS well water, but in water from different wells along the Willamette River. Water chemistry appears to be less variable for these wells (Harold Lorz and Wayne Seim, personal communication). The following additional water chemistry information for the two well water types used in these studies was provided by the respective authors in January 2001.

Many of the studies conducted by Chapman used reverse osmosis treatment to maintain a blended water supply that was of essentially constant ion content throughout the tests. All the test data from Chapman appear to be acceptable; the only test complicated by fluctuating hardness was the 22-month chronic zinc test with sockeye salmon, and that test produced only a NOEC.

Table 5. Predicted Ion Concentrations in WFTS Well Water Based on Measured Hardness

Total Hardness (Mean Measured value) mg/L $CaCO_3$	Predicted Ion Concentrations (mg/L)					
	Ca	Mg	Na	Cl	SO_4	Default[a] K
15.00	4.42	1.40	4.10	4.70	1.18	0.70
20.00	5.78	1.69	4.46	5.34	2.59	0.70
25.00	7.15	1.98	4.82	5.98	4.00	0.70
30.00	8.52	2.26	5.17	6.62	5.41	0.70
35.00	9.89	2.55	5.53	7.26	6.81	0.70
40.00	11.26	2.83	5.88	7.90	8.22	0.70
45.00	12.63	3.12	6.24	8.54	9.63	0.70
50.00	14.00	3.41	6.60	9.17	11.04	0.70
55.00	15.37	3.69	6.95	9.81	12.45	0.70
60.00	16.74	3.98	7.31	10.45	13.85	0.70
65.00	18.11	4.27	7.67	11.09	15.26	0.70

NMED Exhibit 80

70.00	19.47	4.55	8.02	11.73	16.67	0.70
75.00	20.84	4.84	8.38	12.37	18.08	0.70
80.00	22.21	5.13	8.74	13.01	19.49	0.70

[a] Value not corrected. Assume default value of 0.70 mg/L.

Recommended Spreadsheet Addition for Oregon Well Water.

	Hardness (mg/L $CaCO_3$)	Alkalinity (mg/L $CaCO_3$)			Specific Ions[a] (mg/L)						
Applied to:			pH	DOC	Ca	Mg	Ca:Mg	Na	K	Cl	SO_4
Lorz and McPherson 1976	95	66	6.8-7.9	1.6[B]	19	12	1.0	7.6	1.0	7.0	12
Seim et al. 1984	120	126	7.7	1.6[B]	34	8.6	2.4	15	0.7	5.0	2.3

[a] Specific ion values were obtained through personal communication with the primary authors; hardness, alkalinity, and pH values are as reported in the article. The Ca:Mg ratios were calculated on the basis of data provided by authors, then Ca and Mg values used were back-calculated on the basis of these ratios and the measured test hardness (see Equations 1 and 2).
[b] Suggested default value for untreated well water (see Section 2.3).

2.7 *Data for Measurement of Blacksburg/New River Water*

A substantial amount of acute copper toxicity data to various freshwater organisms is reported using dechlorinated City of Blacksburg, VA, tap water. These include studies by Belanger et al. (1989), Cairns et al. (1981), Hartwell et al. (1989), and Thompson et al. (1980). Hardness, alkalinity, and pH values are reported for City of Blacksburg water in all of these studies, but the ionic compositional data are not. This information is required to obtain BLM-normalized LC50s for these data.

Recommendation: According to Don Cherry (personal communication), tests conducted at Virginia Polytechnic Institute and State University used City of Blacksburg, VA, tap water, which is drawn from the nearby New River. Don Cherry collected a sample of New River water for analysis under Work Assignment 1-20. The results of the analysis are provided in Appendix D-5. The sample was of untreated natural water prior to any treatment by the City of Blacksburg. Values for treated New River water (city) were provided by Jerry Higgins, Water Superintendent, City of Blacksburg. Table 6 summarizes the measured values for New River and City of Blacksburg dechlorinated tap water.

Historically, hardness and alkalinity vary substantially in dechlorinated City of Blacksburg tap water and in raw New River water (Table 6). Some of this difference may be attributed to seasonal effects. For example, strong seasonal influence was observed in both well water (influenced by surface water, i.e., WFTS well water; see Section 2.6) and a natural surface water (St. Louis River, MN; refer ahead to Section 2.19). Previously, we plotted ion concentrations against hardness for each of these two water types (Figures 1 through 6 and Appendix D-6). The relationships were good in almost all cases (positive, R^2 = 0.5 to 0.9), and the resultant regression equations were used to scale ion concentrations according to reported water hardness. Incomplete datasets, however, preclude the use

NMED Exhibit 80

of the same approach for City of Blacksburg tap and raw New River water. Instead, we recommend using the ion and hardness values from the City of Blacksburg water sample and USGS NASQAN ion data, respectively (Table 6), to generate surrogate ion values for the respective waters that were not reported in the previous studies (indicated by the shaded area in Table 6). The operation is simply to multiply ion concentrations for the "acquired data" by the ratio of hardness values in City of Blacksburg and NASQAN water and the corresponding test waters as was done in Section 2.1. We used the NASQAN ion data as the basis for scaling the raw New River water ion estimates because NASQAN represents data collected over several representative years, including the years in the timeframe in which the studies of interest were initiated and completed. The exception was with DOC. We felt that the DOC value obtained from the sample of New River water collected in August 2000 would be more representative than the few values generated from NASQAN (all pre-1980).

2.8 *Cu Concentrations and Alkalinity*

The methods sections of both Belanger and Cherry (1990) and Belanger et al. (1989) state that total and dissolved Cu were measured, but it is not clear whether the reported LC50s are based on total or dissolved copper concentration. Also, in Belanger and Cherry (1990), pH was adjusted with sodium hydroxide (NaOH) or nitric acid (HNO_3), but only nominal pHs were reported. Alkalinity and hardness after pH adjustment were not reported. Can alkalinity be adjusted for these tests?

Recommendation: The concentration Cu in algae is reported on a total metal basis in Belanger et al. (1989) and Belanger and Cherry (1990). The Cu in water is reported on an acid-soluble basis. The acid-soluble concentration of Cu in water was used to derive the LC50. For all intents and purposes, acid-soluble Cu can be considered as dissolved Cu because the acidification of the filtrate after filtration is probably sufficient to obtain most of the Cu associated with colloidal material. Normally a digestion procedure is required to convert all Cu to the dissolved form. If the sample had not been filtered, it would not have been acceptable because it could have been elevated by dissolution of particulate copper.

The pH levels achieved in the batch culture pH tests in Belanger and Cherry (1990) were reported as 6.15, 8.02, and 8.95. Given the proximity of these values to the desired target pH values of 6, 8, and 9, respectively, it would appear that the researchers were able to closely approximate the nominal pH levels, including those selected for the acute heavy metal tests (also pH 6, 8, and 9, respectively). Assuming that the target pH values of 6, 8, and 9 were achieved in the acute tests, adjustment with NaOH and HNO_3 would have affected alkalinity, but probably not hardness or the major anion and cation concentrations, except possibly Na. The contribution to Na by the addition of NaOH was probably small, so no further adjustment would be necessary.

NMED Exhibit 80

Table 6. Comparison of Values for Untreated (Natural) and Treated (Dechlorinated City of Blacksburg, VA) New River Water

Source	Water Type	pH	Total Hardness (mg/L $CaCO_3$)	Total Alkalinity (mg/L $CaCO_3$)	Specific Ions (mg/L)							Ca:Mg ratio	DOC (mg/L)
					Ca	Mg	Na	K	Cl	SO_4	NO_3

Belanger et al. 1989	New R.	8.2	94	70	23	8.8	5.2	1.6	6.2	20	-	1.6	2
Belanger and Cherry 1990	New R.	6, 8, 9	98	74	24	9.1	5.4	1.6	6.4	21	-	1.6	2

[a] Data provided by Gerard (Jerry) Higgins of Blacksburg-Christianburg VPI Water Authority, Blacksburg, VA. Values presented are from a grab sample collected January 31, 2000. Organic carbon (originally measured and reported as TOC) is assumed to be 100 percent dissolved.

[b] Sample provided by Don Cherry, Virginia Polytechnic Institute and State University, Blacksburg, VA, and analyzed by Environmental Health Laboratories, South Bend, IN. Values presented are from a grab sample collected August 2000. The value for Mg of 0.6 mg/L appears to be a reporting error, and was not used for subsequent calculations of total hardness or scaling of ion values.

[c] Data obtained from USGS NASQAN database. Values presented are means of 213 samples, except for DOC, which is a mean of seven samples, collected and analyzed from January 1973 to August 1995.

[d] Shaded area indicates mean values estimated from previously (NASQAN) or recently measured (Cherry 2000 or City of Blacksburg; nonadjusted) ion values. All values have been rounded to two significant figures. Shaded values were derived according to text above using the approach outlined in Section 2.1.

NMED Exhibit 80

Using a nomograph found in Faust and Aly (1981), alkalinity at pH 6 should be approximately 33 percent of the alkalinity at pH 8, and alkalinity at pH 9 should be 5 percent higher than the alkalinity at pH 8 (Table 7). Therefore, the values for alkalinity in Table 7 should be used for the acute toxicity tests presented in Belanger and Cherry (1990) in this case. For other analyses, different adjustment factors may be appropriate, based on other interpretations from the Faust and Aly nomograph or other methods as well. Appropriate consideration should also be given to the test system equilibration with the atmosphere.

Table 7. Estimated Alkalinity in Natural Surface Water Based on pH

Source Water	Nominal pH	Alkalinity (mg/L $CaCO_3$)
New River	6	24.5
	8.1	74.2[a]
	9	77.9
Clinch River	6	47.6
	8.3	144[a]
	9	152
Amy Bayou	6	40.2
	8.3	122[a]
	9	128

[a] Indicates values reported in text.

2.9 *Calculation of DOC and Humic Acid*

What was the technical approach used to calculate DOC and percent humic acid (HA) for the Winner (1985) toxicity tests?

Recommendation: At a nominal HA concentration of 0.0 mg/L in soft and medium hardness test waters, the DOC is assumed to be that of the ultrapure laboratory water, which is estimated to be 0.3 mg/L (approximately one-half of the recommended default value for DOC in laboratory water; see Section 2.3). At nominal HA concentrations of 0.15, 0.75, and 1.50 mg/L, the DOC is calculated by dividing by a value of 2, based on the assumption in the BLM User's Guide (Di Toro et al. 2000) that the percent carbon in HA is 0.50 (see example below and Table 8). Because the water used to obtain these HA concentrations was ultrapure laboratory water, 0.3 mg carbon/L was added; final rounded values of 0.38, 0.68, and 1.1 are recommended.

Table 8. Estimates of Dissolved Organic Carbon and Percent Humic Acid for the Winner (1985) Toxicity Tests

Humic Acid Added (mg/L)[a]	Calculated DOC (mg/L)	Calculated Percent Humic Acid
0	0.3	10
0.15	0.38	28
0.75	0.68	60
1.5	1.1	74

NMED Exhibit 80

[a] As indicated in Table 3 of Winner (1985).

2.10 *Alkalinity of Lake Superior Water*

For the Lind et al. (manuscript) tests conducted in Lake Superior water (adjusted with $CaSO_4$ or $MgSO_4$), is there any way to estimate alkalinity values?

Recommendation: For tests conducted in Lake Superior water, assume an alkalinity of 42 mg/L $CaCO_3$ (see Section 2.5).

2.11 *Availability of LC50s*

The LC50s reported by Collyard et al. (1994) are shown graphically in publication. The LC50s provided in Table 1 are interpolated from the figure. Are the actual measured LC50s available from the authors?

Recommendation: The actual LC50s generated and presented graphically in Collyard et al. (1994) have been archived at U.S. EPA-Duluth, as reported by Gerald Ankley (personal communication, 3 November 2000). These values are not readily available in any other form. The data are acceptable as is on the basis of recommendations in the Guidelines (Stephan et al. 1985). Precedence for the use of values gleaned from graphical data is provided in the 2001 Update of Ambient Water Quality Criteria for Cadmium (U.S. EPA 2001).

2.12 *Cl and Na Concentrations*

Cl and Na ion concentrations of the tap water used for testing in Rice and Harrison (1983) were derived from the addition of 20 mg/L sodium chloride (NaCl). What are the specific concentrations of the individual ions from the addition of the salt? What concentrations do you suggest using for K and SO_4 in this water?

Recommendation: The Cl content of the tap dilution water used in Rice and Harrison (1983) was reported as having been derived from the addition of 20 mg/L of NaCl. Assuming that the initial Na and Cl concentrations in tap water were essentially zero, the concentrations of these ions can be calculated in the following way:

The molecular weight of NaCl is 58.44 g/mol. The atomic weight of Na is 22.98 mg/L and the atomic weight of Cl is 35.453 mg/L.

The concentration of Na is:

20 mg NaCl/L * 1 mmol NaCl/58.44 mg NaCl = 0.342 mmol NaCl/L.
0.342 mmol NaCl * 1 mmol Na/1 mmol NaCl * 22.98 mg Na/1 mmol Na = 7.86 mg Na/L.

The concentration of Cl is:

20 mg NaCl/L × 1 mmol NaCl/58.44 mg NaCl = 0.342 mmol NaCl/L.

NMED Exhibit 80

0.342 mmol NaCl × 1 mmol Na/1 mmol NaCl × 35.453 mg Cl/1 mmol Cl
= 12.12 mg Cl/L.

Given the potentially large dichotomy between the default ion concentrations and measured hardness of the water used in this study, we recommend adjusting the default SO_4 concentration according to measured hardness as in Section 2.1. We do not, however, recommend adjusting the current default value of 1.0 mg/L for K.

2.13 *Calculating DOC in Dilution Water*

The dilution water used in the acute copper toxicity tests with cutthroat trout in Chakoumakos et al. (1979) was a different mix of spring water and de-ionized water for each test. Ca and Mg concentrations were measured and reported for each of the test waters used, but measurements of the other ions were reported only for the undiluted spring water. Based on a percentage dilution, ions other than Ca and Mg were estimated in the following way: hardness was measured in the spring water and in each of the test waters; the proportion of spring water was calculated for each test using these measured hardness values; this proportion was then multiplied by the concentration of, for example, Na in the spring water to get an estimated Na value for each test. TOC in the spring water was 3.3 mg/L. Should the same approach as that used to estimate the other ions be used to calculate DOC, which was only measured in undiluted spring water?

Recommendation: The concentrations of the major cations and anions in the dilution water used by Chakoumakos et al. (1979) were calculated based on the percent dilution of natural spring water with de-ionized water. The same correction can be used to estimate DOC, with the following assumptions. First, the TOC in spring water was 100 percent dissolved. Second, the DOC of de-ionized water was 0.5 mg/L. If these assumptions are acceptable, the DOCs for H/H, M/H, L/H, H/M, M/M, L/M, H/L, M/L, and L/L would be 3.3, 1.5, 0.75, 3.3, 1.7, 0.94, 2.8, 1.5, and 0.87 mg/L, respectively.

2.14 *Ionic Composition of Chehalis River Water*

The ionic composition of Chehalis River, WA, water is needed to fill in existing data gaps used for BLM analysis of acute toxicity reported in Mudge et al. (1993). The publication states, "Water quality data collected during this bioassay program is similar to historical data for Chehalis River (WPPSS 1982) and other Pacific NW streams (Samuelson 1976)." Are data from Samuelson (1976) acceptable for use in approximating these ion concentrations? Furthermore, are there any dissolved or ionic LC50s available other than those reported in the publication?

Recommendation: The following additional water chemistry information for the Chehalis River dilution water used in the studies reported by Mudge et al. (1993) was provided by the author on 20 November 2000. These measurements were made on Chehalis River water at the time of testing. A corresponding value for DOC was obtained from the NASQAN dataset.

Recommended spreadsheet addition for Chehalis River dilution water

		Specific Ions (mg/L)						
Applied to:	DOC (mg/L)	Ca	Mg	Ca:Mg	Na	K	Cl	SO_4

Mudge et al. 1993	3.2[a]	7.1	2.4	1.8	5.1	0.65	4.5 (May) 4.2 (Jun) 3.1 (Sep)	4.0 (May) 3.5 (May-Jul) 2.3 (Sep)

[a] Value from the USGS NASQAN dataset, 1980-1982, when the tests were conducted.

2.15 *Chemistry of Water in Howarth and Sprague (1978)*

What is the ionic composition and organic carbon content of test waters used in Howarth and Sprague (1978)? The waters used for testing were various mixes of University of Guelph (Guelph, ON, Canada) well water and de-ionized well water. The de-ionized well water was reported as "having retained its original chloride content (22 mg/l)," but the values for the other major anion and cation concentrations were not reported. Furthermore, the equation provided for calculating alkalinity from pH and hardness (supposedly accounting for 96.7 percent of the variability) appears unreliable. For example, using the equation and a total water hardness of 364 mg/L $CaCO_3$ at pH 9, one obtains an estimated alkalinity value of 341 mg/L $CaCO_3$. In contrast, the measured alkalinity reported in the text for this level of hardness and pH was 263 mg/L $CaCO_3$.

Recommendation: The equation provided in the text of Howarth and Sprague (1978) for calculating alkalinity appears unreliable. The calculated alkalinity does not approximate measured alkalinity within a reasonable degree of accuracy. Values of hardness, pH, and alkalinity in Dixon and Sprague (1981a), which used the same water source in their toxicity tests, give greater evidence of this; i.e., using the measured value of hardness of 374 mg/L $CaCO_3$ and a pH of 7.75, the alkalinity calculated with the equation is 98 mg/L $CaCO_3$. This compares rather poorly with the measured alkalinity of 223 mg/L $CaCO_3$. Instead, alkalinity can be estimated using the nomograph from Faust and Aly (1981) as in Section 2.8.

It is possible to apply the procedure used with the Chakoumakos et al. (1979) data here, i.e., using the ratio of hardness in full-strength well water and de-ionized well water to calculate the dilution of the other major ion concentrations. However, no values are given for Na or K in University of Guelph well water. This study is also complicated by the reverse-osmosis unit used to create the de-ionized well water. In particular, the statement concerning the retention of the original Cl concentration in the de-ionized well water implies an ionic exchange that would also require a cation (to maintain charge balance). The cation involved is unknown. As discussed in a phone conversation with John Sprague on 17 November 2000, and later that day with Scott Howarth (Environment Canada), NaCl may have leached through the RO unit. Assuming that Na and Cl leached through the unit in equivalent proportions, a value of 14 mg/L for Na can be back-calculated from the reported Cl concentration of 22 mg/L.

Default DOC concentrations of 1.6 and 0.5 mg/L were assumed for the well water and de-ionized water used in the tests, respectively (see Section 2.3). The DOC concentrations were adjusted for each particular test water hardness level based on the proportion of well water and de-ionized water used to achieve the desired test hardness level. In the example provided in Table 9, the dilution factor of 0.27, based on the ratio of the average hardness of well water (366 mg/L $CaCO_3$) versus the average hardness of well plus de-ionized well water (100 mg/L $CaCO_3$), was applied to the starting DOC concentrations to achieve an estimate of the DOC concentrations at 100 mg/L $CaCO_3$). Table

NMED Exhibit 80

9 shows the results of similar adjustments made for the major anions and cations based on the data reported in Howarth and Sprague (1978).

2.16 *Default Values for Analyte Concentrations*

What value should be used when a specific analyte is not detected at its designated detection limit?

Recommendation: The use of half the detection limit (DL) is most appropriate when the concentration of an analyte is not detected. One-half the DL will closely approximate a replacement value for censored data in a log-normally distributed population that includes several measured values (Berthouex and Brown 1994; Dolan and El-Shaarawi 1991). This way some of the "nondetect" samples will actually be counted as detected.

Table 9. Example Calculations to Estimate Water Chemistry of Tests Conducted at 100 mg/L $CaCO_3$ by Howarth and Sprague (1978) Using a Mixture of University of Guelph Well Water and De-ionized Water

Parameter (units in mg/L)	De-ionized water	Well Water	Example Calculations for Mixture
Hardness	0	366	100 (i.e., 0.27 dilution factor)
Ca	0	77 (from Dixon & Sprague 1981)	21
Mg	0	43 (from Dixon & Sprague 1981)	12
Na	14 (assuming NaCl used for the softening process)	14 (estimated from [Cl])	14
K	0	2.4 (based on personal communication from Dr. Patricia Wright, Univ. of Guelph, Guelph, ON)	0.66
Cl	22 (stated as not having changed from the water softening process)	22	22
SO_4	0	129	35
DOC	0.5 (default value for de-ionized waters)	1.6 (default value for well waters)	0.8
Alkalinity (calculated using ratios as in Section 2.8):			
at pH 6	0[a]	81.5	22
at pH 7	0[a]	205	55
at pH 8	0[a]	250	N/A
at pH 9	0[a]	263	70

[a] Alkalinity in de-ionized well water is assumed to be 0.0 mg/L.

NMED Exhibit 80

2.17 *Organic Carbon Content of Samples*

Can any information be obtained on the organic carbon content of the spring water / City of Cincinnati, OH, tap water mixes used in Brungs et al. (1973), Geckler et al. (1976), Horning and Neiheisel (1979), Mount (1968), Mount and Stephan (1969), and Pickering et al. (1977)?

Recommendation: The water used for all tests was a mixture of spring-fed pond water (originating at the Newtown Fish Farm) and carbon-filtered, demineralized Cincinnati tap water. The water was mixed to achieve the desired test hardness level and discharged to a large (several thousand gallon) concrete reservoir that fed the test system. The detention time varied anywhere from 30 to 90 days, depending on the study, which was sufficient to allow the growth of phytoplankton and zooplankton in moderate abundance. No additional information regarding the TOC (DOC) concentration or treatment of this water is available at this time. The recommended organic carbon content of spring/city water mix is currently a conservative 1.6 mg/L, but could be as high as 2.5 mg/L, the highest DOC concentration recorded for a natural surface or well water used for studies included in this report (see Section 2.3). Considering the long retention time, and the fact that the natural water was spring-fed pond water, the more conservative DOC value of 2.5 mg/L is recommended for this water.

2.18 *Additional Water Chemistry Data Needed*

Additional water chemistry data are needed for Bennett et al. (1995) and Richards and Beitinger (1995). In the case of Richards and Beitinger 1995, only the ranges of measured pH, alkalinity, and hardness across all tests were given.

Recommendation: Detailed pH, alkalinity, and hardness values were provided by both Bennett et al. (1995) and Richards and Beitinger (1995) (Appendixes D-7 and D-9, respectively). The studies performed by Bennett et al. were conducted using dechlorinated City of Denton, TX, tap water (from Lake Roy Roberts). The author was not able to provide any additional data regarding the ionic composition of this water; however, based on supplementary data, mean values of pH, alkalinity, and temperature were 8.07 and 89.7 mg/L $CaCO_3$ and 21.4 C, respectively. Richards and Beitinger's studies were conducted using standard reconstituted (hard) water. To estimate the ionic composition of this water, refer to recommendations provided in Section 2.1.

2.19 *Estimating Data for Waters*

Values for DOC, TSS, Ca, Mg, Na, K, SO_4, and Cl are needed for the following natural waters:

Water Body	Reference
American River, California – sand filtered	Finlayson and Verrue 1982
Clinch River – 11µm filtered	Belanger et al. 1989
	Belanger and Cherry 1990
Amy Bayou	Belanger and Cherry 1990
Blaine Creek, Kentucky – 1.6 µm filtered	Dobbs et al. 1994
S. Kawishiwi	Lind et al. manuscript
St. Louis River	Lind et al. manuscript
Lake One	Lind et al. manuscript

NMED Exhibit 80

Colby Lake	Lind et al. manuscript
Cloquet Lake	Lind et al. manuscript
Greenwood Lake	Lind et al. manuscript
Embarrass River	Lind et al. manuscript
Green Duwamish River	Buckley 1983
Chehalis River	Mudge et al. 1993
Pinto Creek, AZ	Lewis 1978
Naugatuck River	Carlson et al. 1986

Recommendation: On the following pages are data (current and/or historical, presented as arithmetic means) from selected natural waters that were retrieved from NASQAN, STORET, or a secondary source (as indicated). As mentioned earlier (see Sections 2.6 and 2.7), given the reasonably good correlation between most of the major anion and cations (except K) and water hardness in natural surface and well waters, we recommend using the ion and hardness values retrieved from these various sources to estimate the ion concentrations in the test water used in the previous studies. The operation, again, is simply to multiply the ion concentrations listed below by the ratio of hardness values presented below and the earlier test waters.

Note that additional data were not available for Blaine Creek, KY, or Pinto Creek, AZ, and although additional data were obtained from the City of Sacramento, CA, regarding the American River, the default DOC value (8.2 mg/L) for California streams may be artificially high on the basis of reported values of DOC in the Sacramento River (1.2 mg C/L), of which the American River is a tributary. Therefore, the data from Finlayson and Verrue (1982) have been relegated to "other data." Likewise, Amy Bayou is a highly contaminated and dynamic system (Don Cherry, personal communication), and BLM normalization is not recommended for these data. A large annual variability in water quality also excludes the use of surrogate STORET data for the Embarrass River, MN, for BLM analysis (Lind et al. manuscript).

[b] Na data for this lake were not available. The Na value given here is based on data for Lake One, MN, and was scaled based on hardness: Na = 0.1 mg Na/L * (17 mg/L $CaCO_3$ / 10 mg/L $CaCO_3$).
[c] K data for this lake were not available. The K value given here is from data for Lake One, MN. This value was not scaled on the basis of hardness (see discussion of K-hardness relationship in Sections 2.1 and 2.7).

St. Louis River, MN (Appendix C-6). Source: NASQAN

Note: for the St. Louis River dataset (1973 to 1993), a question arose as to which data would be most representative for estimating the ion concentrations in St. Louis River water for BLM analysis. In order to determine this, the relationship between hardness and Na ion for all 20 years was plotted. Linear regression was used to fit the data. Most data showed very high coefficient correlation (0.8-0.94). For each of these 20 regression lines, the slope and intercept coefficients were plotted on separate graphs as functions of time (Figures 7 and 8). The following conclusions were derived:

- A significant event occurred in 1976 and perhaps 1977 that affected the water balance of the St. Louis River. A wastewater treatment plant was built, which substantially improved the water quality (Jesse Anderson, Minn. Pollution Control Bd., personal communication).

- For the 1979-1993 period, hardness and ion concentrations did not change significantly as absolute values. Therefore, general equations (which could be used to extrapolate water chemistry data till year 2000 and before 1979) can be obtained connecting hardness, alkalinity, pH, and the major ion concentrations.

- The exponential growth in the values between 1973 and 1979 shows that averaging values on seasonal and annual basis is not appropriate. The constant values for the slopes and intercepts for 1979-1993 allow mean monthly and annual interpretation of the data.

- The regression equations derived for 1977 alone are recommended to predict ion concentrations based on the water hardness levels measured in the Lind et al. (manuscript). The equations derived for each ion are provided in Appendix D-6 with the corresponding figures.

Appendix C-1. Calculations for Ionic Composition of Standard Laboratory-Reconstituted Water

Molecular Weights	Atomic Weights
$NaHCO_3$ = 84.03	Na = 22.98
$CaSO_4.2H_2O$ = 172.12	Ca = 40.08
$MgSO_4$= 120.37	Mg = 24.31
KCl = 74.55	K = 39.10
SO_4 = 96.06	Cl = 35.45

Example Calculation

[Na] in very soft water:
12 mg $NaHCO_3$/L x 1 mmol $NaHCO_3$/84.03 mg $NaHCO_3$ = 0.143 mmol $NaHCO_3$/L.
0.143 mmol $NaHCO_3$/L x (1 mmol Na/1 mmol $NaHCO_3$) x 22.98 mg Na/1 mmol Na = 3.3 mg Na/L.

[Ca] in very soft water:
7.5 mg $CaSO_4$.2H2O/L x 1 mmol $CaSO_4.2H_2O$/172.12 mg $CaSO_4.2H_2O$ = 0.044 mmol $CaSO_4.2H_2O$/L.
0.044 mmol $CaSO_4.2H_2O$/L x (1 mmol Ca/1 mmol $CaSO_4.2H_2O$) x 40.08 mg Ca/1 mmol Ca = 1.8 mg Ca/L.

[Mg] in very soft water:
7.5 mg $MgSO_4$/L x 1 mmol $MgSO_4$/120.37 mg $MgSO_4$ = 0.062 mmol $MgSO_4$/L.
0.062 mmol $MgSO_4$/L x (1 mmol Mg/1 mmol $MgSO_4$) x 24.31 mg Mg/1 mmol Mg = 1.5 mg Mg/L.

[K] in very soft water:
0.5 mg KCl/L x 1 mmol KCl/74.55 mg KCl = 0.0067 mmol KCl/L.
0.0067 mmol KCl/L x (1 mmol K/1 mmolKCl) x 39.102 mg K/1 mmol K = 0.26 mg K/L.

[Cl] in very soft water:
0.5 mg KCl/L x 1 mmol KCl/74.55 mg KCl = 0.0067 mmol KCl/L.
0.0067 mmol KCl/L x (1 mmol Cl/1 mmolKCl) x 35.453 mg Cl/1 mmol K = 0.24 mg Cl/L.

[SO_4] in very soft water:
7.5 mg $CaSO_4.2H_2O$/L x 1 mmol $CaSO_4.2H_2O$/172.12 mg $CaSO_4.2H_2O$ = 0.044 mmol $CaSO_4.2H_2O$/L.
0.044 mmol $CaSO_4.2H_2O$/L x (1 mmol SO_4/1 mmol $CaSO_4.2H_2O$) x 96.064 mg Ca/1 mmol Ca = 4.2 mg Ca/L.

[SO_4] in very soft water:
7.5 mg $MgSO_4$/L x 1 mmol $MgSO_4$/120.37 mg $MgSO_4$ = 0.062 mmol $MgSO_4$/L.
0.062 mmol $MgSO_4$/L x (1 mmol SO_4/1 mmol $MgSO_4$) x 96.064 mg Mg/1 mmol Mg = 6.0 mg Mg/L.

Total SO_4 = 10.2 mg/L

Conversion Factors to calculate water hardness (as $CaCO_3$) from [Ca] and [Mg]:

[Ca] x 2.497
[Mg] x 4.116

NMED Exhibit 80

Saltwater Conversion Factors for Converting Nominal or Total Copper Concentrations to Dissolved Copper Concentrations

The U.S. EPA changed its policy in 1993 of basing water quality criteria for metals from a total metal criteria to a dissolved metal criteria. The policy states "the use of dissolved metal to set and measure compliance with water quality standards is the recommended approach, because dissolved metal more closely approximates the bioavailable fraction of metal in the water column than does total recoverable metal" (Prothro 1993). All of the criteria for metals to this date were based upon total metal and very few data were available with dissolved concentrations of the metals. A problem was created by the new policy of how to derive dissolved metal concentrations for studies in which this form of the metal was not measured. The U.S. EPA attempted to develop correction factors for each metal for which criteria exist for both fresh- and saltwater (Lussier et al. 1995; Stephan 1995). In the case of saltwater, a correction for copper was not derived.

Several saltwater studies are available that report nominal, total, and dissolved concentrations of copper in laboratory water (Table 1) from site-specific water effect ratio (WER) studies. These studies show relatively consistent ratios for the nominal-to-dissolved concentrations and for the total-to-dissolved concentrations. Calculation of a mean ratio (conversion factor) to convert nominal and total copper concentrations to dissolved copper permits the use of the results for critical studies without dissolved copper measurements.

Three studies, each with multiple tests per study, were useful for deriving the conversion factors. One study was conducted for the lower Hudson River in the New York/New Jersey Harbor (SAIC 1993). The tests were conducted with harbor site water and with EPA Environmental Research Laboratory - Narragansett water from Narragansett Bay, Massachusetts. Only the tests with laboratory water were used for this exercise. Three series of 48-hour static tests were conducted with various animals. Salinity ranged from 28 to 32 ppt during all the tests. Series 1 tests were not used to calculate ratios for dissolved-to-total or dissolved-to-nominal copper concentrations, because in many instances, concentrations of measured copper did not increase as nominal concentrations increased. Of the series 2 tests, only the coot clam (*Mulinia lateralis*) tests were successful and used to calculate ratios. Three replicate tests without ultraviolet (UV) light present and one test with UV light present were reported with total and dissolved copper measurements made at 0 hr and 48 hr (end) of the tests. Dissolved-to-total and dissolved-to-nominal ratios were calculated for the four tests each with two time intervals. The mean ratio for the dissolved-to-total measurements is 0.943 and the mean ratio for the dissolved-to-nominal is 0.917. A third series of static tests was conducted by SAIC and the mussel (*Mytilus sp.*) test was the only successful test. Again the tests were conducted as three replicate tests without UV light and a fourth with UV light. The mean test ratio for dissolved-to-total copper was 0.863 and the dissolved-to-nominal mean test ratio was 0.906.

The summer flounder (*Paralichthys dentatus*) was exposed to copper in laboratory water for 96 hours in a static test (CH2MHill 1999a). The water was collected from Narragansett Bay and diluted with laboratory reverse osmosis water to dilute the solution to 22 ppt salinity. Three tests were run with copper concentrations measured at the start of the tests as total recoverable and dissolved copper. Five exposure concentrations were used to conduct the tests. Only the two lowest concentrations were used to derive ratios for dissolved-to-total and dissolved-to-nominal copper mean ratios. These concentrations were at the approximate 500 µg/L or lower concentrations, and are in the range of most copper concentrations routinely tested in the laboratory. The mean dissolved-to-total and dissolved-to-nominal ratios were 0.947 and 0.836, respectively.

Three 48-hour static tests were conducted with the blue mussel (*Mytilus edulis*) in water from the

NMED Exhibit 80

same source and treated in the same manner as the summer flounder tests (CH2MHill 1999b). Salinity was diluted to 20 ppt. Exposures were made at eight concentrations of copper and total and dissolved copper concentrations were measured only at the start of the tests. Mean ratios for the dissolved-to-total and dissolved-to-nominal copper were calculated by combining the ratios calculated for each of the test concentrations. The mean dissolved-to-total and dissolved-to-nominal ratios were 0.979 and 0.879, respectively.

A study was conducted by the City of San Jose, CA to develop a WER for San Francisco Bay in which copper was used as a toxicant and the concentrations used in the laboratory exposures were measured as total and dissolved copper (Environ. Serv. Dept., City of San Jose 1998). Mussels and the purple sea urchin (*Strongylocentrotus purpuratus*) were used as the test organisms. Tests were conducted in filtered natural sea water from San Francisco Bay that was diluted to a salinity of 28 ppt. The mussel test was of 48-hour duration and the purple sea urchin test was of 96-hour duration. Five concentrations of copper were used in the toxicity tests with the concentrations measured at the start of each test. (During each test, a single concentration of copper was measured at the termination of the test and this value was not used in the calculations.) Twenty-two tests were conducted during a 13-month period with the mussel and two tests were conducted with the purple sea urchin. The mean dissolved-to-total and dissolved-to-nominal ratios for the mussel tests were 0.836 and 0.785, respectively. The mean dissolved-to-total and dissolved-to-nominal ratios for the purple sea urchin were 0.883 and 0.702, respectively.

For some of the tests, control concentrations had measured concentrations of total and dissolved copper. These values were not used to calculate ratios for dissolved-to-total and dissolved-to-nominal copper concentrations. All mean ratios were calculated as the arithmetic mean and not as a geometric mean of the available ratios. When the data are normally distributed, the arithmetic mean is the appropriate measure of central tendency (Parkhurst 1998) and is a better estimator than the geometric mean. All concentrations of copper used to calculate ratios should be time-weighted averages (Stephan 1995). In all instances of data used to calculate ratios, the concentrations were identical to time-weighted values because either only one value was available or if two were available they were of equal weight.

Based on the information presented above the overall ratio for correcting total copper concentrations to dissolved copper concentrations is 0.909 based upon the results of six sets of studies. This is comparable to its equivalent factor in freshwater, which is 0.960 ± 0.037 (Stephan 1995). When it is necessary to convert nominal copper concentrations to dissolved copper concentrations the conversion factor is 0.838 based upon the same studies. The means of both conversion factors have standard deviations of less than ten percent of the means (Table 1).

NMED Exhibit 80

Table D-1. Summary of Saltwater Copper Ratios

Species	Mean Dissolved-to-Total Ratio	Mean Dissolved-to-Nominal Ratio	Reference
Coot clam, *Mulinia lateralis*	0.943	0.917	SAIC 1993
Summer flounder, *Paralichthys dentatus*	0.947	0.836	CH2MHill 1999a
Blue mussel, *Mytilus sp*	0.863	0.906	SAIC 1993
Blue mussel, *Mytilus edulis*	0.979	0.879	CH2MHill 1999b
Blue mussel, *Mytilus sp*	0.836	0.785	Environ. Serv. Dept., City of San Jose 1998
Purple sea urchin, *Strongylocentrotus purpuratus*	0.883	0.702	Environ. Serv. Dept., City of San Jose 1998
Arithmetic Mean	0.909	0.838	
Standard Deviation	±0.056	±0.082

Appendix F. Regression Plots

Appendix F. Analyses of Chronic Data

The following pages contain figures and other information related to the regression and probability distribution analyses that were performed to calculate chronic EC20s. The initial parameter estimates are shown in the tables below. In the figures that follow, circles denote measured responses and solid lines denote estimated regression lines.

Evaluation of the Chronic Data Available for Freshwater Species

Following is a species-by-species discussion of each chronic test on copper evaluated for this document. Also presented are the results of regression analysis and probability distribution analysis of each dataset that was from an acceptable chronic test and contained sufficient acceptable data. For each such dataset, this appendix contains a figure that presents the data and regression/probability distribution line.

Brachionus calyciflorus. The chronic toxicity of copper was ascertained in 4-day renewal tests conducted at regular intervals throughout the life of the freshwater rotifer, *B. calyciflorus* (Janssen et al. 1994). The goal of this study was to develop and examine the use of this rotifer as a viable test organism. The effect of copper on the age-specific survivorship and fertility of *B. calyciflorus* was determined, but no individual replicate data were provided and only three copper concentrations were tested, which precludes these data from further regression analysis. Chronic limits based on the intrinsic rate of natural increase were 2.5 µg/L total copper (NOAEC) and 5.0 µg/L total copper (LOAEC). The chronic value determined via traditional hypothesis testing is 3.54 µg/L total copper (Table 2a).

Campeloma decisum. Adult *C. campeloma* were exposed to five concentrations of total copper and a control (Lake Superior water) under flow-through conditions in two 6-week studies conducted by Arthur and Leonard (1970). Adult survival in the two separate chronic copper toxicity test trials was markedly reduced in the two highest copper concentrations, 14.8 and 28.0 µg/L, respectively. The authors reported that growth, as determined from cast exoskeleton, was not measurable for this test species, although the authors did observe that the adult snails would not consume food at the two highest copper concentrations. Control survival was 80 percent or greater. Chronic values of 10.88 µg/L total copper were obtained for survival based on the geometric mean of the NOAEC and LOAEC of 8.0 and 14.8 µg/L, respectively, in both tests. The corresponding EC20s were 8.73 and 10.94 µg/L (Table 2a).

Ceriodaphnia dubia. The chronic toxicity of copper to *C. dubia* was determined in ambient river water collected upstream of known point-source discharges of domestic and industrial wastes as part of a water effect ratio study (Carlson et al. 1986). In this study, survival and young production of *C. dubia* were assessed using a 7-day life-cycle test. Organisms were not affected at total copper concentrations ranging from 3 to 12 µg/L (5 to 10 µg/L dissolved copper). There was a 62.7 percent reduction in survival and 97 percent reduction in the mean number of young produced per female at 32 µg/L total copper (27 µg/L dissolved copper). No daphnids survived to produce young at 91 µg/L total copper. Control survival during the study was 80 percent, which included one male. The chronic value EC20 selected for *C. dubia* in this study, 9.17 µg/L derived from a nonlinear regression evaluation, was based on mean number of young produced (reproduction).

The effects of water hardness on the chronic toxicity of copper to *C. dubia* were assessed by Belanger et al. (1989) using 7-day life-cycle tests. *C. dubia* 2 to 8 hours old were exposed to copper in ambient surface water from the New and Clinch Rivers, Virginia. Mean water hardness levels were 179 and 94 mg/L as $CaCO_3$, respectively. Test water was renewed on days 3 and 5. The corresponding chronic values for reproduction based on the NOAEC and LOAEC approach were 7.9 and <19.3 µg/L dissolved copper, respectively. The EC20 value for number of young (neonates) produced in Clinch River water (water hardness of 94 mg/L as $CaCO_3$) was 19.36 µg/L dissolved copper. The EC20 for young produced in New River water was not calculated. The chronic values were converted to total copper using the freshwater conversion factor for copper 0.96 (e.g., 7.897/0.96). The resulting total chronic values for the New and Clinch rivers are 8.23 and 20.17 µg/L, respectively.

NMED Exhibit 80

Copper was one of 12 toxicants examined by Oris et al. (1991) in their comparisons between a 4-day survival and reproduction toxicity test utilizing *C. dubia* and a standard 7-day life-cycle test for the species. The reported 7-day chronic values for survival and reproduction (mean total young per living female) in two tests based on the traditional hypothesis testing techniques were 24.5 and 34.6 µg/L total copper. Comparable point estimates for these 7-day tests could not be calculated using regression analysis.

Daphnia magna. Blaylock et al. (1985) reported the average numbers of young produced for six broods of *D. magna* in a 14-day chronic exposure to copper. A significant reduction was observed in the mean number of young per female at a concentration of 30 µg/L total copper, the highest copper concentration tested. At this concentration, young were not produced at brood intervals 5 and 6. Reproduction was not affected at 10 µg/L total copper. The chronic value determined for this study (17.32 µg/L total copper) was based on the geometric mean of the NOAEC, 10 µg/L, and LOAEC, 30 µg/L.

Van Leeuwen et al. (1988) conducted a standard 21-day life-cycle test with *D. magna*. The water hardness was 225 mg/L as $CaCO_3$. Carapace length was significantly reduced at 36.8 µg/L total copper, although survival was 100 percent at this concentration. Carapace length was not affected at 12.6 µg/L total copper. No daphnids survived at 110 µg/L concentration. The highest concentration not significantly different from the control for survival was 36.8 µg/L. The lowest concentration significantly different from the control based on survival was 110 µg/L, resulting in a chronic value of 63.6 µg/L for survival. The chronic value based on carapace length was 21.50 µg/L. The 21-day EC10 as reported by the author was 5.9 µg/L total copper.

Chronic (21-day) renewal toxicity tests were conducted using *D. magna* to determine the relationship between water hardness (nominal values of 50, 100, and 200 mg/L as $CaCO_3$, respectively) and the toxicity of total copper (Chapman et al. unpublished manuscript). All test daphnids were <1 day old at the start of the tests. The dilution water was well water from the Western Fish Toxicology Station (WFTS), Corvallis, Oregon. Test endpoints were reproduction (total and live young produced per female) and adult survival. The survival of control animals was 100 percent at nominal water hardness levels of 50 and 200 mg/L as $CaCO_3$, and 80 percent at a hardness of 100 mg/L as $CaCO_3$. The chronic values for total young produced per female (fecundity) based on the geometric mean of the NOAEC and LOAEC were 13.63, 29.33, and 9.53 µg/L at the nominal hardness levels of 50, 100, and 200 mg/L as $CaCO_3$, respectively. The corresponding EC20 values for reproduction calculated using nonlinear regression analysis were 12.58, 19.89, and 6.06 µg/L total copper. The chronic toxicity of copper to *D. magna* was somewhat ameliorated from an increase in water hardness from 50 to 100 mg/L as $CaCO_3$, but slightly increased from 100 to 200 mg/L as $CaCO_3$.

Daphnia pulex. Winner (1985) evaluated the effects of water hardness and humic acid on the chronic toxicity (42-day) of copper to *D. pulex*. Contrary to the expectation that sublethal endpoints are more sensitive indicators of chronic toxicity, reproduction was not a sensitive indicator of copper stress in this species. Water hardness also had little effect on the chronic toxicity of copper (similar to *D. magna* trends), but humic acid significantly reduced chronic toxicity of copper when added to the varying water types. The survival chronic values based on the NOAEC and LOAEC values for the three low to no humic acid studies were 4.90, 7.07, and 12.25 µg/L total copper at hardnesses of 57.5, 115, and 230 (0.15 mg/L HA) µg/L as $CaCO_3$, respectively. The EC20 values calculated for the low and high hardness studies using nonlinear regression techniques were 2.83 and 9.16 µg/L at hardness values of 57.5 and 230 (0.15 mg/L HA) µg/L as $CaCO_3$, respectively.

NMED Exhibit 80

Clistoronia magnifica. The effects of copper on the lifecycle of the caddisfly, *C. magnifica*, were examined in Nebeker et al. (1984b). The test included continuous exposure of first-generation aquatic larvae and pupae through to a third generation of larvae. A significant reduction in adult emergence occurred at 13.0 µg/L total copper from first-generation larvae. No observed adverse effect to adult emergence occurred at 8.3 µg/L total copper. Percent larval survival was close to the control value of 80 percent. The chronic value based on hypothesis testing was 10.39 µg/L total copper. The corresponding EC20 value for adult emergence was 7.67 µg/L total copper.

Oncorhynchus mykiss. The growth and survival of developing *O. mykiss* embryos continuously and intermittently exposed to copper for up to 85 days post-fertilization was examined by Seim et al. (1984). Results only from the continuous exposure study are considered here for deriving a chronic value. A flow-through apparatus was used to deliver six concentrations and a control (untreated well water; average of 3 µg/L copper) to a single incubation chamber. Continuous copper exposure of steelhead embryos in the incubation chambers was begun 6 days post-fertilization. At 7 weeks post-fertilization, when all control fish had hatched and reached swim-up stage, subsamples of approximately 100 alevins were transferred to aquaria and the same exposure pattern continued. Dissolved oxygen remained near saturation throughout the study. Water hardness averaged 120 mg/L as $CaCO_3$. Survival of steelhead embryos and alevins exposed continuously to total copper concentrations in the range of 3 (controls) to 30 µg/L was greater than 90 percent or greater. Survival was reduced at 57 µg/L and completely inhibited at 121 µg/L. A similar effect on survival was observed for embryos and alevins exposed to a mean of 51 (peak 263) and 109 (peak 465) µg/L of copper in the intermittent exposure, respectively. The adverse effect of continuous copper exposure on growth (measured on a dry weight basis) was observed at concentrations as low as 30 µg/L. (There was a 30 percent reduction in growth during the intermittent exposure at 16 µg/L.) The chronic limits for survival of embryos and alevin steelhead trout exposed continuously to copper were 16 and 31 µg/L, respectively (geometric mean = 22.27 µg/L). The EC20 for biomass for the continuous exposure was 27.77 µg/L.

Besser et al. (2001) conducted an ELS toxicity test with copper and the rainbow trout, *O. mykiss*, starting with eyed embryos and continuing for 30 days after the fish reached the swim-up stage. The total test period was 58 days. The test was conducted in ASTM moderately hard reconstituted water with a hardness of approximately 160 to 180 mg/L as $CaCO_3$. Twenty-five eyed embryos were held in each of four replicate egg cups at each concentration. Survival was monitored daily. At the end of the test, surviving fish in each replicate chamber were weighed (dry weight). Dry weights were used to determine growth and biomass of surviving fish. The no observed effect concentrations (NOECs) for survival and biomass were both 12 µg/L and the lowest observed effect concentrations (LOECs) for survival and biomass was also the same for both endpoints, 22 µg/L. The chronic values for biomass and survival based on the geometric mean of the NOEC and LOEC were 16.25 µg/L. The corresponding EC20 for biomass was 20.32 µg/L.

Oncorhynchus tshawytscha. The draft manuscript prepared by Chapman (1975/1982) provides the results from a 4-month egg through fry partial chronic test conducted to determine the effects of copper on survival and growth of *O. tshawytscha*. Continuous exposure occurred from several hours post-fertilization through hatch, swim-up, and feeding fry stages. The test was terminated after 14 weeks post-hatch. The dilution water was WFTS well water. Because of the influence of the nearby Willamette River on the hardness of this well water, reverse osmosis water was mixed periodically with ambient well water to attain a consistent hardness. The typical hardness of this well water was approximately 23 mg/L as $CaCO_3$. Control survival exceeded 90 percent for the test. The measured total copper concentrations during the test were 1.2 (control), 7.4, 9.4, 11.7, 15.5, and 20.2 µg/L, respectively. Copper adversely affected survival at 11.7 µg/L copper and higher, and growth was reduced at all copper concentrations tested compared with the growth of control fish. The chronic limits for copper in this study were

NMED Exhibit 80

estimated to be less than 7.4 µg/L. The EC20 value estimated for biomass is 5.92 µg/L total copper based on a logistic nonlinear regression model.

Salmo trutta. McKim et al. (1978) examined the survival and growth (expressed as standing crop) of embryo-larval and early juvenile brown trout to copper. The most sensitive exposure was with embryos exposed for 72 days. The NOAEC and LOAEC, as obtained from the figure, were 20.8 and 43.8 µg/L total copper, respectively. Data were not available to calculate point estimates at the 20 percent effect level using regression analysis. The chronic value selected for this species was 29.91 µg/L total copper (geometric mean of 20.8 and 43.8 µg/L total copper).

Salvelinus fontinalis. Sauter et al. (1976) examined the effects of copper on selected freshwater fish species at different hardness levels (softwater at 37.5 mg/L as $CaCO_3$; hardwater at 187 mg/L as $CaCO_3$) during a series of partial life-cycle (PLC) tests. The species tested were brook trout (*Salvelinus fontinalis*), channel catfish (*Ictalurus punctatus*), and walleye (*Stizostedion vitreum*). Because of the poor embryo and larval survival of control animals (in all cases less than 70 percent), results from tests with channel catfish and walleye were not included in Table 2a. One of the replicate control chambers from the PLC tests conducted with brook trout in hard water also exhibited poor hatchability (48 percent) and survival (58 percent) between 31 and 60 days of exposure. Therefore, the data for brook trout in hard water were not included in the subsequent EC20 (regression) analysis either.

The softwater test with brook trout was conducted using untreated well water with an average water hardness of 35 mg/L as $CaCO_3$. This PLC exposure consisted of six copper concentrations and a control. Hatchability was determined by examining randomly selected groups of 100 eggs from each replicate exposure tank. Growth and survival of fry were determined by impartially reducing the total sample size to 50 fry per tank and assessing their progress over 30 day intervals up to 60 days post-hatch. The chronic limits based on the growth (wet weight and total length) of larval brook trout after 60 days of exposure to copper in soft water were <5 and 5 µg/L. The resultant chronic value for soft water based on hypothesis testing was <5 µg/L. The corresponding EC20 values based on total length, wet weight, and biomass (the product of wet weight and survival) for brook trout in the soft-water exposures after 60 days were not amenable to nonlinear regression analysis.

McKim et al. (1978) examined survival and growth (expressed as standing crop) of embryo-larval and early juvenile brook trout exposed to copper. The embryo exposure was for 16 days, and the larval-early-juveniles exposure lasted 60 days. The NOAEC and LOAEC were 22.3 and 43.5 µg/L total copper, respectively. Data were not available to calculate point estimates at the 20 percent effect level using regression analysis. The chronic value for this species was 31.15 µg/L total copper (geometric mean of 22.3 and 43.5 µg/L total copper).

Salvelinus namaycush. McKim et al. (1978) examined the survival and growth (expressed as standing crop) of embryo-larval and early juvenile lake trout exposed to copper. The embryo exposure was for 27 days, and the larval-early-juveniles exposure lasted 66 days. The NOAEC and LOAEC were 22.0 and 43.5 µg/L total copper, respectively. Data were not available to calculate point estimates at the 20 percent effect level using regression analysis. The chronic value for this species was 30.94 µg/L total copper (geometric mean of 22.0 and 43.5 µg/L total copper).

Esox lucius. McKim et al. (1978) examined the survival and growth (expressed as standing crop) of embryo-larval and early juvenile northern pike exposed to copper. The embryo exposure was for 6 days, and the larval-early-juveniles exposure lasted 34 days. The NOAEC and LOAEC were 34.9 and 104.4 µg/L total copper, respectively. The authors attributed the higher tolerance of *E. lucius* to copper to the very short embryonic exposure period compared with salmonids and white sucker, *Catostomus*

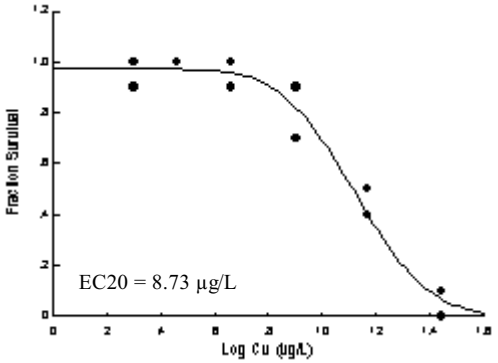
NMED Exhibit 80

commersoni. Data were not available to calculate point estimates at the 20 percent effect level using regression analysis. The chronic value for this species was 60.36 µg/L total copper (geometric mean of 34.9 and 104.4 µg/L total copper).

Pimephales notatus. An experimental design similar to that described by Mount and Stephan (1967) and Mount (1968) was used to examine the chronic effect of copper on the bluntnose minnow, *P. notatus* (Horning and Neiheisel 1979). Measured total copper concentrations were 4.3 (control), 18.0, 29.9, 44.1, 71.8, and 119.4 µg/L, respectively. The experimental dilution water was a mixture of spring water and demineralized City of Cincinnati tap water. Dissolved oxygen was kept at 5.9 mg/L or greater throughout the test. Total water hardness ranged from 172 to 230 mg/L as $CaCO_3$. The test was initiated with 22 6-week-old fry. The fish were later separated according to sex and thinned to a sex ratio of 5 males and 10 females per duplicated test chamber. Growth (total length) was significantly reduced in parental and first (F_1) generation *P. notatus* after 60 days of exposure to the highest concentration of copper tested (119.4 µg/L). Survival of parental *P. notatus* exposed to this same high test concentration was also lower (87 percent) at the end of the test compared with the other concentrations (range of 93 to 100 percent). Copper at concentrations of 18 µg/L and greater significantly reduced the number of eggs produced per female. The number of females available to reproduce was generally the same up to about 29.9 µg/L of copper. The chronic limits were based on an NOAEC and LOAEC of <18 and 18 µg/L for number of eggs produced per female. An EC20 was not estimated by nonlinear regression; nevertheless, in this case an EC20 is likely to be substantially below 18 µg/L.

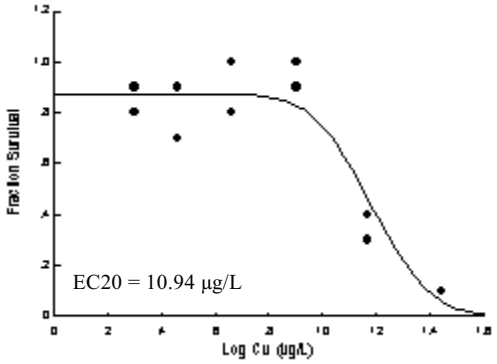
Pimephales promelas. The results from a 30-day ELS toxicity test to determine the chronic toxicity of copper to *P. promelas* using dilution water from Lake Superior (hardness ranging from 40 to 50 mg/L as $CaCO_3$) was included in Table 2a from a manuscript prepared by Lind et al. in 1978. In this experiment, five test concentrations and a control were supplied by a continuous-flow diluter. The exposure began with embryos 1 day post-fertilization. Pooled results from fish dosed in replicate exposure chambers were given for mean percentage embryo survival to hatch, mean percentage fish survival after hatch, and mean fish wet weight after 30 days. The percentage of embryo survival to hatch was not affected by total copper concentrations as high as 52.1 µg/L total copper. Survival after hatch, however, was compromised at 26.2 µg/L, and mean wet weight of juvenile fathead minnows was significantly reduced at 13.1 µg/L of copper. The estimated EC20 value for biomass was 9.376 µg/L total copper.

Catastomus commersoni. McKim et al. (1978) examined the survival and growth (expressed as standing crop) of embryo-larval and early juvenile white sucker exposed to copper. The embryo exposure was for 13 days, and the larval-early-juvenile exposure lasted 27 days. The NOAEC and LOAEC were 12.9 and 33.8 µg/L total copper, respectively. The resulting chronic value based on hypothesis testing for this species was 20.88 µg/L total copper (geometric mean of 12.9 and 33.8 µg/L total copper).



Lepomis macrochirus. Results from a 22-month copper life-cycle toxicity test with bluegill (*L. macrochirus*) were reported by Benoit (1975). The study included a 90-day embryo-larval survival and growth component. The tests were conducted at the U.S. EPA National Water Quality Laboratory in Duluth, Minnesota, using Lake Superior water as the dilution water (average water hardness = 45 mg/L as $CaCO_3$). The test was initiated in December 1969 with 2-year-old juvenile *L. macrochirus*. In May 1971, the fish were sexed and randomly reduced to three males and seven females per tank. Spawning commenced on 10 June 1971. The 90-day embryo-larval exposure was initiated when 12 lots of 50 newly hatched larvae from one of the two control groups were randomly selected and transferred to duplicate grow-out chambers at 1 of 6 total copper concentrations: 3 (control), 12, 21, 40, 77, and 162 µg/L, respectively. In the 22-month juvenile through adult exposure, survival, growth, and reproduction were unaffected at 77 µg/L of copper and below. No spawning occurred at 162 µg/L. Embryo hatchability and

NMED Exhibit 80



survival of 4-day-old larvae at 77 µg/L did not differ significantly from those of controls. However, after 90 days of exposure, survival of larval *L. macrochirus* at 40 and 77 µg/L was significantly lower than for controls, and no larvae survived at 162 µg/L. Growth remained unaffected at 77 µg/L. Based on the 90-day survival of bluegill larvae, the chronic limits were estimated to be 21 and 40 µg/L (geometric mean = 28.98 µg/L). The corresponding EC20 for embryo-larval survival was 27.15 µg/L.

Appendix G. Example Water Quality Criteria Values Using the BLM and the Hardness Equation

Appendix G: Representative water quality criteria values using the BLM and the Hardness equation approaches for waters with a range in pH, Hardness, and DOC concentrations. The BLM calculation assumed that alkalinity was correlated with pH, and that other major ions were correlated with hardness based on observed correlations in EPA synthetic water recipes.

High control mortalities occurred in all except one test reported by Sauter et al. (1976). Control mortality exceeded 10% in one test by Mount and Norberg (1984). Pilgaard et al. (1994) studied interactions of copper and hypoxia, but failed to run a hypoxic control. Beaumont et al. (1995a,b) studied interactions of temperature, acid pH and copper, but never separated pH and copper effects. The 96-hour values reported by Buikema et al. (1974a,b) were subject to error because of possible reproductive interactions (Buikema et al. 1977).

Young and Harvey (1988, 1989)
Zia and Alikhan (1989)

Anderson (1994), Anderson et al. (1994), Viarengo et al. (1993), and Zaroogian et al. (1992) reported on *in vitro* exposure effects. Benedeczky et al. (1991) studied only effects of injected copper. Ferrando et al. (1993b) studied population effects of copper and cladoceran predator on the rotifer prey, but the data are difficult to interpret. A similar problem complicated use of the cladoceran competition study of LeBlanc (1985).

Training materials on Copper BLM: Implementation

US Environmental Protection Agency
Office of Science and Technology
Standards and Health Protection Division
1200 Pennsylvania Avenue, N.W. (MC 4305T)
Washington, D.C. 20460

NMED Exhibit 81

1. Implementation

1.1 What options are available to states and tribes for adopting and implementing the updated national recommended criteria statement?

States and tribes have flexibility in implementing the updated copper criteria. States and tribes can implement the BLM-based criteria as a performance-based approach and may choose either incremental or statewide implementation depending on their needs and resources. For many states and tribes, EPA regards incremental implementation as the most feasible and efficient means of implementing the updated criteria.

For states and tribes choosing to implement the BLM-based criteria using an incremental approach, EPA recommends moving as quickly as possible to adopt the BLM methodology into State or tribal water quality standards (while retaining the hardness criteria) to utilize the latest available science to develop site-specific copper criteria on a targeted basis. This approach should result in more appropriate criteria more quickly for waters where the hardness-based copper criteria may be potentially over-protective, such as waters with high DOC, or potentially under-protective, such as waters with low pH. Under this approach, the hardness-based criterion remains in State (or tribal) water quality standards and applies to all waters except for those where site-specific criteria are derived using the BLM.

States choosing to use the BLM on a targeted basis may consider adding a paragraph to their water quality standards noting that site-specific criteria for copper may be developed on a case-by-case basis using the approach described in EPA's *Aquatic Life Ambient Freshwater Quality Criteria – Copper 2007 Revision* (EPA-822-R-07-001). Or, states may choose to include a footnote indicating that if a site-specific criterion is generated using the BLM, the BLM-derived value becomes the site-specific copper criterion (see 40 CFR §131.36(b)(2) for an example). EPA recommends that states and tribes maintain an updated listing of the water bodies for which the BLM has been used as the basis for a site-specific freshwater copper criterion.

This incremental or targeted approach would provide states and tribes with the flexibility to use the BLM on a limited basis where it will have the most impact. Once developed for particular water segments, BLM-based criteria would provide the basis for permitting and assessment decisions.

In situations where states or tribes choose not to use the BLM, the state (or tribe) may continue to use the WER method as a means of developing site-specific criteria. Done this way, there would be two ways to develop site-specific criteria: 1) using the hardness-based criteria with a WER, and 2) using the BLM on a targeted basis. The permitting authority may consider requiring individual dischargers to collect the monitoring data in order to use the BLM, which EPA expects in most cases would be less expensive to obtain than site-specific toxicology data to develop a WER.

NMED Exhibit 81

An alternative implementation approach would be where states or tribes choose to adopt the national criteria recommendation (the BLM) as the statewide standard. States and tribes can develop numeric results up front when adopting the revised criteria or later when developing permits or conducting assessments. Under this approach, the BLM-based criteria would replace the hardness-based criteria for copper. This approach allows states and tribes to use the latest available science to apply a copper criterion to each site that would best reflect predicted effects on aquatic life based on the behavior of copper in the receiving stream. States and tribes can incorporate BLM input parameters into their statewide monitoring programs to ensure that data are available to use the BLM. The additional monitoring data may later prove to be useful if and when the BLM is developed and calibrated for other metals, such as zinc and silver.

This statewide implementation option could likely result in increased costs to state monitoring programs, because some of the BLM input parameters (particularly DOC) are not routinely monitored. In addition, selecting this option may obligate the state or tribe to use the BLM, even for waters where the hardness-based criteria may be adequate.

1.2 Have any states or tribes used the BLM to calculate site-specific copper criteria?

Yes. Colorado has used the BLM as an alternative means to develop site-specific WER for several effluent dominated stream segments. The Colorado Water Quality Division developed informal guidance regarding use of the BLM. This informal guidance suggests the following:

- Water quality samples should be taken above and below wastewater treatment facilities. The downstream sample should be taken where the effluent has fully mixed with the receiving water. More than one sampling site is recommended for stream segments longer than five miles.
- Water quality samples should be taken below each National Pollutant Discharge Elimination System (NPDES) permit discharge for stream segments with more than one NPDES permit.
- Water quality data should adequately describe seasonal attributes of a stream.
- At least one year of water quality data is recommended, with a minimum of 24 sampling events.

The suggestions outlined in Colorado's informal guidance should not be construed as EPA's recommendations for how to use the BLM; rather, the guidelines are presented here as an illustrative example of how one State has used the BLM.

Additionally, Massachusetts Department of Environmental Protection (MA DEP) evaluated the applicability of the BLM to develop site-specific copper criteria in the Taunton River watershed. Water quality samples were collected at 13 sites (10 in stream locations and three publicly-owned treatment works (POTWs) discharge points) in the watershed; samples were taken in the spring (to capture average to high flow conditions)

NMED Exhibit 81

and the summer (to capture low flow conditions). Samples were taken both upstream and downstream of three POTWs discharging to the Taunton River and its tributaries.

1.3 How does the BLM compare to the WER method in terms of cost?

In general, EPA expects the water chemistry data required by the BLM to be less expensive than WER toxicity testing on a per site basis. States routinely monitor for some of the BLM input parameters; therefore, the need for a state or tribe to initiate monitoring for all 10 input parameters to use the BLM represents a worst-case scenario. States and tribes may choose to work with direct dischargers to collect monitoring data for the BLM. Parameter estimation techniques may also eventually reduce the implementation costs.

It is difficult to do a direct cost comparison of the BLM and WER method because the cost of data collection and analysis will vary depending on the location and site-specific conditions of the site. Currently, dischargers typically pay for WER testing, while the costs of using the BLM may be borne by the discharger or the state (or tribe), depending on how states (and tribes) choose to implement the updated criteria.

Costs associated with implementing the BLM include those for field work (including sample collection containers and technician-hours in the field) and laboratory services (including analytical services and other lab charges, such as sample handling and disposal and reporting forms). EPA estimates that the total cost for one set of 10 input parameters is approximately $325. Depending on the number of data sets collected, BLM-related costs may range from $325 (the cost of an “instantaneous criterion”) to $1300 (the cost of one sampling event per season, for a total of four) or more per site. There could be additional costs that vary depending on the location and complexity of the site, including study design to define the site, statistical evaluation of the sampling scheme, and transportation.

Costs associated with the Streamlined WER method to develop a site-specific criterion include the costs of two (or more) sampling events (with a representative sample of upstream water and effluent taken for each sampling event), side-by-side toxicity tests for laboratory and site water with one test species; and other measurements (including hardness, pH, alkalinity, total suspended solids (TSS), and DOC for both the site water and the laboratory water). EPA estimates the cost of the Streamlined WER method (two samples and one test species) to be approximately $10,000.

Costs associated with the 1994 Interim WER method (the “non-streamlined” method) are likely to be higher, given that the Interim WER method recommends three sampling events for one species, and one sampling event with a second species (for a total of four WER tests). EPA estimates the cost of using the1994 Interim WER method at a relatively simple site to be on the order of $20,000. Some more complex applications of the WER method have costs over $100,000.

NMED Exhibit 81

1.4 Will existing site-specific freshwater copper criteria derived using the WER method need to be revised using the BLM?

A state or tribe may choose to retain the WER-adjusted hardness criterion or use the BLM on a targeted basis to develop site-specific criteria. EPA developed different BLM implementation options for states and tribes to consider (see Question 1.1).

1.5 If the BLM results in a different criterion than a state currently has, will a use attainability analysis (UAA) be needed to change a use?

A UAA would not be required if application of the BLM for copper resulted in different criteria, assuming that the state or tribe would not be revising the underlying designated use. In that circumstance, a UAA would not be necessary regardless of whether application of the BLM results in a more or less stringent copper criterion. On the other hand, if the designated use would be revised to a different aquatic life use subcategory, and a less stringent criterion for copper (or any other parameter) would also be adopted, a UAA would need to be prepared pursuant to 40 CFR 131.10(j)(2).

NMED Exhibit 81

Madam Hearing Officer.

EXAMINATION

BY COMMISSIONER DOMINGUEZ:

Q. Good afternoon, Mr. Fulton. Thank you for your testimony today.

My line of questioning shall be a little bit broader in scope than my colleague to your right. If my questions get outside the scope of your testimony, I'm sure that Ms. Olson will object.

With that leg out, if I heard you correctly, you provided testimony at the prior Triennial Review, or you were at or attended the Triennial Review. Is that correct?

A. That's correct, Commissioner Dominguez.

Q. So you probably recall there was a point in time where there was a fair amount of discussion about the best available science and what constitutes best available science.

The Copper Criteria that's being proposed in this Petition, in your

professional opinion, is this the best available science?

A. Yes. In my best professional opinion the Proposal in front of the Commission today, Site-Specific Water Quality Criteria for copper, was developed and reflects the best available science.

Q. Okay. Thank you.

Dr. White talked about, you know, there was 18-plus years of very robust data sets that were used to arrive at what you have arrived at. Is the 2007 EPA guidance best suited for Site-Specific Criteria development partially due to just the sheer volume of data that's necessary to actually get to an end point?

A. That's a really good question; I think one can make that argument or come to that conclusion.

You know, there's a number of sites that probably have non-detect copper, and so copper is just no concern. You know, why would that particular site want to spend all the resources that is required in the Copper BLM?

As you saw today it takes effort to collect the data necessary to evaluate the BLM and to analyze the data necessary to evaluate the BLM.

Conversely, other states have fully adopted the BLM, but that's a complex process because it's, for some of the reasons I mentioned in my testimony, a complex piece of software. Adopting software creates challenges, and fully adopting the complex software requires pretty robust implementation guidance, and statewide implementation guidance.

In that regard there is probably something to be said for adopting it on a segment-specific basis.

Q. Thank you for laying a foundation to my next question:

If a state was going to look at adopting something statewide, is it more realistic to utilize the software versus developing equations like you have for these specific sites?

A. Well as you saw today there is a lot of work that went into developing

those equations. However, there is obvious benefit to it because of the reasons I've mentioned; it is fewer parameters. It's very transparent to look at an equation. I can see, you know, the appeal for statewide adoption of similar equations.

However I think that other states have shown that the software can effectively be adopted statewide. I think the question of adopting the software statewide, you know, depends on whether it could be streamlined by making assumptions for missing parameters.

For example, what does a site do if they don't have DOC, or a given Cad ion or N ion; would they use some reference value? I think it's entirely possible to do both. I think that just adopting the software version statewide requires a different set of analyses and uncertainties than we faced for the Plateau given the, you know, robustness and availability of data that we had for the Plateau.

Q. Okay. Thank you for that answer.

Part of where this line of questioning is coming from is, of course, EPA came out with this around 2007. That was probably about the time I started on this Commission, and I've sat through more Triennial Reviews than I care to remember, and there is a common thread through all of them that the amount of resources that it takes to adopt the 2007 guidance from EPA, this State has never really had the resources to do that. It's been a common theme up until the point where you guys have Petitioned for the site-specific.

My hat is off to the Petitioners for the amount of work that went into this site-specific, because I think we have to move towards the best science available.

I think that's what the public expects this Commission to do for protection of waters is to utilize the best science available, so I applaud the effort in moving that direction, realizing this is a fairly small step in the big

scheme of things statewide, but I think it's a proper step, so thank you.

That's all the questions I have.

HEARING OFFICER ORTH: Thank you.

Vice Chair Zemlick.

EXAMINATION

BY VICE CHAIRWOMAN ZEMLICK:

Q. Thank you for your testimony.

They have asked a lot of my questions, but the one remaining is along the lines of what my colleagues asked:

Do you have a sense for what sort of threshold there may be in terms of the amount of data required to develop these site-specific thresholds for other locations in the state?

A. Yeah, good question. Thank you, Commissioner, for the question:

At a minimum, you know, any time we talk about Site-Specific Water Quality Criteria generally speaking, the objective is to capture the variation that may be expected within a given water body,

OFFICE OF WATER AND
HAZARDOUS MATERIALS

To the Reader:

Thousands of fine scientists throughout the country have contributed directly or indirectly to this publication on "Quality Criteria for Water." This volume represents a stock-taking effort on the part of this Agency to identify as precisely as possible at this time, on a national scale, the various water constituents that combine to form the concept of "Quality Criteria for Water". This process of definition will continue far into the future because research related to water quality is a never-ending evolutionary process, and the water environment is so complex that man's efforts to define it will never attain finite precision.

Water quality criteria do not have direct regulatory use, but they form the basis for judgment in several Environmental Protection Agency and State programs that are associated with water quality considerations. The criteria presented in this publication should not be used as absolute values for water quality. As it is stated in the chapter on "The Philosophy of Quality Criteria" there is variability in the natural quality of water and certain organisms become adapted to that quality, which may be considered extreme in other areas. These criteria represent scientific judgments based upon literature and research about the concentration-effect relationship to a particular water quality constituent upon a particular aquatic species within the limits of experimental investigation. They should be used with considered judgment and with an understanding of their development. The judgment associated with their use should include the natural quality of water under consideration, the kinds of organisms that it contains, the association of those species to the particular species described in this volume upon which criteria values have been placed, and the local hydrologic conditions.

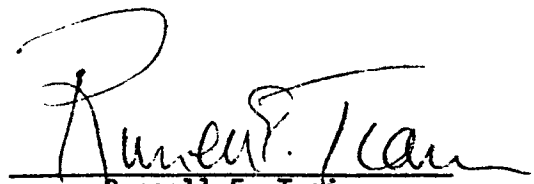
It must be emphasized that national criteria can never be developed to meet the individual needs of each of the Nation's waterways--the natural variability within the aquatic ecosystem can never

be identified with a single numerical value. Water quality criteria will change in the future as our knowledge and perception of the intricacies of water improve. There is no question but that criteria for some constituents will change within a period of only two years based upon research now in progress. That is a mark of continuing progressive research effort, as well as a mark of a better understanding by man of the environment that he inhabits.

This, then, is the challenge for the future: to expand upon our present baseline of knowledge of the cause-effect relationships of water constituents to aquatic life and of the antagonistic and synergistic reactions among many quality constituents in water; and to mold such future knowledge into realistic, environmentally protective criteria to insure that the water resource can fulfill society's needs.

Eckardt C. Beck
Deputy Assistant Administrator
for Water Planning and Standards

FOREWORD



The Federal Water Pollution Control Act Amendments of 1972 require the Administrator of the Environmental Protection Agency to publish criteria for water quality accurately reflecting the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare which may be expected from the presence of pollutants in any body of water, including ground water. Proposed Water Quality Criteria were developed and a notice of their availability was published on October 26, 1973 (38 FR 29646). This present volume represents a revision of the proposed water quality criteria based upon a consideration of comments received from other Federal agencies, State agencies, special interest groups, and individual scientists.

This volume, Quality Criteria for Water, addresses the effects of those basic water constituents and pollutants that are considered most significant in the aquatic environment in the context of our present knowledge and experience. The format for criteria presentation has been altered substantially from the proposed volume. It is believed that the alphabetical arrangement of the water quality constituents and the form in which the information is arranged will be of considerable help to the reader in using this volume. For each basic water constituent or pollutant there is a recommended criterion, an introduction, a rationale supporting the recommended criterion and a list of the references cited in the development of the recommendation.

NMED Exhibit 83

The thrust of this volume is to recommend criteria levels for a water quality that will provide for the protection and propagation of fish and other aquatic life and for recreation in and on the water in accord with the 1983 goals of P.L. 92-500. Criteria also are presented for the domestic water supply use. Generally, these water uses are the highest achievable beneficial uses and water quality that supports these uses will also be suitable for agricultural and industrial uses. In those few exceptions, criteria are presented to provide a safe water quality for agricultural use, or water quality conditions associated with agricultural and industrial uses are discussed in the rationale supporting a criterion recommendation.

Guidelines to implement the consideration of criteria presented in this volume in the development of water quality standards, and in other water-related programs of this Agency, are being developed and will be available for use by the States, other agencies, and interested parties in the near future.

Russell E. Train
Administrator

NMED Exhibit 83

PREFACE

The genesis of water quality criteria in the United States began in the early 1900's. Marsh[1/], in 1907, published on the effects of industrial wastes on fish. Shelford[2/], in 1917, published effect data on fish for a large number of gas-waste constituents. In this early publication he reiterated that the toxicity of waste differs for different species of fish and generally is greater for the smaller and younger fish. Powers[3/], working with Shelford, experimented with the goldfish as a test animal for aquatic toxicity studies.

A monumental early effort to describe and record the effects of various concentrations of a great number of substances on aquatic life was that of Ellis in 1937. Ellis[4/] reviewed the existing literature for 114 substances in a 72-page document and listed lethal concentrations found by the various authors. He provided a rationale for the use of standard test animals in aquatic bioassay procedures and he used the common goldfish, Crassius auratus and the entomostracan, Daphnia magna, as test species in which experiments were made in constant temperature cabinets.

Early efforts to summarize knowledge concerning water quality criteria

NMED Exhibit 83

took the form of a listing of the concentration, the test organism, the results of the test within a time period, and the reference for a cause-effect relationship for a particular water contaminant. In early bioassay efforts insufficient attention was given to the quality of the dilution water used for the experiment and to the effects of such dilution water on the relative toxicity of the tested contaminant. As a result, conclusions from citations of such references were, at best, difficult to formulate and most often were left to the discretion of the reader.

In 1952, the State of California[5/] published a 512-page book on "Water Quality Criteria" that contained 1,369 references. This classic reference summarized water quality criteria promulgated by State and interstate agencies, as well as the legal application of such criteria. Eight major beneficial uses of water were described. Three-hundred pages of the document were devoted to cause-effect relationships for major water pollutants. The concentration-effect levels for the pollutant in question were discussed for each of the designed water uses.

The State of California's 1952 Water Quality Criteria edition was expanded and tremendously enhanced into a second edition edited by Messrs. Jack E. McKee and Harold W. Wolf and published in 1963 by the Resources Agency of California, State Water Quality Control Board[6/]. This edition, which included 3,827 cited references, was a monumental effort in bringing together under one cover the world's literature on water quality criteria as of the date of publication. Criteria were identified and referenced for a host of water quality

NMED Exhibit 83

characteristics according to their effects on domestic water supplies, industrial water supplies, irrigation waters, fish and other aquatic life, shellfish culture, and swimming and other recreational uses. Specific values were arranged in ascending order, with appropriate references, as they had been reported damaging to fish or as not harmful to fish in the indicated time and under the conditions of exposure. The results of such a tabulation presented a range of values and, as would be expected by those investigating such conditions, there was often an overlap in values between those concentrations that had been reported by others as harmful. Such an anomaly is due to differences in investigative techniques among investigators, the characteristics of the water used as a dilutent for the toxicant, the physiological state of the test organisms, and variations in the temperature under which the tests were conducted. Nevertheless, the tabulation of criteria values for each of the water quality constituents has been helpful through time to predict a range within which a water quality constituent would have a deleterious effect upon the receiving waterway.

In 1966 the Secretary of the Interior appointed a number of nationally recognized scientists to a National Technical Advisory Committee to develop water quality criteria for five specified uses of water: domestic water supply, recreation, fish and wildlife, agricultural, and industrial. In 1968 the report was published[7/]. This report constituted the most comprehensive documentation to date on water quality requirements for particular and defined water uses. The book was intended to be used as a basic reference by personnel in State water pollution control agencies engaged in water quality studies and water quality standards setting activities. In some respects, this volume represented

---

7/ Water Quality Criteria, A Report of the National Technical Advisory Committee to the Secretary of the Interior. U.S. Government Printing Office, Washington, D.C. (1968).

NMED Exhibit 83

a marriage between the best available experimental or investigative criteria recorded in the literature and the judgments of recognized water quality experts with long experience in associated management practices. Its publication heralded a change in the concepts of water quality criteria from one that listed a series of concentration-effect levels to another that recommended concentrations that would ensure the protection of the quality of the aquatic environment and the continuation of the designated water use. When a specific aquatic life recommendation for a particular water pollutant could not be made because of either a lack of information or conflicting information, a recommendation was made to substitute a designated application factor based upon data obtained from a 96-hour bioassay using a sensitive aquatic organism and the receiving water as a diluent for the toxicity test.

The U.S. Environmental Protection Agency contracted with the National Academy of Sciences and the National Academy of Engineering to embellish the concept of the 1966 National Technical Advisory Committee's Water Quality Criteria and to develop a water quality criteria document that would include current knowledge. The result was a 1974 publication that presented water quality criteria as of 1972[8/].

The Federal Water Pollution Control Act Amendments of 1972 (P.L. 92-500) mandated that the Environmental Protection Agency publish water quality criteria accurately reflecting the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare which may be expected from the presence of pollutants in any body of water.

8/ Water Quality Criteria, 1972. National Academy of Sciences, National Academy of Engineering. U.S. Government Printing Office, Washington, D.C. (1974).

NMED Exhibit 83

Section 304(a) of P.L. 92-500 states, "(1) The Administrator, after consultation with appropriate Federal and State agencies and other interested persons, shall develop and publish, within one year after October 18, 1972 (and from time to time thereafter revise) criteria for water quality accurately reflecting the latest scientific knowledge (A) on the kind and extent of all identifiable effects on health and welfare including, but not limited to, plankton, fish, shellfish, wildlife, plant life, shorelines, beaches, esthetics, and recreation which may be expected from the presence of pollutants in any body of water, including ground water; (B) on the concentration and dispersal of pollutants, or their byproducts, through biological physical, and chemical processes; and (C) on the effects of pollutants on biological community diversity, productivity, and stability, including information on the factors affecting rates of eutrophication and rates of organic and inorganic sedimentation for varying types of receiving waters.

"(2) The Administrator, after consultation with appropriate Federal and State agencies and other interested persons, shall develop and publish, within one year after October 18, 1972 (and from time to time thereafter revise) information (A) on the factors necessary to restore and maintain the chemical, physical, and biological integrity of all navigable waters, ground waters, waters of the contiguous zone, and the oceans; (B) on the factors necessary for the protection and propagation of shellfish, fish, and wildlife for classes and categories of receiving waters and to allow recreational activities in an on the water; and (C) on the measurement and classification of water quality; and (D) for the purpose of Section 303 of this title, on and the identification of pollutants suitable for maximum daily load measurement correlated with the achievement of water quality objectives.

NMED Exhibit 83

"(3) Such criteria and information and revisions thereof shall be issued to the States and shall be published in the Federal Register and otherwise made available to the public."

Section 101(a)(2) of P.L. 92-500 states, "It is the national goal that wherever attainable, an interim goal of water quality which provides for the protection and propagation of fish, shellfish, and wildlife, and provides for recreation in and on the water, will be achieved by July 1, 1983."

The objectives of this volume are to respond to these sections of the Act and thus establish water quality criteria. The QCW will be expanded periodically in the future to include additional constituents as data become available. While the NAS/NAE 1972 Water Quality Criteria considered aluminum, antimony, bromine, cobalt, fluoride, lithium, molybdenum, thallium, uranium and vanadium, these presently are not included in this volume; however, they should be given consideration in the development of State Water Quality Standards and quality criteria may be developed for them in future volumes of the QCW. In particular geographical areas or for specific water uses such as the irrigation of certain crops, some of these constituents may have harmful effects. Until such time that criteria for the 10 aforementioned constituents are developed, information relating to their effects on the aquatic ecosystem may be found in the NAS/NAE 1972 Water Quality Criteria.

NMED Exhibit 83

PREPARATION OF THIS VOLUME

A volume of this scope results from the efforts of many dedicated people and includes technical specialists located throughout the Agency's operational programs and in its research laboratories. The responsibility for coordinating compilation efforts and in preparing manuscript was assigned to the Criteria Branch of the Criteria and Standards Division within the Office of Water Planning and Standards, EPA.

NMED Exhibit 83

THE PHILOSOPHY OF QUALITY CRITERIA

Water quality criteria specify concentrations of water constituents which, if not exceeded, are expected to support an aquatic ecosystem suitable for the higher uses of water. Such criteria are derived from scientific facts obtained from experimental or *in situ* observations that depict organism responses to a defined stimulus or material under identifiable or regulated environmental conditions for a specified time period.

Water quality criteria are not intended to offer the same degree of safety for survival and propagation at all times to all organisms within a given ecosystem. They are intended not only to protect essential and significant life in water, as well as the direct users of water, but also to protect life that is dependent on life in water for its existence, or that may consume intentionally or unintentionally any edible portion of such life.

The criteria levels for domestic water supply incorporate available data for human health protection. Such values are different from the criteria levels necessary for protection of aquatic life. The Agency's interim primary drinking water regulations (40 *Federal Register* 59566 December 24, 1975), as required by the Safe Drinking Water Act (42 U.S.C. 300f, *et seq.*), incorporate applicable domestic water supply criteria. Where pollutants are identified in both the quality criteria for domestic water supply and the Drinking Water Standards, the concentration levels are identical. Water treatment may not significantly affect the removal of certain pollutants.

What is essential and significant life in water? Do Daphnia or stonefly nymphs qualify as such life? Why does 1/100th of a concentration that is lethal to 50 percent of the test organisms (LC50) constitute a criterion in some instances, whereas 1/20 or 1/10th of some effect levels constitute a criterion in other instances? These are questions that often are asked of those who undertake the task of criteria formulation.

The universe of organisms composing life in water is great in both kinds and numbers. As in the human population, physiological variability exists among individuals of the same species in response to a given stimulus. A much greater response variation exists among species of aquatic organisms. Thus, aquatic organisms do not exhibit the same degree of harm, individually or by species, from a given concentration of a toxicant or potential toxicant within the environment. In establishing a level or concentration of a quality constituent as a criterion it is necessary to ensure a reasonable degree of safety for those more sensitive species that are important to the functioning of the aquatic ecosystem even though data on the response of such species to the quality constituent under consideration may not be available. The aquatic food web is an intricate relationship of predator and prey organisms. A water constituent that may in some way destroy or eliminate an important segment of that food web would, in all likelihood, destroy or seriously impair other organisms associated with it.

Although experimentation relating to the effects of particular substances under controlled conditions began in the early 1900's, the effects of any substance on more than a few of the vast number of aquatic organisms have not

NMED Exhibit 83

been investigated. Certain test animals have been selected by investigators for intensive investigation because of their importance to man, because of their availability to the researcher and because of their physiological responses to the laboratory environment. As general indicators of organism responses such test organisms are representative of the expected results for other associated organisms. In this context Daphnia or stoneflies or other associated organisms indicate the general levels of toxicity to be expected among untested species. In addition, test organisms are themselves vital links within the food web that results in the fish population in a particular waterway.

The ideal data base for criteria development would consist of information on a large percentage of aquatic species and would show the community response to a range of concentrations for a tested constituent during a long time period. This information is not available but investigators are beginning to derive such information for a few water constituents. Where only 96-hour bioassay data are available, judgmental prudence dictates that a substantial safety factor be employed to protect all life stages of the test organism in waters of varying quality, as well as to protect associated organisms within the aquatic environment that have not been tested and that may be more sensitive to the test constituent. Application factors have been used to provide the degree of protection required. Safe levels for certain chlorinated hydrocarbons and certain heavy metals were estimated by applying an 0.01 application factor to the 96 hour LC50 value for sensitive aquatic organisms. Flow-through bioassays have been conducted for some test indicator organisms over a substantial period of their life history. In a few other cases, information is available for the organism's natural life or for more than one generation of the species. Such data may indicate a minimal effect level, as well as a no-effect level.

NMED Exhibit 83

The word "criterion" should not be used interchangeably with, or as a synonym for, the word "standard." The word "criterion" represents a constituent concentration or level associated with a degree of environmental effect upon which scientific judgment may be based. As it is currently associated with the water environment it has come to mean a designated concentration of a constituent that when not exceeded, will protect an organism, an organism community, or a prescribed water use or quality with an adequate degree of safety. A criterion, in some cases, may be a narrative statement instead of a constituent concentration. On the other hand a standard connotes a legal entity for a particular reach of waterway or for an effluent. A water quality standard may use a water quality criterion as a basis for regulation or enforcement, but the standard may differ from a criterion because of prevailing local natural conditions, such as naturally occurring organic acids, or because of the importance of a particular waterway, economic considerations, or the degree of safety to a particular ecosystem that may be desired.

Toxicity to aquatic life generally is expressed in terms of acute (short-term) or chronic (long-term) effects. Acute toxicity refers to effects occurring in a short time period; often death is the end point. Acute toxicity can be expressed as the lethal concentration for a stated percentage of organisms tested, or the reciprocal, which is the tolerance limit of a percentage of surviving organisms. Acute toxicity for aquatic organisms generally has been expressed for 24- to 96-hour exposures.

Chronic toxicity refers to effects through an extended time period. Chronic toxicity may be expressed in terms of an observation period equal to the lifetime of an organism or to the time span of more than one generation. Some chronic effects may be reversible, but most are not.

NMED Exhibit 83

Chronic effects often occur in the species population rather than in the individual. If eggs fail to develop or the sperm does not remain viable, the species would be eliminated from an ecosystem because of reproductive failure. Physiological stress may make a species less competitive with others and may result in a gradual population decline or absence from an area. The elimination of a microcrustacean that serves as a vital food during the larval period of a fish's life could result ultimately in the elimination of the fish from an area. The phenomenon of bioaccumulation of certain materials may result in chronic toxicity to the ultimate consumer in a food chain. Thus, fish may mobilize lethal toxicants from their fatty tissues during periods of physiological stress. Egg shells of predatory birds may be weakened to a point of destruction in the nest. Bird chick embryos may have increased mortality rates. There may be a hazard to the health of man if aquatic organisms with toxic residues are consumed.

The fact that living systems, i.e. individuals, populations, species and ecosystems can take up, accumulate, and bioconcentrate man-made and natural toxicants is well documented. In aquatic systems biota are exposed directly to pollutant toxicants through submersion in a relatively efficient solvent (water) and are exposed indirectly through food webs and other biological, chemical, and physical interactions. Initial toxicant levels, if not immediately toxic and damaging, may accumulate in the biota or sediment over time and increase to levels that are lethal or sublethally damaging to aquatic organisms or to consumers of these organisms. Water quality criteria reflect a knowledge of the capacity for environmental accumulation, persistence, and effects of specific toxicants in specific aquatic systems.

NMED Exhibit 83

Ions of toxic materials frequently cause adverse effects because they pass through the semipermeable membranes of an organism. Molecular diffusion through membranes may occur for some compounds such as pesticides, polychlorinated biphenyls and other toxicants. Some materials may not pass through membranes in their natural or waste-discharged state, but in water they may be converted to states that have increased ability to affect organisms. For example, certain microorganisms can methylate mercury thus producing a material that more readily enters physiological systems. Some materials may have multiple effects; for example an iron salt may not be toxic, an iron floc or gel may be an irritant or clog fish gills to effect asphyxiation, iron at low concentrations can be a trace nutrient but at high concentrations it can be a toxicant. Materials also can affect organisms if their metabolic byproducts cannot be excreted. Unless otherwise stated, criteria are based on the total concentration of the substance because an ecosystem can produce chemical, physical and biological changes that may be detrimental to organisms living in or using the water.

In prescribing water quality criteria certain fundamental principles dominate the reasoning process. In establishing a level or concentration as a criterion for a given constituent it was assumed that other factors within the aquatic environment are acceptable to maintain the integrity of the water. Interrelationships and interactions among organisms and their environment, as well as the interrelationships of sediments and the constituents they contain to the water above, are recognized as fact.

Antagonistic and synergistic reactions among many quality constituents in water also are recognized as fact. The precise definition of such reactions and their relative effects on particular segments of aquatic life have not been identified with scientific precision. Historically, much of the data to support criteria development was of an ambient concentration-organism response nature. Recently, data are becoming

NMED Exhibit 83

available on long-term chronic effects on particular species. Studies now determine carcinogenic, teratogenic, and other insidious effects of toxic materials.

Some unpolluted waters in the nation may exceed designated criteria for particular constituents. There is variability in the natural quality of water and certain organisms become adapted to that quality which may be considered extreme in other areas. Likewise, it is recognized that a single criterion cannot identify minimal quality for the protection of the integrity of water for every aquatic ecosystem in the nation. To provide an adequate degree of safety to protect againstlong-term effects may result in a criterion that cannot be detected with present analytical tools. In some cases, a mass balance calculation can provide a means of assurance that the integrity of of the waterway is not being degraded.

Water quality criteria do not have direct regulatory impact, but they form the basis for judgment in several Environmental Protection Agency programs that are derived from water quality considerations. For example, water quality standards developed by the States under Section 303 of the Act and approved by EPA are to be based on the water quality criteria, appropriately modified to take account of local conditions. The local conditions to be considered include actual and projected uses of the water, natural background levels of particular constituents, the presence or absence of sensitive important species, characteristics of the local biological community, temperature and weather, flow characteristics, and synergistic or antagonistic effects of combinations of pollutants.

NMED Exhibit 83

Similarly, by providing a judgment on desirable levels of ambient water quality, water quality criteria are the starting point in deriving toxic pollutant effluent standards pursuant to Section 307(a) of the Act. Other EPA programs that make use of water quality criteria include drinking water standards, the ocean dumping program, designation of hazardous substances, dredge spoil criteria development, removal of in-place toxic materials, thermal pollution, and pesticide registration.

To provide the water resource protection for which they are designed, quality criteria should apply virtually to all of the nation's navigable waters with modifications for local conditions as needed. To violate quality criteria for any substantial length of time or in any substantial portion of a waterway may result in an adverse effect on aquatic life and perhaps a hazard to man or other consumers of aquatic life.

Quality criteria have been designed to provide long-term protection. Thus, they may provide a basis for effluent standards, but it is not intended that criteria values become effluent standards. It is recognized that certain substances may be applied to the aquatic environment with the concurrence of a governmental agency for the precise purpose of controlling or managing a portion of the aquatic ecosystem; aquatic herbicides and aquatic piscicides are examples of such substances. For such occurrences, criteria obviously do not apply. It is recognized further that pesticides applied according to official label instructions to agricultural and forest lands may be washed to a receiving waterway by a torrential rainstorm. Under such conditions it is believed that such diffuse source inflows should receive consideration

NMED Exhibit 83

similar to that of a discrete effluent discharge and that in such instances the criteria should be applied to the principal portion of the waterway rather than to that peripheral portion receiving the diffuse inflow.

The format for presenting water quality criteria includes a concise statement of the dominant criterion or criteria for a particular constituent followed by a narrative introduction, a rationale that includes justification for the designated criterion or criteria, and a listing of the references cited within the rationale. An effort has been made to restrict supporting data to those which have either been published or are in press awaiting publication. A particular constituent may have more than one criterion to ensure more than one water use or condition, i.e., hard or soft water where applicable, suitability as a drinking water supply source, protection of human health when edible portions of selected biota are consumed, provision for recreational bathing or water skiing, and permitting an appropriate factor of safety to ensure protection for essential warm or cold water associated biota.

Criteria are presented for those substances that may occur in water where data indicate the potential for harm to aquatic life, or to water users, or to the consumers of the water or of the aquatic life. Presented criteria do not represent an all-inclusive list of constituent contaminants. Omissions from criteria should not be construed to mean that an omitted quality constituent is either unimportant or non-hazardous.

NMED Exhibit 83

AESTHETIC QUALITIES

CRITERIA:

All waters free from substances attributable to wastewater or other discharges that:

(1) settle to form objectionable deposits;

(2) float as debris, scum, oil, or other matter to form nuisances;

(3) produce objectionable color, odor, taste, or turbidity;

(4) injure or are toxic or produce adverse physiological responses in humans, animals or plants; and,

(5) produce undesirable or nuisance aquatic life.

RATIONALE

Aesthetic qualities of water address the general principles laid down in common law. They embody the beauty and quality of water and their concepts may vary within the minds of individuals encountering the waterway. A rationale for these qualities cannot be developed with quantifying definitions; however, decisions concerning such quality factors can portray the best in the public interest.

Aesthetic qualities provide the general rules to protect water against environmental insults; they provide minimal freedom requirements from pollution; they are essential properties to protect the nation's waterways.

NMED Exhibit 83

ALKALINITY

CRITERION:

20 mg/l or more as $CaCO_3$ for freshwater aquatic life except where natural concentrations are less.

INTRODUCTION:

Alkalinity is the sum total of components in the water that tend to elevate the pH of the water above a value of about 4.5 It is measured by titration with standardized acid to a pH value of about 4.5 and it is expressed commonly as milligrams per liter of calcium carbonate. Alkalinity, therefore, is a measure of the buffering capacity of the water, and since pH has a direct effect on organisms as well as an indirect effect on the toxicity of certain other pollutants in the water, the buffering capacity is important to water quality. Examples of commonly occurring materials in natural waters that increase the alkalinity are carbonates, bicarbonates, phosphates and hydroxides.

RATIONALE:

The alkalinity of water used for municipal water supplies is important because it affects the amounts of chemicals that need to be added to accomplish coagulation, softening and control of corrosion in distribution systems. The alkalinity of water assists in the neutralization of excess acid produced during the addition of such materials as aluminum sulfate during chemical coagulation. Waters having sufficient alkalinity do not have to be supplemented with artificially added materials to increase the alkalinity. Alkalinity resulting from naturally occurring materials such as carbonate and bicarbonate is not considered a health hazard in drinking water supplies, per se, and naturally occurring

NMED Exhibit 83

maximum levels up to approximately 400 mg/l as calcium carbonate are not considered a problem to human health (NAS, 1974).

Alkalinity is important for fish and other aquatic life in freshwater systems because it buffers pH changes that occur naturally as a result of photosynthetic activity of the chlorophyll-bearing vegetation. Components of alkalinity such as carbonate and bicarbonate will complex some toxic heavy metals and reduce their toxicity markedly. For these reasons, the National Technical Advisory Committee (NTAC, 1968) recommended a minimum alkalinity of 20 mg/l and the subsequent NAS Report (1974) recommended that natural alkalinity not be reduced by more than 25 percent but did not place an absolute minimal value for it. The use of the 25 percent reduction avoids the problem of establishing standards on waters where natural alkalinity is at or below 20 mg/l. For such waters, alkalinity should not be further reduced.

The NAS Report recommends that adequate amounts of alkalinity be maintained to buffer the pH within tolerable limits for marine waters. It has been noted as a correlation that productive waterfowl habitats are above 25 mg/l with higher alkalinities resulting in better waterfowl habitats (NTAC, 1968).

Excessive alkalinity can cause problems for swimmers by altering the pH of the lacrimal fluid around the eye, causing irritation.

For industrial water supplies high alkalinity can be damaging to industries involved in food production, especially those in which acidity accounts for flavor and stability, such as the carbonated beverages. In other instances, alkalinity is desirable because water with a high alkalinity is much less corrosive.

NMED Exhibit 83

A brief summary of maximum alkalinities accepted as a source of raw water by industry is included in Table 1. The concentrations listed in the table are for water prior to treatment and thus are only desirable ranges and not critical ranges for industrial use.

The effect of alkalinity in water used for irrigation may be important in some instances because it may indirectly increase the relative proportion of sodium in soil water. As an example, when bicarbonate concentrations are high, calcium and magnesium ions that are in solution precipitate as carbonates in the soil water as the water becomes more concentrated through evaporation and transpiration. As the calcium and magnesium ions decrease in concentration, the percentage of sodium increases and results in soil and plant damage. Alkalinity may also lead to chlorosis in plants because it causes the iron to precipitate as a hydroxide (NAS, 1974). Hydroxyl ions react with available iron in the soil water and make the iron unavailable to plants. Such deficiencies induce chlorosis and further plant damage. Usually alkalinity must exceed 600 mg/l before such affects are noticed, however.

*[Abstracted from Thurston et al. (1974)]

INTRODUCTION:

Ammonia is a pungent, colorless, gaseous, alkaline compound of nitrogen and hydrogen that is highly soluble in water. It is a biologically active compound present in most waters as a normal biological degradation product of nitrogenous organic matter. It may also reach ground and surface waters through discharge of industrial wastes containing ammonia as a byproduct or wastes from industrial processes using "ammonia water".

When ammonia dissolves in water, some of the ammonia reacts with the water to form ammonium ions. A chemical equilibrium is established which

NMED Exhibit 83

contains un-ionized ammonia (NH_3), ionized ammonia (NH_4^+), and hydroxide ions (OH^-). The equilibrium for these chemical species can be expressed in simplified form by the following equation:

$$NH_3 + H_2O \rightleftharpoons NH_3 \cdot H_2O \rightleftharpoons NH_4^+ + OH^-$$

In the above equation NH_3 represents ammonia gas combining with water. The term $NH_3 \cdot H_2O$ represents the un-ionized ammonia molecule which is loosely attached to water molecules. Dissolved un-ionized ammonia will be represented for convenience as NH_3. The ionized form of ammonia will be represented as NH_4^+. The term total ammonia will refer to the sum of these ($NH_3 + NH_4^+$).

The toxicity of aqueous solutions of ammonia is attributed to the NH_3 species. Because of the equilibrium relationship among NH_3, NH_4^+, and OH^-, the toxicity of ammonia is very much dependent upon pH as well as the concentration of total ammonia. Other factors also affect the concentration of NH_3 in water solutions, the most important of which are temperature and ionic strength. The concentration of NH_3 increases with increasing temperature, and decreases with increasing ionic strength. In aqueous ammonia solutions of dilute saline concentrations, the NH_3 concentration decreases with increasing salinity.

A table of percent NH_3 for aqueous ammonia solutions of zero salinity at different values of pH and temperature is given below. This percentage can be used to determine the amount of total ammonia which is in the most toxic (NH_3) form.

NMED Exhibit 83

*[Thurston, et al. (1974)]

RATIONALE:

It has been known since early in this century that ammonia is toxic to fishes and that the toxicity varies with the pH of the water. Chipman (1934) demonstrated that undissociated ammonia (NH_3) was the chemical species toxic to goldfish, amphipods, and cladocerans. He concluded from his studies that the toxicity of ammonium salts was pH-dependent and was directly related to the concentration of undissociated ammonia. Chipman's work was confirmed by Wuhrmann, et al. (1947) who concluded that the NH_3 fraction was toxic to fish and that the NH_4^+ fraction had little or no toxicity. Further studies by Wuhrmann and Woker (1948) and Downing and Merkens (1955) agreed with these earlier findings. Tabata (1962), however, has attributed some degree of toxicity to fishes and invertebrates to the NH_4^+ species (less than 1/50th that of NH_3).

NMED Exhibit 83

In most natural waters, the pH range is such that the NH_4^+ fraction of ammonia predominates; however, in highly alkaline waters, the NH_3 fraction can reach toxic levels. Many laboratory experiments of relatively short duration have demonstrated that the lethal concentrations for a variety of fish species are in the range of 0.2 to 2.0 mg/l NH_3 with trout being the most sensitive and carp the most resistant. Although coarse fish such as carp survive longer in toxic solutions than do salmonids, the difference in sensitivity between fish species to prolonged exposure is probably less than the tenfold range given as the lethal range. The lowest lethal concentration reported for salmonids is 0.2 mg/l NH_3 for rainbow trout fry (Liebmann, 1960). The toxic concentration for Atlantic salmon smolts (Herbert and Shurben, 1965) and for rainbow trout (Ball, 1967) was found to be only slightly higher. Although the concentration of NH_3 below 0.2 mg/l may not kill a significant proportion of a fish population, such concentration may still exert an adverse physiological or histopathological effect (Flis, 1968; Lloyd and Orr, 1969; Smith and Piper, 1974). Fromm (1970) found that at total ammonia ($NH_3 + NH_4^+$) concentrations of 3 mg/l ammonia nitrogen, the trout became hyperexcitable; at 5 mg/l, ammonia excretion by rainbow trout was inhibited; and at 8 mg/l (approximately 1 mg/l NH_3), 50 percent died within 24 hours. Burrows (1964) found progressive gill hyperplasia in fingerling chinook salmon during a six-week exposure to a total ammonia concentration (expressed as NH_4) of 0.3 mg/l (0.002 mg/l NH_3), which was the lowest concentration applied. Reichenbach-Klinke (1967) also noted gill hyperplasia, as well as pathological effects on

NMED Exhibit 83

the liver and blood of various species at a concentration of 0.27 mg/l NH_3. Flis (1968) noted that exposure of carp to sublethal NH_3 concentrations resulted in extensive necrotic changes and tissue disintegration in various organs.

Herbert and Shurben (1965) reported that the resistance of yearling rainbow trout to ammonia increased with salinity (i.e. dilution with about 30 percent sea water) but above that level resistance appeared to decrease. Katz and Pierro (1967) subjected fingerling coho salmon to an ammonia waste at salinity levels of 20, 25, and 29 parts per thousand (i.e. dilution with about 57-83 percent sea water) and also found that toxicity increased with increased salinity. In saline waters the NH_4^+/NH_3 ratio must be adjusted by consideration of the activity of the charged species and total ionic strength of the solution. In dilute saline waters this ratio will change to favor NH_4^+, and thereby reduce the concentration of the toxic NH_3 species. At higher salinity levels the reported toxic effects of ammonia to fish must therefore be attributed to some mechanism other than changes in the NH_4^+/NH_3 ratio. Data on the effect of ammonia on marine species are limited and the information on anadromous species generally has been reported in conjunction with studies on freshwater species.

Although the NH_3 fraction of total ammonia increases with temperature, the toxic effect of NH_3 *vs.* temperature is not clear. Burrows (1964) has reported that the recovery rate from hyperplasia in gill tissues of chinook salmon exposed first to ammonia at sublethal levels and then to fresh water was less at 6°C than at 14°C. In this experiment, comparison was made between two different age classes of salmon.

NMED Exhibit 83

Levels of un-ionized ammonia in the range of 0.20 to 2 mg/l have been shown to be toxic to some species of freshwater aquatic life. To provide safety for those life forms not examined, 1/10th of the lower value of this toxic effect range results in a criterion of 0.020 mg/l of un-ionized ammonia. This criterion is slightly lower than that recommended for European inland fisheries (EIFAC, 1970) for temperatures above 5° C and pH values below 8.5. Measurement of values of total ammonia for calculation of values in the range of 0.020 mg/l NH_3 is well within current analytical capability.

ARSENIC

CRITERIA:

50 ug/l for domestic water supplies (health);

100 ug/l for irrigation of crops.

INTRODUCTION:

Arsenic is a shiny, gray, brittle element possessing both metallic and non-metallic properties. Compounds of arsenic are ubiquitous in nature, insoluble in water and occur mostly as arsenides and arsenopyrites. Samplings from 130 water stations in the United States have shown arsenic concentrations of 5 to 336 ug/l with a mean level of 64 ug/l (Kopp, 1969). Arsenic normally is present in sea water at concentrations of 2 to 3 ug/l.

Arsenic exists in the trivalent and pentavalent states and its compounds may be either organic or inorganic. Trivalent inorganic arsenicals are more toxic than the pentavalent forms both to mammals and aquatic species. Though most forms of arsenic are toxic to humans, arsenicals have been used in the medical treatment of spirochaetal infections, blood dyscrasias and dermatitis (Merck Index, 1968). Arsenic and arsenicals have many diversified industrial uses such as hardening of copper and lead alloys, pigmentation in paints and fireworks, and the manufacture of glass, cloth and electrical semiconductors. Arsenicals are used in the formulation of herbicides for forest management and agriculture.

NMED Exhibit 83

RATIONALE:

Arsenic concentrations in most community drinking water supplies in the United States range from a trace to approximately 0.1 mg/l (McCabe, et al., 1970).

Inorganic arsenic is absorbed readily from the gastrointestinal tract, the lungs, and to a lesser extent from the skin, and becomes distributed throughout the body tissues and fluids (Sollman, 1957). It is excreted via urine, feces, sweat, and the epithelium of the skin (Ducoff, et al., 1948; Musil and Dejmal, 1957).

After cessation of continuous exposure, arsenic excretion may continue for as long as 70 days (DuBois and Geiling, 1959).

Since the early nineteenth century arsenicals have been suspected of being carcinogenic (Paris, 1820; Sommers and McManus, 1953; Boutwell, 1963; Hueper and Payne, 1963).

According to Frost (1967), the most toxic arsenicals are well tolerated at concentrations of 10 to 20 ppm arsenic in the diet. The least toxic arsenicals can be fed without injury at levels which contribute up to at least 1000 ppm arsenic in the diet. He concluded that arsenicals appear remarkably free of carcinogenic properties.

In man, subacute and chronic arsenic poisoning may be insidious and pernicious. The symptoms of mild chronic poisoning are fatigue

NMED Exhibit 83

and loss of energy. In more severe intoxication the following symptoms may be observed: gastrointestinal catarrh, kidney degeneration, tendency to edema, polyneuritis, liver cirrhosis, bone marrow injury, exfoliate dermatitis and altered skin pigmentation (DiPalma, 1965; Goodman and Gilman, 1965). No true tolerance of arsenic has ever been demonstrated (Dubois and Geiling, 1959). During chronic exposure, trivalent arsenic accumulates mainly in bone, muscle, and skin and to a lesser degree in the liver and kidneys (Smith, 1967).

Reports from epidemiological studies in Taiwan indicate that 0.3 mg/l arsenic in drinking water resulted in increased incidences of hyperkeratosis and skin cancer with increased consumption of water (Chen and Wu, 1962; Tseng, et al., 1968; Yeh, et al., 1968). A similar situation has been reported in Argentina (Trelles, et al., 1970). Dermatological manifestations of arsenicism were noted in children in Antofagasta, Chile who used a water supply containing an arsenic concentration of 0.8 mg/l. A new water supply was provided and preliminary data showed that the quantity of arsenic in hair decreased (Borgono and Grieber, 1972).

Arsenicism affecting two members of a family whose well water concentration varied from 0.5 to 2.75 mg/l arsenic over a period of several months was reported in Nevada (Craun and McCabe, 1971). A study in California indicated that a greater proportion of the population had elevated concentrations of arsenic in hair when their drinking water had more than 0.12 mg/l arsenic than when concentrations were lower, but illness was not noted (Goldsmith, et al., 1972). In none of the cited incidents of apparent correlation of arsenic in drinking water with increased incidence of hyperkeratosis and skin cancer has there been any confirmed evidence that arsenic was the etiologic agent in the production of carcinomas.

NMED Exhibit 83

It is estimated that the total intake of arsenic from food averages 900 ug/day (Schroeder and Balassa, 1966). At the concentration of 50 ug/l recommended for drinking water supply and an average intake of 2 liters of water per day, the intake from water could reach 100 ug/day or approximately 10 percent of the total ingested arsenic.

Although arsenic is concentrated in aquatic organisms, it is evidently not progressively concentrated along a food chain. In addition, arsenic consumed as an organically-bound species in flesh appears to have low toxicity (Ferguson and Gavis, 1972). Surber and Meehan (1931) found that fish-food organisms generally can withstand concentrations of approximately 1.73 mg/l of arsenious trioxide (1.3 mg/l arsenic) in a sodium arsenite solution. Concentrations of 4 mg/l sodium arsenite (2.3 mg/l as arsenic) in confined outdoor pools have been found to reduce survival and growth of fish and to reduce bottom fauna and plankton populations (Gilderhus, 1966).

Trivalent arsenic is highly toxic to invertebrates. Conversely, pentavalent arsenic is of relatively low toxicity. In Lake Erie water Daphnia were observed to exhibit initial symptoms of immobility at 18 to 31 mg/l of sodium arsenate or 4.3 to 7.5 mg/l as arsenic (Anderson, 1944, 1946). The lethal threshold of sodium arsenate for minnows has been reported to be 234 mg/l as arsenic at 16° C to 20° C (Wilber, 1969).

Ambient arsenic concentrations in sea water are reported to be accumulated by oysters and other molluscan shellfish (Sautet, et al., 1964;

NMED Exhibit 83

Lowman, et al., 1971). Wilber (1969) reported concentrations of 100 mg/kg in shellfish.

Beginning in 1926 and for many years thereafter, sodium arsenite was used for the control of vascular aquatic plants in the public lakes of Wisconsin (Mackenthun, 1950). Dosages up to 10 mg/l of the white arsenic equivalent were used depending on the physical character of the area to be treated. Harm to fish life within the lakes or to fishing was not noted.

Lueschow (1964) found that Wisconsin lakes naturally may contain 10 ug/l of arsenic. Pewaukee Lake, Wisconsin, a lake of 2300 acres, received 215,174 pounds of arsenic for aquatic vegetation control in a 14-year period beginning in 1950. From 1959 to 1964, arsenic concentrations in the lake's outlet reached a maximum of 463 ug/l arsenic and consistently were above 100 ug/l. The mean arsenic concentration in lake bottom muds was 208 ug/g on a dry weight basis. A single sample of Cladophora sp. collected from Pewaukee Lake in 1962 contained 1258 ug/g arsenic (dry weight). Fresh shoots of mature Myriophyllum sp. stems contained 228 and 561 ug/g arsenic (dry weight).

Benthic invertebrates, Chaoborus punctipennis and Tendipedidae, were present in Pewaukee Lake in populations that reached 288 per square foot. Lueschow concluded that the trivalent inorganic arsenic was 10 to 15 times more toxic to Tendipedes plumosus than the pentavalent form. His studies indicate that the trivalent inorganic arsenic is converted to pentavalent arsenic within 30 days and that long-term survival of

NMED Exhibit 83

typical benthic organisms would be normal at concentrations as high as 1,920 ug/g arsenic (dry weight) in lake muds.

The data cited above indicate that freshwater fish-food organisms are adversely affected by concentrations of arsenic as low as 1.3 mg/l, and the mobility of the freshwater crustacean Daphnia is impaired by a concentration of arsenic as low as 4.3 mg/l. However, these data are not considered to be sufficient to recommend any numerical criterion for freshwater aquatic life. Such data as do exist indicate that the 50 ug/l criterion established for domestic water supplies should be protective of aquatic life.

Rasmussen and Henry (1965) found that arsenic at 0.5 mg/l in nutrient solutions produced toxicity symptoms in seedlings of the pineapple and orange. Below this concentration, no symptoms of toxicity were found. Clements and Heggeness (1939) reported that 0.5 mg/l arsenic as arsenite in nutrient solutions produced an 80 percent yield reduction in tomatoes. Following a review of available literature the National Academy of Sciences (NAS, 1974) suggests that a concentration of 100 ug/l could be used for 100 years on sandy soils, and a concentration of 2 mg/l used for a period of 20 years or 0.5 mg/l used for 100 years on clayey soils with an adequate margin of safety. Because of these factors, a criterion of 100 ug/l for the irrigation of crops is recommended. The herbicidal properties of arsenic in water to aquatic vegetation also are recognized. Although data are not sufficiently precise to recommend a criterion, such data as do exist indicate that 100 ug/l would be protective of aquatic vegetation.

NMED Exhibit 83

BARIUM

CRITERION:

1 mg/l for domestic water supply (health).

INTRODUCTION:

Barium is a yellowish-white metal of the alkaline earth group. It occurs in nature chiefly as barite, $BaSO_4$, and witherite, $BaCO_3$, both of which are highly insoluble salts. The metal is stable in dry air, but readily oxidized by humid air or water.

Many of the salts of barium are soluble in both water and acid, and soluble barium salts are reported to be poisonous (Lange, 1961; NAS, 1974). However, barium ions generally are thought to be rapidly precipitated or removed from solution by adsorption and sedimentation (McKee and Wolf, 1963; NAS, 1974).

While barium is a malleable, ductile metal, its major commercial value is in its compounds. Barium compounds are used in a variety of industrial applications including the metallurgic, paint, glass and electronics industries, as well as for medicinal purposes.

RATIONALE:

Concentrations of barium in domestic drinking water supplies generally range from less than 0.6 ug/l to approximately 10 ug/l with upper limits in a few midwestern and western states ranging from 100 to 3,000 ug/l (PHS, 1962/1963; Katz, 1970; Little, 1971). Barium enters the body primarily through air and water, since

NMED Exhibit 83

appreciable amounts are not contained in foods (NAS, 1974).

The fatal dose of barium for man is reported to be 550 to 600 mg. Ingestion of soluble barium compounds may also result in effects on the gastrointestinal tract causing vomiting and diarrhea and on the central nervous system causing violent tonic and clonic spasms followed in some cases by paralysis (Browning, 1961; and Patty, 1962, cited in Preliminary Air Pollution Survey of Barium and Its Compounds, 1969). Barium salts are considered to be muscle stimulants, especially for the heart muscle (Sollmann, 1957). By constricting blood vessels, barium may cause an increase in blood pressure. On the other hand, it is not likely that barium accumulates in the bone, muscle, kidney, or other tissues because it is readily excreted (Browning, 1961; McKee and Wolf, 1963).

Stokinger and Woodward (1958) developed a safe concentration for barium in drinking water based on the limiting values for industrial atmospheres, an estimate of the amount absorbed into the blood stream, and daily consumption of two liters of water. From these factors they arrived at a limiting concentration of 2 mg/l for a healthy adult human population, to which a safety factor was applied to allow for any possible accumulation in the body. Since barium is not removed by conventional water treatment processes and because of the toxic effect on the heart and blood vessels, a limit of 1 mg/l is recommended for barium in domestic water supplies.

Experimental data indicate that the soluble barium concentration in fresh and marine water generally would have to exceed 50 mg/l before toxicity to aquatic life would be expected. In most natural waters, there is sufficient sulfate or carbonate to precipitate the barium present in the water as a virtually insoluble, non-toxic compound. Recognizing that the physical and chemical properties of barium generally will preclude the existence of the toxic soluble form under usual marine and freshwater conditions, a restrictive criteria for aquatic life appears unwarranted.

NMED Exhibit 83

BERYLLIUM

CRITERIA:

11 ug/l for the protection of aquatic life in soft fresh water;*

1,100 ug/l for the protection of aquatic life in hard fresh water;*

100 ug/l for continuous irrigation on all soils; except

500 ug/l for irrigation on neutral to alkaline fine-textured soils.

INTRODUCTION:

Beryllium is not likely to occur at significantly toxic levels in ambient natural waters (McKee and Wolf, 1963). Although the chloride and nitrate salts of beryllium are very water soluble, and the sulfate is moderately so, the carbonate and hydroxide are almost insoluble in cold water (Lange, 1961). Kopp and Kroner (1967) reported that for 1,577 surface water samples collected at 130 sampling points in the United States, 85 samples (5.4 percent) contained from 0.01 to 1.22 ug/l with a mean of 0.19 ug/l beryllium. The concentration of beryllium in sea water is 6×10^{-4} ug/l (Goldberg, et al., 1971).

RATIONALE:

The major human toxic hazard potential of beryllium is via the inhalation of beryllium-containing fumes and dusts that might emanate from processing and fabrication operations. Beryllium could enter waters in effluents from certain metallurgical plants (NAS, 1974).

*See criteria for Hardness (p. 147). The beryllium concentration that will be protective of a given aquatic ecosystem can be obtained by conducting flow-through bioassays using ambient water and native species of fish and invertebrates.

NMED Exhibit 83

Contact dermatitis, characterized by itching and reddened, elevated, or fluid-accumulated lesions, which appear particularly on the exposed surfaces of the body, may occur either on an allergic basis or from primary irritation following contact with soluble beryllium salts (Van Ordstrand, et al., 1945; McCord, 1951). A latent period is occasionally noted, indicating the development of delayed hypersensitivity (NIOSH, 1972).

Ocular effects may occur as inflammation of the conjunctiva in "splash burn" or in association with contact dermatitis (Van Ordstrand, et al., 1945). Splashes may also cause corneal burns closely resembling those produced by acids and alkalies, and fluid accumulation and reddening around the eye socket are frequently noted (NIOSH, 1972).

Beryllium is demonstrably toxic by most routes of administration (NIOSH, 1972), but its oral toxicity is notably different from that by other routes. The sulfate, for example, while highly toxic by all other routes at a single dose level, is practically non-toxic by mouth at a level several thousand-fold greater by multiple dose (Reeves, 1965; Stokinger and Stroud, 1951).

Tarzwell and Henderson (1960) obtained 96-hour LC_{50} values ranging from 0.15 mg/l beryllium (when tested as the nitrate and chloride) to 0.2 mg/l beryllium (when tested as the sulfate) for fathead minnows in soft water (20 mg/l $CaCO_3$, total alkalinity of 18 mg/l, and pH of 7.4), and from 11 mg/l beryllium (as sulfate) to 20 mg/l beryllium (as nitrate) for fathead minnows in hard water (400 mg/l $CaCO_3$, total alkalinity of

NMED Exhibit 83

360 mg/l, and pH of 8.2). For bluegill they obtained 96-hour LC_{50} values of 1.3 mg/l beryllium in soft water and 12 mg/l beryllium in hard water (both as the sulfate.)

Slonim (1973) obtained 96-hour LC_{50} static bioassay values of 0.19 mg/l beryllium for the common guppy, Poecilia reticulata, in soft water with a hardness of 20 to 25 mg/l as $CaCO_3$, total alkalinity of 16 to 18 mg/l, and pH of 6.3 to 6.5, and 20.3 mg/l beryllium in hard water with a hardness of 400 to 500 mg/l, alkalinity of 185 to 230 mg/l, and pH of 7.8 to 8.2.

Slonim and Slonim (1973) studied the influence of water hardness on the toxicity of beryllium sulfate to the common guppy, Poecilia reticulata, by simultaneously conducting static bioassays at 400, 275, 150, and 22 mg/l hardness as $CaCO_3$. The 96-hour LC_{50} values were 20.0, 13.7, 6.1, and 0.16 mg/l, respectively. In a water hardness of 22 mg/l, 80 percent of the test fish survived 0.1 mg/l beryllium for 96 hours, whereas 100 percent survived control conditions. In a water hardness of 150 mg/l, 70 percent survived 5 mg/l beryllium for 96 hours and 100 percent survived 2.5 mg/l beryllium.

Slonim and Ray (1975) studied the influence of water hardness on the toxicity of beryllium sulfate to two species of salamander larvae by conducting static bioassays at hardness levels of 400 mg/l and 20 to 25 mg/l as $CaCO_3$. In hard water all of the test organisms survived exposure to 10 mg/l beryllium throughout the exposure period, whereas there was a significant decline in survival with time in soft water.

NMED Exhibit 83

The 96-hour LC_{50} values were 26.3 mg/l beryllium in hard water, and 4.7 mg/l beryllium in soft water.

Based on the fathead minnow and bluegill data of Tarzwell and Henderson (1960), the observations of Slonim and Ray (1975) on salamander larva survival, and the observations of Slonim and Slonim (1973) on guppy survival, the criterion for the protection of aquatic biota is established at 1.1 mg/l beryllium in hard fresh water. This value assumes an application factor of 0.1 of the 96-hour LC_{50} value for fathead minnows. For soft fresh water, in view of the reported approximate 100-fold increase in acute fish toxicity over that found in hard water, the criterion for the protection of aquatic biota is set at 0.011 mg/l beryllium.

Beryllium has been reported to be concentrated 1000 times in marine organisms (Goldberg, et al., 1971). The average concentration factors for marine benthic algae, phytoplankton, and zooplankton also have been reported as 110, 1000, and 15 mg/l, respectively (Lowman, et al., 1971). Riley and Roth (1971) reported levels of 1.1 to 18 mg/l beryllium for various species of marine algae. The 96-hour TLm value for beryllium resulting from tests performed on the killifish, Fundulus heteroclitus, was 41 mg/l (Jackim, et al., 1970). These data do not represent an adequate base upon which to establish a marine criterion.

Beryllium has been shown to inhibit photosynthesis in terrestrial plants (Bollard and Butler, 1966), and to be toxic to some varieties

NMED Exhibit 83

of citrus seedlings at 2.5 mg/l beryllium (Haas, 1932). Romney, et al. (1962) found that beryllium at 0.5 mg/l in nutrient solutions reduced the growth of bush beans, and Romney and Childress (1965) found that concentrations of 2 mg/l or greater in nutrient solutions reduced the growth of tomatoes, peas, soybeans, lettuce, and alfalfa plants. Additions of soluble beryllium salts at levels equivalent to 4 percent of the cation-adsorption capacity of two acid soils reduced the yields of ladino clover; beryllium carbonate and beryllium oxide at the same levels did not reduce yields, suggesting that beryllium in calcareous soils might be less active than in acid soils. Williams and LeRiche (1968) found that beryllium at 2 mg/l in nutrient solutions was toxic to mustard, whereas 5 mg/l was required for growth reduction in kale. In view of its toxicity in nutrient solutions in acid soils, the criteria for beryllium in irrigation waters are 0.10 mg/l for use on all soils, except 0.50 mg/l for use on neutral to alkaline fine-textured soils.

NMED Exhibit 83

BORON

CRITERION:

750 ug/l for long-term irrigation on sensitive crops.

INTRODUCTION:

Boron is not found in its elemental form in nature; it is usually found as a sodium or calcium borate salt. Boron salts are used in fire retardants, the production of glass, leather tanning and finishing industries, cosmetics, photographic materials, metallurgy, and for high energy rocket fuels. Elemental boron also can be used in nuclear reactors for neutron absorption. Borates are used as "burnable" poisons.

RATIONALE:

Boron is an essential element for growth of plants but there is no evidence that it is required by animals. The maximum concentration found in 1,546 samples of river and lake waters from various parts of the United States was 5.0 mg/l; the mean value was 0.1 mg/l (Kopp and Kroner, 1967). Ground waters could contain substantially higher concentrations at certain places. The concentration in sea water is reported as 4.5 mg/l in the form of borate (NAS, 1974). Naturally occurring concentrations of boron should have no effects on aquatic life.

The minimum lethal dose for minnows exposed to boric acid at 20° C for 6 hours was reported to be 18,000 to 19,000 mg/l in distilled water and 19,000 to 19,500 mg/l in hard water (Le Clerc and Devlaminck, 1955; Le Clerc, 1960).

NMED Exhibit 83

In the dairy cow, 16 to 20 g/day of boric acid for 40 days produced no ill effects (McKee and Wolf, 1963).

Sensitive crops have shown toxic effects at 1000 ug/l or less of boron (Richards, 1954). Bradford (1966), in a review of boron deficiencies and toxicities, stated that when the boron concentration in irrigation waters was greater than 0.75 mg/l, some sensitive plants such as citrus began to show injury. Biggar and Fireman (1960) showed that with neutral and alkaline soils of high absorption capacities, water containing 2 mg/l boron might be used for some time without injury to sensitive plants. The criterion of 750 ug/l is thought to protect sensitive crops during long-term irrigation.

CADMIUM

CRITERIA:

10 ug/l for domestic water supply (health).

Aquatic Life:

Fresh Water

Soft Water*	Hard Water*	
0.4 ug/l	1.2 ug/l	for cladocerans and salmonid fishes;
4.0 ug/l	12.0 ug/l	for other, less sensitive, aquatic life.

Marine

5.0 ug/l

INTRODUCTION:

Cadmium is a soft, white, easily fusible metal similar to zinc and lead in many properties and readily soluble in mineral acids. Biologically, cadmium is a nonessential, nonbeneficial element recognized to be of high toxic potential. It is deposited and accumulated in various body tissues and is found in varying concentrations throughout all areas where man lives. Within the past two decades industrial production and use of the metal has increased. Concomitantly, there have been incidences of acute cases of clinically identifiable cadmiosis. Cadmium may function in or may be an etiological factor for various human pathological processes including testicular tumors, renal dysfunction, hypertension, arteriosclerosis, growth inhibition, chronic diseases of old age, and cancer.

*See Criteria for Hardness (p. 147). The cadmium concentration that will be protective of a given aquatic ecosystem can be obtained by conducting flow-through bioassays using ambient water and native species of fish and invertebrates.

NMED Exhibit 83

Cadmium occurs in nature chiefly as a sulfide salt, frequently in association with zinc and lead ores. Accumulations of cadmium in soils in the vicinity of mines and smelters may result in high local concentrations in nearby waters. The salts of the metal also may occur in wastes from electroplating plants, pigment works, textile and chemical industries. Seepage of cadmium from electroplating plants has resulted in groundwater cadmium concentrations of 0.01 to 3.2 mg/l (Lieber and Welsch, 1954). Kopp and Kroner (1967) on one occasion reported 120 ug/l dissolved cadmium in the Cuyahoga River at Cleveland, Ohio. However, dissolved cadmium was found in less than 3 percent of 1,577 water samples examined for the United States, with a mean of slightly under 10 ug/l. Most fresh waters contain less than 1 ug/l cadmium and most analyses of sea water indicate an average concentration of about 0.15 ug/l (Fleischer, et al., 1974).

RATIONALE:

Cadmium has been shown to be toxic to man when ingested or inhaled. Exposure by the former route causes symptoms resembling food poisoning. A group of school children became ill after eating popsicles containing 13 to 15 mg/l cadmium (Frant and Kleeman, 1941), and this level, equivalent to 1.3 to 3.0 mg of cadmium ingested, commonly is considered the emetic threshold concentration.

In a specially designed study, five groups of rats were exposed to drinking water containing cadmium concentrations of 0.1 mg/l to 10 mg/l. Although no visible toxic effects were noted, the content of cadmium in the kidney and liver increased in direct proportion

NMED Exhibit 83

to the dose at all levels of exposure. At the end of one year, tissue concentrations were approximately double those found after six months (Ginn and Volker, 1944). Later work confirmed that virtually no absorbed cadmium was eliminated (Decker, et al., 1958).

Drinking water containing excessive cadmium led to the occurrence of itai-itai disease among the Japanese (Kobayashi, 1970). Within 15 years 200 cases of this disease were recorded in the Jintsu River Valley, half of which resulted in death. The disease is characterized by rheumatic symptoms with intense pain in the bones caused by a loss of bone minerals with the bones becoming as flexible as soft tissues. Yamagata and Shigematsu (1970) estimated that a daily intake of 600 ug cadmium would not produce itai-itai disease in an endemic area.

Studies in animals (Ferm, et al., 1969; Chernoff, 1973) as well as observations in human fetuses (Chaube, et al., 1973; and Friberg, et al., 1974) indicate that the placenta is not a complete barrier against the transfer of cadmium. About 6 percent of the cadmium that enters the stomach via food or drink is absorbed into the body tissues and about 30 percent of the cadmium inhaled into the lungs by breathing and smoking is absorbed (EPA, In Press). Presently there are no known physiological needs for cadmium and no mechanism by which the body maintains cadmium at a constant safe level. Once absorbed, it is stored largely in the kidneys and liver and is excreted at an extremely slow rate.

NMED Exhibit 83

Chronic kidney disease (renal tubular dysfunction) will begin to occur in an individual when the cadmium accumulated in the kidneys reaches a critical concentration. While the critical concentration varies from one individual to another, the threshold of observed effect is about 200 ppm of cadmium in the renal cortex (Friberg, et al., 1974). Individuals have been found with several times this level without evidence of kidney disease. At a 10 ug/l criterion, as recommended in drinking water, the maximum daily intake of cadmium would not exceed 20 ug from water, assuming a 2-liter daily consumption. The daily intake from other sources is up to 60 ug in the population of the United States (Schroeder, et al., 1961).

Pickering and Gast (1972) conducted two separate flow-through tests on the chronic toxicity of cadmium to the fathead minnow, Pimephales promelas, using water of 202 mg/l hardness, 157 mg/l alkalinity, and 7.7 pH. Five cadmium concentrations from 4 to 350 ug/l were delivered to the exposure chambers in each test over the life history of the fish. A concentration of 57 ug/l cadmium decreased survival of developing embryos. At levels from 4.5 to 37 ug/l no adverse effect on survival, growth, or reproduction was found. Eaton (1974b) exposed bluegill sunfish, Lepomis macrochirus, to five cadmium concentrations ranging from 31 to 2,140 ug/l for 11 months in a flow-through system using water of the same hardness as above. Nine of the 18 adult bluegill sunfish exposed to 80 ug/l died by the end of the test, while all of those exposed to 31 ug/l and the control survived. Although at 80 ug/l cadmium the hatchability of eggs was not measurably affected, the survival and growth of the resulting larvae were severely reduced after 60 days. Larvae exposed to 31 ug/l cadmium survived and grew about as well as the control fish. Sixty days

after hatching in hard water, growth and survival of channel catfish fry, Ictalurus punctatus, was reduced significantly at a cadmium concentration of 17 ug/l but not at 12 ug/l (Eaton, 1974a). Thus, in hard water, a criterion of 12 ug/l cadmium represents a demonstrated no-effect level for catfish and therefore was chosen to protect non-salmonid freshwater fish species. No data are available upon which to base an acceptable concentration for the chronic exposure of sensitive vertebrates or invertebrates in hard water, therefore a criterion is proposed which is reduced from the less sensitive aquatic life value by the same factor (0.1) as the criterion for soft water, i.e. 1.2 ug/l for salmonids and invertebrates.

Spehar (1974) reported on chronic toxicity tests with cadmium using a topminnow native to Florida in water with a hardness of 41 to 45 mg/l as $CaCO_3$, alkalinity of 38 to 43 mg/l, and a pH of 7.4. There was a significant reduction in the number of eggs produced per female at 8.1 ug/l cadmium, but fish in 4.1 ug/l were unaffected. A criterion of 4.0 ug/l cadmium is selected as offering protection to warm water fish species in soft water.

Three consecutive generations of brook trout, Salvelinus fontinalis, were exposed to cadmium concentrations rangipg from 6.4 ug/l to 0.5 ug/l in a test water of similar hardness (Benoit, et al., In Press). Second generation fish exposed to 6.4 and 3.4 ug/l cadmium were smaller at three months than fish exposed to lower concentrations. Both first and second generation fish suffered extensive mortalities during spawning in 3.4 ug/l cadmium. Egg hatchability, survival, growth, and reproduction of fish exposed to 1.7 ug/l were equal to those of control fish.

NMED Exhibit 83

When embryos and larvae-juveniles of brook trout, Salvelinus fontinalis; brown trout, Salmo trutta; lake trout, Salvelinus namaycush; northern pike, Esox lucius; white suckers, Catastomus commersoni; smallmouth bass, Micropterus dolomieui; and coho salmon, Oncorhynchus kisutch, were exposed to cadmium concentrations ranging from 0.4 to 100 ug/l in soft water, all suffered a reduction in standing crop at 12 ug/l. Standing crop survival times and weights were virtually equal among the four species when exposed to 4 ug/l; 1.2 ug/l was the highest cadmium concentration not causing a reduction among the other three salmonid species after 30 to 120 days of exposure (Eaton, 1974a).

Tests in water with 23 mg/l hardness, 18 mg/l alkalinity, and a pH of 7.3 in a flow-through system indicated a 96-hour LC50 of 2.0 ug/l for the initial feeding stage of chinook salmon, Oncorhynchus tshawytscha, and 0.92 ug/l for 5-month-old steelhead trout, Salmo gairdneri. A criterion of 0.4 ug/l for cadmium is believed to offer protection to the cladocerans and salmonids in soft water (Eaton, 1974a).

Anderson, et al., (1975) , determined the 10-day LC50 for the midge Tanytarsus dissimilis to be 3.4 ug/l in a flow-through system, soft water (48 mg/l) bioassay involving at least one molt. A concentration of 3.1 ug/l retarded growth but 1.9 ug/l elicited no obvious effect. Biesinger and Christensen (1972) measured the toxicity of cadmium to Daphnia magna during an entire life cycle in test water with a hardness of 45 mg/l, alkalinity of 42 mg/l, and a pH of 7.7. It was found that

NMED Exhibit 83

50 percent of the daphnids exposed to cadmium concentrations of 5 ug/l were killed in three weeks. The production of young was reduced by 50 percent compared to the controls in a cadmium concentration of 0.7 ug/l. Several invertebrate species have been found much less sensitive to cadmium in acute tests than in the midge and cladoceran exposures cited above. (Rehwoldt, et al., 1973; Thorp and Lake, 1974; Warnick and Bell, 1969). These data support a criterion for some invertebrates in soft water that is identical to that for salmonids.

Steward and Pesche, as reported by Eisler (1974), stated that for grass shrimp, Palaemonetes pugio, which were subjected to cadmium chloride in flowing sea water, 69 percent died in 43 days in 500 ug/l cadmium and 10 percent died in a 250 ug/l cadmium solution. Hermit crabs, Pagurus longicarpus, all died in a 250 ug/l cadmium solution, and 30 percent died in 43 days in a 120 ug/l solution. In 63 days, 40 percent died in a 60 ug/l cadmium solution. All of the controls survived.

Eisler (1971) found that the 96-hour LC50 for three species of marine decapod crustaceans ranged between 320 and 420 ug/l at 20° C and 20 mg/l alkalinity. The 96-hour LC25 was 180 ug/l for the hermit crab, Pagurus longicarpus, and the grass shrimp, Palaemonetes vulgaris, and 80 ug/l for the sand shrimp, Crangon septemspinosa.

Zaroogian, as reported by Eisler (1974), states that adult oysters, Crassostrea virginica, exposed to 10 ug/l cadmium between April 1973 and August 1973 accumulated 18,000 ug/kg of cadmium in wet whole

meat, which exceeds the human emetic threshold of 13,000 to 15,000 ug/kg. Oysters retained virtually all of the accumulated cadmium for at least several months and some histopathology was evident. Under natural conditions, significantly greater numbers of larvae from cadmium-stressed oysters failed to develop when compared to controls after 48 or 72 hours. A criterion of one-half of the level at which oysters accumulate cadmium in excess of the human emetic threshold (i.e. 5 ug/l) is believed to provide protection for consumers of oysters.

Data by Page, et al. (In Press), show that the yield of beans, beets, and turnips was reduced about 25 percent by 0.10 mg/l cadmium in nutrient solutions; whereas cabbage and barley yields decreased 20 to 50 percent at 1.0 mg/l.

Yamagata and Shigematsu (1970) have demonstrated that foods cultured on cadmium-polluted soils irrigated with cadmium-polluted water can accumulate sufficient cadmium to be hazardous to humans who consume these foods. Chaney (1973) suggests that it is not the cadmium concentration per se in the soil that determines cadmium accumulation by plants and that as long as the ratio of zinc to cadmium is 100 or greater, foods will not accumulate hazardous concentrations of cadmium. The subject is complex and additional research is needed to resolve potential hazards associated with the cadmium-zinc-soil-plant system.

NMED Exhibit 83

Fish and certain invertebrates have been found to be sensitive to low levels of cadmium in water. Salmonids and cladocerans appear to be the most sensitive among organisms tested. Increased hardness and/or alkalinity have been demonstrated to decrease the toxicity of cadmium in acute freshwater mortality tests, but may have less of an effect at low cadmium levels. Edible marine organisms can concentrate cadmium levels and become hazardous to be ultimate consumer. Lowman, et al. (1971) reported a concentration factor of 1,000 for cadmium in fish muscle. The criteria necessary to protect fish and other aquatic life are more stringent than those necessary to protect a public water supply or other uses. Data support a division of criteria for "hard" and "soft" water environments.

The data used to develop a criteria for cadmium were obtained over a range of hardness, alkalinity and pH values. Their usefullness in developing criteria will be limited to the range of physical parameters for which experimental data are available. Interpolation of the present data will be required to derive criteria for aquatic ecosystems which do not approximate the experimental conditions.

NMED Exhibit 83

CHLORINE

CRITERIA:

Total residual chlorine:

2.0 ug/l for salmonid fish;
10.0 ug/l for other freshwater and marine organisms.

INTRODUCTION:

Elemental chlorine is a greenish-yellow gas that is highly soluble in water. It reacts readily with many inorganic substances and all animal and plant tissues. The denaturing effect of chlorine on animal and plant tissues forms the basis for its use as an effective water or wastewater disinfectant. When chlorine dissolves in water, it hydrolyzes according to the reaction: $Cl_2 + H_2O \longrightarrow HOCl + H^+ + CL^-$. Unless the concentration of the chlorine solution is above 1000 mg/l, all chlorine will be in the form of HOCl or its dissociated ions H^+ and OCl^-. The HOCl is a weak acid and is dissociated according to the equation, $HOCl \rightleftharpoons H^+ + OCl^-$.

The ratio between HOCl and OCl^- is a function of the pH, with 96 percent HOCl remaining at pH 6, 75 percent at pH 7, 22 percent at pH 8, and 3 percent at pH 9. The relationship of HOCl to pH is significant as the undissociated form appears to be the bactericidal agent in the use of chlorine for disinfection (Moore, 1951).

Chlorine is not a natural constituent of water. Free available chlorine (HOCl and OCl^-) and combined available chlorine (mono- and

NMED Exhibit 83

di-chloramines) appear transiently in surface or ground waters as a result of disinfection of domestic sewage or from industrial processes that use chlorine for bleaching operations or to control organisms that grow in cooling water systems.

RATIONALE:

Chlorine, in the free available form reacts readily with nitrogenous organic materials to form chloramines. These compounds are toxic to fish. Chloramines have been shown to be slightly less toxic to fish than free chlorine, but their toxicity is considered to be close enough to free chlorine that differentiation is not warranted (Merkens, 1958). Since the addition of chlorine or hypochlorites to water containing nitrogenous materials rapidly forms chloramines, toxicity in most waters is related to the chloramine concentration. The toxicity to aquatic life of chlorine will depend upon the concentration of total residual chlorine, which is the amount of free chlorine plus chloramines. The persistence of chloramines is dependent on the availability of material with a lower oxidation-reduction potential.

In field studies in Maryland and Virginia, Tsai (1973) observed that downstream from plants discharging chlorinated sewage effluents, the total numbers of fish species were drastically reduced with the stream bottom clear of aquatic organisms characteristically present in unchlorinated wastewater discharges. No fish were found in water with a chlorine residual above 0.37 mg/l and the species diversity

NMED Exhibit 83

index reached zero at 0.25 mg/l. A 50 percent reduction in the species diversity index occurred at 0.10 mg/l. Of the 45 species of fish observed in the study areas, the brook trout and brown trout were the most sensitive and were not found at residual chlorine levels above about 0.02 mg/l. In studies of caged fish placed in waters downstream from chlorinated wastewater discharges, the Michigan Department of Natural Resources (1971) reported that 50 percent of the rainbow trout died within 96 hours at residual chlorine concentrations of 0.014 to 0.029 mg/l. Some fish died as far as 0.8 miles (1.3 km) downstream from the outfall.

Studies described by Brungs (1973) indicate that salmonids are the most sensitive fish to chlorine. A residual chlorine concentration of 0.006 mg/l was lethal to trout fry in two days (Coventry, et al., 1935). The 7-day LC_{50} for rainbow trout was 0.08 mg/l with an estimated median period of survival of one year at 0.004 mg/l (Merkens, 1958). Rainbow trout were shown to avoid a concentration of 0.001 mg/l (Sprague and Drury, 1969). Dandy (1972) demonstrated that brook trout had a mean survival time of 9 hours at 0.35 mg/l, 18 hours at 0.08 mg/l and 48 hours at 0.04 mg/l, with mortality of 67 percent after 4 days at 0.01 mg/l. Pike (1971) observed a 50 percent brown trout mortality at 0.02 mg/l within 10.5 hours and 0.01 mg/l with 43.5 hours.

The range of acutely lethal residual chlorine concentrations is narrow for various species of warm water fish. Arthur (1972) determined

NMED Exhibit 83

96-hour LC_{50} values for the walleye, black bullhead, white sucker, yellow perch, largemouth bass, and the fathead minnow. The observed concentration range was 0.09 to 0.30 mg/l.

Using fathead minnows in a continuous bioassay technique at Michigan treatment plants, Zillich (1972) found that an average concentration of 0.16 to 0.21 mg/l killed all of the test fish and that concentrations as low as 0.07 mg/l caused some mortalities. Pyle (1960) demonstrated a 50 percent mortality of smallmouth bass exposed to 0.5 mg/l within 15 hours. The mean 96-hour LC_{50} value for golden shiners was 0.19 mg/l (Esvelt, et al., 1971). Arthur and Eaton (1971), working with fathead minnows and the freshwater crustacean, Gammarus pseudolimnaeus, in dilute wastewater, found that the 96-hour LC_{50} of total residual chlorine for Gammarus was 0.22 mg/l and that all fathead minnows were dead after 72 hours at 0.15 mg/l. At concentrations of .09 mg/l, all fish survived until the seventh day when the first death occurred. In exposure to 0.05 mg/l residual chlorine, these investigators found reduced survival of Gammarus and at 0.0034 mg/l there was reduced reproduction. Growth and survival of fathead minnows after 21 weeks were not affected by continuous exposure to 0.043 mg/l residual chlorine. The highest level showing no significant effect was 0.016 mg/l. Working with secondary wastewater effluent, Arthur (1972) found that reproduction by Gammarus was reduced by residual concentrations above 0.012 mg/l residual chlorine.

In marine water, 0.05 mg/l was the critical chlorine level for young Pacific salmon exposed for 23 days (Holland, et al., 1960). The

NMED Exhibit 83

lethal threshold for chinook salmon and coho salmon for a 72-hour exposure was noted by these investigators to be less than 0.01 mg/l chlorine. Studies on the effect of residual chlorine to marine phytoplankton indicate that continuous exposure to 0.10 mg/l reduced primary production by 70 percent while 0.2 mg/l for 1.5 hours reduced primary production by 25 percent (Carpenter, et al., 1972). Laboratory studies on ten species of marine phytoplankton indicate that a 50 percent reduction in growth rate occurred at chlorine concentrations of 0.075 to 0.250 mg/l during a 24-hour exposure period (Gentile, et al., 1973). Oysters are sensitive to chlorine concentrations of 0.01 to 0.05 mg/l and react by reducing pumping activity. At chlorine concentrations of 1.0 mg/l, effective pumping could not be maintained (Galtsoff, 1946).

Chlorine residuals of 10 ug/l have been shown to kill adult salmonid fish in a period of several days in fresh water and the fry of these species have been killed in chlorine residuals of 6 ug/l. The criterion of 2 ug/l chlorine should afford protection to this group of fish when exposed on a continuing basis. Considering the data presented above, a criterion of 10 ug/l should afford protection to other freshwater fish and marine aquatic life (Brungs, In Press). Brungs (1973) reported that aquatic organisms may tolerate short-term exposure to higher levels of residual chlorine than the concentrations which have adverse chronic effects. Basch and Truchan (In Press) have shown that repeated daily exposure at these levels will have toxic effects on aquatic life.

CHROMIUM

CRITERIA:

50 ug/l for domestic water supply (health);

100 ug/l for freshwater aquatic life

INTRODUCTION:

Chromium is the seventeenth most abundant nongaseous element in the earth's crust (Schroeder, 1970); its concentration range in the continental crust is 80 to 200 mg/kg, with an average of 125 mg/kg (NAS, 1974a). Although chromium has oxidation states ranging from Cr^{-2} to Cr^{+6}, the trivalent form most commonly is found in nature. Chromium is found rarely in natural waters, ranking twenty-seventh or lower among the elements in seawater and generally is well below 1 ug/l. Kopp (1969) reported that for 1,577 surface water samples collected at 130 sampling points in the United States, 386 samples contained from 1 to 112 ug/l; the mean was 9.7 ug/l chromium. Durum, et al.,(1971) in a similar survey of 700 samples, found that none contained over 50 ug/l of hexavalent chromium and 11 contained over 5 ug/l. Chromium is found in air, soil, some foods, and most biological systems; it is recognized as an essential trace element for humans (NAS, 1974a).

RATIONALE:

The earliest consequences of mild chromium deficiency in experimental animals is a reduced sensitivity of peripheral tissues to insulin; more severe deficiency in rats and mice results in fasting hyperglycemia,

NMED Exhibit 83

glycosuria, and mild growth retardation that is probably due, at least in part, to reduced insulin activation. Glucose intolerance is a common human problem, and one of its many possible causes is chromium deficiency (NAS, 1974a).

The biological activity of chromium, i.e., its effect as an essential metal, is restricted to its trivalent state, Cr^{3+}. The Cr^{3+} ion forms complexes that are stable at or below pH 4, but which readily hydrolyze at "high" pH values; resulting in the formation of polynucleate bridge complexes. At the normal pH of blood, Cr^{3+} exists in large, insoluble macro-molecules which precipitate and become biologically inert; Cr^{3+} must therefore be supplied as a complex of suitable stability in order to be utilized.

Because of the present inadequacy of knowledge about the forms and biological availability of chromium in foods, it is not possible to quantify human dietary requirements. It is known that adult urinary loss is 5 to 10 ug/day, and since this constitutes the major portion of the daily loss, at least this much must be replaced to maintain balance. Based on rat studies indicating that absorption of various Cr^{3+} compounds can range from below 1 percent to 25 percent of a given dose, and assuming that the human case is similar, a dietary intake of 20 to 500 ug/day would balance urinary losses. It is estimated that daily chromium intakes in the U.S. are marginal and vary from 5 to 100 ug (WHO, 1973); it seems unlikely that any Cr^{3+} ingested via public drinking water would be appreciably assimilated.

NMED Exhibit 83

No harmful effects were observed when food or water containing moderate amounts of Cr^{3+} was administered to laboratory animals, e.g., cats that were fed chromic phosphate or oxydicarbonate at 50 to 1000 mg/day for 80 days, or rats drinking water containing 25 mg/l for a year or 5 mg/l throughout their lives (NAS, 1974a).

Hexavalent chromium, on the other hand, is irritating and corrosive to the mucous membranes; it is absorbed via ingestion, through the skin, and by inhalation, and is toxic when introduced into laboratory animals systemically (NAS, 1974a). Knowledge of the harmful human health effects of hexavalent chromium has been obtained almost entirely from occupational health effects. Lung cancer, ulceration and perforation of the nasal septum, and a variety of other respiratory complications and skin effects have been observed.

Symptoms of excessive dietary intake of chromium in man are unknown, and chromium deficiency is of greater nutritional concern than over-exposure. Chromium is the only element whose tissue concentration appears to decline with increasing age in the U.S. population; lung concentrations do not decline with age, suggesting that lung chromium is not in equilibrium with that in the rest of the body (NAS, 1974a).

Berg and Burbank (1972) compared concentrations of eight carcinogenic trace metals in water supplies (after Kopp and Kroner, 1967) with State cancer mortalities for major U.S. water basins, and no significant correlations were found for chromium. It should be emphasized that these data are not conclusive.

NMED Exhibit 83

The U.S. Public Health Service Drinking Water Standard (USPHS, 1962) states that the presence of hexavalent chromium in excess of 0.05 mg/l shall constitute grounds for rejection of the supply, and no harmful human health effects have been reported at this level. The NAS/NAE Committee on Water Quality Criteria recommended (NAS, 1974) that public water supply sources for drinking water contain no more than 0.05 mg/l total chromium, largely on the basis that lifetime tolerable levels of chromate ion are not known for man. There are insufficient data on the effect of the defined treatment process on chromate chromium removal. Chromium as Cr^{3+} is not likely to be present in waters of pH 5 and above because the hydrated oxide is very sparingly soluble.

A family of four individuals is known to have drunk water for a period of 3 years at a chromium level of 0.45 mg/l without known effects on their health as determined by a single medical examination (Davids and Lieber, 1951). A study was designed by MacKenzie, et al. (1958) to determine the toxicity of hexavalent and trivalent chromium ions to rats at various drinking water levels. After one year at levels of 0.45 to 25 mg/l, this study showed no evidence of toxic response in body weight, food consumption, blood changes, or mortality. However, significant accumulation of chromium occurred in the tissues at concentrations greater than 5 mg/l. Recent studies (Naumova, 1965) demonstrated that 0.1 mg of $K_2Cr_2O_7$/kg enhances the secretory and motor activity of the dog intestine.

NMED Exhibit 83

From these and other studies (Gross and Heller, 1946; Brard, 1935; Conn, et al., 1932; Schroeder, et al., 1963; Schroeder, et al., 1963a), it appears that a concentration of 50 ug/l of chromium in domestic water supply incorporates a reasonable safety factor to avoid any hazard to human health.

In addition, the possibility of dermal effects from bathing in water containing 50 ug/l chromium would likewise appear remote, although chromium is recognized as a potent skin sensitizer. Domestic water supplies should, therefore, contain no more than 50 ug/l total chromium.

Fish appear to be relatively tolerant of chromium, but some aquatic invertebrates are quite sensitive. Toxicity varies with species, chromium oxidation state, and pH. Pickering and Henderson (1966) conducted static bioassays with four warm water fish species; fathead minnows, Pimephales promelas; bluegill, Lepomis macrochirus; goldfish, Carassius auratus; and guppies, Poecilia reticulata. They obtained soft water (hardness - 20 mg/l; alkalinity - 18 mg/l; pH - 7.5) 96-hour LC_{50} values for hexavalent chromium ranging from 17.6 mg/l for fathead minnows to 118 mg/l for bluegill; hard water (hardness - 360 mg/l; alkalinity - 300 mg/l; pH - 8.2) 96-hour LC_{50} values for hexavalent chromium ranging from 27.3 mg/l for fathead minnows to 133 mg/l for bluegill. Their 96-hour LC_{50} trivalent chromium values (chromium potassium sulfate) ranged from 3.33 mg/l for guppies to 7.46 mg/l for bluegill in soft water. The LC_{50} for fathead minnows exposed to potassium chromate in soft water was 45.6 mg/l.

NMED Exhibit 83

Pickering (NAS, 1974) found 96-hour LC_{50} and safe hexavalent chromium concentrations of 33 mg/l and 1.0 mg/l, respectively, for fathead minnows in hard water. Pickering's Cr^{3+} data for fathead minnows in hard water showed a 96-hour LC_{50} of 27 mg/l and a safe concentration of 1.0 mg/l. Benoit (In Press) obtained soft water (45 mg/l hardness) 96-hour LC_{50} and safe hexavalent chromium values of 59 mg/l and 0.2 mg/l, respectively, for brook trout, Salvelinus fontinalis, and 69 and 0.2 mg/l, respectively, for rainbow trout, Salmo gairdneri.

Olson (1958) found the growth and survival of chinook salmon, Oncorhynchus kisutch, alevins and juveniles to be significantly reduced at hexavalent chromium concentrations of 0.2 mg/l. He saw no detrimental effects on salmon alevins at trivalent chromium concentrations of 0.2 mg/l. Beisinger and Christensen (1972) reported a 16 percent reproductive impairment in Daphnia magna in soft water (45 mg/l as $CaCO_3$) at a concentration of 0.33 mg/l of trivalent chromium.

The data available indicate hexavalent chromium to be somewhat more toxic than trivalent chromium in the case of chinook salmon, and since significant effects were seen on fish at 0.2 mg/l of hexavalent chromium a recommended criterion of 0.10 mg/l should provide adequate protection for both freshwater invertebrates and fish.

Lowman, et al. (1971) reported marine chromium concentration factors of 1,600 in benthic algae, 2,300 in phytoplankton, 1,900 in zooplankton, 440 in molluscan soft parts, and 70 in fish muscle.

NMED Exhibit 83

Raymont and Shields (1964) reported chromium threshold toxicity levels of 5 mg/l for small prawns, Leander squilla, 20 mg/l (as Na_2CrO_4) for the shore crab, Carcinas maenus, and 1 mg/l for the polychaete, Nereis virens. Doudoroff and Katz (1953) found that mummichogs, Fundulus heteroclitus, tolerated 200 mg/l $K_2Cr_2O_4$ in seawater for over a week.

Holland, et al. (1960) reported that 31.8 mg/l chromium (as K_2CrO_4) in sea water was 100 percent fatal to coho salmon, Oncorhynchus kisutch, and Gooding (1954) reported that 17.8 mg/l hexavalent chromium in sea-water was toxic to the same species.

Clendenning and North (1960) showed that 5.0 mg/l hexavalent chromium reduced photosynthesis by 50 percent in the giant kelp, Macrocystis pyrifera, during 4 days of exposure.

Based on the foregoing discussion of the marine toxicity of chromium, its accumulation at all trophic levels, and the sensitivity of lower aquatic forms to chromium, the freshwater criterion should protect marine populations.

NMED Exhibit 83

FECAL COLIFORM BACTERIA

CRITERION:

Bathing Waters

Based on a minimum of not less than five samples taken over a 30-day period, the fecal coliform bacterial level should not exceed a log mean of 200 per 100 ml, nor should more than 10 percent of the total samples taken during any 30 day period exceed 400 per 100 ml.

Shellfish Harvesting Waters

Not to exceed a median fecal coliform bacterial concentration of 14 MPN per 100 ml with not more than 10 percent of samples exceeding 43 MPN per 100 ml for the taking of shellfish.

INTRODUCTION:

It was recognized even before the microbial etiology of disease was known, that water can serve as a medium for the transfer of disease. The cause-effect relationship of disease transmission and specific fecally-associated microbes was initially defined by Von Fritsch in 1880, when he identified *Klebsiella spp.* in human feces. Further confirmation of the

NMED Exhibit 83

relationship between fecally-associated microbes and potential disease was developed by Escherich when he described Bacillus coli (Escherichia coli) as an indicator of pollution (Wolf, 1972; Guarraia, 1972). Since these early observations, the role of biological indicator organisms in defining water quality has become essential and addresses three categories generally: to identify environmental changes; to quantify pollution levels; or to be used in laboratories to study under controlled conditions phenomena which could be extrapolated to the environment (Butler, et al., 1972).

Microbiological indicators have been used to determine or indicate the safety of water for drinking, swimming and shellfish harvesting. As our knowledge concerning microbiology has increased, so has our understanding of the complex interrelationship of the various organisms with disease. Viruses causing a number of diseases and non-fecally associated bacteria causing infections of the ear, eye, nose and throat all have been isolated from water (Bonde, 1974; Scarpino, 1974). The relationship between numbers of specific disease causing organisms in water and the potential for transmission of disease remains elusive since the number of organisms required to cause disease varies depending upon the organism, the host, and the manner in which the bacteria and host interact. For example, in some instances a single cell of Salmonella, or a single plaque-forming unit (PFU) may be all that is necessary to cause a

NMED Exhibit 83

disease; however, in other instances the numbers of bacteria necessary to cause an illness may be up to 10^6 to 10^7 or even more viable organisms. The use to which water is put (i.e., swimming or drinking) the type of water, (marine or fresh), and the geographical location are all factors to be weighed in determining safe microbiological criteria.

Ideally, a microbiological indicator organism should fulfill all of the following criteria: (1) It should be applicable to all types of water, (2) it should be present whenever pathogens are present with a survival time equal to that of the hardiest enteric pathogen, and (3) the indicator should not reproduce in contaminated waters thus resulting in inflated values (Scarpino, 1974). Unfortunately, no such indicator organisms are known. Use has been made of coliform or fecal coliform bacteria as indicators of pollution.

Bacteria of the coliform group are considered the primary indicators of fecal contamination and are one of the most frequently applied indicators of water quality. The coliform group is made up of a number of bacteria including the genera Klebsiella, Escherichia, Serratia, Erwinia and Enterobacteria. Total coliform bacteria are all gram negative asporogenous rods and have been associated with feces of warmblooded animals.

NMED Exhibit 83

and with soil. The fecal coliform bacteria, which comprise a portion of the total coliform group, are able to grow at 44.5° C and ferment lactose producing acid and gas. Use of fecal coliform bacteria has proven to be of more sanitary significance than the use of total coliform bacteria because they are restricted to the intestinal tract of warm-blooded animals and are now used to define water quality for swimming. Arguments have been advanced for the use of Escherichia coli as the indicator of choice for fresh fecal pollution (Bonde, 1966). However, the methods for its identification require time, complex biochemical reactions, and experienced microbiologists, and the information gained by the additional work and expense involved in its identification may not provide sufficient additional information above the elevated temperature test (for fecal coliform bacteria) to warrant its use.

Enterococci were recognized as early as 1890 as being indicators of recent fecal pollution from warm-blooded animals (Geldreich and Kenner, 1969). The enterococci possess many characteristics which make them an ideal indicator system since they do not multiply in the aquatic environment and are serologically characteristic. However, there are numerous biotypes, and no good standardized method is available for biochemical testing. Such methodology is essential since identification is based primarily upon biochemical characterization.

Additional microbial systems have also been proposed as potential indicators of fecal pollution. Clostridium perfringens, an anaerobic spore former, has been associated frequently with sewage pollution. However, in a suspension of fecal material the ratio of Cl. perfringens to E. coli may differ from that in the effluent from a sewage treatment plant, in seawater or in sludge. Also the spores of Cl. perfringens are resistant and will vegetate upon culturing, hence it would be difficult to associate their presence with recent pollution.

Presence of microorganisms other than fecal coliform bacteria may also be indicative of water quality; however, the strict correlation between a pollutant problem other than fecal pollution and the numbers of the indicator organism is not always clear. The pseudomonads that are comprised of numerous free living saprophytes found in both fresh and marine waters have only one of its members as a known pathogen, Pseudomonas aeruginosa, which may be an indicator of pollution from the presence of warm-blooded animals (Ringem and Drake, 1952; Taylor, 1968; Reitler and Seligaman, 1957). While the number of P. aeruginosa in sewage usually is quite low and occurs too sporadically to be of value as an indicator organism for fecal pollution (Bonde, 1974), this organism may be an indicator of human pollution other than fecal.

NMED Exhibit 83

Bacterial pathogens, which occur in bathing waters and may cause disease even when not ingested are Klebsiella pneumoniae and Pseudomonas aeruginosa.

RATIONALE:

Bathing Waters

Pollution of aquatic systems by the excreta of warmblooded animals creates public health problems for man and animals and potential disease problems for aquatic life. It is known that enteric microbial pathogens may inhabit the gut of most warmblooded animals and are shed in feces. The presence of bacterial, viral, protozoan, and possibly fungal species which are either pathogens for or possess the potential to infect man and other organisms is indicated by the presence of the fecal coliform group of bacteria. Thus, the number of fecal coliforms present is indicative of the degree of health risk associated with using the water for drinking, swimming, or shellfish harvesting.

Arguments against the use of fecal coliform bacteria to define swimming quality in waters have noted the paucity of epidemiological evidence linking fecal coliform levels in bathing waters and the incidence of disease (Moore, 1959; 1971).

84

A problem of potential medical significance is the transfer of characteristics which will alter the resistance of pathogenic bacteria, i.e. the R-factor (RTF - resistance transfer factor), to certain antibiotics, heavy metals and ultraviolet light. The significance of this, while not fully known, suggests that human pathogens in water may become resistant to common antibiotic therapy once the bacteria infect man or animals. One example of this problem has been already reported. Recently an outbreak of typhoid fever was found to be caused by Salmonella typhi containing the chloramphenical and amphicillin resistant factor (Datta and Olearte, 1974; Olearte and Galindo, 1973).

Disease transmission via the aquatic route including drinking water, recreational water, and seafood from polluted water, has been and continues to be a problem. Presently, the indicator systems considered to be the most practical are the coliform and the fecal coliform groups. Additional microbiological problems, which can be anticipated by the presence of specific bacteria or viruses, are recognized. Correlation between human pollution sources and the numbers and significance of the microbial system in question remain elusive. Nevertheless, as the relationships become clear additional criteria for water quality will evolve. Berg (1974) has shown that Polio Virus I at a concentration of 2 plaque forming units (PFU), a standard means for measuring virus concentrations in tissue culture, will cause disease in 67 percent of the uninnoculated population.

NMED Exhibit 83

However, the lack of epidemiological correlation between fecal coliform levels in coastal swimming waters and the incidence of disease may not have validity in fresh waters and it does not take into account non-reported diseases which may develop as an unrecognized result of swimming in polluted waters. Epidemiological evidence is but one consideration in setting microbiological criteria. The presence of fecal coliform bacteria indicates degradation of water quality and a relative risk of disease transmission.

In studies conducted in Lake Michigan at Chicago, Illinois (Smith, et al., 1951), in an inland river (Smith and Woolsey, 1952) and in tidal waters at Long Island, New York (Smith and Woolsey, 1961), a statistically significant increase in the incidence of illness was observed among swimmers who used the Lake Michigan beaches on selected days and the Ohio River beach of poorest water quality. The mean total coliform bacteria content of fresh waters was 2,300 per 100 ml and 2,700 per 100 ml, respectively. No relationship between the total coliform levels and swimming-related diseases was found at the ocean beach. These studies demonstrated that an appreciably higher overall illness incidence may be expected among swimmers when compared to non-swimmers, but the data are inconclusive. The data provide a positive correlation between total coliform numbers and the increased risk of disease associated with swimming in these waters. The diseases found were infections of the eye, ear,

NMED Exhibit 83

nose, and throat, as well as intestinal ailments (Stevenson, 1953).

Outbreaks of typhoid fever (Salmonella typhi) have been associated with swimmers in "heavily" polluted beaches in western Australia (Kovacs, 1959; Snow, 1959). In this case, a sewer outfall pipe was located one mile from the bathing beach where the typhoid outbreaks occurred and the sewer was overloaded because of rapid population growth. Use of a log mean of 200 fecal coliform bacteria per 100 ml, with the provision that 10 percent of the total samples during a thirty-day period not exceed 400 fecal coliforms per 100 ml, allows for variations in environmental conditions such as shifts in wind direction, current flow, and tidal fluctuations. At levels above the 200 fecal coliforms per 100 ml the risk of exposure to pathogenic microbes increases. Correlation between the fecal coliform level and microbial pathogen levels is the important relationship, since the fecal coliforms themselves serve as an indicator of the quality of water in relation to fecally associated microbial pathogens. Direct demonstration of the microbial pathogens is not always feasible.

Detection of Salmonella has shown that in fecally polluted marine waters the level may vary between 1 and 1,000 per liter (McCoy, 1964). Occurrences of viruses in ocean waters at levels of 60 plaque-forming units (PFU) per liter have been found

NMED Exhibit 83

(Shuval, et al., 1971). It is estimated that these values may represent only 10 to 50 percent of the total viral pathogens present because of the limited recovery efficiency of the methods used. Also, other viruses associated with feces may be present but may not grow in the tissue culture systems used.

Another important consideration in determining the safe microbiological criterion is the minimum dosage necessary to infect a bather. As few as 3 to 5 organisms of S. typhosa have been reported to cause infection, whereas, 1×10^5 to 1×10^7 cells for other Salmonella serotypes may be required to produce disease. Similarly, massive concentrations of cells of enteropathogenic E. coli have been reported necessary to produce infections in adult volunteers. Alteration of gastric function either by raising the pH in the stomach or by facilitating gastric emptying can reduce this dosage several orders of magnitude. Recent data from experiments with adult volunteers indicate that the infectious dose for Shigella flexneri 2a is less than 200 cells (Geldreich, 1974). Although enteric viruses are found in relatively small numbers in polluted waters, their occurrence could be hazardous since the minimum infective dose for humans has not been firmly established. For children, the minimum infective dose may be 1 or 2 PFU (Plotkin and Katz, 1967), while for adults the minimum infective dose may be the same or higher.

NMED Exhibit 83

However, less is known concerning the minimal infective dose for pathogenic bacteria that cause ear, eye, nose, and throat ailments (Geldreich, 1974).

Use of fecal coliform bacteria as a single parameter for monitoring recreational water quality must ultimately relate to the probable occurrence of waterborne pathogens. Currently, the only relationship which has been developed between the fecal coliform indicator and waterborne pathogens is that of Salmonella to fecal coliform density. Data which have been developed indicate a sharp increase in the frequency of Salmonella detection when fecal coliform densities are above 200 organisms per 100 ml of freshwater. When there are over 200 fecal coliforms per 100 ml, Salmonella isolation should approach 100 percent frequency. Data from estuarine waters were grouped to include the level of 1 to 70 fecal coliforms that is of interest to investigators of shellfish waters. For this range, below 70 fecal coliforms per 100 ml, only 6.7 percent of the 184 Salmonella examinations were positive. At the 200 fecal coliform level, the 28.4 percent occurrence of Salmonella in estuarine waters was essentially identical with data compiled from freshwater environments. In polluted estuarine waters containing fecal coliforms ranging from 201 to above 2,000, a recovery of

NMED Exhibit 83

Salmonella was seen 60 percent of the time. The recovery rate of Salmonella in estuarine waters is lower than that in fresh waters. In fresh water, Salmonella were recovered 85 to 98 percent of the time, in the range of from 201 to 2,000 fecal coliforms. The lower value for isolation of Salmonella from estuarine waters may be related to limitations of Salmonella methodology (Geldreich, 1972). It must be noted that any projection of the qualitative recoveries of Salmonella into a comparison with fecal coliform quantification has recognized limitations. Such projections do nevertheless suggest that the 200 fecal coliform per 100 ml limit for recreational waters is a useful water quality value.

Evaluation of the microbiological suitability for marine and fresh waters should be based upon the fecal coliform levels. As determined by either the multiple-tube fermentation for marine water or the membrane filter method for fresh water, and based upon a minimum of not less than five samples taken over not more than a 30-day period, the fecal coliform bacterial level should not exceed a log mean of 200 per 100 ml, nor should more than 10 percent of total samples during any 30-day period exceed 400 per 100 ml.

Shellfish

Shellfish, being filter feeders, require a high quality of water in order to be microbiologically safe for human consumption

NMED Exhibit 83

as either raw or partially cooked. Fecal coliform bacteria, other bacterial pathogens, and viruses found in water and sediments are concentrated by shellfish, depending upon temperature, density of pathogens, currents, depth, water chemistry, and shellfish feeding activity (Van Donsel and Geldreich, 1971; Metcalf and Stiles, 1968). Once concentration of pathogens occurs, flushing of microorganisms will not necessarily occur at the same rate (Janssen, 1974; Kelly and Arcisy, 1954). Because of the established relationship between coliform levels and enteric pathogens, shellfish waters historically have been classified on the basis of total coliform levels.

An attempt by the National Shellfish Program has been made to correlate fecal coliform bacteria to enteric pathogens. Ideally, any specific fecal coliform bacterial limit for shellfish should be based on a correlation with pathogenic occurrences in the aquatic environment and with epidemiological evidence of increased health risk among shellfish consumers. However, these data are not available and calculations have been based on health risks incurred through increased pathogen occurrence in waters of differing levels of fecal contamination. Recent data in shellfish growing waters have shown that Salmonella occurred in 4.7 percent of water samples having fecal coliform densities of 1 to 29 per 100 ml (Slanetz et al., 1974). Oysters growing in these waters accumulated from 33 to 2200 fecal coliform bacteria

NMED Exhibit 83

per 100 grams of shellfish meat, with Salmonella occurrence at 6.1 percent.

Shellfish contamination is intensified further by the normal accumulation of waterborne organisms in bottom sediments through the action of sedimentation. Investigation of both the overlying water and bottom sediments from lakes and streams has indicated a 100- to 1000-fold increase in fecal coliform densities at the water-sediment interface (Van Donsel and Geldreich, 1971). Enteric viruses (Coxsackie B3) in the bottom sediment of shellfish growing waters along the New Hampshire estuary have been found when the fecal coliform densities were as low as 10 organisms per 100 ml in the overlying waters (Slanetz et al., 1965)

Indicators of fecal pollution more specific than the total coliforms in shellfish waters have been sought. Candidate organisms or groups of organisms include E. coli and the fecal coliform group. The fecal coliforms have a higher positive correlation with fecal contamination from all warm blooded animals than does E. coli (Geldreich, 1974). Usually E. coli is the most numerous bacterium of the fecal coliform group; however, under some conditions other fecal coliforms may predominate (Sears et al., 1950). Analysis of data comparing the correlation of fecal coliforms and E. coli to fecal coliform sources confirms the fact that the fecal coliforms

NMED Exhibit 83

reflect sanitary quality of water. In comparing results of the fecal coliform test to those of the E. coli procedure in shellfish waters, E. coli was reported to range from 75 to 90 percent of the fecal coliform population with the fecal coliform bacteria giving a 96.6 percent correlation (Presnell, 1974). Therefore, the use of the fecal coliform test avoids the undesirable risk of excluding some fecal contamination.

The microbiological criterion for shellfish water quality has been accepted by international agreement to be 70 total coliforms per 100 ml, using a median MPN, with no more than 10 percent of the values exceeding 230 total coliforms. No evidence of epidemiological outbreak from consumption of raw shellfish which were grown in waters meeting this bacteriological criterion has been demonstrated. This standard has proven to be a practical limit when supported by sanitary surveys of the growing waters, acceptable quality in shellfish meats and good epidemiological evidence. However, evidence from field investigations suggests that not all total coliform occurrences can be associated with fecal pollution (Gallagher, et al., 1969). Thus, attention has been directed toward the adoption of the fecal coliform test to measure more precisely the occurrence and magnitude of fecal pollution in shellfish growing waters.

A series of studies was initiated by the National Shellfish Sanitation Program and data relating the occurrence of total

NMED Exhibit 83

coliforms to numbers of fecal coliforms were compiled. Information was received from 15 States and 2 Canadian provinces and was arbitrarily divided into 4 geographical areas: northwest, southern states, mid-Atlantic, and northeast. A total of 3,695 coliform values and 3,574 fecal coliform values were included in the tabulations. The prime objective was to determine the correlation between the two indicator groups and secondarily, to determine whether or not coliform data could be used as a basis for evaluation of a potential fecal coliform standard.

The data show that a 70 coliform MPN per 100 ml at the 50th percentile was equivalent to a fecal coliform MPN of 14 per 100 ml. The data, therefore, indicate that a median value for a fecal coliform standard is 14 and the 90th percentile should not exceed 43 for a 5 tube, 3 dilution method (Hunt and Springer, 1973).

Evaluation of the microbiological suitability of waters for recreational taking of shellfish should be based upon the fecal coliform bacterial levels. When possible, samples should be collected under those conditions of tide and reasonable rainfall when pollution is most likely to be maximum in the area to be classified. The median fecal coliform value should not exceed an MPN of 14 per 100 ml and not more than 10 percent of the samples should exceed an MPN of 43.

NMED Exhibit 83

COLOR

CRITERIA:

Waters shall be virtually free from substances producing objectionable color for aesthetic purposes;

the source of supply should not exceed 75 color units on the platinum-cobalt scale for domestic water supplies; and

increased color (in combination with turbidity) should not reduce the depth of the compensation point for photosynthetic activity by more than 10 percent from the seasonally established norm for aquatic life.

INTRODUCTION:

Color in water principally results from degradation processes in the natural environment. Although colloidal forms of iron and manganese occasionally are the cause of color in water, the most common causes are complex organic compounds originating from the decomposition of naturally-occurring organic matter (AWWA, 1971). Sources of organic material include humic materials from the soil such as tannins, humic acid and humates; decaying plankton; and other decaying aquatic plants. Industrial discharges may contribute similar compounds, for example those from the pulp and paper and tanning industries. Other industrial discharges may contain brightly colored substances such as those from certain processes in textile and chemical industries.

Surface waters may appear colored because of suspended matter which comprises turbidity. Such color is referred to as apparent color and is differentiated from true color caused by colloidal humic materials (Sawyer, 1960). Natural color is reported in color "units" which generally are determined by use of the platinum-cobalt method (Standard Methods, 1971).

NMED Exhibit 83

There is no general agreement as to the chemical composition of natural color, and in fact, the composition may vary chemically from place to place (AWWA, 1971). Black and Christman (1963a) characterized color-causing colloids examined as aromatic, polyhydroxy, methoxy carboxylic acids. Shapiro (1964) characterized color-causing constituents as being dialyzable and composed of aliphatic, polyhydroxy, carboxylic acids with molecular weights varying from less than 200 to approximately 400. The colloidal fraction of color exists in the 3.5 to 10 mμ diameter range (Black and Christman, 1963b). These same authors summarized other characteristics of color observed in laboratory studies of natural waters: color is caused by light scattering and fluorescence rather than absorption of light energy and pH affects both particle size of the color-causing colloids and the intensity of color itself.

RATIONALE:

Color in water is an important constituent in terms of aesthetic considerations. To be aesthetically pleasing, water should be virtually free from substances introduced by man's activities which produce objectionable color. "Objectionable color" is defined to be a significant increase over natural background levels. Non-natural colors such as dyes should not be perceptible by the human eye as such colors are especially objectionable to those who receive pleasure by viewing water in its natural state. Because of the extreme variations in the natural background amount of color, it is meaningless to attempt numerical limits. The aesthetic attributes of water depend on one's appreciation of the water setting.

NMED Exhibit 83

The effects of color on public water supplies also are principally aesthetic. The 1962 Drinking Water Standards (PHS, 1962) recommended that color in finished waters should not exceed 15 units on the platinum-cobalt scale. Water consistently can be treated using standard coagulation, sedimentation and filtration processes to reduce color to substantially less than 15 color units when the source water does not exceed 75 color units (AWWA, 1971; NAS, 1974).

The effects of color in water on aquatic life principally are to reduce light penetration and thereby generally reduce photosynthesis by phytoplankton and to restrict the zone for aquatic vascular plant growth.

The light supply necessary to support plant life is dependent on both intensity and effective wave lengths (Welch, 1952). In general, the rate of photosynthesis increases with the intensity of the incident light. Photosynthetic rates are most affected in the red region and least affected in the blue-violet region of incident light (Welch, 1952). It has been found that in colored waters the red spectrum is not a region of high absorption so that the effective penetration, and therefore the intensity for photosynthesis, is not as restricted as are other wave lengths. It should be emphasized that transmission of all parts of the spectrum is affected by color, but the greatest effect is on the shortwave or blue end of the spectrum (Birge and Juday, 1930). In highly colored waters (45 to 132 color units) Birge and Juday (1930) measured the light transmission as a percentage of the incident level and found very little blue, 50 percent or less yellow, and 100 to 120 percent red.

NMED Exhibit 83

The light intensity required for some aquatic vascular plants to photosynthetically balance the oxygen used in respiration may be 5 percent of full sunlight during maximum summer illumination periods (NTAC, 1968). As much as 10 percent of the incident light may be required for plankton to likewise photosynthetically produce sufficient oxygen to balance their respiration requirements (NTAC, 1968). The depth at which such a compensation point is reached, called the compensation depth, delineates the zone of effective photosynthetic oxygen production. To maintain satisfactory biological conditions, this depth cannot be substantially reduced.

Industrial requirements as related to water color have been summarized (NAS, 1974). Table 2 lists the maximum value used as a source of water for various industries and industrial uses. Through treatment, such waters can be made to meet almost any industrial requirement.

Table 2.

Maximum color of surface waters that have been used as sources for industrial water supplies.

Industry or Industrial Use	Color, units
Boiler make-up	1,200
Cooling water	1,200
Pulp and paper	360
Chemical and allied products	500
Petroleum	25

COPPER

CRITERIA:

1.0 mg/l for domestic water supplies (welfare).

For freshwater and marine aquatic life, 0.1 times a 96-hour LC50 as determined through nonaerated bioassay using a sensitive aquatic resident species.

INTRODUCTION:

Copper occurs as a natural or native metal and in various mineral forms such as cuprite and malachite. The most important copper ores are sulfides, oxides, and carbonates. Copper has been mined and used in a variety of products by man since prehistoric times. Uses for copper include electrical products, coins, and metal plating. Copper frequently is alloyed with other metals to form various brasses and bronzes. Oxides and sulfates of copper are used for pesticides, algicides, and fungicides. Copper frequently is incorporated into paints and wood preservatives to inhibit growth of algae and invertebrate organisms, such as the woodborer, Teredo, on vessels.

Copper is an essential trace element for the propagation of plants and performs vital functions in several enzymes and a major role in the synthesis of chlorophyll. A shortage of copper in soil may lead to chlorosis which is characterized by yellowing of plant leaves. In copper deficient soils it may be added as a trace nutrient supplement to other fertilizers.

NMED Exhibit 83

Copper is required in animal metabolism. It is important in invertebrate blood chemistry and for the synthesis of hemoglobin. In some invertebrate organisms a protein, hemocyanin, contains copper and serves as the oxygen-carrying mechanism in the blood. An overdose of ingested copper in mammals acts as an emetic.

In examining over 1500 surface water samples from the United States, Kopp and Kroner (1967) found soluble copper in 74 percent of the samples with an average concentration of 15 µg/l and a maximum concentration of 280 µg/l of copper. The average concentration of copper in seawater approximately 3.0 µg/l (Mero, 1964).

RATIONALE:

Concentrations of copper found in natural waters are not known to have an adverse effect on humans. Prolonged oral administration of excessive quantities of copper may result in liver damage, but water supplies seldom have sufficient copper to effect such damages. Young children require approximately 0.1 mg/day of copper for normal growth and the daily requirement for adults was estimated to be about 2 mg/day (Sollman, 1957). Copper in excess of 1 mg/l may impart some taste to water. Because of a possible undesirable taste in drinking water at higher concentrations, a limit of 1 mg/l is recommended.

Testing precipitated copper in lake bottom muds resulting from copper sulfate application to control nuisance algae, Mackenthun and Cooley (1952) concluded that the toxic limit to a midge, Tendipides plumosus,

NMED Exhibit 83

and a fingernail clam, Pisidium idahoense was about 9,000 mg/kg of copper in mud on a dry weight basis.

The toxicity of copper to aquatic life is dependent on the alkalinity of the water as the copper ion is complexed by anions present, which in turn affect toxicity. At lower alkalinity copper is generally more toxic to aquatic life. Other factors affecting toxicity include pH and organic compounds. Relatively high concentrations of copper may be tolerated by adult fish for short periods of time; the critical effect of copper appears to be its higher toxicity to young or juvenile fish.

Doudoroff and Katz (1953), in reviewing literature on the acute toxicity of copper, concluded that in most natural fresh waters in the United States copper concentrations below 25 µg/l as copper evidently are not rapidly fatal for most common fish species. In acute tests Jones (1964) reported that copper sulfate in soft water (12 mg/l $CaCO_3$) was toxic to rainbow trout at 60 µg/l copper. In very hard water (320 mg/l $CaCO_3$) the toxic concentration was 600 µg/l copper. A summary of acute toxicity data is given in Table 3. In checking this table the reader should consider the species tested, pH, alkalinity, and hardness if alkalinity is not given (in most natural waters alkalinity parallels hardness). In general the salmonids are very sensitive and the centrarchids are less sensitive to copper.

NMED Exhibit 83

TABLE 3

The acute toxicity (24-, 48-, 96-hr TL50 values) of copper to several species of fish in water of various water qualities.

Species	Size	Compound	Exposure time (hr)	Exposure type	Temperature (°C)	Concentration (mg/l)	pH	Alkalinity	Hardness	Reference
Rainbow trout (Salmo gairdneri)	4 month old (7g)	Copper	96	FT*	11.6-12.4	0.02 Cu	6.8-7.0	17-26	20-25	(6)

NMED Exhibit 83

Sprague and Ramsay (1965) determined the level beyond which the organism can no longer survive for an indefinite period of time for juvenile Atlantic salmon, Salmo salar, at 17° C. For copper in a water with a total hardness of 14 mg/l as $CaCO_3$ this level was 32 µg/l. At 28 µg/l copper there were no salmon deaths in 168 hours.

Sprague (1964) found that Atlantic salmon, Salmo salar, tended to avoid a concentration of copper as low as 4.0 µg/l.

Mount and Stephan (1969) reported that in chronic tests with fathead minnows in water with a hardness of 200 mg/l as $CaCO_3$, 33 µg/l copper did not affect survival or the physical appearance of the fish but did prevent spawning. No effects were noted at 14.5 µg/l copper. In soft water with a hardness of 30 mg/l as $CaCO_3$, the no-effect level for the fathead minnow, Pimephales promelas, was about 10.6 ug/l copper. These investigators reported application factors of between 0.13 and 0.22 and between 0.03 and 0.08, respectively, for soft and hard water. The maximum concentration of copper having no detectable effect on the brown bullhead, Ictalurus nebulosus, in 600 days in water with a hardness of 202 mg/l as $CaCO_3$ was determined to be between 16 and 27 µg/l (Brungs et al., 1973). Benoit (1975) exposed bluegills (Lepomis macrochirus) to copper in soft water for 22 months and found the "no-effect" level to be 21 ug/l copper.

McKim and Benoit (1971) conducted chronic tests with brook trout, Salvelinus fontinalis, exposed to copper in water with a mean alkalinity of 41.6 mg/l as $CaCO_3$. A copper concentration of 17.5 µg/l did not adversely affect survival, growth, or spawning of adult brook trout or the hatchability of the eggs; however this concentration affected the survival and growth of juveniles. The "no-effect" level established

NMED Exhibit 83

for the young brook trout was 9.5 µg/l copper. In a second generation exposure of brook trout to copper, McKim and Benoit (1974) found that exposure to "sublethal concentrations of copper from yearling through spawning to 3 month juveniles" was sufficient to establish a "no-effect" concentration (i.e., the "no-effect" level noted above caused no adverse effects on the second generation). These authors reported an application factor of between 0.17 and 0.10 of the 96-hour LC50 value for the brown trout only.

Biesinger and Christensen (1972) found a 16 percent reproductive impairment at 22 µg/l copper for Daphnia magna in chronic (3-week) tests in water with a total hardness of 45.3 mg/l as $CaCO_3$. The 3-week LC50 was 44 µg/l copper. The total copper concentration having no effect on Campeloma decisum, Physa integra, and Gammarus pseudolimnaeus in chronic studies was between 8.0 and 14.8 µg/l in water with a total hardness of 45.3 mg/l as $CaCO_3$ (Arthur and Leonard, 1970).

The concentration of copper that has been associated experimentally with no harmful effect for several aquatic species is about 5 to 15 µg/l. This is very close to the average ambient freshwater concentration now found where copper occurs in measurable quantity. In waters with high alkalinity and/or with much organic material many species will be able to tolerate higher ambient copper concentrations. In such cases, the criterion should not exceed 0.1 of the 96-hour LC50 (the approximate mean application factor from tests reported above) as determined through bioassays using sensitive resident species.

Copper is present in sea water at a concentration of approximately 3 µg/l but copper added to the marine environment is readily precipitated in the alkaline and saline environment. Toxicity of copper to fishes in

NMED Exhibit 83

marine waters has not been studied, but for Nereis virens, a polychaete invertebrate, the toxic threshold for copper was 100 µg/l (Raymont and Shields, 1964). Copper is toxic to oysters at concentrations above 100 µg/l (Galtsoff, 1932). Clendenning and North (1960) found inhibition of photosynthesis in the giant kelp, Macrocystis pyrifera, at copper concentrations of 60 µg/l. This commercially important marine plant is used for several industrial processes and for important food additives. In areas where this plant is especially significant it may be prudent to establish a restrictive copper criterion.

Adult softshell clams, Mya arenaria, were the most sensitive marine macroorganisms tested in static copper toxicity bioassays. LC0, LC50 and LC100 values after 168 hours at 30 o/oo salinity and 22°C were 25, 35 and 50 ug/l, respectively. At 17°C, these values were 75, 86 and 100 ug/l, respectively, for the same time period (unpublished manuscript). Copper is selectively concentrated over zinc by adult softshell clams, Mya arenaria, Concentrations of greater then 20 ug/l are fatal after exposure of several weeks (Pringle, et al., 1968). The 9-day LC50 for newly hatched Fundulus heteroclitus larvae was 160 ug/l (Gentile, 1975).

These data are insufficient to derive a satisfactory criteria number, but it is apparent that copper does exhibit toxicity to the few species tested. Therefore, it is recommended that .1 of the 96-hour LC50 for a sensitive aquatic species present be adopted.

NMED Exhibit 83

The only known industrial use of water affected by copper is the production of textiles which requires a minimum concentration (as low as 10 µg/l) for some select processes. If needed, the low concentrations found in natural water may be reduced readily by various forms of treatment including coagulation and precipitation or ion exchange resins. Thus, no water quality criterion for copper in industrial water supplies is proposed.

The minimum reported concentration of copper that begins to exhibit toxicity to some agricultural plants is 100 µg/l, which is considerably more than the average found in the Nation's waters. The adverse effect of copper on plants can be overcome readily by proper management through irrigation or by the addition of materials such as lime, phosphate. fertilizers, or iron salts to the soil (Reuther and Labanauskas, 1966). No criterion is proposed for copper in water used for agricultural purposes.

Copper sulfate has been used widely in the control of algae in water supply reservoirs and in recreational lakes. At Madison, Wisconsin, its use for such purposes began in 1918 (Mackenthun and Cooley, 1952). Copper sulfate was used first as a fish poison in 1914, and in 1953 it was used experimentally by the Massachusetts Division of Fisheries and Game in accelerating fish movements in ponds which were being fyke-trapped for the removal of overabundant par and weed species. It has since been used as a standard accessory tool in netting operations (Tompkins and Bridges, 1958).

CYANIDE

CRITERIA:

5.0 ug/l for freshwater and marine aquatic life and wildlife.

INTRODUCTION:

Cyanide is one of the simplest and most readily formed organic moieties. Cyanide and compounds of cyanide are almost universally present where life and industry are found. Besides being very important in a number of manufacturing processes, they are found in many plants and animals as metabolic intermediates which generally are not stored for long periods of time.

In addition to the simple hydrocyanic acid (HCN), the alkali metal salts such as potassium cyanide (KCN) and sodium cyanide (NaCN), are commonly occurring forms and sources of cyanide. The latter compounds are readily dissolved in water; the extent of HCN formation is pH-dependent. A significant fraction of the cyanide exists as HCN molecules up to a pH of approximately 8, and the fraction increases rapidly as the pH of the solution decreases. When these simple salts dissociate in aqueous solution, the cyanide ion combines with the hydrogen ion to form hydrocyanic acid, which is toxic to aquatic life. Chemically, the cyanide ion behaves similarly to the halide ions--chloride, fluoride, bromide and iodide.

NMED Exhibit 83

The cyanide ion combines with numerous heavy metal ions to form metallocyanide complexes. The stability of these anions is highly variable. Those formed with zinc and cadmium are not stable; dissociation and production of hydrocyanic acid in near neutral or acidic environments is rapid. In turn, some of the metallocyanide anions are extremely stable. Cobaltocyanide is difficult to destroy with highly destructive acid distillation in a laboratory. The iron cyanides are also very stable but exhibit the phenomenon of photodecomposition, and in the presence of sunlight the material dissociates to release the cyanide ion, thus affecting toxicity; at night the reaction may reverse to produce a less toxic form or state.

A wide variety of organic compounds may contain cyanide functional groups. These compounds belong to a class of organic chemicals called nitriles, few of which dissociate to liberate cyanide ions or molecular HCN. In addition, there are also complex organic acids, alcohols, esters, and amides that contain the cyanide radicals. These organic compounds are used for numerous products or may be a waste by-product. Their toxicity, persistence, and chemistry in the aquatic environment are not well known except for a few specific compounds.

Cyanide toxicity is essentially an inhibition of oxygen metabolism, i.e., rendering the tissues incapable of exchanging oxygen. The cyanogen compounds are true noncumulative protoplasmic poisons (can be detoxified readily) since they arrest the activity of all forms of animal life. Cyanide shows a very specific type of toxic action. It

NMED Exhibit 83

inhibits the cytochrome oxidase system which facilitates electron transfer from reduced metabolites to molecular oxygen. The ferric iron-porphyrin molecule responsible for the catalytic action of cytochrome oxidase is the reactive site where cyanide combines with ferric(+++) iron atoms to form a reversible complex. Other enzymes containing a metal porphyrin molecule, e.g., peroxidases and xanthine oxidase, are also strongly inhibited by cyanide. Only undissociated HCN inhibits the consumption of oxygen in the tissues, causing cellular asphyxia (histotoxic anoxia) by attaching itself to the iron of the prosthetic group of the enzyme cytochrome oxidase.

Hydrocyanic acid can be absorbed readily and carried in the plasma but does not combine with hemoglobin because its iron atom is divalent (ferrous). Instead, cyanide combines with methemoglobin, a mildly oxidized form of hemoglobin in which the iron atom is trivalent (ferric). Methemoglobin, which cannot carry oxygen, normally represents only a small fraction of the total hemoglobin. Since it forms an irreversible and innocuous complex with cyanide, it is an active cyanide detoxifying agent. Amyl nitrite and other agents can be used to increase the level of methemoglobin to counteract cyanide toxicity. A few of the ways in which cyanide can be metabolized within a pattern of normal physiology are by the production of thiocyanate, reaction with hydroxocobalamin to form the harmless cyanocobalamin, combination with amino acids, oxidation to carbon dioxide and formate, etc. The conversion of only free cyanide and not organically bound cyano groups

NMED Exhibit 83

to thiocyanate (SCN^-) by action of the enzyme rhodanese is considered to be the primary method of detoxification of cyanide. Rhodanese is absent from blood and skeletal muscle, but is abundant in the liver. Thiocyanate is eliminated irregularly and slowly in the urine.

The action of cyanide on the respiration of the cell and the primary methods of detoxification of cyanide have been noted above. However, it should be pointed out that cyanide does not completely abolish cellular respiration. It is possible that a small amount of residual respiratory activity is made possible by cytochrome b activity, since this substance does not require the cyanide-susceptible cytochrome oxidase. An alternative explanation of residual respiratory activity of the cyanide-poisoned system is found in the action of the flavin aerobic dehydrogenases, which can transfer hydrogen to molecular oxygen without the cytochrome system.

The persistence of cyanide in water is highly variable. This variability is dependent upon the chemical form of cyanide in the water, the concentration of cyanide, and the nature of other constituents. Cyanide may be destroyed by strong oxidizing agents such as permanganates and chlorine. Chlorine is commonly used to oxidize strong cyanide solutions to produce carbon dioxide and ammonia; if the reaction is not carried through to completion, cyanogen chloride may remain as a residual and this material is also toxic. If the pH of the receiving waterway is acid and the stream is well aerated,

NMED Exhibit 83

gaseous hydrogen cyanide may evolve from the waterway to the atmosphere. At low concentrations or toxicity and with acclimated microflora, cyanide may be decomposed by microorganisms in both anaerobic and aerobic environments or waste treatment systems.

Hydrocyanic acid probably is the most toxic form of cyanide in water. The ratio of hydrocyanic acid to total cyanide is quite variable. Under natural conditions this variation is due to fluctuations in pH. Photochemical action can also affect this ratio. Fluctuation in pH is caused by acid wastewater discharges, and photosynthetic and respiration cycles of aquatic plant life affect the formation, stability and toxicity of HCN. Since such chemical and physical conditions will dictate the form of cyanide, the cyanide criteria must be based on the concentration of total cyanide present in the water.

RATIONALE:

Cyanide ingested by humans at quantities of 10 mg or less per day is not toxic and is biotransformed to the less toxic thiocyanate. Lethal toxic effects from the ingestion of water containing cyanide occur only when cyanide concentrations are high and overwhelm the detoxifying mechanisms of the human body. Continuous long-term consumption of up to nearly 5 mg per day has shown no injurious effects (Bodansky and Levy, 1923).

NMED Exhibit 83

A review of the available pertinent data on the acute toxicity of simple cyanides to fish reveals the following minimum lethal (threshold) concentrations of free cyanide from data obtained from experiments ranging from 12 minutes to 10 days: brook trout, Salvelinus fontinalis (Karsten, 1934); rainbow trout, Salmo gairdneri (Herbert and Merkens, 1952); brown trout, Salmo trutta (Burdick, et al., 1958); smallmouth bass, Micropterus dolomieu (Burdick, et al., 1958); bluegills, Lepomis macrochirus (Doudoroff, et al., 1966); and fathead minnows, Pimephales promelas (Doudoroff, 1956), are reported to be 50, 70 (60 determined concentration), 70, 104, 150, and 180 ug/l as cyanide, respectively.

Research at the University of Minnesota has revealed that the minimum lethal (threshold) concentrations, as determined from continuous flow bioassays in which routine analyses for cyanide were performed, are generally lower than the above reported values. The threshold concentrations, expressed as mg/l cyanide, for the brook trout, Salvelinus fontinalis; bluegill, Lepomis macrochirus; and fathead minnow, Pimephales promelas, were determined to be 0.057 at 10°C, 0.104 at 25°C, and 0.120 at 25°C, respectively (Broderius, 1974).

In review it can be concluded that free cyanide concentrations in the range from 50 to 100 ug/l as cyanide have proven eventually

NMED Exhibit 83

fatal to many sensitive fishes, and levels much above 200 ug/l probably are rapidly fatal to most fish species.

Downing (1954), Cairns and Scheier (1958), and Burdick, et al. (1958) have shown that the toxicity of free cyanides increases with any reduction in dissolved oxygen below the 100 percent saturation level. Cairns and Scheier (1958) observed that even periodic lowering of dissolved oxygen decreased the tolerance of bluegills to cyanide.

The tolerance of fish to cyanide solutions that are rapidly lethal has been reported to decrease with a rise in temperature. This increased toxicity may be explained in part by the increased metabolism of fish at higher temperatures.

Contradictory information from the literature indicates the uncertainty between the relationship of toxicity of simple cyanides to fish and the pH of the test solution. However, since undissociated hydrogen cyanide has been demonstrated to be the toxic cyanide species in simple cyanide solutions, changes in the pH of natural waters below a value of about 8.3 should have no measurable effect on the acute toxicity of simple cyanides to fish. There is no apparent relationship among toxicity to fish, the alkalinity and the hardness of the dilution water.

Cyanide is acutely toxic to most fishes at concentrations ranging from 50 to 200 ug/l (Herbert and Merkens, 1952; Burdick, et al., 1958; Cairns and Scheier, 1958; Doudoroff, 1956; Turnbull, et al., 1954; Lipschuetz and Cooper, 1955; Washburn, 1948).

NMED Exhibit 83

Some information on chronic or sublethal effects of cyanide is also available. Leduc (1966) found increased intestinal secretions in the fish, Cichlasoma bimaculatum, at concentrations as low as 20 ug/l and reduced swimming capability at concentrations of 40 ug/l. Costa (1965) reported that three common species of fish detected and avoided cyanide concentrations of 26 ug/l in approximately an hour or less. Exposure to cyanide concentrations as low as 10 ug/l reduced the swimming ability or endurance of brook trout, Salvelinus fontinalis (Neil, 1957). Growth, or food conversion efficiency of coho salmon, Oncorhynchus kisutch, was reduced at hydrogen cyanide concentrations of 20 ug/l. Small freshwater fish of the family Cichlidae exposed to a cyanide concentration of 15 ug/l lost weight more rapidly than the control fish in water free from cyanide (Leduc, 1966).

The effects of cyanide on marine life have not been investigated adequately to determine separate water quality criteria, but based on the physiological mechanisms of cyanide, toxicity to marine life probably is similar to that of freshwater life. Since marine waters generally are alkaline, the toxicity of cyanide should be less than in fresh waters where pH fluctuations occur more readily and frequently. Thus, an additional factor exists to provide a margin of safety and compensation for a lack of specific data on which to base the criterion for marine aquatic life.

Cyanide has not been reported to have any direct effect on recreational uses of water other than its effects on aquatic life. No information is available on adverse effects of cyanide in agricultural

NMED Exhibit 83

practices nor in industrial uses of water containing cyanide.

Since cyanide concentrations as low as 10 ug/l have been reported to cause adverse effects on fish, an ambient concentration of 5 ug/l is believed to provide protection with a reasonable margin of safety.

NMED Exhibit 83

GASES, TOTAL DISSOLVED

CRITERION:

To protect freshwater and marine aquatic life, the total dissolved gas concentrations in water should not exceed 110 percent of the saturation value for gases at the existing atmospheric and hydrostatic pressures.

RATIONALE:

Fish in water containing excessive dissolved gas pressure or tension are killed when dissolved gases in their circulatory system come out of solution to form bubbles (emboli) which block the flow of blood through the capillary vessels. In aquatic organisms this is commonly referred to as "gas bubble disease". External bubbles (emphysema) also appear in the fins, on the opercula, in the skin and in other body tissues. Aquatic invertebrates are also affected by gas bubble disease, but usually at supersaturation levels higher than those lethal to fish.

NMED Exhibit 83

The standard method of analyzing for gases in solutions has been the Van Slyke method (Van Slyke, et al., 1934); now gas chromatography also is used for determination of individual and total gases. For determination of total gas pressure, Weiss has developed the saturometer, a device based upon a thin-wall silicone rubber tube that is permeable to gases but impermeable to water; gases pass from the water through the tube, thus raising the internal gas pressure which is measured by a manometer or pressure gauge connected to the tube (NAS, 1974). This method alone does not separate the total gas pressure into the separate components, but Winkler oxygen determinations can be run simultaneously, and gas concentrations can be calculated.

Total dissolved gas concentrations must be determined because analysis of individual gases may not determine with certainty that gas supersaturation exists. For example, water could be highly supersaturated with oxygen, but if nitrogen were at less than saturation, the saturation as measured by total gas pressure might not exceed one hundred percent. Also, if the water was highly supersaturated with dissolved oxygen, the oxygen alone might be sufficient to

NMED Exhibit 83

create gas pressures or tensions greater than the criterion limits, but one would not know the total gas pressure or tension, or by how much the criterion was exceeded. The rare and inert gases such as argon, neon, and helium are not usually involved in causing gas bubble disease as their contribution to total gas presures is very low. Dissolved nitrogen (N_2), which comprises roughly 80 percent of the earth's atmosphere, is nearly inert biologically and is the most significant cause of gas bubble disease in aquatic animals. Dissolved oxygen, which is extremely bioactive, is consumed by the metabolic processes of the organism and is less important in causing serious gas bubble disease though it may be involved in initiating emboli formation in the blood (Nebeker, et al., 1976a.).

Percent saturation of water containing a given amount of gas varies with the absolute temperature and with the pressure. Because of the pressure changes, percent saturation with a given amount of gas changes with depth of the water. Gas supersaturation decreases by 10 percent per meter of increase in water depth due to hydrostatic pressure; a gas that is at 130 percent saturation at the

NMED Exhibit 83

surface would be at 100 percent saturation at 3 meters' depth. Compensation for altitude may be needed because a reduction in atmospheric pressure changes the water/gas equilibria resulting in changes in solubility of dissolved gases.

There are several ways that total dissolved gas supersaturation can occur:

(1) Excessive biological activity--dissolved oxygen concentrations often reach supersaturation due to excessive algal photosynthesis. Renfro (1963) reported gas bubble disease in fishes resulting, in part, from algal blooms. Algal blooms often accompany an increase in water temperature and this higher temperature further contributes to supersaturation.

(2) Lindroff (1957) reported that water spillage at hydropower dams caused supersaturation. When excess water is spilled over the face of a dam it entrains air as it plunges to the stilling or plunge pool at the base of the dam. The momentum of the fall carries the water and

NMED Exhibit 83

entrained gases to great depths in the pool and, under increased hydrostatic pressure, the entrained gases are driven into solution causing supersaturation of dissolved gases.

(3) Gas bubble disease may be induced by discharges from power generating and other thermal sources (Marcello, et al., 1975). Cool, gas-saturated water is heated as it passes through the condenser or heat exchanger. As the temperature of the water rises, percent saturation increases due to the reduced solubility of gases at higher temperatures. Thus the discharged water becomes supersaturated with gases and fish or other organisms living in the heated water may exhibit gas bubble disease (DeMont and Miller, 1972; Malouf, et al., 1972; and Keup, 1975).

In recent years, gas bubble disease has been identified as a major problem affecting valuable stocks of salmon and trout in the Columbia River system (Rulifson and Abel, 1971). The disease is caused by high concentrations of dissolved atmospheric gas which "enter" the river's water during heavy spilling at hydroelectric dams. A report by

NMED Exhibit 83

Ebel, et al. (1975) presents results from field and laboratory studies on the lethal, sublethal, and physiological effects of gas on fish, depth distribution of fish in the river (fish can compensate for some high concentrations of gas by moving deeper into the water column), detection and avoidance of gas concentrations by fish, intermittent exposure of fish to gas concentrations, and bioassays of many species of fish exposed to different concentrations of gas. Several conclusions resulting from these studies are:

(1) When either juvenile or adult salmonids are confined to shallow water (1 m), substantial mortality occurs at and above 115 percent total dissolved gas saturation.

(2) When either juvenile or adult salmonids are free to sound and obtain hydrostatic compensation either in the laboratory or in the field, substantial mortality still occurs when saturation levels (of total dissolved gases) exceed 120 percent saturation.

NMED Exhibit 83

(3) On the basis of survival estimates made in the Snake River from 1966 to 1975, it is concluded that juvenile fish losses ranging from 40 to 95 percent do occur and a major portion of this mortality can be attributed to fish exposure to supersaturation by atmospheric gases during years of high flow.

(4) Juvenile salmonids subjected to sublethal periods of exposure to supersaturation can recover when returned to normally saturated water, but adults do not recover and generally die from direct and indirect effects of the exposure.

(5) Some species of salmon and trout can detect and avoid supersaturated water; others may not.

(6) Higher survival was observed during periods of intermittent exposure than during continuous exposure.

(7) In general, in acute bioassays, salmon and trout were less tolerant than the non-salmonids.

NMED Exhibit 83

Dawley and Ebel (1975) found that exposure of juvenile spring chinook salmon, Oncorhynchus tshawytscha, and steelhead trout, Salmo gairdneri, to 120 percent saturation for 1.5 days resulted in over 50 percent mortality; 100 percent mortality occurred in less than 3 days. They also determined that the threshold level where significant mortalities begin occurring is at 115 percent nitrogen saturation (111 percent total gas saturation in this test).

Rucker (1974), using juvenile coho salmon, Oncorhynchus kisutch, determined the effect of individual ratios of oxygen and nitrogen and established that a decrease in lethal effect occurred when the nitrogen content fell below 109 percent saturation even though total gas saturation remained at 119 percent saturation, indicating the importance of determining the concentration of the individual components (O_2 and N_2) of the atmospheric supersaturation. Nebeker, et al. (1976a), using juvenile sockeye salmon, Oncorhynchus nerka, also showed that there was a significant increase in fish mortality when the nitrogen concentration was increased while holding the total percent saturation constant. They also showed that there

NMED Exhibit 83

was no significant difference in fish mortality at different CO_2 concentrations.

Research completed by Bouck, et al. (1975) showed that gas supersaturated water at and above 115 percent total gas saturation is acutely lethal to most species of salmonids, with 120 percent saturation and above rapidly lethal to all salmonids tested. Levels as low as 110 percent will produce emphysema in most species. Steelhead trout were most sensitive to gas-supersaturated water followed by sockeye salmon, Oncorhynchus nerka. Chinook salmon, Oncorhynchus tshawytscha, were intermediate in sensitivity. Coho salmon, Oncorhynchus kisutch, were significantly the more tolerant of the salmonids though still much more susceptible than non-salmonids like bass or carp.

Daphnia magna exhibited a sensitivity to supersaturation similar to that of the salmonids (Nebeker, et al., 1975), with 115 percent saturation lethal within a few days; stoneflies exhibited an intermediate sensitivity similar to bass with mortality at 130 percent saturation; and crayfish

NMED Exhibit 83

were very tolerant, with levels near 140 percent total gas saturation resulting in mortality.

No differences are proposed in the criteria for freshwater and marine aquatic life as the data available indicate that there probably is little difference in overall tolerances between marine and freshwater species.

The development of gas bubble disease in menhaden, Brevoortia sp., and their tolerance to gas saturation in laboratory bioassays and in the field (Pilgrim Nuclear Power Station Discharge Canal) are discussed by Clay, et al. (1975) and Marcello, et al. (1975). At 100 percent and 105 percent nitrogen saturation, no gas bubbles developed externally or in any of the internal organs of menhaden. At 105 percent nitrogen saturation, however, certain behavioral changes became apparent. Fish sloughed off mucus, swam erratically, were more excitable, and became darker in color. Menhaden behavioral changes observed at 110 percent nitrogen saturation were similar to those noted at 105 percent. In addition, at 110 percent gas emboli were found in the intestines, the pyloric caeca, and occasionally the

NMED Exhibit 83

operculum. The behavioral changes described were also observed at 115 percent, and clearly defined subcutaneous emphysema was observed in the fins and occasionally in the eye. At 120 percent and 130 percent nitrogen saturation, menhaden developed (within a few hours) classic symptoms of gas bubble disease. Externally, emboli were evident in all fins, the operculum, and within the oral cavity. Exophthalmia also occurred and emboli developed in internal organs. The bulbous arteriosis and swim bladder were severely distended, and emboli were found along the length of the gill arterioles resulting in hemostasis. At water temperatures of 30°C, menhaden did not survive, regardless of gas saturation level. At water temperatures of 15°, 22°, and 25°C, 100 percent of the menhaden died within 24 hours at 120 percent and 130 percent gas saturation. Fifty percent died after 96 hours at 115 percent (22°C). Menhaden survival after 96 hours at 110 percent nitrogen saturation ranged from 92 percent at 22° and 25° to 83 percent at 15°C. Observations on the relationship between the mortality rate of menhaden and gas saturation levels at Pilgrim Station during the April 1975 incident suggest that the fish may tolerate somewhat higher gas saturation levels in nature.

NMED Exhibit 83

It has been shown by Bouck, et al. (1975) and Dawley, et al. (1975) that survival of salmon and steelhead smolts in seawater is not affected by prior exposure to gas supersaturation while in fresh water. No significant mortality of juvenile coho and sockeye salmon occurred when they were exposed to sublethal concentrations of supersaturated water and then transferred to seawater (Nebeker, et al. 1976b).

NMED Exhibit 83

HARDNESS

INTRODUCTION:

Water hardness is caused by the polyvalent metallic ions dissolved in water. In fresh waters these are principally calcium and magnesium although other metals such as iron, strontium, and manganese contribute to the extent that appreciable concentrations are present. Hardness commonly is reported as an equivalent concentration of calcium carbonate ($CaCO_3$).

The concept of hardness comes from water supply practice. It is measured by soap requirements for adequate lather formation and as an indicator of the rate of scale formation in hot water heaters and low pressure boilers. A commonly used classification is given in the following table (Sawyer, 1960).

Classification of Water by Hardness Content

Conc., mg/l $CaCO_3$	Description
0 - 75	soft
75 - 150	moderately hard
150 - 300	hard
300 and up	very hard

Natural sources of hardness principally are limestones which are dissolved by percolating rainwater made acid by dissolved carbon dioxide. Industrial and

NMED Exhibit 83

industrially related sources include the inorganic chemical industry and discharges from operating and abandoned mines.

Hardness in fresh water frequently is distinguished in carbonate and non-carbonate fractions. The carbonate fraction is chemically equivalent to the bicarbonates present in water. Since bicarbonates generally are measured as alkalinity, the carbonate hardness usually is considered equal to the alkalinity.

RATIONALE:

The determination of hardness in raw waters subsequently treated and used for domestic water supplies is useful as a parameter to characterize the total dissolved solids present and for calculating chemical dosages where lime-soda softening is practiced. Because hardness concentrations in water have not been proven health related, the final level achieved principally is a function of economics. Since hardness in water can be removed with treatment by such processes as lime-soda softening and zeolite or ion exchange systems, a criterion for raw waters used for public water supply is not practical.

The effects of hardness on freshwater fish and other aquatic life appear to be related to the ions causing the hardness rather than hardness. Both the NTAC (NTAC, 1968) and NAS (NAS, 1974) panels have recommended against the use of the term hardness but suggest the inclusion of the concentrations of the specific ions. This procedure should avoid confusion in future studies but is not helpful in evaluating previous studies. For most existing data, it is difficult to determine whether toxicity of various metal ions is reduced because of the formation of metallic hydroxides and carbonates caused by the associated increases in alkalinity, or because of an antagonistic effect of one of the principal cations contributing to hardness, e.g., calcium, or a combination of both

NMED Exhibit 83

effects. Stiff (1971) presented a theory (without proof) that if cupric ions were the toxic form of copper while copper carbonate complexes were relatively non-toxic, then the observed difference in toxicity of copper between hard and soft waters can be explained by the difference in alkalinity rather than hardness. Doudoroff and Katz (1953), in their review of the literature on toxicity, presented data showing that increasing calcium in particular reduced the toxicity of other heavy metals. Under usual conditions in fresh water and assuming that other bivalent metals behave similarly to copper, it is reasonable to assume that both effects occur simultaneously and explain the observed reduction of toxicity of metals in waters containing carbonate hardness. The amount of reduced toxicity related to hardness, as measured by a 40-hour LC_{50} for rainbow trout, has been estimated to be about four times for copper and zinc when the hardness was increased from 10 to 100 mg/l as $CaCO_3$ (NAS, 1974).

Limits on hardness for industrial uses are quite variable. Table 4 lists maximum values that have been accepted by various industries as a source of raw water (NAS, 1974). Subsequent treatment generally can reduce hardness to tolerable limits although costs of such treatment are an important factor in determining its desirability for a particular water source.

Hardness is not a determination of concern for irrigation use of water. The concentrations of the cations, calcium and magnesium, which comprise hardness, are important in determining the exchangeable sodium in a given water. This particular calculation will be discussed under total dissolved solids rather than hardness.

NMED Exhibit 83

Table 4

Maximum Hardness Levels Accepted
by Industry as a Raw Water Source*

Industry	Maximum Concentration mg/l as $CaCO_3$
Electric Utilities	5,000
Textile	120
Pulp and Paper	475
Chemical	1,000
Petroleum	900
Primary Metals	1,000

* Requirements for final use within a process may be essentially zero which requires treatment for concentration reductions.

IRON

CRITERIA:

0.3 mg/l for domestic water supplies (welfare).

1.0 mg/l for freshwater aquatic life.

INTRODUCTION:

Iron is the fourth most abundant, by weight, of the elements that make up the earth's crust. Common in many rocks it is an important component of many soils, especially the clay soils where usually it is a major constituent. Iron in water may be present in varying quantities dependent upon the geology of the area and other chemical components of the waterway.

Iron is an essential trace element required by both plants and animals. In some waters it may be a limiting factor for the growth of algae and other plants; especially this is true in some marl lakes where it is precipitated by the highly alkaline conditions. It is a vital oxygen transport mechanism in the blood of all vertebrate and some invertebrate animals.

The ferrous, or bivalent (Fe^{++}), and the ferric, or trivalent (Fe^{+++}) irons, are the primary forms of concern in the aquatic environment, although other forms may be in organic and inorganic wastewater streams. The ferrous (Fe^{++}) form can persist in waters void of dissolved oxygen and originates usually from groundwaters or mines when these are pumped or drained. For practical purposes the ferric (Fe^{+++}) form is insoluble. Iron can exist in natural organometallic or humic compounds and colloidal forms. Black or brown swamp waters may contain iron concentrations of several mg/l in the presence or absence of dissolved oxygen, but this iron form has litte effect on aquatic

NMED Exhibit 83

life because it is complexed or relatively inactive chemically or physiologically.

In stratified lakes with anaerobic hypolimnia, soluble ferrous iron occurs in the deep, anaerobic waters. During the autumnal or vernal overturns and with aeration of these lakes, it is oxidized rapidly to the ferric ion that precipitates to the bottom sediments as a hydroxide, $Fe(OH)_3$, or with other anions. If hydrogen sulfide (H_2S) is present in anaerobic bottom waters or muds, ferrous sulfide (FeS) may be formed. Ferrous sulfide is a black compound and results in the production of black mineral muds.

Prime iron pollution sources are industrial wastes, mine drainage waters, and iron-bearing groundwaters. In the presence of dissolved oxygen, iron in water from mine drainage is precipitated as a hydroxide, $Fe(OH)_3$. These yellowish or ochre precipitates produce "yellow boy" deposits found in many streams draining coal mining regions of Appalachia. Occasionally ferric oxide (Fe_2O_3) is precipitated forming red waters. Both of these precipitates form as gels or flocs that may be detrimental, when suspended in water, to fishes and other aquatic life. They can settle to form flocculant materials that cover stream bottoms thereby destroying bottom-dwelling invertebrates, plants or incubating fish eggs. With time these flocs can consolidate to form cement-like materials, thus consolidating bottom gravels into pavement-like areas that are unsuitable as spawning sites for nest building fishes; particularly this is detrimental to trout and salmon populations whose eggs are protected in the interstices of gravel and incubated with oxygen-bearing waters passing through the gravel.

NMED Exhibit 83

RATIONALE:

Iron is an objectionable constituent in water supplies for either domestic or industrial use. Iron appreciably affects the taste of beverages (Riddick, et al., 1958) and can stain laundered clothes and plumbing fixtures. A study by the Public Health Service (Cohen, et al., 1960) indicates that the taste of iron may be detected readily at 1.8 mg/l in spring water and at 3.4 mg/l in distilled water.

The daily nutritional requirement for iron is 1 to 2 mg, but intake of larger quantities is required as a result of poor absorption. Diets contain 7 to 35 mg per day and average 16 mg (Sollman, 1957). The iron criterion in water is to prevent objectionable tastes or laundry staining (0.3 mg/l) constitutes only a small fraction of the iron normally consumed and is of aesthetic rather than toxicological significance.

Warnick and Bell (1969) obtained 96-hour LC_{50} values of 0.32 mg/l iron for mayflies, stoneflies, and caddisflies; all are important fish food organisms. Brandt (1948) found iron toxic to carp, Cyprinus carpio, at concentrations of 0.9 mg/l when the pH of the water was 5.5. Pike, Esox lucius, and trout (species not known) died at iron concentrations of 1 to 2 mg/l (Doudoroff and Katz, 1953). In an iron polluted Colorado stream, neither trout nor other fish were found until the waters were diluted or the iron had precipitated to effect a concentration of less than 1.0 mg/l even though other water quality constituents measured were suitable for the presence of trout (FWPCA, 1967).

Ferric hydroxide flocs have been observed to coat the gills of white perch Roccus americanus, minnows and silversides, Menidia sp. (Olsen, et al.,

NMED Exhibit 83

1941). The smothering effects of settled iron precipitates may be particularly detrimental to fish eggs and bottom-dwelling fish food organisms. Iron deposits in the Brule River, Michigan and Wisconsin were found to have a residual long-term adverse effect on fish food organisms even after the pumping of iron-bearing waters from deep shaft iron mines had ceased (West, et al., 1963). Settling iron flocs have also been reported to trap and carry diatoms downward in waters (Olsen, et al., 1941).

Ellis (1937) found that in 69 of 75 study sites with good fish fauna, the iron concentration was less than 10.0 mg/l. The European Inland Fisheries Advisory Commission (1964) recommended that iron concentrations not exceed 1.0 mg/l in waters to be managed for aquatic life.

Based on field observations principally, a criterion of 1 mg/l iron for freshwater aquatic life is believed to be adequately protective. As noted, data obtained under laboratory conditions suggest a greater toxicity for iron than that obtained in natural ecosystems. Ambient natural waters will vary with respect to alkalinity, pH, hardness, temperature and the presence of ligands which change the valence state and solubility, and therefore the toxicity of the metal.

The effects of iron on marine life have not been investigated adequately to determine a water quality criterion. Dissolved iron readily precipitates in alkaline sea waters. Fears have been expressed that these settled iron flocs may have adverse effects on important benthic commercial mussels and other shellfish resources.

NMED Exhibit 83

Iron has not been reported to have a direct effect on the recreational uses of water other than its effects on aquatic life. Suspended iron precipitates may interfere with swimming and be aesthetically objectionable. Deposits of yellow ochre or reddish iron oxides can be aesthetically objectionable.

Iron at exceedingly high concentrations has been reported to be toxic to livestock and interfere with the metabolism of phosphorus (NAS, 1974). Dietary supplements of phosphorus can be used to overcome this metabolic deficiency (McKee and Wolf, 1963). In aerated soils, iron in irrigation waters is not toxic. Precipitated iron may complex phosphorus and molybdenum making them less available as plant nutrients. In alkaline soils, iron may be so insoluble as to be deficient as a trace element and result in chlorosis, an objectionable plant nutrient deficiency disease. Rhoades (1971) reported a reduction in the quality of tobacco because of precipitated iron oxides on the leaves when the crop was spray irrigated with water containing 5 mg/l of soluble iron.

For some industries, iron concentrations in process waters lower than that prescribed above for public water supplies are required or desirable. Examples include high pressure boiler feed waters; scouring, bleaching, and dyeing of textiles; certain types of paper production; some chemicals; some food processing; and leather finishing industries.

NMED Exhibit 83

LEAD

CRITERIA:

50 ug/l for domestic water supply (health);

0.01 times the 96-hour LC_{50} value, using the receiving or comparable water as the diluent and soluble lead measurements (non-filtrable lead using an 0.45 micron filter), for sensitive freshwater resident species.

INTRODUCTION:

In addition to their natural occurrence, lead and its compounds may enter and contaminate the global environment at any stage during mining, smelting, processing, and use. The annual increase in lead consumption in the U.S. during the 10-year period from 1962-1971 averaged 2.9 percent, largely due to increased demands for electrochemical batteries and gasoline additives (Ryan, 1971). In 1971 the total U.S. lead consumption was 1,431,514 short tons, of which 42 percent came from recycled lead (Ryan, 1971). Of the 1971 U.S. lead consumption, approximately 25 percent was as metallic lead or lead alloy (Ryan, 1971; NAS, 1972). Non-industrial sources that may contribute to the possibility of ingestion of lead by man include the indoor use of lead-bearing paints and plaster, improperly glazed earthenware, lead fumes on ashes produced in burning lead battery casings, and exhaust from internal combustion engines.

Most lead salts are of low solubility. Lead exists in nature mainly as lead sulfide (galena); other common natural forms are lead carbonate (cerussite), lead sulfate (anglesite), and lead chlorophosphate (pyromorphite). Stable complexes result also from the interaction of

NMED Exhibit 83

lead with the sulfhydryl, carboxyl, and amine coordination sites characteristically found in living matter. The toxicity of lead in water, like that of other heavy metals, is affected by pH, hardness, organic materials and the presence of other metals. The aqueous solubility of lead ranges from 500 ug/l in soft water to 3 ug/l in hard water.

Lead enters the aquatic environment through precipitation, lead dust fallout, erosion and leaching of soil, municipal and industrial waste discharges, and the runoff of fallout deposits from streets and other surfaces. Extrapolations from recent studies (EPA, 1972; University of Illinois, 1972) indicate that nationally as much as 5,000 tons of lead per year may be added to the aquatic environment as a result of urban runoff.

Mediterranean and Pacific surface waters contain up to 0.20 and 0.35 mg/l of lead, respectively (NAS, 1972), which is about 10 times the estimated pre-industrial lead content of marine waters. The lead content of rivers and lakes also has increased in recent years (NAS, 1972). It may be inferred from available data that the mean natural lead content of the world's lakes and rivers ranges from 1 to 10 ug/l (Livingstone, 1963); the lead content of rural U.S. soils is 10 to 15 ug/g (Chow and Patterson, 1962), and the usual range of lead-in-soil concentrations is 2 to 200 ppm, exclusive of areas near lead ore deposits (Motto, et al., 1970), although many urban soil concentrations are much higher.

In the analyses of over 1,500 stream samples, Kopp and Kroner report that lead was observed at measurable levels with a

NMED Exhibit 83

frequency of under 20 percent. The mean concentration of the positive occurrences was 23 ug/l. The highest incidence of occurrence of lead was observed in the Western Great Lakes Basin where the frequency was slightly above 40 percent. The highest recorded concentration was 140 ug/l in the Ohio River at Evansville, Indiana.

RATIONALE:

As far as is known, lead has no beneficial or desirable nutritional effects. Lead is a toxic metal that tends to accumulate in the tissues of man and other animals. Although seldom seen in the adult population, irreversible damage to the brain is a frequent result of lead intoxication in children. Such lead intoxication most commonly results from ingestion of lead-containing paint still found in older homes. The major toxic effects of lead include anemia, neurological dysfunction, and renal impairment. The most common symptoms of lead poisoning are anemia, severe intestinal cramps, paralysis of nerves (particularly of the arms and legs), loss of appetite, and fatigue; the symptoms usually develop slowly. High levels of exposure produce severe neurologic damage, often manifested by encephalopathy and convulsions; such cases frequently are fatal. Lead is strongly suspected of producing subtle effects (i.e., effects due to low level or long term exposures insufficient to produce overt symptoms) such as impaired neurologic and motor development and renal damage in children (EPA, 1973). Subclinical lead effects are distinct from those of residual damage following lead intoxication.

Biochemical effects of lead include inhibition of erythrocyte delta-aminolevulinic acid dehydrase (ALAD) activity, increased urinary

NMED Exhibit 83

excretion of delta-aminolevulinic acid (ALA-U), and increased blood lead concentration. The increase in ALA-U is of particular interest because it rarely is produced by any substance other than lead; it is related directly to inhibition of ALAD, the enzyme that converts ALA-U to porphobilinogen. Recent work indicates that lead interferes with heme biosynthesis, and thus elevates ALA-U excretion, at levels well below 40 ug/100 ml whole blood (Secchi, et al., 1974; Haeger-Aronsen, et al., 1974). As a result of this work, the Center for Disease Control has recommended that the upper limit of normal for lead in the blood of children be revised downward from 40 ug to 30 ug/100 ml whole blood. An ad hoc committee, appointed by the U.S. Public Health Service to establish a daily permissible intake of lead without excessive body lead burden in children, concluded that the level of such intake is 300 ug from all sources (King, 1971). The gastrointestinal absorption and retention of lead is greater in children than in adults, 53 percent and 18 percent, respectively, as shown in recent studies (Alexander, et al., 1973). The average daily intake of lead from diet and air among young children probably amounts to up to 2/3 of the daily permissible intake, leaving a very narrow margin of safety (King, 1971; Lin-Fu, 1973). Compared to adults, food and air intake by children is proportionally greater than their weight, e.g., a 1-year-old child, with only about 1/7 of the body weight of an adult, has 1/4 to 1/3 of the daily adult air intake and 40 to 60 percent of the dietary intake of an adult (NAS, 1972), so that his lead intake is proportionally greater on a body weight basis. Alexander, et al. (1973) have suggested a daily limit of lead intake for 0-5 year-olds of 10 ug/kg.

NMED Exhibit 83

Considerable evidence has been developed demonstrating that laboratory animals on high lead dosages show teratogenic effects; however, no such effects have been observed in cattle or sheep (NAS, 1972). Epidemiologic studies have demonstrated no relationship between lead exposure and cancer incidence in man, but it is known that lead at concentrations of one percent or more in the diet causes renal cancer in rats (NAS, 1972).

The lead content in public water supplies in the U.S. in 1962 ranged from traces to 62 ug/l (Dufor and Becker, 1964). Continuous monitoring of the U.S. water supplies since 1962 has demonstrated that their lead content has, in general, not exceeded the U.S. Public Health Service standard of 50 ug/l (USPHS, 1962). McCabe (1970) reported on 2,595 distribution samples and showed that 73 percent contained less than the USPHS limit. McCabe, et al. (1970) found that the range of lead concentrations in finished U.S. community water was from non-detectable to 0.64 mg/l. Of the 969 water supplies surveyed, 1.4 percent exceeded 0.05 mg/l of lead. Five of the water supplies in this sample contained sufficient lead to equal or exceed Kehoe's (1966) estimated maximum safe level of lead intake (600 ug/day) without considering the possible additional contributions to the total intake by other sources and routes of exposure. In drinking water lead should be kept to a minimum; a criterion of 50 ug/l is attainable and protective. Experience indicates that fewer than four percent of the water samples analyzed exceed the 50 ug/l limit and that the majority of these are due to corrosion problems and are not due to naturally occurring lead content in raw waters.

NMED Exhibit 83

For the fathead minnow, Pimephales promelas, Pickering and Henderson (1966) have determined the 96-hour TLm values for lead (chloride) to be 5.6 to 7.3 mg/l in soft water (20 to 45 mg/l as $CaCO_3$) Brown (1968) reported a 96-hour LC_{50} of 1 mg/l for rainbow trout, Salmo gairdneri, in soft water (50 mg/l as $CaCO_3$). The 96-hour LC_{50} value for lead in hard water was 482 mg/l for fathead minnows (Pickering and Henderson, 1966). Other short-term fish toxicity data are in Table 5.

Preliminary information on 2- to 3-month exposures of rainbow and brook trout indicated detrimental effects at 0.10 mg/l of lead in soft water (20-45 mg/l as $CaCO_3$) (NAS, 1974). Growth of guppy species was affected by 1.24 mg/l of lead (Crandall and Goodnight, 1962); Jones (1939) and Hawksley (1967) found chronic or sublethal effects on three-spine stickelback species from lead concentrations of 0.1 and 0.3 mg/l, and the conditioned behavior of goldfish, Carassius auratus, in a light-dark shuttlebox was adversely affected by 0.07 mg/l of lead in soft water (50 ppm $CaCO_3$ added to deionized tap water) (Weir and Hine, 1970).

A concentration of 30 ug/l lead in a 3-week exposure produced 16 percent reproductive impairment in Daphnia magna in water with a hardness of 45 mg/l $CaCO_3$ (Biesinger and Christensen, 1972). The 96-hour LC_{50} for rainbow trout species in hard water (alkalinity 243 mg/l) for total lead was 471 mg/l and the highest mean continuous flow concentration that did not have an adverse effect on survival, growth, and reproduction was 0.12 and 0.36 mg/l (Davies and Everhart, 1973).

NMED Exhibit 83

For dissolved lead, the 96-hour LC_{50} was 1.38 mg/l and the no-effect level was 18 to 32 ug/l. Total and free lead were considered to be the same in soft water. The 18-day LC_{50} in soft water (alkalinity 26.4 mg/l) was 140 ug/l and the highest mean continuous flow concentration that did not have an adverse effect on survival, growth and reproduction was 6.0 to 11.9 ug/l. The no-effect concentrations were determined on the occurrence of abnormal black tails caused by chronic lead exposure. Acute toxicity values for several species of fish in water of various qualities are presented in Table 5. When referring to this table, the reader should consider the species tested, pH, alkalinity, and hardness if alkalinity is not given (in most natural waters alkalinity parallels hardness). In general, the salmonids are most sensitive to lead in soft water, but the influence of pH, and other factors on the solubility and form of the lead preclude the recommendation of a freshwater criteria based on acute toxicities alone.

NMED Exhibit 83

There are few data from which to draw conclusions about the relationship of safe levels for a given species in hard and soft water. The differences in lethal levels between very soft and very hard water is 100 to 500 times because of insolubility and precipitation. The single source of information for chronic and acute effects in hard and soft water is for rainbow trout (Davies and Everhart, 1973) and shows these significant factors:

Hardwater data were reported in terms of both total and free lead. The static acute hard water bioassay (mean hardness, 353.5 mg/l; methyl orange alkalinity, 243.1 mg/l; and pH, 8.02) demonstrated 96-hour TL_{50} (50 percent tolerance limit) concentration of 471 mg/l total lead and 1.38 mg/l free lead.

In the chronic hard water tests, lead-attributed mortalities occurred at levels of 3240 ug/l total lead and 64 ug/l free lead, while the maximum acceptable toxicant concentrations, based on the occurrence of black tails, were found to be 120 ug/l to 360 ug/l total lead and 18 ug/l to 32 ug/l free lead.

Soft water data were reported in terms of free lead. The flow-through acute soft water bioassay (mean hardness, 27.2 mg/l; methyl orange alkalinity, 26.4 mg/l; and pH 6.88) demonstrated an 18-day TL_{50} (50 percent tolerance limit) of 140 ug/l free lead.

NMED Exhibit 83

In the chronic soft water tests, lead-attributed mortalities occurred in fry and fingerling fish at a concentration of 95.2 ug/l, while three-year-old brood fish produced viable eggs and fry when exposed to any but the highest (27.9 ug/l) concentration. The maximum acceptable toxicant concentration, based on the occurrence of black tails, was determined to be between 11.9 and 6.0 ug/l.

A criterion involving an application factor of 0.01 multiplied by the acute 96-hour LC_{50} value expressed as dissolved lead is used to estimate the safe concentration for various fish species. Based upon the existing data, as well as upon the sensitivity of various species of fish to other metals, it is highly probable that salmon, trout, minnows and catfish will be especially sensitive to lead as compared to bass, sunfish and perch. Therefore, tests for acute toxicity should be performed on the more sensitive species when establishing standards for lead. This approach requires the experimental determination of LC_{50} values before a criterion can be determined, but the extreme effect of various water characteristics on lead solubility and toxicity warrants this additional effort.

Berry (1924) found that a concentration of lead nitrate of 25 mg/l was required to cause toxic effects to oats and tomato plants. At a concentration of 50 mg/l, plant death occurred. Hopper (1937) found that 30 mg/l of lead in nutrient solutions was toxic to bean plants.

NMED Exhibit 83

Wilkins (1957) found that lead at 10 mg/l as lead nitrate reduced root growth. Since dissolved lead contents in soils were usually from 0.05 to 5.0 mg/kg (Brewer, 1966), little toxicity can be expected. It was shown that the principal entry of lead into plants was from aerial deposits rather than from absorption from soils (Page, et al., 1971), indicating that lead that falls into the soil is not available to plants.

There is no question that some marine organisms can concentrate the lead present in sea water. Wilder (1952) reported lobster dying in 6 to 20 days when held in lead-lined tanks. Calabrese, et al. (1973) found a 48-hour LC_{50} of 1730 ug/l and a 48-hour LC_{50} of 2450 ug/l for oyster, Crassostrea virginica, eggs. The remarkable ability of the eastern oyster, Crassostrea virginica, to concentrate lead was demonstrated (Pringle, et al., 1968) by exposing them to flowing sea water containing lead concentrations of 25 ug/l, 50 ug/l, 100 ug/l, and 200 ug/l; after 49 days, the total accumulation of lead amounted to 17, 35, 75, and 200 ppm (wet weight), respectively, and those oysters exposed to the two highest lead levels, upon gross examination, showed considerable atrophy and diffusion of the gonadal tissue, edema, and less distinction of hepatopancreas and mantle edge.

North and Clendenning (1958) reported that lead nitrate at 4.1 mg/l of lead showed no deleterious effect on the photosynthesis rate in kelp, Macrocystis pyrifera, exposed for four days. However, there are insufficient data upon which to base a marine criterion at this time.

NMED Exhibit 83

MANGANESE

CRITERIA:

50 ug/l for domestic water supplies (welfare);

100 ug/l for protection of consumers of marine mollusks.

INTRODUCTION:

Manganese does not occur naturally as a metal but is found in various salts and minerals, frequently in association with iron compounds. The principal manganese-containing substances are manganese dioxide (MnO_2), pyrolusite, manganese carbonate (rhodocrosite) and manganese silicate (rhodonite). The oxides are the only important minerals mined. Manganese is not mined in the United States except when manganese is contained in iron ores that are deliberately used to form ferro-manganese alloys.

The primary uses of manganese are in metal alloys, dry cell batteries, micro-nutrient fertilizer additives, organic compounds used in paint driers and as chemical reagents. Permanganates are very strong oxidizing agents of organic materials.

Manganese is a vital micro-nutrient for both plants and animals. When manganese is not present in sufficient quantities, plants exhibit chlorosis (a yellowing of the leaves) or failure of the leaves to develop properly. Inadequate quantities of manganese in domestic animal food results in reduced reproductive capabilities and deformed or poorly maturing young. Livestock feeds usually have sufficient manganese, but beef cattle on a high corn diet may require a supplement.

NMED Exhibit 83

RATIONALE:

Although inhaled manganese dusts have been reported to be toxic to humans, manganese normally is ingested as a trace nutrient in food. The average human intake is approximately 10 mg/day (Sollman, 1957). Very large doses of ingested manganese can cause some disease and liver damage but these are not known to occur in the United States. Only a few manganese toxicity problems have been found throughout the world and these have occurred under unique circumstances, i.e., a well in Japan near a deposit of buried batteries (McKee and Wolf, 1963).

It is possible to partially sequester manganese with special treatment but manganese is not removed in the conventional treatment of domestic waters (Riddick, et al., 1958; Illig, 1960). Consumer complaints arise when manganese exceeds a concentration of 150 ug/l in water supplies (Griffin, 1960). These complaints are concerned primarily with the brownish staining of laundry and objectionable tastes in beverages. It is possible that the presence of low concentrations of iron may intensify the adverse effects of manganese. Manganese at concentrations of about 10 to 20 ug/l is acceptable to most consumers. A criterion for domestic water supplies of 50 ug/l should minimize the objectionable qualities.

McKee and Wolf (1963) summarized data on toxicity of manganese to freshwater aquatic life. Ions of manganese are found rarely at concentrations above 1 mg/l. The tolerance values reported range from 1.5 mg/l to over 1000 mg/l. Thus, manganese is not considered to be a problem in fresh waters. Permanganates have been reported to kill fish in 8 to 18 hours at concentrations of 2.2 to 4.1 mg/l, but permanganates are not persistent because they rapidly oxidize organic materials and are

NMED Exhibit 83

thereby reduced and rendered nontoxic.

Few data are available on the toxicity of manganese to marine organisms. The ambient concentration of manganese is about 2 ug/l (Fairbridge, 1966). The material is rapidly assimilated and bioconcentrated into nodules that are deposited on the sea floor. The major problem with manganese may be concentration in the edible portions of mollusks, as bioaccumulation factors as high as 12,000 have been reported (NAS, 1974). In order to protect against a possible health hazard to humans by manganese accumulation in shellfish, a criterion of 100 ug/l is recommended for marine water.

Manganese is not known to be a problem in water consumed by livestock. At concentrations of slightly less than 1 mg/l to a few milligrams per liter, manganese may be toxic to plants from irrigation water applied to soils with pH values lower than 6.0. The problem may be rectified by liming soils to increase the pH. Problems may develop with long-term (20 year) continuous irrigation on other soils with water containing about 10 mg/l of manganese (NAS, 1974). But as stated above, manganese rarely is found in surface waters at concentrations greater than 1 mg/l. Thus, no specific criterion for manganese in agricultural waters is proposed. In select areas, and where acidophilic crops are cultivated and irrigated, a criterion of 200 ug/l is suggested for consideration.

Most industrial users of water can operate successfully where the criterion proposed for public water supplies is observed. Examples of industrial

NMED Exhibit 83

tolerance of manganese in water are summarized for industries such as dyeing, milk processing, paper, textiles, photography and plastics (McKee and Wolf, 1963). A more restrictive criterion may be needed to protect or ensure product quality.

MERCURY

CRITERIA:

2.0 ug/l for domestic water supply (health);

0.05 ug/l for freshwater aquatic life and wildlife;

0.10 ug/l for marine aquatic life.

INTRODUCTION:

Mercury is a silver-white, liquid metal solidifying at -38.9° C to form a tin-white, ductile, malleable mass. It boils at 356.9° C, has a specific gravity of 13.6 and a vapor pressure of 1.2×10^{-3} mm of mercury. Mercury has three oxidation states: (1) zero (elemental mercury); (2) +1 (mercurous compounds); and (3) +2 (mercuric compounds). Mercury is widely distributed in the environment and biologically is a non-essential or non-beneficial element. Historically it was recognized to possess a high toxic potential and was used as a germicidal or fungicidal agent for medical and agricultural purposes.

Human poisoning by mercury or its compounds clinically has been recognized. Although its toxic properties are well known, dramatic instances of toxicosis in man and animals have occurred recently, e.g., the Minamata Bay poisonings (Irukayama, et al., 1962; Irukayama, 1967). In addition to the incidents in Japan, poisonings have also occurred in Iraq, Pakistan and Guatemala as a result of ingestion of flour and seed treated with methyl and ethylmercury compounds (Bakir, et al., 1973). Mercury intoxication may be acute or chronic and toxic effects vary with the form of mercury and its mode of entry into the organism. The mercurous salts are less soluble than the mercuric and consequently are less toxic. For man, the fatal oral dose of mercuric salts ranges from 20 mg to 3.0 g (Stokinger, 1963). Symptoms of acute, inorganic mercury poisoning include pharyngitis, gastroenteritis, vomiting followed by ulcerative hemorrhagic colitis, nephritis,

NMED Exhibit 83

hepatitis, and circulatory collapse. Chronic mercury poisoning results from exposure to small amounts of mercury over extended time periods. Chronic poisoning from inorganic mercurials most often has been associated with industrial exposure, whereas poisoning from the organic derivatives has been the result of accidents or environmental contamination. Alkyl compounds are the derivatives of mercury most toxic to man, producing illness, irreversible neurological damage, or death from the ingestion of amounts in milligrams (Berglund and Berlin, 1969).

The mercury content of unpolluted U.S. rivers from 31 States where natural mercury deposits are unknown is less than 0.1 ug/l (Wershaw, 1970). Jenne (1972) found also that the majority of U.S. waters contained less than 0.1 ug/l of mercury. The lower limit of detection in these studies was 0.1 ug/l. Total mercury values of 0.045 ug/l recently were determined in Connecticut River water by Fitzgerald and Lyons (1973) using more sensitive methods. Marine waters have been shown to contain concentrations of mercury from a low of .03 to a high of 0.2 ug/l, but most marine waters fall within the range of .05 to .19 ug/l mercury (Robertson, et al., 1972). Mining, agriculture and waste discharges contribute to the natural levels found.

RATIONALE:

Several forms of mercury, ranging from elemental to dissolved inorganic and organic species, are expected to occur in the environment. The recent discovery that certain microorganisms have the ability to convert inorganic and organic forms of mercury to the highly toxic methyl or dimethyl mercury has made any form of mercury potentially hazardous to the environment

NMED Exhibit 83

(Jensen and Jernelov, 1969). In studies on the biochemical kinetics of mercury methylation, Bisogni and Lawrence (1973) demonstrated that in water, under naturally occurring conditions of pH and temperature, inorganic mercury can be converted readily to methylmercury.

Wood (1974) has argued further that whenever mercury in any form is added to the aquatic environment, a combination of microbially catalyzed reactions and chemical equilibrium systems is capable of leading to steady state concentrations of dimethyl mercury, methylmercuric ion, metallic mercury, mercuric ion, and mercurous ion. Thus, it is evident that the total mercury level should be the basis for a mercury criterion instead of any particular form in which it may be found within a sample.

Hannerz (1968), using 0.1 mg/l of several mercury compounds in ponds, concluded that algae and other aquatic plants accumulate mercury primarily by surface adsorption. This study demonstrated that all of the mercury compounds used were taken up by fish both directly from the water and from food. The accumulation rate was shown to be fast, while the elimination rate was slow, leading to concentration factors of 3,000-fold and higher. According to McKim (1974), concentration factors by fish in excess of 10,000 times the amount of mercury in the surrounding water have been demonstrated.

In a test period of 20 to 48 weeks, several species of fish accumulated more than 0.5 ug/gm mercury in their tissues from a water habitat containing 0.018 to 0.030 ug/l methylmercury (McKim, et al., In Press) representing concentration factors of from 27,800 to 16,600.

NMED Exhibit 83

Quantities of ingested mercury safe for man can be estimated from data presented in "Methyl Mercury in Fish" (1971). From epidemiological evidence, the lowest whole-blood concentration of methylmercury associated with toxic symptoms is 0.2 ug/g. This blood concentration can be compared to 60 ug/g mercury in hair. These values, in turn, correspond to prolonged continuous exposure at approximately 0.3 mg/70 kg body weight/day. By using a safety factor of 10, the maximum dietary intake from all sources, including air, water, and food, should not exceed 30 ug/person/day mercury. Although the safety factor is computed for adults, limiting ingestion by children to 30 ug/day of mercury is believed to afford some lesser degree of safety. If the exposure to mercury were from fish alone, the limit would allow for a maximum daily consumption of 60 grams (420 g/week) of fish containing 0.5 mg/kg mercury. A drinking water criterion of 2.0 ug/l would permit a daily intake of 4 ug mercury assuming an average consumption of 2 liters of water per day. If the mercury is not all in the alkyl form, a greater margin of safety will exist.

The levels of mercury in tissues of livestock consumed by humans should not exceed 0.5 mg/kg mercury. The tissue concentration of 0.5 mg/kg correlates approximately with a blood level of 0.1 ug/l. A mercury level of less than 1.0 ug/l in livestock water is considered compatible with these concentrations, thus a mercury concentration of 0.05 ug/l will provide an adequate safety factor.

Several chronic toxicity tests have been conducted to measure the adverse effects of organomercurials on survival, growth, and reproduction of several fish species. In a 3-year chronic toxicity study involving

NMED Exhibit 83

three generations of brook trout, Salvelinus fontinalis, exposed to methylmercuric chloride, gross toxic symptoms were observed after six-months' exposure of yearling trout to 2.9 ug/l of mercury (McKim, et al., In Press). Spawning occurred at all lower mercury concentrations tested, but the offspring of parental fish exposed to 0.93 ug/l of mercury exhibited reduction in growth 90 days after hatching. After 24-months' exposure of second generation fish to 0.93 ug/l, behavioral symptoms were noted, there was no spawning, and mortality was 94 percent. No adverse effects were observed in the brook trout exposed to methylmercuric chloride concentrations of 0.29 ug/l mercury and below. A full life cycle chronic toxicity test was conducted with fathead minnows, Pimephales promelas, exposed to methylmercuric chloride (Mount, 1974). All died after three months' exposure to concentrations of 0.80 and 0.41 ug/l mercury. Ninety-two percent of the fish exposed to 0.23 ug/l mercury also died within the three-month period. Spawning was completely inhibited at 0.12 ug/l mercury with males not developing sexually. No toxic effects were noted on survival or growth of the offspring produced in 0.07 ug/l of mercury.

Two chronic toxicity tests were conducted with one invertebrate, Daphnia magna. Mercury as mercuric chloride and methylmercuric chloride caused significant reproductive impairment at concentrations of 2.7 ug/l and 0.04 ug/l mercury, respectively (Biesinger, 1974).

Matida, et al. (1971) found that the LC_{50} for phenylmercuric acetate, methylmercuric chloride, and mercuric chloride with rainbow trout fingerlings, Salmo gairdneri, were 8.5, 30, and 310 ug/l, respectively. Wobeser (1973) examined the toxicity of methylmercuric chloride to two life stages

NMED Exhibit 83

of rainbow trout. The 96-hour LC_{50} for newly hatched sac fry was 24 ug/l of mercury, while rainbow trout fingerlings had a 96-hour LC_{50} value of 42 ug/l.

Eisler (1974) found that concentrations of 1.0 ug/l mercury represent a distinct threat to selected species of marine organisms and, based on a comparison with freshwater species, the accumulation of mercury is similar in fresh and marine water.

Because of methylation and bioconcentration of methylmercury, mercury limits must take into consideration the food chain transport path from aquatic organisms to man. Regardless of the mercury form present, the major portion of the mercury will ultimately reside in the bottom sediments where, through microbial action, mono- and dimethylmercury can be formed.

These forms of mercury are bioconcentrated many-fold in fish and other aquatic organisms because of the very rapid uptake and the relative inability of the fish to excrete methylmercury from their tissues. As a result, methylmercury in fish tissues may exceed the 0.5 mg/kg FDA guideline. This occurs in water concentrations that have no observed toxic effects on the fish. Methylation rates are highly dependent upon water quality conditions, but sufficient evidence exists to suggest that the process can occur in the pH range of 5 to 9 under aerobic or anaerobic conditions; hence, it is assumed that methylation can and will occur in natural waters.

Demethylation processes can deplete methylmercury concentrations in water. Methylmercury appears to persist for sufficient time periods, however to allow uptake by aquatic organisms. Hence, demethylation processes can have an effect on uptake rates of methylmercury, but do not terminate the transport path. It appears that the methylation process takes place at the water/sediment interface, particularly in the sediment area in which the benthic organisms are most active. The movement of benthos within the sediments contributes

NMED Exhibit 83

to the methylation process by physically expanding the area of water/ sediment interface. Through ingestion of the detritus in the sediments, benthos acquire a body burden of mercury that will in turn be transported to fish upon ingestion.

The FDA established guideline for mercury in edible fish is 0.5 mg/kg. Thus, the maximum level of mercury in receiving waters should be based on the premise that this level should not be exceeded. A mercury concentration factor for certain freshwater species has been shown to be in excess of 10,000.

Upon dividing the 0.5 mg/l FDA temporary tolerance by the 10,000-fold accumulation factor, a level of 0.05 ug/l for total mercury in fresh water results, which can be assumed to protect the human consumer of freshwater fish. It was pointed out above that 0.04 ug/l mercury as methylmercuric chloride caused significant reproductive impairment to Daphnia magna. Recognizing, however, that natural total mercury concentrations in fresh water are in the same range, and that a total mercury level of 0.05 ug/l would be divided among several chemical forms which differ markedly in their toxicity, it is believed that a criterion of 0.05 ug/l total mercury will offer a reasonable level of protection to freshwater aquatic life as well as to the human consumer.

Recognizing that seawater contains about 0.1 ug/l mercury and that this level is 1/10 of that found by Eisler (1974) to represent a threat to selected species of marine organisms, it is recommended that the criterion for the protection of marine aquatic life be 0.1 ug/l.

NMED Exhibit 83

MIXING ZONES

INTRODUCTION:

A mixing zone is an area contiguous to a discharge where receiving water quality may neither meet all quality criteria nor requirements otherwise applicable to the receiving water. It is obvious that any time an effluent is added to a receiving waterway, where the effluent is poorer in quality, there will be a zone of mixing. The mixing zone should be considered as a place where wastes and water mix and not as a place where effluents are treated.

RATIONALE:

Because damage to the aquatic resource can occur when quality standards are violated, the permissible size of a mixing zone is dependent upon the acceptable amount of damage. The permissible size depends in part on the size of the particular receiving water; the larger the water body, the larger the mixing zone may be without violating quality standards in more than a given percentage of the total area or volume of the receiving water. Likewise, the greater number of mixing zones within a reach of river or within a water body, the smaller each must be in order to maintain an appropriate mixing zone to water body ratio. Future industrial and population growths must be considered in designating such areas for wastes admixture.

As a guideline, the quality for life within a mixing zone should be such that the 96-hour LC_{50} for biota significant to the indigenous aquatic community is not exceeded; the mixing zone should be free from effluent substances that will settle to form objectionable deposits, free from effluent-associated materials that float to form unsightly masses, and free from effluent-associated substances that produce objectionable color, odor, or turbidity.

NMED Exhibit 83

A prime purpose in designating the location, size, and area constraints of a mixing zone is to protect the aquatic life within the receiving waterway. Shallow water areas, generally, are the nursery areas for aquatic ecosystems. Designating offshore mixing areas or providing a larger available volume or area for mixing offshore as a viable alternative to a smaller shoreside area has a lesser potential for adverse biotic effects than a comparable discharge area in shallow water. Offshore, diffusion will tend to occur in all directions and not be constrained by a land barrier. Mixing zones may be less harmful biologically when located deep within the receiving water and, wherever possible, beneath the light-penetration area where photosynthesis occurs and algae and associated protozoa and other organisms provide the extensive base for the aquatic food web.

An axiom of environmental quality is that different areas vary in ecological importance, one from the other. Generally the highest importance, and therefore the greatest protection, must be placed on shallow-water shoreline areas of rivers, lakes and coastal zones and on the nation's wetlands. These are commonly the areas that protect the young and supply the food not only for the animals that live in open waters but also for those animals that depend upon water in some measure for their existence. Likewise, one local aquatic area may have a higher social or ecological value than another, and the higher that value the greater the protection from degradation that is warranted within a waste mixing area.

Mixing zones should be located in such a manner that they do not form a barrier to the migratory routes of aquatic species. On a given reach of a stream or river , it would be good practice to limit the total mixing zone area to one-third of the receiving water width. In the same fashion, the combined

NMED Exhibit 83

areas of all mixing zones within a lake should not exceed ten percent of the lake surface area. In some cases, this maximum should be reduced depending on lake volume and other local conditions. Within an estuary, the maximal dimension of the mixing area should not exceed 10 percent of the cross-sectional area of the waterway. It is not the objective of this rationale to outline limits for effluents, but to provide the reader with some of the general biological and physical considerations necessary for the establishment of mixing zones.

In essence, the positioning of mixing zones should be accomplished in a manner that will provide the greatest protection to aquatic life and for the various uses of water. Generally, shoreline and surface areas for waste admixture should be discouraged in preference to deep water, offshore designations. The relative social and ecological values of the aquatic life that may inhabit a particular waterway area should be given due consideration in zone definition. (Fetterolf, 1973; NAS, 1974) The designation of particular mixing zones is a task that should follow the biological, physical and chemical appraisal of the receiving waterway.

NICKEL

CRITERION:

0.01 of the 96-hour LC50 for freshwater and marine aquatic life.

INTRODUCTION:

Nickel is a silver-white, metallic element seldom occurring in nature in the elemental form. Nickel salts are soluble and can occur as a leachate from nickel-bearing ores. Kopp and Kroner (1967) detected nickel in the Lake Erie Basin at a frequency of 53 percent and a mean concentration of 56 ug/l. At several selected stations, dissolved nickel ranged from 3 to 86 ug/l and suspended nickel from 5 to 900 ug/l. Nickel is present in sea water at 5 to 7 ug/l (NAS, 1974).

RATIONALE:

Nickel is considered to be relatively non-toxic to man (Schroeder, et al., 1961) and a limit for nickel is not included in the EPA National Interim Primary Drinking Water Regulations ((40 FR 59566, December 24, 1975)The toxicity of nickel to aquatic life, as reported by McKee and Wolf (1963), indicates tolerances that vary widely and that are influenced by species, pH, synergistic effects and other factors. The survival curves for sticklebacks in soft tap water indicate a lethal limit of 800 ug/l nickel (Jones, 1939). Pickering and Henderson (1964) reported that 96-hour LC_{50} values of nickel in soft water for four species of fish varied from 4.6 to 9.8 mg/l, and in hard

NMED Exhibit 83

water for two fish species, the 96-hour LC_{50} varied from 39.2 to 42.4 mg/l. The 96-hour LC_{50} values for two species of aquatic insects were reported by Warnick and Bell (1969) to be 4.0 and 33.5 mg/l nickel. Biesinger and Christensen (1972) found that the three-week LC50 value for Daphnia magna in soft water was 130 ug/l nickel; 95 ug/l caused a 50 percent impairment in reproductivity, and 30 ug/l caused a 16 percent impairment.

In continuous bioassay tests designed to determine chronic effects, Pickering (1974) demonstrated that nickel concentrations of 380 ug/l and lower in hard water did not adversely affect survival, growth, or reproduction of the fathead minnow. Nickel concentrations of 730 ug/l caused a significant reduction both in the number of eggs per spawning and in the hatchability of the eggs.

Calabrese, et al.,(1973) reported a 48-hour LC50 of 1,180 ug/l for American oyster embryo, Crassostrea virginica, for larvae of the hard shell clam, Mercenaria mercenaria (Calabrese & Nelson, 1974). Jones (1939) reported a 96-hour LC50 of 800 ug/l for the euryhaline stickleback, Gasterosteus aculeatus. Gentile (1975) found that the 96-hour LC50 for the marine copepod, Acartia tonsa was 625 ug/l.

Nickel salts have been shown to be injurious to plants. In sand and nickel solution experiments, Vanselow (1966) demonstrated that at 0.5 to 1.0 mg/l, nickel is toxic to a number of plants. The toxicity exhibited to plants by nickel varied widely with the species. McKee and Wolf (1963) indicated that nickel was extremely toxic to citrus. Chang and Sherman (1953) found

that tomato seedlings were injured by 0.5 mg/l nickel. Hop plants were shown to be injured by nickel at 1.0 mg/l (Legg and Ormerod, 1958). Plants exhibiting less susceptibility to nickel were: oats, with toxic effects at 2.5 mg/l (Crooke, 1954); corn at 2 mg/l; and tobacco with no toxic effects at 3.0 mg/l (Soane and Saunders, 1959).

Data indicate that, (1) nickel in water is toxic to plant life at concentrations as low as 500 ug/l, (2) nickel adversely affects reproduction of a freshwater crustacean at concentrations as low as 95 ug/l, (3) marine clam larvae can be killed by concentrations of nickel as low as 310 ug/l, and (4) reproduction of the fathead minnow is detrimentally affected by nickel at concentrations as low as 730 ug/l. Concentrations of nickel at or below 100 ug/l should not be harmful to irrigated plants or marine and freshwater aquatic organisms.

NMED Exhibit 83

NITRATES; NITRITES

CRITERION:

10 mg/l nitrate nitrogen (N) for domestic water supply (health).

INTRODUCTION:

Two gases (molecular nitrogen and nitrous oxide) and five forms of nongaseous, combined nitrogen (amino and amide groups, ammonium, nitrite, and nitrate) are important in the nitrogen cycle. The amino and amide groups are found in soil organic matter and as constituents of plant and animal protein. The ammonium ion is either released from proteinaceous organic matter and urea, or is synthesized in industrial processes involving atmospheric nitrogen fixation. The nitrite ion is formed from the nitrate or the ammonium ions by certain microorganisms found in soil, water, sewage, and the digestive tract. The nitrate ion is formed by the complete oxidation of ammonium ions by soil or water microorganisms; nitrite is an intermediate product of this nitrification process. In oxygenated natural water systems nitrite is rapidly oxidized to nitrate. Growing plants assimilate nitrate or ammonium ions and convert them to protein. A process known as denitrification takes place when nitrate-containing soils become anaerobic and the conversion to nitrite, molecular nitrogen, or nitrous oxide occurs. Ammonium ions may also be produced in some circumstances.

Among the major point sources of nitrogen entry into water bodies are municipal and industrial wastewaters, septic tanks, and feedlot discharges. Diffuse sourcescof nitrogen include farm-site fertilizer and animal wastes, lawn fertilizer, leachate from waste disposal in dumps or sanitary landfills, atmospheric fallout, nitric oxide and nitrite

NMED Exhibit 83

discharges from automobile exhausts and other combustion processes, and losses from natural sources such as mineralization of soil organic matter (NAS, 1972). Water reuse systems in some fish hatcheries employ a nitrification process for ammonia reduction; this may result in exposure of the hatchery fish to elevated levels of nitrite (Russo, et al., 1974).

RATIONALE:

In quantities normally found in food or feed, nitrates become toxic only under conditions in which they are, or may be, reduced to nitrites. Otherwise, at "reasonable" concentrations, nitrates are rapidly excreted in the urine. High intake of nitrates constitutes a hazard primarily to warm blooded animals under conditions that are favorable to their reduction to nitrite. Under certain circumstances, nitrate can be reduced to nitrite in the gastrointestinal tract which then reaches the bloodstream and reacts directly with hemoglobin to produce methemoglobin, with consequent impairment of oxygen transport.

The reaction of nitrite with hemoglobin can be hazardous in infants under three months of age. Serious and occasionally fatal poisonings in infants have occurred following ingestion of untreated well waters shown to contain nitrate at concentrations greater than 10 mg/l nitrate nitrogen (N) (NAS, 1974). High nitrate concentrations frequently are found in shallow farm and rural community wells, often as the result of inadequate protection from barnyard drainage or from septic tanks (USPHS, 1961; Stewart, et al., 1967). Increased concentrations of nitrates also have been found in streams from farm tile drainage in areas of intense fertilization and farm crop production (Harmeson, et al., 1971). Approximately 2000 cases of infant methemoglobinemia

NMED Exhibit 83

have been reported in Europe and North America since 1945; 7 to 8 percent of the affected infants died (Walton, 1951; Sattelmacher, 1962). Many infants have drunk water in which the nitrate nitrogen content was greater than 10 mg/l without developing methemoglobinemia. Many public water supplies in the United States contain levels that routinely are in excess of this amount, but only one U.S. case of infant methemoglobinemia associated with a public water supply has ever been reported (Vigil, et al., 1965). The differences in susceptibility to methemoglobinemia are not yet understood but appear to be related to a combination of factors including nitrate concentration, enteric bacteria, and the lower acidity characteristic of the digestive systems of baby mammals. Methemoglobinemia symptoms and other toxic effects were observed when high nitrate well waters containing pathogenic bacteria were fed to laboratory mammals (Wolff, et al., 1972). Conventional water treatment has no significant effect on nitrate removal from water (NAS, 1974).

Because of the potential risk of methemoglobinemia to bottle-fed infants, and in view of the absence of substantiated physiological effects at nitrate concentrations below 10 mg/l nitrate nitrogen, this level is the criterion for domestic water supplies. Waters with nitrite nitrogen concentrations over 1 mg/l should not be used for infant feeding. Waters with a significant nitrite concentration usually would be heavily polluted and probably bacteriologically unacceptable.

NMED Exhibit 83

Westin (1974) determined that the respective 96-hour and 7-day LC_{50} values for chinook salmon, Oncorhynchus tshawytscha, were 1310 and 1080 mg/l nitrate nitrogen in fresh water and 990 and 900 mg/l nitrate nitrogen in 15 o/oo saline water. For fingerling rainbow trout, Salmo gairdneri, the respective 96-hour and 7-day LC_{50} values were 1360 and 1060 mg/l nitrate nitrogen in fresh water, and 1050 and 900 mg/l nitrate nitrogen in 15 o/oo saline water. Trama (1954) reported that the 96-hour LC_{50} for bluegills, Lepomis macrochirus, at 20° C was 2000 mg/l nitrate nitrogen (sodium nitrate) and 420 mg/l

NMED Exhibit 83

nitrate nitrogen (potassium nitrate). Knepp and Arkin (1973) observed that largemouth bass, Micropterus salmoides, and channel catfish, Ictalurus punctatus, could be maintained at concentrations up to 400 mg/l nitrate (90 mg/l nitrate nitrogen) without significant effect upon their growth and feeding activities.

The 96-hour and 7-day LC_{50} values for chinook salmon, Oncorhynchus tshawytscha, were found to be 0.9 and 0.7 mg/l nitrite nitrogen in fresh water (Westin, 1974). Smith and Williams (1974) tested the effects of nitrite nitrogen and observed that yearling rainbow trout, Salmo gairdneri, suffered a 55 percent mortality after 24 hours at 0.55 mg/l, fingerling rainbow trout suffered a 50 percent mortality after 24 hours of exposure at 1.6 mg/l, and chinook salmon, Oncorhynchus tshawytscha, suffered a 40 percent mortality within 24 hours at 0.5 mg/l. There were no mortalities among rainbow trout exposed to 0.15 mg/l nitrite nitrogen for 48 hours. These data indicate that salmonids are more sensitive to nitrite toxicity than are other fish species, e.g., minnows, Phoxinus laevis, that suffered a 50 percent mortality within 1.5 hours of exposure to 2030 mg/l nitrite nitrogen, but required 14 days of exposure for mortality to occur at 10 mg/l (Klingler, 1957), and carp, Cyprinus carpio, when raised in a water reuse system, tolerated up to 1.8 mg/l nitrite nitrogen (Saeki, 1965).

Gillette, et al. (1952) observed that the critical range for creek chub, Semotilus atromaculatus, was 80 to 400 mg/l nitrite nitrogen. Wallen, et al. (1957) reported a 24-hour LC_{50} of 1.6 mg/l nitrite nitrogen, and 48- and 96-hour LC_{50} values of 1.5 mg/l nitrite

NMED Exhibit 83

nitrogen for mosquitofish, Gambusia affinis. McCoy (1972) tested the nitrite susceptibility of 13 fish species and found that logperch, Percina caprodes, were the most sensitive species tested (mortality at 5 mg/l nitrite nitrogen in less than 3 hours of exposure), whereas carp, Cyprinus carpio, and black bullheads, Ictalurus melas, survived 40 mg/l nitrite nitrogen for a 48-hour exposure period; the common white sucker, Catostomus commersoni, and the quillback, Carpiodes cyprinus, survived 100 mg/l for 48 and 36 hours, respectively.

Russo, et al. (1974) performed flow-through nitrite bioassays in hard water (hardness = 199 mg/l $CaCO_3$, alkalinity = 176 mg/l $CaCO_3$, pH = 7.9) on rainbow trout, Salmo gairdneri, of four different sizes, and obtained 96-hour LC_{50} values ranging from 0.19 to 0.39 mg/l nitrite nitrogen. Duplicate bioassays on 12-gram rainbow trout were continued long enough for their toxicity curves to level off, and asymptotic LC_{50} concentrations of 0.14 and 0.15 mg/l were reached in 8 days; on day 19, additional mortalities occurred. For 2-gram rainbow trout, the minimum tested level of nitrite nitrogen at which no mortalities were observed after 10 days was 0.14 mg/l; for the 235-gram trout, the minimum level with no mortality after 10 days was 0.06 mg/l.

It is concluded that: (1) levels of nitrate nitrogen at or below 90 mg/l would have no adverse effects on warm water fish (Knepp and Arkin, 1973); (2) nitrite nitrogen at or below 5 mg/l should be protective of most warm water fish (McCoy, 1972); and (3) nitrite nitrogen at or below 0.06 mg/l should be protective of salmonid fishes (Russo, et al., 1974; Russo and Thurston, 1975). These levels

NMED Exhibit 83

either are not known to occur or would be unlikely to occur in natural surface waters.

Recognizing that concentrations of nitrate or nitrite that would exhibit toxic effects on warm or cold water fish could rarely occur in nature, restrictive criteria are not recommended.

NMED Exhibit 83

OIL AND GREASE

CRITERIA:

For domestic water supply: Virtually free from oil and grease, particularly from the tastes and odors that emanate from petroleum products.

For aquatic life:

(1) 0.01 of the lowest continuous flow 96-hour LC50 to several important freshwater and marine species, each having a demonstrated high susceptibility to oils and petrochemicals.

(2) Levels of oils or petrochemicals in the sediment which cause deleterious effects to the biota should not be allowed.

(3) Surface waters shall be virtually free from floating nonpetroleum oils of vegetable or animal origin, as well as petroleum derived oils.

INTRODUCTION:

It has been estimated that between 5 and 10 million metric tons of oil enter the marine environment annually (Blumer, 1970). A major difficulty encountered in the setting of criteria for oils and grease is that these are not definitive chemical categories, but include thousands of organic compounds with varying physical, chemical, and toxicological properties. They may be volatile or non-volatile, soluble or insoluble, persistent or easily degraded.

RATIONALE:

Field and laboratory evidence have demonstrated both acute lethal toxicity and long-term sublethal toxicity of oils to aquatic organisms. Events such as the Tampico Maru wreck of 1957 in Baja, California, (Diaz-Piferrer, 1962), and the No. 2 fuel oil spill in West Falmouth,

NMED Exhibit 83

Massachusetts,in 1969 (Hampson and Sanders, 1969), both of which caused immediate death to a wide variety of organisms, are illustrative of the lethal toxicity that may be attributed to oil pollution. Similarly, a gasoline spill in South Dakota in November 1969 (Bugbee and Walter, 1973), was reported to have caused immediate death to the majority of freshwater invertebrates and 2500 fish, 30 percent of which were native species of trout. Because of the wide range of compounds included in the category of oil, it is impossible to establish meaningful 96-hour LC_{50} values for oil and grease without specifying the product involved. However, as the data in Table 6 show, the most susceptible category of organisms, the marine larvae, appear to be intolerant of petroleum pollutants, particularly the water soluble compounds, at concentrations as low as 0.1 mg/l.

The long-term sublethal effects of oil pollution refer to interferences with cellular and physiological processes such as feeding and reproduction which do not lead to immediate death of the organism. Disruption of such behavior apparently can result from petroleum product concentrations as low as 10 to 100 ug/l (see Table 7).

Table 7 summarizes some of the sublethal toxicities for various petroleum pollutants and various aquatic species. In addition to sublethal effects reported at the 10 to 100 ug/l level, it has been shown that petroleum products can harm aquatic life at concentrations as low as 1 ug/l (Jacobson and Boylan, 1973).

Bioaccumulation of petroleum products presents two especially important public health problems: (1) the tainting of edible, aquatic

NMED Exhibit 83

Table 6

Summary of lethal toxicities of various petroleum products to aquatic organisms (a thorough discussion of duration and test conditions is found in Moore, Dwyer & Katz, 1973)

TYPE ORGANISM	Soluble Hydrocarbons	Dispersants	#2 Fuel Oil/ Kerosene	Fresh Crude	Gasoline	Diesel Fuel	Refinery Effluents	Waste Oil	Lubricants	Residuals	Weathered Crude
Marine Flora	(29) (29) 10 ppm-650 ppm	(29) (31) 1.2 ppm-313 mg/l [ppm]	(31) <100 µl/l [ppm]	(31) Toxic to many salt marsh plants				(14) 10 ppm			(29) Coating more
Finfish	(29) (29) 5 ppm-50 ppm	(29) (29) 1 ppm->10,000 mg/l (ppm)	(40) 550 µg/ml (ppm)	(35) 88 mg/l (ppm) (31) 18 mg/l. [x10³ ppm]	(29) 91 ppm	(29) 284-420 ppm		(14) 2700 ppm		(29) 2000-510,000 mg/l [ppm]	Significant than lethal toxicity
Larvae and eggs	(29) (29) 0.1 ppm-1 ppm	(29) (29) 1 ppm-42 ppm	(31) 0.1 µl/l [ppm] (40) 4 µg/ml [ppm]	(31) 0.1 µl/l [ppm] (27) (29) 100 ppm				(14) 1->25ppm		(29) No effect reported	
Pelagic Crustacea	(29) (29) 1 ppm-10 ppm	(29) (29) 5 ppm-100 ppm	(29) (29) 5 ppm-50ppm	(29) 0.1 ml/l [x10³ ppm]- (29) 40 ppt [x10³ ppm]				(14) 15->50ppm			
Benthic Crustacea	(29) (29) 1 ppm-10 ppm	(29) (29) 2 ppm-100 ppm	(29) (29) 5 ppm-50 ppm	(15) 0.56 mg/l [ppm]						(29) >10,000 ppm	
Gastropods	(29)* (29)* 10 ppm-100 ppm	(29) (29) 5 ppm-2000 ppm	(29) (29) 50ppm-500ppm	(29) Toxicity reported for several species, but no concentration given.						(29) No effect reported	
Bivalves	(29) (29) 5 ppm-500 ppm	(29) (29) 0.5 ppm-100 ppm	(31) 30-40 ml/l [x10³ ppm]	(31) 1 ml/l [x10³ ppm]- (20) 10⁵ ppm						(29) Incorporation	
Other Benthic Invertebrates	(29) (29) 1 ppm-10 ppm	(29) (29) 5 ppm-100,000ppm	(29) (29) 5 ppm-50 ppm	(29) 100-5100 ppm						(31) 1,952-2,417 mg/l [ppm]	
Freshwater Finfish	(41) (34) 10 ppm-4,924 ppm	(31) 10 ppm	(31) 1,000-150,000 mg/l [ppm]	(12) 0.[illegible] mg/l [ppm] (30) 500 mg/l [ppm]	(26) [ppm] (31) 180 mg/l [ppm]	(31) 160-4000 mg/l [ppm]	(13) ~39 ppm		(31) 3000-180,000 mg/l [ppm]		
Freshwater Flora		(31) 200 ppm									
Mammals & Birds	Most lethal (or sub-lethal) effects are caused by physical coating, entanglement, ingestion of fine oil droplets, or incorporation of hydrocarbons through food chains.										

Note: 1) Numbers in brackets represent reported values (volume to volume or weight to volume basis) converted to ppm.
2) Numbers in parentheses refer to references.
3) Asterisks indicate values estimated by Moore, Dwyer, & Katz, 1973 (However estimates are supported by examples given therein)
4) In some cases, the above values have been taken from summary type presentations (for example: Moore, Dwyer & Katz, 1973); the corresponding reference numbers therefore do not necessarily refer to the original publication.
5) The manner in which the above values are reported is only an attempt to exemplify the ranges in threshold lethal toxicities, based on some of the existing published data, and should therefore not be regarded as absolute limits of toxicity for a given category of toxicant or test organism. It must be understood that there exists numerous additional published data that fall within the ranges suggested above, and possibly data that may suggest further widening these ranges. It is not the author's intention to herein summarize all of the toxicity values reported thus far for petroleum and petroleum products.

TABLE 7

SUMMARY OF SOME SUBLETHAL EFFECTS OF PETROLEUM PRODUCTS ON MARINE LIFE

TYPE ORGANISM	SPECIES	REFERENCE	TYPE PETROLEUM PRODUCT	CONCENTRATION	SUBLETHAL RESPONSE
Marine Flora					
	phytoplankton (Chlorella vulgaris)	Kauss, et al, 1972*2	crude Naphthelene	1ppm 3ppm	suppress growth Reduction of bicarbonate uptake
	phytoplankton (diatoms and dinoflagellates)	Mironov, 1970*1,2	"oil"	10^{-1} 10^{-4} ppm	Inhibition or delay in cellular division
	phytoplankton (Asterionella japonica)	Aubert, et al., 1969*1	Kerosene	3ppm; 3Fppm	Depression of growth rate
	phytoplankton (Phaeodactylum tricornutum)	Lacaze, 1967*1	Kuwait crude	"1 ppm"	Depression of growth rate
	phytoplankton (Monochrysis lutheri)	Strand, et al., 1971*1	Kuwait crude; dispersant emulsions	20-100 ppm	inhibition of growth; reduction of bicarbonate uptake at 50 ppm
	phytoplankton (Phaeodactylum tricornutum, Skeletonema costotum, Chlorella sp., Chlamydomonas sp.)	Nuzzi, 1973*1	Extracts of outboard motor oils, No. 6 fuel oil, No. 2 fuel oil.		
	phytoplankton	Gordon and Prouse, 1973*-	Venezuelan crude, No. 2 and 6 Fuel oils.	10-200 mg/l (ppm)	stimulation of photosynthesis at 10-30 mg/l decrease in photosynthesis at 100-200 Mg/l No. 2 fuel oil.
	Kelp (Macrocystis angustifolia	Wilber, 1968*2	Toluene	10 ppm	75% reduction in photosynthesis within 96 hr
	Lichen (Lichen pygmaea)	Brown, 1972*1	Kuwait crude, BP_{1002}	0.1-100 ppm	1 ppm emulsified decrease total C^{14} Fixation
Larvae and eggs	Pink Salmon fry (Oncorhynchus gorbuscha)	Rice, 1973	Prudhoe Bay crude	1.6 ppm	Avoidance effects, could have effect on migration behavior
	Black sea turbot (Rhombus maeoticus)	Mironov, 1967	"oil"	0.01 ppm	Irregularity and delay in hatching-resulting larvae deformed and inactive
	Plaice larvae (Pleuronectes platessa)	Wilson, 1970*2	BP 1002	0-10 ppm	Disruption of photomotor and feeding behavior
	Cod fish larvae (Gadus morrhua)	Kuhnhold, 1970*1	Iranian Crude	Aqueous extracts from 10^{2} ppm, 10^{-} ppm	Adverse effect on behavior leading to death
	Lobster larvae (Homarus americanus)	Wells, 1972*1	Venezuelan crude	6 ppm	delay molt to 4th stage
	Sea Urchin larvae (Strongylocentrotus [illegible])	Allen, 1971*2	extracts of Bunker C	0.1-1 ppm	interference with fertilized egg development
	Barnacle larvae (Balanus)	Mironov, 1970	"Oil"	.0-100 ml/l(ppm)	abnormal development
	Crab larvae (Pachygrapsus crassipes)	Mironov, 1970	"Oil"	10-100 ml/l(ppm)	initial increase in respiration

NMED Exhibit 83

SUMMARY OF SOME SUBLETHAL EFFECTS OF PETROLEUM PRODUCTS ON MARINE LIFE

TYPE ORGANISM	SPECIES	REFERENCE	TYPE PETROLEUM PRODUCT	CONCENTRATION	SUBLETHAL RESPONSE
FISH	Chinook salmon (Oncorhynchus tshawytscha) Striped Bass (Morone saxatilis)	Anderson & Bailey, 1973*1	Benzene	5, 10 ppm	Initial increase in respiration.
	Menidia menidia	Gardner, et al,1973	Crude (whole fraction) (water-soluble (water-insoluble	140 ppm (v/v) 12 ppm estimated 588 ppm (v/v)	Histological damage to chemoreceptors.
CRUSTACEANS	Lobster, (Homarus americanus)	Blumer, et al,1973	Crude, kerosene	10 ppm	Effects of chemoreception, feeding times, stress behavior, regression, growth
	Pollicipes polymerus	Straughan, 1971	Crude-Santa Barbara	Field study after blowout.	Apparent decrease in adult brooding; no recruitment in oiled areas.
	Lobster (H. americanus)	Atema and Stein, 1972	La Rosa Crude	Extracts	Delay in feeding.
	Pachygrapsus crassipes	Kittredge, 1971*1	Crude	Dilutions of diethyl ether extracts (1:100)	Inhibition of feeding.
	Uca pugnax	Krebs, 1973*1	No. 2 Fuel oil	Field observations after W.Falmouth spill	Adverse effects on sexual behavior.
MOLLUSCS	Mussel (Mytilus edulis)	Gilfillan,1973*2	Crude	1 ppm	Reduction in carbon budget (increase in respiration; decrease in feeding.)
	Snail (Nassarius absoletus)	Blumer, et al,1973	Kerosene	Saturated extract diluted 10^{10}	40% reductin in chemotactic perception of food.
	Snail (Nassarius obsoletus)	Jacobson & Boylan 1973	Kerosene	0.001 - 0.004 ppm	Reductin in chemotactic perception of food
	Clam (Mya arenaria)	Barry and Yevich, 1974	No. 2 fuel oil	collected from field	Gonadal tumors
	Oyster (Crassostrea virginica)	Mackin and Hopkins, 1961	Bleedwater		Reduced growth and glycogen content
	Snail (Littorina littorea)	Perkins, 1970*1	BP 1002	30 ppm	significant inhibition to growth
	Oyster (Crassostrea virginica)	Menzel, 1968; in Nelson-Smith, 1973	"oil"	0.01 ppm	market tainting
	Mussel (Mytilus edulis)	Blumer, et al, 1971*1	No. 2 fuel oil	collected from field after spill	Inhibition in development of gonads
OTHER BENTHIC INVERTEBRATES	Polychaeta (Capitella capitata)	Bellan, et al, 1973*1	Detergent	0.01-10 ppm	Decrease in survival, fecundity

NMED Exhibit 83

species, and (2) the possibility of edible marine organisms incorporating the high boiling, carcinogenic polycyclic aromatics in their tissues. Nelson-Smith (1971) reported that 0.01 mg/l of crude oil caused tainting in oysters. Moore, et al. (1973) reported that concentrations as low as 1 to 10 ug/l could lead to tainting within very short periods of time. It has been shown that chemicals responsible for cancer in animals and man (such as 3,4-benzopyrene) occur in crude oil (Blumer, 1970). It has also been shown that marine organisms are capable of incorporating potentially carcinogenic compounds into their body fat where the compounds remain unchanged (Blumer, 1970).

Oil pollutants may also be incorporated into sediments. There is evidence that once this occurs in the sediments below the aerobic surface layer, petroleum oil can remain unchanged and toxic for long periods, since its rate of bacterial degradation is slow. For example, Blumer (1970) reported that No. 2 fuel oil incorporated into the sediments after the West Falmouth spill persisted for over a year, and even began spreading in the form of oil-laden sediments to more distant areas that had remained unpolluted immediately after the spill. The persistence of unweathered oil within the sediment could have a long-term effect on the structure of the benthic community or cause the demise of specific sensitive important species. Moore, et al. (1973) reported concentrations of 5 mg/l for the carcinogen, 3,4-benzopyrene in marine sediments.

NMED Exhibit 83

Mironov (1967) reported that 0.01 mg/l oil produced deformed and inactive flatfish larvae. Mironov (1970) also reported inhibition or delay of cellular division in algae by oil concentrations of 10^{-4} to 10^{-1} mg/l. Jacobsen and Boylan (1973) reported a reduction in the chemotactic perception of food by the snail, Nassarius obsoletus, at kerosene concentrations of 0.001 to 0.004 mg/l. Bellen, et al. (1972) reported decreased survival and fecundity in worms at concentrations of 0.01 to 10 mg/l of detergent.

Because of the great variability in the toxic properties of oil, it is difficult to establish a numerical criterion which would be applicable to all types of oil. Thus, an application factor of 0.01 of the 96-hour LC50 as determined by using continuous flow with a sensitive resident species should be employed for individual petrochemical components.

There is a paucity of toxicological data on the ingestion of the components of refinery wastewaters by humans or by test animals. It is apparent that any tolerable health concentrations for petroleum derived substances far exceed the limits of taste and odor. Since petroleum derivatives become organoleptically objectionable at concentrations far below the human chronic toxicity, it appears that hazards to humans will not arise from drinking oil-polluted waters (Johns Hopkins University, 1956; Mckee and Wolf, 1963). Oils of animal or vegetable origin generally are non-toxic to humans and aquatic life.

NMED Exhibit 83

In view of the problem of petroleum oil incorporation in sediments, its persistence and chronic toxic potential, and the present lack of sufficient toxicity data to support specific criteria, concentrations of oils in sediments should not approach levels that cause deleterious effects to important species or the bottom community as a whole.

Petroleum and nonpetroleum oils share some similar physical and chemical properties. Because they share common properties, they may cause similar harmful effects in the aquatic environment by forming a sheen, film or discoloration on the surface of the water. Like petroleum oils, nonpetroleum oils may occur at four levels of the aquatic environment: (a) floating on the surface, (b) emulsified in the water column, (c) solubilized, and (d) settled on the bottom as a sludge. Analogous to the grease balls from vegetable oil and animal fats are the tar balls of petroleum origin which have been found in the marine environment or washed ashore on beaches.

Oils of any kind can cause: (a) drowning of waterfowl because of loss of buoyancy, exposure because of loss of insulating capacity of feathers, and starvation and vulnerability to predators due to lack of mobility, (b) lethal effects on fish by coating epithelial surfaces of gills, thus preventing respiration, (c) potential fish kills due to biochemical oxygen demand, (d) asphyxiation of benthic life forms when floating masses become engaged with surface debris and settle on the bottom, and (e) adverse aesthetic effects of fouled shorelines and beaches. These and other effects have been documented in the U. S. Department of Health, Education and Welfare report on "Oil Spills Affecting the Minnesota and Mississippi Rivers" and the 1975 "Proceedings of the Joint Conference on Prevention and Control of Oil Spills."

NMED Exhibit 83

Oils of animal or vegetable origin generally are chemically non-toxic to humans or aquatic life; however, floating sheens of such oils result in deleterious environmental effects described in this criterion.
Thus, it is recommended that surface waters shall be virtually free from floating non-petroleum oils of vegetable or animal origin. This same recommendation applies to floating oils of petroleum origin since they too may produce the above effects.

NMED Exhibit 83

DISSOLVED OXYGEN

CRITERIA:

Aesthetics: Water should contain sufficient dissolved oxygen to maintain aerobic conditions in the water column and, except as affected by natural phenomena, at the sediment-water interface.

Freshwater aquatic life: A minimum concentration of dissolved oxygen to maintain good fish populations is 5.0 mg/liter. The criterion for salmonid spawning beds is a minimum of 5.0 mg/liter in the interstitial water of the gravel.

INTRODUCTION:

Dissolved oxygen historically has been a major constituent of interest in water quality investigations. It generally has been considered as significant in the protection of aesthetic qualities of water as well as for the maintenance of fish and other aquatic life. Traditionally, the design of waste treatment requirements was based on the removal of oxygen demanding materials so as to maintain the dissolved oxygen concentration in receiving waters at prescribed levels. Sophisticated techniques have been developed to predict the dissolved oxygen concentration under various hydrologic, hydrographic, and waste loading conditions (Velz, 1970). Dissolved oxygen concentrations are an important gage of existing water quality and the ability of a water body to support a well balanced aquatic fauna.

RATIONALE:

The aesthetic qualities of water require sufficient dissolved oxygen present to avoid the onset of septic conditions with its attendant malodorous emissions. Insufficient dissolved oxygen in the water column causes the anaerobic decomposition of any organic materials present. Such decomposition tends to cause the formation of noxious gases such as hydrogen sulfide and the development of carbon dioxide and methane in the sediments which bubble to the surface or which tend to float settled sludge as mats which are composed of various organic materials.

Dissolved oxygen in bodies of water used for municipal water supplies is desirable as an indicator of satisfactory water quality in terms of low residuals of biologically available organic materials. In addition, dissolved oxygen in the water column prevents the chemical reduction and subsequent leaching of iron and manganese principally from the sediments (Environmental Protection Agency, 1973). These metals cause additional expense in the treatment of water or affect consumers' welfare by causing taste and staining plumbing fixtures and other surfaces which contact the water in the presence of oxygen (NAS, 1974).

NMED Exhibit 83

Dissolved oxygen also is required for the biochemical oxidation of ammonia ultimately to nitrate in natural waters. This reduction of ammonia reduces the chlorine demand of waters and increases the disinfection efficiency of chlorination (NAS, 1974).

The disadvantage of substantial quantities of dissolved oxygen in water used as a source of municipal water supply is the increased rates of corrosion of metal surfaces in both the water treatment facilities and in the distribution system (NAS, 1974).
Such corrosion, in addition to the direct damage, can increase the concentration of iron (and other metals) which may cause taste in the water, as well as staining.

A discussion of oxygen criteria for freshwater fish must take into account these facts: (1) fish vary in their oxygen requirements according to species, age, activity, temperature, and nutritional state; (2) they are found from time to time, and can survive for a while, at oxygen concentrations considerably below that considered suitable for a thriving population; and (3) although there is much literature on the oxygen consumption of fish and the effects of varying oxygen concentrations on behavior and survival, few investigators have employed methods or sought endpoints that can be related with confidence to maintaining a good fish population.

To allow for the differences among requirements affected by species and other variables, the dissolved oxygen criteria are based on the concentration that will support a well-rounded population of fish (Ellis, 1937) as it would occur under natural conditions. A population of fish is composed of a number of different but more or less interdependent species, of different feeding and reproductive habits, but which will include game and pan fish (bass, pike, trout, perch, sunfish, crappie, depending upon the location), some so-called rough or coarse fish (carp, buffalo, bullhead, sucker, chub), and large numbers of smaller 'forage' fish (e.g., minnows). Theoretically it should be possible to base oxygen criteria on the needs of the most sensitive component of such a population, but there is not enough information for this at present; that is why the criteria must be based on oxygen concentrations known to permit the maintenance and well-being of the population as a whole.

The requirement that the data be applicable to naturally occurring populations imposes limits on the types of research that can be used as a basis for the criterion. Aside from a few papers on feeding, growth, and survival in relation to oxygen concentration, very little of the laboratory-based literature has a direct bearing; field data are in general more useful. Field studies have the disadvantage that the numbers of variables encountered in the natural environment (temperature, pH, dissolved solids, food supply, and the like, as well as dissolved oxygen) make it necessary to be conservative in relating fish abundance and distribution to oxygen concentration alone, but enough observations have been made under a variety of conditions that the importance of oxygen concentration seems clear.

NMED Exhibit 83

Field studies, in which fish catches have been related to dissolved oxygen concentrations measured at the same time, indicate that a dissolved oxygen concentration of 3 mg/liter is too low to maintain a good fish population (Thompson, 1925; Ellis, 1937; Brinley, 1944), and this finding is supported by laboratory observations that in the vicinity of 3 mg/liter and below feeding is diminished or stopped (Lindroth, 1949; Mount, 1960; Herrmann, et al., 1962), and growth is reduced (Hamdorf, 1961; Itazawa, 1971), even when the lowered oxygen concentration occurs for only part of the day (Stewart, et al., 1967).

A dissolved oxygen concentration of 4 mg/liter seems to be about the lowest that will support a varied fish population (Ellis, 1937), even in the winter (Thompson, 1925), and for a well-rounded population including game fish it should be above that. Both Ellis (1937) and Brinley (1944) set the minimum for a well rounded population at 5 mg/liter. It should be pointed out, however, that Thompson found the greatest variety of species at 9 mg/liter, Ellis found good populations more frequently at 6 than at 5 mg/liter, and Brinley reported the best concentrations for game fish populations to be above 5 mg/liter. The belief that 5 mg/liter is adequate is supported by the fact that the introduced rainbow trout thrives in Lake Titicaca (Everett, 1973) where, because of the altitude, the oxygen concentration in fully saturated water is not over 5 mg/liter.

Fish embryonic and larval stages are especially vulnerable to reduced oxygen concentrations because their ability to extract oxygen from the water is not fully developed and they cannot move away from adverse conditions. Although many species can develop at oxygen concentrations as low as 2.5 to 3 mg/liter, the effects of a reduced oxygen concentration even as high as 5 or 6 mg/liter can cause a partial mortality or at the least retard development (Brungs, 1971; Siefert et al., 1973, 1974, 1975; Carlson et al., 1974; Carlson and Siefert, 1974; Garside, 1966; Gulidov, 1969; Hamdorf, 1961). Unless it is extreme, however, the retardation need not be permanent or detrimental to the species (Brannon, 1965; Eddy, 1972). For most fish, maintaining a minimum of 5 mg/liter in the water mass in the vicinity of the embryos and larvae should suffice.

Special treatment is required for species, such as the salmonids, that bury their fertilized eggs in gravel. The flow through gravel is often slow, especially if siltation has occurred, and if it is slow enough the developing fish and other organisms can easily deplete the oxygen supply enough to cause damage, especially if the concentration in the water is relatively low before it enters the gravel (Cooper, 1965; Coble, 1961; Brannon, 1965). With a permeable gravel and abundant flow, 5 mg/liter in the overlying water should be enough. This concentration could well be inadequate, however, with a less porous gravel and a slower flow. Since the permeability and flow have so important a bearing on the initial oxygen concentration required to maintain the intragravel concentration, and since these characteristics vary with location, it is proposed that the criterion for salmonid spawning beds be stated as not less than 5 mg/liter in the gravel. This would require that the concentration in the water entering the gravel be 5 mg/liter or more, increasing as the intragravel flow rate decreased.

NMED Exhibit 83

Decreased dissolved oxygen levels, if sufficiently severe, can adversely affect aquatic insects and other animals upon which fish feed. Sprague (1963) has evaluated such effects on several crustaceans while others have evaluated caddisfly larvae and stonefly nymphs (Doudoroff and Shumway, 1970). However, many other invertebrates are less sensitive to lowered dissolved oxygen concentrations and may be equally suitable fish food. Doudoroff and Shumway (1970) concluded that as long as dissolved oxygen concentrations remain entirely satisfactory for fish, no material impairment of the food resources for fish ascribable to dissolved oxygen insufficiency will occur.

NMED Exhibit 83

ALDRIN-DIELDRIN

CRITERIA:

.003 ug/l for freshwater and marine aquatic life.

The persistence, bioaccumulation potential and carcinogenicity of aldrin-dieldrin cautions human exposure to a minimum.

RATIONALE:

Since dieldrin is a highly persistent chemical which bioaccumulates in aquatic organisms used for human food and is also considered a potential human carcinogen, levels of dieldrin in waterways should be kept as low as feasible. Action by the Environmental Protection Agency in suspending the production and use of dieldrin should result in a gradual decrease in concentrations in the environment. Such additions should not be permitted without substantial documentation that alternatives are either infeasible or potentially more hazardous. The persistence, bioaccumulative properties and carcinogenic potential of dieldrin should be taken into account when determining the uses of water with measurable amounts of dieldrin.

Aldrin is metabolically converted to dieldrin by aquatic organisms. Residues in goldfish, Carassius auratus, exposed to aldrin for 32 days were found to consist of 93.9 percent or more dieldrin except for visceral fat where residues were 100 percent dieldrin after 31.5 to 92.4 days' exposure (Gakstatter, 1968). Epoxidation of aldrin to dieldrin was found to occur also at lower trophic levels. The relative rates of this conversion were low for algae and high for the protozoa (Kahn, et al., 1972). Because of this metabolic conversion and because of evidence that dieldrin is as toxic or slightly more toxic than aldrin to aquatic organisms

NMED Exhibit 83

(Jensen and Gaufin, 1966; Henderson, et al., 1959), an acceptable water concentration is based on the presence of either aldrin or dieldrin or the sum of both.

In two studies comprising five long-term oral studies feeding dieldrin to CF-1 mice at various concentrations, liver enlargements and tumors were detectable. Appearance of tumors was dose responsive since tumors occurred 9 months following treatment with 10 ppm; 19 months with 5 ppm; and 23 months with 2.5 ppm. Further, the group all experienced a decrease in survival rates. At intake rates of 1.25 ppm and 1 ppm dieldrin, no liver enlargements were detected clinically and survival was not affected (Walker, et al., 1972).

The best evidence that aldrin-dieldrin poses a cancer hazard to man is provided by mouse laboratory data. Although the liver was the principal organ affected in the mouse and was a major site of action in rats, there was an increase of tumors in the lungs and other organs (Keller, et al., 1974).

Ninety-six-hour LC50 values of 16, 7.9, and 8.5 ug/l dieldrin have been reported for the fathead minnow, Pimephales promelas; bluegill, Lepomis macrochirus; and green sunfish, Lepomis cyanellus, respectively (Tarzwell and Henderson, 1956).

The LC50 for the stonefly naiad, Acroneuria pacifica, exposed to dieldrin in a continuous flow bioassay system for 20 days was 0.2 ug/l (Jensen and Gaufin, 1966). The 48-hour EC50 (immobilization value at 15°C) for daphnids, Simocephalus serrulatus and Daphnia pulex, to dieldrin was 0.24 mg/l and 0.25 mg/l, respectively (Sanders and Cope, 1966).

NMED Exhibit 83

The sailfin molly, Poecilia latipinna, appears to be the most sensitive freshwater fish species tested for chronic effects; growth rates and reproductive performance were adversely affected during a 34-week exposure to dieldrin at 0.75 ug/l (Lane and Livingston, 1970). Guppy, Poecilia reticulata, populations were affected by levels of dieldrin at 1.8 ug/l water concentration during a 14-month exposure. Exposed populations developed greater total numbers of individuals than did controls. This phenomenon may have been caused by slight change in the feeding behavior of the adults induced by dieldrin, consisting of inhibition of the normal predation by the adults upon the fry (Cairns, et al., 1967).

Residue accumulation of dieldrin and aldrin is well documented. Levels of dieldrin in fish tissue from Lake Michigan have been as much as 100,000 times (wet weight basis) the dieldrin levels occurring in the water (Reinert, 1970). Lake water concentrations in Lake Michigan were in the 1 to 3 nanogram/liter range, and whole-fish concentrations ranged from a low of 0.03 ppm for lake whitefish to 0.20 ppm for lake herring, 0.23 ppm for bloater, and 0.28 ppm for kiyi. Laboratory exposures of fish, invertebrates, and algae have indicated that residue accumulation

NMED Exhibit 83

of aldrin and dieldrin is significant. The Reticulate sculpin, Cottus perplexus, exposed to 8.6, 1.7, 0.86, 0.17, 0.086, and 0.017 ug/l dieldrin in water for 32 days were found to have tissue concentrations (wet weight basis) often exceeding 50,000 times the water exposure level (Chadwick and Brockson, 1969). The sailfin molly, Poecilia latipinna, exposed for 34 weeks at 12, 6, 3, 1.5, and 0.75 ug/l dieldrin in water concentrated dieldrin in all tissues (wet weight basis) at least 10,000 times (Lane and Livingston, 1970). At the termination of a 64-week exposure of the ostracod, Chlamydotheca arcuata, to water concentrations of aldrin at 0.01 and 0.10 ug/l and dieldrin at 0.01 and 0.10 ug/l, dieldrin recovery from the tissue (dry weight basis) was 12,000 to 260,000 times the initial theoretical water concentrations (Kawatski and Schmulbach, 1971). In a model ecosystem study, residue accumulation factors (wet weight basis) for dieldrin were determined to be 114,935 times water concentration for the snail, 7,480 times water concentration for algae, 6,145 times water concentration for fish, 2,145 times water concentration for Daphnia, 1,280 times water concentration for Elodea, 247 times water concentration for the crab, and 1,015 times water concentration for the clam (Sanborn and Yu, 1973). In continuous flow exposure to less than 0.1 ug/l aldrin in water for a three-day period, residue accumulation factors (dry weight basis) were determined for cladocera, Daphnia magna, to be

NMED Exhibit 83

141,000 times water concentration; ephemeroptera, Hexagenia billineata, 31,400 times water concentration; and diptera, Chironomus sp., 22,800 times water concentration (Johnson, et al., 1971); for the alga, Scenedesmus obliquus, 1,282 times water concentration after 1.5 days; 13,954 times water concentration for Daphnia magna after 3 to 4 days, and an estimated 49,307 times water concentration for the guppy, Poecilia reticulata, after 18 days' exposure (Reinert, 1972).

In relating accumulation factors to the acceptable level of aldrin and dieldrin allowable in water, it is necessary to know the significance of tissue residue levels. Data on the toxicity of ingested levels of aldrin and dieldrin in aquatic organisms are few. In rainbow trout, Salmo gairdneri, fed dietary dieldrin dosages of 0.36, 1.08, 3.6, and 10.8 ug dieldrin per gram of food (ppm), brain concentrations of three amino acids associated with ammonia detoxifying mechanisms - glutamate, aspartate, and alanine - were significantly altered. In the two highest dosages the brain ammonia concentration increased (Mehrle and Bloomfield, 1974). The implication is that brain ammonia detoxifying mechanisms play an important role in maintaining ammonia values within physiological limits, and that fish carrying body burdens of dieldrin would be less tolerant to increased concentrations of ammonia in water.

Some data available on terrestrial vertebrates indicate that aldrin-dieldrin dietary levels as low as 1 ppm may produce observable effects. In long-term feeding studies 1 ppm dieldrin affected reproduction in the

NMED Exhibit 83

Hungarian partridge (Neill, et al., 1969). Slight eggshell thinning was noted in mallard ducks fed 3 ppm dieldrin (Lehner and Egbert, 1969). Deer were affected by long-term feeding at 2 ppm dieldrin (Murphy and Korschgen, 1970). A guideline of 0.3 ppm has been set by the Food and Drug Administration as an upper limit on food for human consumption.

Considering the 100,000-fold bioaccumulation of dieldrin in fish tissue from Lake Michigan cited above (Reinert, 1970) and the FDA tissue residue administrative guideline of 0.3 ppm as a maximum level for human consumption, the resulting maximum water level is 0.003 ug/l. This level is lower than the lowest measured 96-hour LC_{50} (7.9 ug/l for bluegill) by a factor of 0.0004, and lower than the 20 day LC_{50} for the stonefly, Acroneuria pacifica, by a factor of 0.02. It is therefore believed to provide an adequate level of protection for freshwater aquatic life.

In bioassays performed on the mullet, Mugilidae sp., death occurred for 15 percent of the test organisms at 0.5 ug/l dieldrin. When exposed to dieldrin at 1.35 ug/l for four days, fish were found to have degenerative changes in the gills and visceral tissue (Parrish, et al., 1973). A sensitive marine crab, Leptodius floridanus, exhibited delay in development at concentrations of 1 and 0.5 ug/l dieldrin (Epifanio, 1971). At 1 ug/l dieldrin there was a 70 percent mortality of pink shrimp, Penaeus duorarum, within 24 hours and the 96-hour LC_{50} was 0.7 ug/l for the same organism (Parrish, et al., 1973).

A residue accumulation factor of 800 times water concentration (wet weight basis) was found for the estuarine mollusc, Rangia cuneata, for a

NMED Exhibit 83

36-hour exposure with a maximum accumulation factor of 2,000 times water concentration in a 72-hour exposure to dieldrin. The clam showed "no evidence for a cessation of the uptake mechanism over a period of time up to 72 hours" (Petrocelli, et al., 1973). At a water concentration of 0.5 ug/l it was determined that the rate of dieldrin uptake from water by crab larvae, Leptodius floridanus, was 0.191 ppm per day from water (Epifanio, 1973). Bioconcentration factors in estuarine organisms exposed for 96-hours to dieldrin ranged from 2,400 to 21,500 for oysters; 280 to 420 for pink shrimp; 470 to 750 for grass shrimp; and 3,500 to 7,300 for sheepshead minnows (Parrish, et al., 1973). Concentration factors in spot exposed to dieldrin for 35 days were as great as 113,000 in liver, 11,000 in muscle and 6,000 in whole fish. Spot lost all detectable dieldrin after 13 days in dieldrin-free sea water (Parrish, et al., 1973). Marine phytoplankton exposed for two hours have been shown to accumulate dieldrin (Rice and Sikka, 1973). In a study designed to investigate the accumulation and metabolism of dieldrin by species representing different taxonomic divisions of marine phytoplankton, concentration factors observed were: Skeletonema costatum (Bacillariophyta), 15,882; Cyclotella nana (Bacillariophyta), 4,810; Tetraselmis chuii (Euglenophyta), 8,588; Isochrysis galbana (Chrysophyta), 8,238; Olisthodiscus luteus (Xanthophyta), 4,900; and Amphidinium carteri (Pyrrophyta), 982.

No data on bioaccumulation from the environment are available for marine fish. In the absence of such data, there is no reason to assume that the accumulation factor for marine fish would be less than that observed for Lake Michigan fish. Therefore, the freshwater criterion of 0.003 ug/l is also recommended for marine aquatic life.

NMED Exhibit 83

CHLORDANE

CRITERIA:

0.01 ug/l for freshwater aquatic life.
0.004 ug/l for marine aquatic life.

The persistence, bioaccumulation potential and carcinogenicity of chlordane cautions human exposure to a minimum.

RATIONALE:

Since chlordane is a highly persistent chemical which bioaccumulates in aquatic organisms used for human food and also is considered a potential human carcinogen (Train, 1974), levels of chlordane in waterways should be kept as low as feasible. The December 24, 1975 action by the Environmental Protection Agency in suspending the production and use of chlordane should result in a gradual decrease in concentrations in the environment. Such additions should not be permitted without substantial documentation that alternatives are either infeasible or potentially more hazardous. The persistence, bioaccumulative properties and carcinogenic potential of chlordane should be taken into account when determining the uses of water with measurable amounts of chlordane.

Literature references indicate the existence of an extremely wide range for the acute toxicity of chlordane to various species of freshwater fishes. As recorded, these values for 24- to 96-hour exposures range from 5 to 3,000 ug/l (Cardwell, et al., 1975; Katz, 1961; Lawrence, 1950; National Technical Advisory Committee, 1968; Clemens and Sneed, 1959; Macek, et al., 1969). Physical conditions varied among the tests reported and, in addition, most were conducted under

NMED Exhibit 83

static conditions and actual water concentrations were not measured. Although individual acute toxicity values may be questionable, some tests using several species under uniform conditions indicate that variability of experimental techniques alone cannot account for the wide range of values published. A recent study by Cardwell, et al., (1975) utilizing flow-through systems and measured concentrations of chlordane yielded 96-hour LC50 values of 37, 47, and 59 ug/l for fathead minnows, brook trout, and bluegills, respectively. These values fall within the range of the majority of acute toxicity values reported in the literature. The most sensitive fish reported was the pike, which suffered distress after 24 hours at 5 ug/l and 100 percent mortality within this period at 50 ug/l (Ludemann and Neumann, 1962).

Published acute toxicity values for U.S. freshwater invertebrates are similar to those for fishes and range from 4 to 10,000 ug/l (Cardwell, et al., 1975; Naqvi and Ferguson, 1969; National Technical Advisory Committee, 1968; Sanders 1969, 1972). Daphnia magna and Hyallela azteca tested under flow-through conditions yielded 96-hour LC50 values of 28 and 97 ug/l (Cardwell, et al., 1975), falling within the range of the majority of values reported for acute toxicity to invertebrates. The most sensitive species reported was the glass shrimp, Palaemonetes kadiakensis, with 96-hour LC50 values of 10 and 4 ug/l, respectively, in static versus flow-through bioassays (Sanders, 1972). Ludemann and Neumann (1962) found that Chironomus larvae had a 24-hour static test LC50 value of 10 ug/l.

NMED Exhibit 83

Cardwell, et al. (1975), conducted long-term flow-through studies which included reproduction and survival of progeny with several aquatic species. Statistically significant detrimental effects could not be measured at concentrations of 0.5 ug/l (bluegills), 0.7 ug/l (Chironomus No. 51, a midge), 5 ug/l (Hyallela azteca), and 12 ug/l (Daphnia magna). Survival of brook trout larvae to 12 days was reduced by 35 percent at 0.3 ug/l (the lowest concentration tested) but overall effects were decreasing at this level.

Available acute toxicity values indicate that individual species of both fishes and invertebrates vary greatly in sensitivity to chlordane but both groups are within the same general range. Most of these acute toxicity values are also nearer to the lower limits of this sensitivity range. Data for the application factors derived using acute and sub-chronic toxicity concentrations are limited to the study by Cardwell, et al. (1975). These factors were 0.009 and less than 0.008 for the fishes and 0.381 and 0.055 for the invertebrates.

Nominal pesticide concentrations in the water were reported for these tests. The true concentrations of chlordane may have been somewhat lower as Cardwell, et al. (1975), found that concentrations could not be maintained above half of nominal even when the test water was continually replaced. Therefore, the water quality criterion should be set lower than the calculated value using the experimentally determined application factor (0.009 X 5.0 ug/l = 0.045 ug/l). For this reason the calculated value for chlordane is xxxxxxxxxx lowered to a recommended concentration in freshwater that should not exceed 0.01 ug/l. If the proposed freshwater water quality criterion of 0.01 is not exceeded it is estimated that levels reached in freshwater

NMED Exhibit 83

fishes should seldom be greater than 1.0 mg/kg. Based on present knowledge, it is not anticipated that a concentration of this magnitude would be detrimental to piscivorous birds.

Michael, et al. (1956), found that the time required to kill one-half of the brine shrimp, Artemia salina, nauplii exposed to 10 ug/l was 2-3 hours. Butler, et al. (1960), determined that 24 hours' exposure of the oyster, Crassostrea virginica, to 10 ug/l chlordane produced growth inhibition.

Korn and Earnest(1974) found the 96-hour LC50 of chlordane to be 11.8 ug/l for the striped bass, Morone saxatilis. Butler (1963) reported the following 48-hour LC50 values: brown shrimp, Penaeus aztecus -- 4.4 ug/l; juvenile blue crabs, Callinectes sapidus -- 480 ug/l; and juvenile white mullet, Mugil curema -- 5.5 ug/l. Parrish, et al. (In Press), reported the following 96-hour LC50 values: pink shrimp, Penaeus duorarum -- 0.4 ug/l; grass shrimp, Palaemonetes pugio -- 4.8 ug/l; sheepshead minnow, Cyprinodon variegatus -- 24.5 ug/l; and the pinfish, Lagodon rhomboides -- 6.4 ug/l. The EC50 for shell deposition by the eastern oyster, Crassostrea virginica, was found to be 6.2 ug/l. The most sensitive marine species tested was the pink shrimp, Penaeus duorarum, for which a 96-hour LC50 of 0.4 ug/l was reported.

It appears that reported concentrations of "total chlordane" in fishes have been calculated from measurements of one or two of its major components under the assumption that the ratio of components was similar in both the parent compound and the tissue residues. More

NMED Exhibit 83

sophisticated analytical techniques currently available indicate that this assumption is in error and, in addition, the components in tissue residues may have been incorrectly quantified. Fishes can concentrate chlordane directly from water by a factor of 1000 to 3000 times and invertebrates may concentrate to twice this magnitude (Cardwell, et al., 1975). Data on the bioaccumulation of chlordane by estuarine organisms have been reported by Parrish, et al. (In Press). In the 96-hour test, chlordane concentration factors were 3,200 to 8,300 in oysters, Crassostrea virginica ; 4,000 to 6,000 in pink shrimp, Penaeus duorarum ; 1,900 to 2,300 in grass shrimp, Palaemonetes pugio ; 12,600 to 18,700 in pinfish, Lagodon rhomboides . Schimmel, et al.,(In Press), exposed estuarine fishes to trans-chlordane for 96 hours and reported concentration factors ranging from 3,700 to 6,800 in edible portions. Reported concentrations of 10 to 100 ug/kg were common in fish samples obtained throughout the U.S. and a few residues above 1000 ug/kg were observed (Henderson, et al., 1969 and 1971). Corresponding water concentrations are not available, but measurements above nanogram/liter levels have seldom been found in natural waters except near the discharges of manufacturing and formulating operations (Barthel, et al., 1969; Casper, 1967; Godsil and Johnson, 1968). Therefore, allowing for errors in residue measurements and lack of direct correlation, the possibility exists that fishes can concentrate chlordane up to 100,000 times the ambient water concentration. High rates of accumulation could occur in higher trophic level organisms through multiple steps in the food chain although evidence directly related to chlordane is not available to support this hypothesis.

NMED Exhibit 83

Based on the persistence, bioaccumulation potential and carcinogenicity of chlordane, an application factor of .01 is applied to the most sensitive marine aquatic species, the pink shrimp. This results in a marine criterion of .004 ug/l.

NMED Exhibit 83

Chlorophenoxy Herbicides
2, 4-D; 2, 4, 5-TP

CRITERIA:

2, 4-D	100 ug/l	for domestic water supply (health)
2,4,5-TP	10 ug/l	for domestic water supply (health)

RATIONALE:

Two widely used herbicides are 2, 4-D (2, 4-dichlorophenoxyacetic acid) and 2, 4, 5-TP (silvex) [2-(2, 4, 5-trichlorophenoxy) propionic acid]. Each of these compounds is formulated in a variety of salts and esters that may have a marked difference in herbicidal properties, but all are hydrolyzed rapidly to the corresponding acid in the body.

The subacute oral toxicity of chlorophenoxy herbicides has been investigated in a number of species of experimental animals (Palmer and Radeleff, 1964; Lehman, 1965). The dog was found to be sensitive and often displayed mild injury in response to doses of 10 mg/kg/day for 90 days, and serious effects from a dose of 20 mg/kg/day for 90 days. Lehman (1965) reported that the no-effect level of 2, 4-D is 0.5 mg/kg/day in the rat, and 8.0 mg/kg/day in the dog.

NMED Exhibit 83

Data are available on the toxicity of 2, 4-D to man. A daily dosage of 500 mg (about 7 mg/kg) produced no apparent ill effects in a volunteer over a 21-day period (Kraus, 1946). When 2, 4-D was investigated as a possible treatment for disseminated coccidioidomycosis, the patient had no side effects from 18 intravenous doses during 33 days; each of the last 12 doses in the series was 800 mg (about 15 mg/kg) or more, the last being 2000 mg (about 37 mg/kg) (Seabury, 1963). A nineteeth and final dose of 3600 mg (67 mg/kg) produced mild symptoms.

Table 8 illustrates the derivation of the criteria for the two chlorophenoxy herbicides most widely used. The long-term no-effects levels (mg/kg/day) are listed for the rat and the dog. These values are adjusted by a factor of 1/500 for 2, 4-D and 2, 4, 5-TP. The safe levels are then readjusted to reflect total allowable intake per person. Since little 2, 4-D or 2, 4, 5-TP is expected to occur in foods, 20 percent of the safe exposure level can reasonably be allocated to water without jeopardizing the health of the consumer.

NMED Exhibit 83

TABLE 8. DERIVATION OF APPROVAL LIMITS (AL) FOR CHLOROPHENOXY HERBICIDES

Compound	Lowest Long-Term Levels with Minimal or No Effects		Calculated Maximum Safe Levels From all Sources of Exposure			Water	
	Species	mg/kg/day[a]	Safety Factor (X)	mg/kg/day	mg/man/day[b]	% of Safe Level	AL mg/l[c]
2,4-D	Rat	0.5**	1/500	0.1	7.0	20	0.1
	Dog	8.0 **	1/500	0.016	1.12[d]		
2,4,5-TP	Rat	2.6 *	1/500	0.005	0.35	20	0.01
	Dog	0.9 *	1/500	0.002	0.14[d]		

[a] Assume weight of rat = 0.3 kg and of dog = 10 kg; assume average daily food consumption of rat = 0.05 kg and of dog = 0.2 kg.

[b] Assume average weight of human adult = 70 kg.

[c] Assume average daily intake of water for man = 2 liters.

[d] Chosen as basis on which to derive AL.

NMED Exhibit 83

CRITERION:

0.001 ug/l for freshwater and marine aquatic life.

The persistence, bioaccumulation potential and carcinogenicity of DDT cautions human exposure to a minimum.

RATIONALE:

In general, DDT (1,1,1-trichloro-2,2-bis(p-chlorophenyl)ethane) refers to DDT and its metabolites. Acute toxicity to mammals generally is low; however, aquatic organisms exhibit sensitivity to this pesticide at levels in micrograms per liter. Such levels range from a 96-hour LC_{50} of 0.24 ug/l for the crayfish, Orconectes nais (Sanders, 1972), to a 96-hour LC_{50} of 2 ug/l for the largemouth bass, Micropterus salmoides (Macek and McAllister, 1970), to a 96-hour LC_{50} of 27 ug/l for the goldfish, Carassius auratus (Henderson, et al., 1959).

Since DDT is a highly persistent chemical which bioaccumulates in aquatic organisms used for human food and also is considered a potential human carcinogen (Train, 1975), levels of DDT in waterways should be kept as low as feasible. Action by the Environmental Protection Agency in suspending the production and use of DDT should result in a gradual decrease in concentrations in the environment. Such additions should not be permitted without substantial documentation that alternatives are either infeasible or potentially more hazardous. The persistence, bioaccumulative properties and carcinogenic potential of

NMED Exhibit 83

DDT should be taken into account when determining the uses of water containing measurable amounts of DDT.

Two- to 4-day LC50's for freshwater aquatic invertebrates and fish exposed to DDT in water generally have ranged in the low microgram per liter levels with the invertebrates being somewhat more sensitive (Sanders, 1969; Sanders, 1972; Sanders and Cope, 1966 and 1968 Henderson, et al, 1959; Macek and McAllister, 1970). The most sensitive freshwater organism for which there are data is the crayfish, Orconectes nais, which had a 96-hour LC50 of 0.24 ug/l (Sanders, 1972). Of marine organisms the most sensitive are the shrimp, Penaeus duorarum and P. setiferus, for which no survival was observed at 0.12 ug/l after 28 days' exposure and 30 percent mortality observed at 0.05 ug/l after 56 days (Nimmo, et al., 1970)

DDT will accumulate in the food chain. Field data where pesticide levels in both the water and aquatic organisms have been measured depict the quantity attributable to this bioaccumulation. A residue accumulation of up to two million times was calculated for fish from the field data of Reinert (1970). The measured DDT water concentration in his study of Lake Michigan was in the nanogram per liter range. This accumulation is 20 times greater than that observed in the National Water Quality Laboratory, Duluth, Minnesota, where residue accumulation of 100,000 times was observed. If one uses a two million times residue accumulation factor and a DDT water concentration of 0.002 ug/l an expected DDT body burden of 4 mg/kg (ppm) in fish would result.

Other studies show that measurable quantities of DDT can be found in natural waters of North America. DDT averaged 0.02 ug/l in the San Diego River, California, in the spring-fall dry weather flow of 1973 (Young and Beeson, 1974). DDT in ocean water along the west coast has ranged from 0.0023 to 0.0056 ug/l (Cox, 1971). Rivers flowing

into estuaries (Brazos and Colorado in Texas) each have a two-year average of 0.03 ug/l (Manigold and Schulze, 1969).

In laboratory studies, Hansen and Wilson (1970) found that the bio-accumulation factor from water to pinfish, Lagodon rhomboides, was 10,000 times and to Atlantic croaker, Micropogon undulatus, 38,000 times, or an average of about 25,000 times for these fishes. The discrepancy between laboratory and field data may be due to the many additional trophic levels involved in field exposures.

In controlled studies, Heath, et al. (1969) determined that DDE, in concentrations of 10 and 40 ppm DDE in dry feed, impaired reproductive success of penned mallards, Anas platyrhynchos. Eggshells of birds exposed to these concentrations were 13 percent thinner, with 25 percent of the eggs showing cracking after one month. DDT induced thinning of shells at a concentration of 25 ppm with an 18 percent cracking of the shells. Since DDT metabolizes to DDE, eggshell thinning may be partly due to DDE. The association of DDE residues with eggshell thinning was shown for the brown pelican, Pelecanus occidentalis (Blus, et al., 1972). The level of DDE in the eggs which did not produce a significant effect, i.e., thinning, was estimated to be 0.5 mg/kg. However, from the data presented, 2.0 mg/kg represents a conservative estimate of the no-effect level in the eggs.

Feeding studies have shown that black ducks fed DDT in food produced eggs containing residues of about ten-fold the DDT in the diet. Furthermore, a continuous diet of 3.0 mg/kg (wet weight) in natural food

NMED Exhibit 83

adversely affected reproduction (Longcore, et al., 1971). Extrapolating the egg concentration data in ducks to pelicans, an estimate can be made that the diet of pelicans should contain no more than 0.1 the estimated (2.0 mg/kg) no-effect level of DDT in eggs, or about 0.2 mg/kg.

Based on the considerations of bioaccumulation potential in fish, likelihood of conversion to DDE, and dosage levels known to adversely affect birds, it is recommended that DDT concentrations in water should not exceed 0.001 ug/l.

NMED Exhibit 83

CRITERION:

0.1 ug/l for freshwater and marine aquatic life

RATIONALE:

Static LC_{50} bioassays yielded toxicity values for the organophosphorus pesticide, demeton, for carp, goldfish, fathead minnow, channel catfish, guppy, rainbow trout, and bluegill, ranging from 70 ug/l to 15,000 ug/l (Henderson and Pickering, 1958; Ludemann and Neumann, 1962; Macek and McAllister, 1970; McCann and Jasper, 1972; Pickering, et al., 1962). Results of these tests demonstrate an apparent sharp division in species sensitivity, with bluegill, Lepomis macrochirus; rainbow trout, Salmo gairdneri; and guppy, Poecilia reticulata, being susceptible to lower concentrations while the remaining species were comparatively resistant. In the 96-hour exposures toxicity did not increase significantly with time, indicating that concentrations close to nominal may not have been maintained for more than a few hours. Bluegills with a 24-hour LC_{50} of 70 ug/l were the most sensitive fish (McCann and Jasper, 1972).

When fish were exposed to acutely toxic levels of demeton for 12 hours by Weiss (1959 and 1961) the maximum inhibition of brain acetylcholinesterase (AChE) was not reached. The lowest levels of AChE occurred after 24 to 48 hours. It was demonstrated that maximum inhibition could last as long as two weeks after exposure, and subsequent recovery to

NMED Exhibit 83

levels approaching normal took many more weeks. Weiss (1958) reported a significant increase in mortality of fathead minnows exposed for a second time to the organophosphate, Sarin, before the fish had recovered normal brain AChE levels. The resistance of fully recovered fish was equal to that of previously unexposed controls. Weiss and Gakstatter (1964a) reported no significant inhibition of brain AChE in bluegills, goldfish, and shiners, Notemigonus crysoleucas, following 15-day exposures to demeton at continuously replenished, nominal concentrations of 1 ug/l.

Acute toxicity values reported for invertebrates range from 10 to 100,000 ug/l (Ludemann and Neumann, 1962; Sanders, 1972). In general, molluscs and tubifex worms were very resistant while the smaller crustaceans and insect larvae were susceptible. Ludemann and Neumann (1962) reported that Chironomus plumosus larvae were the most sensitive species they tested. A 24-hour exposure at 10 ug/l produced undefined effects while 100 percent were killed at 1000 ug/l. Calculated LC_{50} data for invertebrates apparently are limited to a single, nominal concentration static exposure of Gammarus fasciatus (Sanders, 1972). These 24- and 96-hour LC_{50} values are reported as 500 and 27 ug/l, indicating a time-related effect not observed in the bioassays with fishes. As only a few of the sensitive species have been tested and great variance in response can result with different test methods, caution must be exercised in estimating the sub-acute concentration for aquatic fauna in general. It appears that no study has been made of possible residual effects, other than AChE inhibition, which might result from short exposures to sub-acute concentrations of organophosphates.

NMED Exhibit 83

There are few data on the toxicity of demeton to marine organisms. Butler (1964) reported a 48-hour EC_{50} of 63 ug/l for the pink shrimp, Penaeus duorarum, and a 24-hour LC_{50} of 550 ug/l for the spot, Leiostomus xanthurus.

Chronic demeton toxicity data for freshwater organisms are not currently available. Since there are no data available at this time to indicate long-term no-effect levels for aquatic organisms, a criterion must be derived based partly on the fact that all organophosphates inhibit the production of the AChE enzyme. Demeton is unique, however, in that the persistence of its AChE inhibiting ability is greater than that of ten other common organophosphates, even though its acute toxicity is apparently less. The effective "half-life" of AChE inhibition for demeton is greater than one year (Weiss and Gakstatter, 1964b). Because such inhibition may be additive with repeated exposures and may be compounded by any of the organophosphates, it is recommended that a criterion for demeton be based primarily on its enzyme-inhibiting potential. A criterion of 0.1 ug/l demeton for freshwater and marine aquatic life is recommended since it will not be expected to significantly inhibit AChE over a prolonged period of time. In addition, the criteria recommendation is in close agreement with the criteria for the other organophosphates.

NMED Exhibit 83

ENDOSULFAN

CRITERIA:

0.003 ug/l for freshwater aquatic life;

0.001 ug/l for marine aquatic life.

RATIONALE:

The acute toxicity of endosulfan (also known as thiodan) to different fish species varies widely. Macek, et al. (1969) exposed rainbow trout, Salmo gairdneri, to endosulfan at three temperatures and computed 24-hour and 96-hour LC50s. At 1.6° C, 7.2° C, and 12.7° C the 24-hour LC50's were 13, 6.1, and 3.2 ug/l, respectively. The corresponding 96-hour LC_{50} values were 2.6, 1.7, and 1.5 ug/l. Schoettger (1970), however, reports the 96-hour LC_{50} for rainbow trout to be 0.8 ug/l at 1.5° C and 0.3 ug/l at 10° C. He also determined the 96-hour LC_{50} for the western white sucker, Castostomus commersoni, to be 3.5 ug/l at 10° C and 3.0 ug/l at 19° C.

A massive fish kill in the Rhine River was attributed to a maximum concentrations of 0.7 ug/l endosulfan (Greve and Wit, 1971). The 96-hour LC_{50} at 20° C in a static bioassay using the guppy, Poecilia reticulata, was 4.2 ug/l based on the computed concentration. The measured concentration was only 0.2 ug/l (Herzel and Ludemann, 1971).

The 24-, 48-, and 96-hour LC_{50s} for the amphipod, Gammarus lacustris, were found to be 9.2, 6.4, and 5.8 ug/l (Sanders, 1969). Sanders and Cope (1968) determined the 24-, 48-, and 96-hour LC50's for naiads of the stonefly, Pteronarcys

NMED Exhibit 83

californica, to be 24, 5.6, and 2.3 ug/l, respectively. The 96-hour LC_{50} for Gammarus fasciatus was found to be 6.0 ug/l (Sanders, 1972).

No data are available on the levels to which endosulfan could be expected to accumulate in tissues of aquatic organisms at various water concentrations. Residues in fish are not anticipated to pose a hazard to fish-eating predators because of endosulfan's low oral toxicity to birds (Heath, et al., 1972) and mammals (Lindquist and Dahm, 1957). The U.S. Food and Drug Administration has not set allowable limits for endosulfan in edible fish tissues.

A 0.01 application factor applied to the lowest measured 96-hour LC_{50} for the rainbow trout (which appears to be the most sensitive native freshwater organism) results in a freshwater criterion of 0.003 ug/l.

Portman and Wilson (1971) determined the acute toxicity of endosulfan to a marine fish and several invertebrates by means of static bioassays. The 48-hour LC_{50} for the ~~pogge~~ a fish, Agonus cataphractes, was 30 ug/l; the 48-hour LC_{50} for a mussel, the European cockle, Cardium edule, was greater than 10,000 ug/l; the 48-hour LC_{50} for the shrimp, Crangon crangon, was 10 ug/l.

Butler (1963) reported a 48-hour EC_{50} death or loss of equilibrium of 0.2 ug/l for the brown shrimp, Penaeus aztecus, a 48-hour EC_{50} for juvenile blue crabs, Callinectes sapidus, of 35 ug/l; and a 48-hour EC_{50} of 0.6 ug/l for juvenile white mullet, Mugil curema. A concentration of 65 ug/l resulted in a 50 percent decrease in shell growth of the American oyster, Crassostrea virginica, at 28° C and a salinity

NMED Exhibit 83

of 22 o/oo. Korn and Earnest (1974) report a 96-hour LC_{50} of 0.1 ug/l for the striped bass, Morone saxatilis.

Use of an application factor of 0.01 times the 96-hour LC_{50} of the most sensitive marine organism tested, the striped bass, results in a marine criterion of 0.001 ug/l.

NMED Exhibit 83

ENDRIN

CRITERIA:

0.2 ug/l for domestic water supply (health);

0.004 ug/l for freshwater and marine aquatic life.

RATIONALE:

The highest level of endrin found to have minimal or no long-term effects in the most sensitive animal tested, the dog, is 1.0 mg/kg in the diet or 0.02 mg/kg of body weight/day (Treon, et al., 1955). Where adequate human data are not available for corroboration of the animal results, the total "safe" intake level is assumed to be 1/500 of the "no effect" or "minimal effect" level reported for the most sensitive animal tested.

Applying the available data and based upon the assumptions that 20 percent of the total intake of endrin is from drinking water, that the average person weighs 70 kg and consumes 2 liters of water per day, the formula for calculating a criterion is .02 mg/kg x 0.2 x 70 kg x 1/500 x 1/2 = .00028 mg/l thus deriving the criterion level for domestic water supply of 0.2 ug/l.

Toxicity data for the flagfish, Jordanella floridae, indicate that the "safe" concentration as determined in a long-term exposure involving reproduction is about 0.30 of the 96-hour LC_{50} (Hermanutz, 1974). Ninety-six-hour LC50's for some of the sensitive freshwater fish tested are as follows: bluegills, 0.6 ug/l (Henderson, et al., 1959); rainbow trout, 0.6 ug/l and coho salmon, 0.5 ug/l (Katz, 1961); juvenile striped bass (freshwater and estuarine life-phase), 0.094 ug/l (Korn and Earnest, 1974);

NMED Exhibit 83

cutthroat trout, 0.113 ug/l (Post and Schroeder, 1971). Therefore, the estimated "safe" water concentrations for these sensitive fish, based on the flagfish application factor is approximately 0.03 to 0.18 ug/l.

Stonefly naiads appear to be the most sensitive invertebrates tested. Jensen and Gaufin (1966) found the 30-day LC_{50} for the naiad, Acroneuria pacifica, to be 0.035 ug/l. Based on these data, the safe water concentration should be less than 0.035 ug/l to fully protect stoneflies throughout their entire life cycle, as well as organisms more sensitive than those that have been tested.

Fathead minnows, Pimephales promelas, exposed to 0.015 ug/l in the ambient water had total body residues 10,000 times greater than the water concentrations (Mount and Putnicki, 1966). Residue accumulation up to 10,000-fold was observed in flagfish exposed for 60 days to several concentrations between 0.05 and 0.3 ug/l (Hermanutz, 1974). Concentration factors for estuarine organisms exposed to endrin for 96-hours were a maximum of 1,600 in oysters, 1,100 in pink shrimp, 860 in grass shrimp, 4,500 in sheepshead minnows and 2,500 in the sailfin molly (Schimmel, et al., 1975). Johnson (1967) calculated the concentration in adult medeka tissue to be 17,000 to 26,000 times the water concentration. It is quite possible that some fish would accumulate endrin to 30,000 times water concentration. This degree of accumulation is based only on observations of uptake directly from the water and does not allow for accumulation via the food chain or significantly higher accumulation rates possible in other, untested fish species.

Endrin has been found to be eliminated quickly after termination of exposure. Channel catfish tissue residues were reduced

from 0.41 to 0.02 ug/g (about 95 percent reduction) within 13 days after the addition of endrin to the water was stopped (Argyle, et al., 1973). Marine spot tissue residues of 78.0 ppb were reduced below detection levels within 13 days (Lowe, 1966). Recent unpublished data showing that flagfish eliminated about 95 percent in five days support this observation. This apparent ability to excrete endrin readily may reduce the threat of extremely high residue accumulations.

Levels of 0.1 ug/l have been shown to be 100 percent lethal to the marine spot, Leiostomus xanthuras, within five days, while approximately half the population survived at a level of 0.075 ug/l after 19 days (Lowe, 1966).

Davis and Hidu (1969) reported the 48-hour TLm of American oyster eggs to be 0.79 mg/l and the 14-day TLm for larvae to be greater than 10 mg/l.

Eisler (1969) determined the following 96-hour LC_{50} values: Sand shrimp, Crangon septemspinosa - 1.7 ug/l; grass shrimp, Palaemonetes pugio - 1.8 ug/l; and hermit crab, Pagurus longicarpus - 12 ug/l. The following 96-hour LC_{50} values were reported by Eisler (1970): Atlantic silverside, Menidia menidia - 0.05 ug/l; blue head, Thalassoma bifasciatum - 0.1 ug/l; striped killifish, Fundulus majalis - 0.3 ug/l; striped mullet, Mugil cephalus - 0.3 ug/l; American eel, Anguilla rostrata - 0.6 ug/l; mummichog, Fundulus heteroclitus - 0.6 ug/l; and Northern puffer, Sphoeroides maculatus - 3.1 ug/l. **The 96-hour LC50 for striped bass was 0.094 µg/l**

NMED Exhibit 83

(Korn and Earnest, 1974), shiner perch, Cymatogastes aggregata, 0.12 ug/l and dwarf perch, Micrometrus minimus, 0.13 ug/l (Earnest and Benville, 1972). Ninety-six hour LC50's based on measured concentrations were 0.63 ug/l for sailfin mollies, Poecilia latipinna, 0.38 ug/l for sheepshead minnow, Cyprinodon variegatus, 0.63 ug/l for grass shrimp, Palaemonetes pugio, and 0.037 ug/l for pink shrimp, Penaeus duorarum (Schimmel, et al., 1975). Data on the effects of endrin in an exposure throughout the entire life cycle of the sheepshead minnow indicate that a "safe" concentration to protect for reproductive effects would be about 0.3 of the 96-hour LC50 (Hansen, In Press). An application factor of 0.01 of the 96-hour LC50 may be over protective. Therefore, for endrin this factor should be 0.1. Based on this, the criterion for salt water should be 0.1 of the 96-hour LC50 for pink shrimp: 0.004 ug/l. This criterion should also be protective of freshwater aquatic life.

NMED Exhibit 83

GUTHION

CRITERION:

.01 ug/l for freshwater and marine aquatic life.

RATIONALE:

Ninety-six-hour LC_{50} values for fish exposed to the organophosphorus pesticide, guthion, range from 4 to 4,270 ug/l (Katz, 1961; Pickering, et al., 1962; Lahav and Sarig, 1969; Macek, et al., 1969; Macek and McAllister, 1970). The only long-term fish exposure data available are those obtained recently by Adelman and Smith (unpublished data). Decreased spawning (eggs produced per female) was observed in fathead minnows, Pimephales promelas, exposed during a complete life cycle. An estimated "safe" long-term exposure concentration for fathead minnows lies between 0.3 and 0.5 ug/l. Survival of larvae was reduced at approximately 0.7 ug/l.

An investigation of the persistence of guthion in fish revealed that 50 percent of the chemical was lost in less than 1 week (Meyer, 1965). Analysis of plankton and pondwater in the same study indicated a 50 percent loss of guthion in about 48 hours. Flint, et al. (1970) determined the half-life of guthion at 30° C in pondwater and in a phosphate buffer protected from light in the laboratory. The half-life in pondwater was 1.2 days whereas that in the laboratory solution was 10 days. The more rapid degradation in pondwater was attributed to the effect of sunlight and microorganisms.

Organophosphate pesticides are toxic because they inhibit the enzyme acetylcholinesterase (AChE) which is essential to nerve impulse conduction

NMED Exhibit 83

and transmission (Holland, et al., 1967). Weiss (1958, 1959, 1961) demonstrated that a 40 to 70 percent inhibition of fish brain AChE usually is lethal. Centrarchids generally are considered one of the more sensitive groups of fish to guthion (Pickering, et al., 1962; Weiss and Gakstatter, 1964; Meyer, 1965). Weiss and Gakstatter (1964) found that over a 15-day period bluegills, Lepomis macrochirus, exhibited AChE inhibition at 1.0 ug/l guthion but not at 0.1 ug/l. Exposure at 0.05 ug/l for 30 days also failed to produce inhibition below the range of normal variation, but the authors stated that it appeared there was a downward trend in brain enzyme activity and that if exposure was continued a definite reduction might develop. Weiss (1961) found that about 30 days were required for fathead minnow and bluegill brain AChE levels to recover after 8 to 24 hours exposure to 10 ug/l guthion.

Benke and Murphy (1974) showed that repetitive injection of fish with guthion caused cumulative inhibition of brain AChE and mortality. After substantial inhibition by guthion exposure, it takes several weeks for brain AChE of fishes to return to normal even though exposure is discontinued (Weiss, 1959 and 1961; Carter, 1971). Inhibition of brain AChE of fishes by 46 percent or more has been associated with harmful effects in exposures to other organophosphate pesticides for a life cycle (Eaton, 1970) and for shorter periods (Carter, 1971; Coppage and Duke, 1971; Coppage, 1972; Coppage and Matthews, 1974; Post and Leasure, 1974; Coppage, et al., In Press). In static tests, similar inhibition of AChE and mortality were caused in the sheepshead minnow, Cyprinodon variegatus, in 2, 24, 48, and 72 hours at concentrations of 50, 7, 3.5, and 3 ug/l, respectively (Coppage, 1972). These data indicate that reduction of brain AChE activity of marine fishes by 70 to 80 percent or more in short-term exposures to guthion may be associated with some deaths.

NMED Exhibit 83

There is no evidence to indicate that guthion would cause adverse effects through the food chain. Tissue residue accumulation for whole fish calculated from the data of Meyer (1965) indicate no more than a 20-fold accumulation. LD_{50} toxicity values for birds are relatively high and range from 70 to 2,000 mg/kg (Tucker and Crabtree, 1970).

Ninety-six-hour LC_{50} values for aquatic invertebrates range from 0.10 to 22.0 ug/l (Nebeker and Gaufin, 1964; Gaufin, et al., 1965; Jensen and Gaufin, 1966; Sanders and Cope, 1968; Sanders, 1969 and 1972). Sanders (1972) exposed the grass shrimp, Paleomonetes kadiakensis, to guthion in a continuous flow bioassay for up to 20 days and found that the 5-and 20-day LC_{50} values were 1.2 and 0.16 ug/l, respectively. He found that the amphipod, Gammarus fasciatus, was the most sensitive aquatic organism tested, with a 96-hour LC50 of 0.10 ug/l. Jensen and Gaufin (1966), also using a continuous flow system, exposed two species of stonefly naiads in 4- and 30-day studies. They observed 96-hour and 30-day LC_{50} values for Acroneuria pacifica of 2.0 and 0.24 ug/l, respectively, whereas for Pteronarcys californica the values were 4.6 and 1.3 ug/l, respectively.

Results of other toxicity studies on marine organisms have been reported. The 24-hour LC_{50} for the white mullet, Mugil curema, was found to be 5.5 ug/l guthion (Butler, 1963). The 96-hour LC_{50} for the striped mullet, Mugil cephalus, was determined by Lahav and Sarig (1969) to be 8 ug/l guthion. Portman (1972) reported the 48-hour LC_{50} for the

NMED Exhibit 83

fish, Pleuronectes limanda, to be 10 to 30 ug/l. The 48-hour LC_{50} for the European shrimp, Crangon crangon, was found to be 0.33 ug/l guthion (Portman, 1972). Butler (1963) found that the 24-hour EC_{50} for blue crab, Callinectes sapidus, was 550 ug/l and the 48-hour EC_{50} for pink shrimp, Penaeus duorarum, as 4.4 ug/l guthion. The 48-hour TLm was estimated to be 620 ug/l for fertilized oyster eggs, Crassostrea virginica, and 860 ug/l for fertilized clam eggs, Mercenaria mercenaria (Davis and Hidu, 1969).

A criterion level of 0.01 ug/l for guthion is based upon use of an 0.1 application factor applied to the 96-hour LC50 of 0.1 ug/l for Gammarus and a similar value of 0.3 ug/l for the European shrimp.

NMED Exhibit 83

HEPTACHLOR

CRITERION:

.001 ug/l for freshwater and marine aquatic life.

The persistence, bioaccumulation potential and carcinogenicity of heptachlor cautions human exposure to a minimum.

RATIONALE:

The acute toxicity of heptachlor to mammals is generally low; however, aquatic organisms exhibit sensitivity to this pesticide at microgram per liter levels. Such levels range from a 96-hour LC_{50} of 3 ug/l for the juvenile striped bass, Morone saxatilis (Korn and Earnest, 1974) to a 96-hour LC_{50} of 111.9 ug/l for the threespine stickleback, Gasterosteus aculeatus (Katz, 1961). Sanders and Cope (1968) reported even lower 96-hour LC_{50} values for three species of stoneflies; Pteronarcys californica, 1.1 ug/l; Pteronarcella badia, 0.9 ug/l and Claassenia sabulosa, 2.8 ug/l.

Anderson (1960) found that Daphnia magna were immobilized after 50 hours exposure to 57.77 ug/l. A 48-hour LC_{50} of 42 ug/l heptachlor for Daphnia pulex was reported by Cope (1966). Sanders and Cope (1968) determined the 96-hour LC_{50} values for the stoneflies, Pteronarcys californica, Pteronarcella badia and Claassenia sabulosa to be 1.1, 0.9 and 2.8 ug/l, respectively.

NMED Exhibit 83

Sanders (1972) found the grass shrimp, Palaemonetes kadiakensis, with a 96-hour LC_{50} of 1.8 ug/l, to be the most sensitive among three crustaceans tested in static bioassays. Stoneflies, therefore, appear to be the most sensitive group of freshwater organisms among those tested.

Cope (1966) found the 48-hour LC_{50} for heptachlor to the bluegill, Lepomis macrochirus, and rainbow trout, Salmo gairdneri, to be 26 ug/l and 9 ug/l, respectively. The 96-hour LC_{50} of heptachlor for the bluegill was determined by Weiss (1964) to be 19 ug/l. Katz (1961) found that the 96-hour LC50's of heptachlor for the coho salmon, Oncorhynchus kisutch; chinook salmon, Oncorhynchus tschawytscha; rainbow trout, Salmo gairdneri; and threespine stickleback, Gasterosteus aculeatus, were 59, 17.3, 19.4, and 111.9 ug/l, respectively. The 96-hour LC_{50} of heptachlor to the fathead minnow, Pimephales promelas; bluegill, Lepomis macrochirus; goldfish, Carassius auratus; and guppy, Poecilia reticulata, were determined to be 94, 230 and 170 ug/l, respectively (Henderson, et al., 1959).

Data are available on marine animals exposed to heptachlor in 96-hour flow-through bioassays. The 96-hour LC50 of the marine bluehead, Thalassoma bifasciatum, was determined to be 0.8 ug/l (Eisler, 1970). Korn and Earnest (1974) determined the 96-hour LC50 using juvenile striped bass, Morone saxatilis, to be 3.0 ug/l. Schimmel et al., (In Press) reported the following 96-hour LC50's in flow-through bioassays: pink shrimp, Penaeus duorarum, 0.11 ug/l; grass shrimp, Palaemonetes vulgaris, 1.06 ug/l; sheepshead minnow, Cyprinodon variegatus, 3.68 ug/l; pinfish, Lagodon rhomboides, 3.77 ug/l; spot, Leiostomus xanthurus, 0.85 ug/l. Shell deposition of the American oyster, Crassostrea virginica, was inhibited by 50 percent (EC50) at 1.5 ug/l heptachlor.

285

Heptachlor will accumulate in the food chain. Wilson (1965) demonstrated that oysters can concentrate heptachlor almost 18,000 times (wet weight basis). Andrews et al. (1966) reported concentration factors as high as 1,840 in field tests with bluegill, Lepomis macrochirus. Since the effective (as opposed to the applied) concentration was apparently lower than the initial levels because of sorption and biological uptake, true concentration factors must have been higher than reported. For example, 24 hours after treatment with 24 ug/l the pond water contained only 2 ug/l. Using this concentration and the 46.0 ppm residue found in the fish, a concentration factor of 23,000 can be calculated. The involvement of several trophic levels might also increase the degree of accumulation. Schimmel, et al., (In Press) reported that heptachlor concentration factors ranged from 2,800 to 21,300 in estuarine fishes exposed for 96 hours; oyster bioconcentration factors ranged from 4,500 to 8,500, and factors of 206 to 700 occurred in similar tests with crustaceans.

Birds are sensitive to low dosages of heptachlor in their diet. Heath, et al. (1972) found the 5-day LC_{50} for the young of four species to range from 24 to 54 ppm. All woodcock died from a dietary dosage of 0.72 ppm and some died from 0.22 ppm (Stickel and Stickel, 1965). Residues of this magnitude (0.2 ppm) would result in fish or other aquatic life if they were exposed to 0.01 ug/l of heptachlor and accumulated it at 20,000 times water

NMED Exhibit 83

concentrations. Such residues would pose a hazard to birds as sensitive as woodcock that fed on these fish. Residues of this magnitude fall just under the 0.3 ppm guideline established by the U.S. Food and Drug Administration as the limit allowed in edible fish tissue (U.S. Food and Drug Administration, 1974).

Since heptachlor is a highly persistent chemical which bioaccumulates in aquatic organims used for human food and also is considered a potential human carcinogen (Train, 1974) levels of heptachlor in waterways should be kept as low as feasible. The July 1975 action by the Environmental Protection Agency in suspending the production and use of heptachlor should result in a gradual decrease in concentrations in the environment. Any addition of heptachlor to water should be considered potentially hazardous to humans. Such additions should not be permitted without substantial documentation that alternatives are either infeasible or potentially more hazardous. The persistence, bioaccumulative properties and carcinogenic potential of heptachlor should be taken into account when determining the uses of water containing measurable amounts of heptachlor.

Using an 0.01 application factor to the 96-hour LC50 of 0.1 ug/l for the pink shrimp, a marine criterion of 0.001 ug/l is obtained. Toxicity and demonstrated bioaccumulation potential of heptachlor in freshwater biota reflects the applicability of the marine criterion to freshwater.

NMED Exhibit 83

LINDANE

CRITERIA:

4.0 ug/l for domestic water supply (health);

0.01 ug/l for freshwater aquatic life;

0.004 ug/l for marine aquatic life

RATIONALE:

The highest level of lindane found to have minimal or no long-term effects in the most sensitive mammal tested, the dog, is 15.0 mg/kg in the diet or 0.3 mg/kg of body weight/day (Lehman, 1965). Where adequate human data are not available for corroboration of the animal results, the total "safe" drinking intake level is assumed to be 1/500 of the "no effect" or "minimal effect" level reported for the most sensitive animal tested.

Applying the available data and based upon the assumption that 20 percent of the total intake of lindane is from drinking water, that the average person weighs 70 kg and consumes 2 liters of water per day, the formula for calculating a criterion is 0.3 mg/kg x 0.2 x 70 kg x 1/500 x 1/2 = .004 mg, thus deriving the criterion level for domestic water supply of 4 ug/l.

The brown trout, Salmo trutta, apparently is the fish most sensitive to lindane among those species on which aquatic bioassays have been performed, with a 96-hour LC_{50} of 2 ug/l (Macek and McAllister, 1970). Several authors (Boyd and Ferguson, 1964; Naqvi, et al., 1969; Minchew and Ferguson, 1970) have documented increased resistance to lindane toxicity among fish and

NMED Exhibit 83

invertebrates experiencing previous exposure to the chemical. The most sensitive invertebrates tested appear to be only slightly more sensitive than fish. Two investigators (Snow, 1958; Cope, 1965) reported TLm values of 1 ug/l for stoneflies. Sanders and Cope (1968) reported a TLm for stoneflies of 4.5 ug/l lindane. Macek, et al. (1974) determined the acute and chronic toxicities of lindane to Daphnia magna; the midge, Chironomus tentans; and the scud, Gammarus fasciatus. The midge was the most sensitive of these species, with 2.2 ug/l being the highest concentration producing no observable adverse effect. A concentration of 11 ug/l was determined to be "safe" for Daphnia, the least sensitive, over three consecutive generations of exposure.

A criterion of 0.01 ug/l for fresh waters is derived by applying an application factor of 0.01 to the TLM for the stonefly, 1.0 ug/l. The brown trout, a sensitive human food organism, was shown to have a 96-hour LC_{50} of 2.0 ug/l. Hence the criterion level would provide for a margin of safety for both recreationally important organisms as well as trophic levels in the aquatic environment which are significant in the food chain.

Only limited information is available on accumulation of lindane in fish tissues. However, Macek, et al. (1974) observed whole-body (eviscerated) levels (wet weight) of 500 times the corresponding water concentrations in fathead minnows, Pimephales promelas, that had been exposed for several months. Butler (1967) observed accumulations of up to 250 times exposure concentrations in marine mollusks (wet weight basis).

NMED Exhibit 83

The recommended guideline of the U.S. Food and Drug Administration for lindane in edible fish tissue is 0.3 mg/kg (FDA, 1974). Thus, if the observed 500-fold accumulation were to occur, a lindane criterion of 0.01 ug/l in water would result in a tissue concentration in freshwater fish of .005 mg/kg, which is well below the FDA guideline.

Eisler (1969) reported 96-hour LC_{50} values of 5.0 ug/l for both the hermit crab, Pagurus longicarpus, and the sand shrimp, Crangon septemspinosa, and 10 ug/l for the grass shrimp, Palaemonetes pugio. Butler (1963) found the following 48-hour LC_{50} values: brown shrimp, Penaeus aztecus - 0.4 ug/l; juvenile white mullet, Mugil curema - 30 ug/l; and the longnose killifish, Fundulus similis - 240 ug/l. A 96-hour LC_{50} of 7.3 ug/l for the striped bass, Morone saxatilis was reported by Korn and Earnest (1974). Schimmel (unpublished data) found the pink shrimp, Penaeus duorarum, 96-hour LC50 to be 0.17 ug/l, grass shrimp Palaemonetes pugio, 4.4 ug/l and pinfish, Lagodon rhomboides, 30.6 ug/l in flow-through bioassays.

Until additional data on the effect of lindane to marine organisms are available, it is recommended that a marine criterion be based on 0.01 of the 0.4 ug/l 96-hour LC_{50} value for the brown shrimp. The marine criterion is, therefore, 0.004 ug/l.

Unpublished data suggest that the pink shrimp is a more sensitive species than the brown shrimp; however for purposes of achieving a criterion the published data were used. A level of 0.004 ug/l should provide a margin of safety for both sensitive species.

NMED Exhibit 83

MALATHION

CRITERION:

0.1 ug/l for freshwater and marine aquatic life.

RATIONALE:

The freshwater fish most sensitive to malathion, an organophosphorus pesticide, appear to be the salmonids and centrarchids. Post and Schroeder (1971) report a 96-hour LC_{50} between 120 and 265 ug/l for 4 species of salmonids. Macek and McAllister (1970) found a 96-hour LC_{50} range between 101 and 285 ug/l for 3 species of centrarchids and 3 species of salmonids. Other 96-hour LC50's are: rainbow trout, Salmo gairdneri, 68 ug/l (Cope, 1965); largemouth bass, Micropterus salmoides, 50 ug/l (Pickering, et al., 1962) and chinook salmon, Oncorhynchus tshawytscha, 23 ug/l (Katz, 1961). All of the above tests were in static systems. Eaton (1970) determined a 96-hour LC_{50} for bluegill, Lepomis macrochirus, in a flow-through system at 110 ug/l. Macek and McAllister (1970) reported a similar 96-hour LC_{50} for the bluegill in a static exposure. Static 96-hour LC50s of 120 and 160 ug/l were reported by Post and Schroeder (1971) for brook trout, Salvelinus fontinalis. Bender (1969) indicated that the acute toxicity to fathead minnows, Pimephales promelas, is slightly greater (about 2.0 times) in a static system than in a flow-through system. The flow-through acute toxicity to fathead minnows reported by Mount and Stephan (1967) approximated the static acute toxicity reported by Henderson and Pickering (1958) and Bender (1969).

NMED Exhibit 83

Many aquatic invertebrates appear to be more sensitive than fish to malathion. The 96-hour LC_{50} for Gammarus lacustris was 1.0 ug/l (Sanders, 1969); for Pteronarcella badia, 1.1 ug/l (Sanders and Cope, 1968); and for Gammarus fasciatus, 0.76 ug/l (Sanders, 1972). The 48-hour LC_{50} for Simocephalus serrulatus was 3.5 ug/l and for Daphnia pulex, 1.8 ug/l (Sanders and Cope, 1966). Daphnia were immobilized in 50 hours in 0.9 ug/l (Anderson, 1960). The 24-hour LC50s for two species of midge larvae were 2.1 ug/l (Mulla and Khasawinah, 1969) and 2.0 ug/l (Karnak and Collins, 1974).

Safe life cycle exposure concentrations for the more sensitive invertebrates are not known. The most sensitive aquatic organisms probably have not yet been tested; safe concentrations for the most sensitive invertebrates exposed through a complete life cycle have not been determined; and effects of low concentrations on invertebrate behavior are unknown.

The stability of malathion in water is dependent on the chemical and biological conditions of the water (Paris, et al., 1975). Weiss and Gakstatter (1964) have shown that the half-life of malathion was reduced from about 5 months at pH 6 to one to two weeks at pH 8. Eichelberger and Lichtenberg (1971) found that only 10 percent remained in the Little Miami River (pH

NMED Exhibit 83

7.3-8.0) after 2 weeks. Bender (1969) states that one of the malathion breakdown products may be more toxic than the parent compound.

It has been shown that a measured concentration of 575 ug/l malathion in flowing seawater kills 40 to 60 percent of the marine fish, Lagodon rhomboides, in 3.5 hours and causes about 75 percent brain acetylcholinesterase (AChE) inhibition (Coppage, et al., 1975). Similar inhibition of AChE and mortality were caused in pinfish in 24, 48, and 72 hours at measured concentrations of 142, 92 and 58 ug/l, respectively. A concentration of 31 ug/l caused 34 percent AChE inhibition in pinfish but no deaths in 72 hours. Coppage and Matthews (1974) demonstrated that death may be associated with reductions of brain AChE activity of four marine fishes by 70 to 80 percent or more in short-term exposures to malathion. Coppage and Duke (1971) found that moribund mullet, Mugil cephalus, in an estuary sprayed with malathion (3 oz./acre) during a large-scale mosquito control operation had about 98 percent inhibition of brain AChE This is in agreement with 70 to 80 percent or more inhibition of brain AChE levels at and below which some deaths are likely to occur in short-term exposure. Spot, Leiostomus xanthurus, and Atlantic croaker, Micropogon undulatus, also had substantial inhibition of brain AChE during the spray operation (70 percent or more inhibition).

NMED Exhibit 83

Toxicity studies have been made on a number of marine animals. Eisler (1970) studied the 96-hour LC_{50} for several marine fishes at 20° C in static, aerated seawater. The 96-hour LC_{50} values (in ug/l) were: Menidia menidia, 125; Mugil cephalus, 550; Fundulus majalis, 250; Fundulus heteroclitus, 240; Sphaeroides maculatus, 3,250; Anguilla rostrata, 82, and Thalassoma bifasciatum, 27. Katz (1961) reported the static 24 hour LC_{50} for Gasterosteus aculeatus in 25 o/oo saltwater as 76.9 ug/l active ingredient. The 96-hour LC_{50} for striped bass, Morone saxatilis, in intermittent flowing seawater has been reported as 14 ug/l (U.S. BSFW 1970).

Reporting on studies of the toxicity of malathion on marine invertebrates, Eisler (1969) found the 96-hour LC_{50} (static, 24 o/oo salinity aerated) to be 33 ug/l for sand shrimp, Crangon septemspinosa; 82 ug/l for grass shrimp, Palaemonetes vulgaris; and 83 ug/l for hermit crab, Pagurus longicarpus. Growth of oyster, Crassostrea virginica, was reduced 32 percent by 96-hour exposure to 1 mg/l (Butler, 1963). The 48-hour LC_{50} for fertilized eggs of oysters was estimated by Davis and Hidu (1969) to be 9.07 mg/l and the 14-day LC_{50} for larvae, 2.66 mg/l.

Malathion enters the aquatic environment primarily as a result of its application as an insecticide. Because it degrades quite rapidly in most waters depending on pH, its occurrence is sporadic rather than continuous. Because the toxicity

NMED Exhibit 83

is exerted through inhibition of the enzyme acetylcholinesterase (AChE) and because such inhibition may be additive with repeated exposures and may be caused by any of the organo-phosphorus insecticides, inhibition of AChE by more than 35 percent may be expected to result in damage to aquatic organisms.

An application factor of 0.1 is applied to the 96-hour LC50 data for Gammarus lacustris, G. fasciatis and Daphnia , which are all approximately 1.0 ug/l, yielding a criterion of 0.1 ug/l.

NMED Exhibit 83

METHOXYCHLOR

CRITERIA:

100 ug/l for domestic water supply (health);

0.03 ug/l for freshwater and marine aquatic life.

RATIONALE:

The highest level of methoxychlor found to have minimal or no long-term effects in man is 2.0 mg/kg of body weight/day (Lehman, 1965). Where adequate human data are available for corroboration of the animal results, the total "safe" drinking water intake level is assumed to be 1/100 of the "no effect" or "minimal effect" level reported for the most sensitive animal tested, in this case, man.

Applying the available data and based upon the assumptions that 20 percent of the total intake of methoxychlor is from drinking water, that the average person weighs 70 kg and consumes 2 liters of water per day, the formula for calculating a criterion is 2.0 mg/kg x 0.2 x 70 kg x 1/100 x 1/2 = 0.14 mg/l. A criterion level for domestic water supply of 100 ug/l is recommended.

NMED Exhibit 83

Few data are available on acute and chronic effects of methoxychlor on freshwater fish. Merna and Eisele (1973) observed reduced hatchability of fathead minnow, Pimephales promelas, embryos at 0.125 ug/l and lack of spawning at 2.0 ug/l. Yellow perch, Perca flavescens, exposed to 0.6 ug/l for eight months exhibited reduced growth. The 96-hour LC_{50} concentration was 7.5 and 22 ug/l for the fathead minnow and yellow perch, respectively. Korn and Earnest (1974) obtained a 96-hour LC_{50} of 3.3 ug/l with juvenile striped bass, Morone saxatilis, exposed to methoxychlor in a flowing-water bioassay.

Sanders (1972) determined a 96-hour LC_{50} value of 0.5 ug/l for the crayfish, Orconectes nais. Merna and Eisele (1973) obtained a 96-hour LC_{50} value of 0.61 ug/l for the scud, Gammarus pseudolimnaeus and 96-hour LC50s ranging from 1.59 to 7.05 ug/l for the crayfish, Orconectes nais, and three aquatic insect larvae. In 28-day exposures, reduction in emergence of mayflies, Stenonema sp., and in pupation of caddisflies, Cheumatopsyche sp., were observed at 0.5 and 0.25 ug/l concentrations, respectively. They also found methoxychlor to be degraded in a few weeks or less in natural waters.

Eisele (1974) conducted a study in which a section of a natural stream was dosed at 0.2 ug/l methoxychlor for one year. The near extinction of one species of scud, Hyallella azteca, and

NMED Exhibit 83

reductions in populations of other sensitive species, as well as biomass were observed. Residue accumulation of up to 1,000 times the level in the stream was observed in first-year crayfish, Orconectes nais. Metcalf, et al. (1971) traced the rapid conversion of methoxychlor to water soluble compounds and elimination from the tissues of snails, mosquito larvae, and mosquitofish. Thus, methoxychlor appears to be considerably less bioaccumlative in aquatic organisms than some of the other chlorinated pesticides.

Methoxychlor has a very low accumulation rate in birds and mammals (Stickel, 1973), and relatively low avian (Heath, et al., 1972), and mammalian (Hodge, et al., 1950) toxicities. No administrative guidelines for acceptable levels in edible fish tissues have been established by the U.S. Food and Drug Administration.

The above data indicate that 0.1 ug/l methoxychlor would be just below chronic effect level for the fathead minnow and one-fifth the acute toxicity level in a crayfish species. Therefore, a criterion level of 0.03 ug/l is recommended. This criterion should protect fish as sensitive as striped bass and is ten times lower than the level causing effects on some invertebrate populations in a one-year dosing of a natural stream.

NMED Exhibit 83

Bahner and Nimmo (1974) found the 96-hour LC_{50} of methoxychlor for the pink shrimp, Penaeus duorarum, to be 3.5 ug/l and the 30-day LC_{50} to be 1.3 ug/l. Using an application factor of 0.01 with the pink shrimp acute toxicity of 3.5 ug/l, the recommended criterion for the marine environment is 0.03 ug/l.

Butler (1971) found accumulation factors of 470 and 1,500 for the molluscs, Mercenaria mercenaria, and Mya arenaria, respectively, when exposed to 1 ug/l methoxychlor for 5 days. Using the 1,500 accumulation factor as a basis, a water concentration of 0.2 ug/l would be required to meet the U.S. Food and Drug Administration's guideline for methoxychlor in meat products. Thus, the recommended marine criterion of 0.03 ug/l is an order of magnitude lower than this concentration.

NMED Exhibit 83

MIREX

CRITERION:

0.001 ug/l for freshwater and marine aquatic life.

RATIONALE:

Mirex is used to control the imported fire ant Solenopsis saevissima richteri in the southeastern United States. Its use is essentially limited to the control of this insect and it is always presented in bait. In the most common formulation, technical grade mirex is dissolved in soybean oil and sprayed on corncob grits. The bait produced in this manner consists of 0.3 percent mirex, 14.7 percent soybean oil, and 85 percent corncob grits. The mirex bait often is applied at a rate of 1.4 kilograms per hectare, equivalent to 4.2 grams of toxicant per hectare.

Relatively few studies have been made of the effects of mirex on freshwater invertebrates. Of these, only Ludke, et al. (1971) report chemical analyses of mirex in the water. Their study reported effects on two crayfish species exposed to mirex by three techniques. First, field-collected crayfish were exposed to several sublethal concentrations of technical grade mirex solutions for various periods of time; second, crayfish were exposed to mirex leached from bait (0.3 percent active ingredient); and third, the crayfish were fed mirex bait.

Procambarus blandingi juveniles were exposed to 1 or 5 ug/l for 6 to 144 hours, transferred to clean water and observed for 10 days. After 5 days in clean water, 95 percent of the animals exposed to 1 ug/l for 144 hours were dead. Exposure to 5 ug/l for 6, 24, and 58 hours resulted in 26, 50, and 98 percent mortality 10 days after transfer to clean water.

NMED Exhibit 83

Crayfish, Procambarus hayi, were exposed to 0.1 and 0.5 ug/l for 48 hours. Four days after transfer to clean water, 65 percent of the animals exposed to 0.1 ug/l were dead. At the 0.5 ug/l concentration, 71 percent of the animals were dead after 4 days in clean water. Tissue residue accumulations (wet weight basis) ranged from 940- to 27,210-fold above water concentrations. In leached bait experiments, 10 bait particles were placed in 2 liters of water but isolated from 20 juvenile crayfish. Thirty percent of the crayfish were dead in 4 days and 95 percent were dead in 7 days. Water analysis indicated mirex concentrations of 0.86 ug/l. In feeding experiments, 108 crayfish each were fed one bait particle. Mortality was noticed on the first day after feeding and by the sixth day, 77 percent were dead. In another experiment, all crayfish were dead 4 days after having been fed two bait particles each. From this report it is obvious that mirex is extremely toxic to these species of crayfish. Mortality and accumulation increases with time of exposure to the insecticide. Concentrations as low as 0.1 ug/l or the ingestion of one particle resulted in death.

Research to determine effects of mirex on fish has been concentrated on species which have economic and sport fishery importance. Hyde, et al. (1974) applied mirex bait (0.3 percent mirex) at the standard rate (1.4 kg bait per hectare) to four ponds containing channel catfish, Ictalurus punctatus. Three applications were made over an 8-month period with the first application 8 days after fingerling (average weight 18.4 g) catfish were placed in the ponds. Fish were collected at each subsequent application (approximately 4-month intervals). Two and one-half months after the final application, the ponds were drained, all fish were measured, weighed, and the percent survival was calculated.

NMED Exhibit 83

Mirex residues in the fish at termination of the experiment ranged from 0.015 ug/g (ppm) in the fillet to 0.255 ug/g in the fat.

In another study, Van Valin, et al. (1968) exposed bluegills, Lepomis macrochirus, and the goldfish, Carassius auratus, to mirex by feeding a mirex-treated diet (1, 3, and 5 mg mirex per kg body weight) or by treating holding ponds with mirex bait (1.3, 100, and 1000 ug/l computed water concentration). They reported no mortality or tissue pathology for the bluegills; however, after 56 days of exposure, gill breakdown in goldfish was found in the 100 and 1000 ug/l contact exposure ponds, and kidney breakdown was occurring in the 1000 ug/l ponds. Mortality in the feeding experiments was not related to the level of exposure, although growth of the bluegills fed 5 ug/l mirex was reduced.

In laboratory and field test systems reported concentrations of mirex usually are between 0.5 and 1.0 ug/l (Van Valin, et al., 1968; Ludke, et al., 1971). Although mirex seldom is found above 1 ug/l in the aquatic environment, several field studies have shown that the insecticide is accumulated through the food chain. Borthwick, et al. (1973) reported the accumulation of mirex in South Carolina estuaries. Their data revealed that mirex was transported from treated land and marsh to the estuary animals and that accumulation, especially in predators, occurred. In the test area, water samples consistently were less than 0.01 ug/l. Residues in fish varied from non-detectable to 0.8 ug/g with 15 percent of the samples containing residues. The amount of mirex and the percent of samples containing mirex increased at higher trophic levels. Fifty-four percent of the raccoons sampled contained mirex residues up to 4.4 ug/g

NMED Exhibit 83

and 78 percent of the birds contained residues up to 17 ug/g. Naqvi and de la Cruz (1973) reported average residues for molluscs (0.15 ug/g) fish (0.26 ug/g), insects (0.29 ug/g), crustaceans (0.44 ug/g), and annelids (0.63 ug/g). They also reported that mirex was found in areas not treated with mirex which suggests movement of the pesticide in the environment. Wolfe and Norment (1973) sampled an area for one year following an aerial application of mirex bait (2.1 g mirex/hectare). Crayfish residues ranged from 0.04 to 0.16 ug/g. Fish residues were about 2 to 20 times greater than the controls and averaged from 0.01 to 0.76 ug/g. Kaiser (1974) reported the presence of Mirex in fish from the Bay of Quinte, Lake Ontario, Canada. Concentrations range from 0.02 ug/g in the gonads of the northern long nose gar, Lepistosteus osseus, to 0.05 ug/g in the areal fin of northern pike, Esox lucius. Mirex has never been registered for use in Canada.

Mirex does not appear to be greatly toxic to birds, with LC50's for the young of four species ranging from 547 to greater than 1667 ug/g (Heath, et al., 1972). Long-term dietary dosages caused no adverse effect at 3 ug/g with mallards and 13 ug/g with pheasants (Heath and Spann, 1973). However, it has been reported (Stickel, et al., 1973) that the persistence of mirex in bird tissue exceeds that of all organochlorine compounds tested except for DDE. Delayed mortality occurred among birds subjected to doses above expected environmental concentration.

NMED Exhibit 83

A summary examination of the data available at this time shows a mosaic of effects. Crayfish and channel catfish survival is affected by mirex in the water or by ingestion of the bait particles. Bioaccumulation is well established for a wide variety of organisms but the effect of this bioaccumulation on the aquatic ecosystem is unknown. There is evidence that mirex is very persistent in bird tissue. Considering the extreme toxicity and potential for bioaccumulation, every effort should be made to keep mirex bait particles out of water containing aquatic organisms and

NMED Exhibit 83

water concentrations should not exceed 0.001 ug/l mirex. This value is based upon an application factor of 0.01 applied to the lowest levels at which effects on crayfish have been observed.

Data upon which to base a marine criterion involve several estuarine and marine crustaceans. A concentration of 0.1 ug/l technical grade mirex in flowing sea water was lethal to juvenile pink shrimp, Penaeus durorarum, in a three-week exposure (Lowe, et al., 1971). In static tests with larval stages (megalopal) of the mud crab, Rhithropanopeus harrisii, reduced survival was observed in 0.1 ug/l mirex (Bookhout, et al., 1972). ~~1972)~~. In three of four 28-day seasonal flow-through experiments, Tagatz, et al., (1975) found reduced survival of Callinectes sapidus, Penaeus durorarum, and grass shrimp, Palaemonetes pugio, at levels of 0.12 ug/l in summer, 0.06 ug/l in fall, and 0.09 ug/l in winter.

Since two reports, Lowe, et al., (1971) and Bookhout, et al., (1972), reported that effects of mirex on estuarine and marine crustaceans were observed only after considerable time had elapsed, it seems reasonable that length of exposure is an important consideration for this chemical. This may not be the case in fresh water since the crayfish were affected within 48 hours. Therefore, a 3 to 4 week exposure might be considered "acute" and by applying an application factor of 0.01 to a reasonable average of toxic effect levels as summarized above, a recommended marine criterion of 0.001 ug/l results.

NMED Exhibit 83

PARATHION

CRITERION:

0.04 ug/l for freshwater and marine aquatic life.

RATIONALE:

Acute static LC_{50} values of the organophosphorus pesticide, parathion, for freshwater fish have ranged generally from about 50 ug/l for more sensitive species such as bluegills, Lepomis macrochirus, to about 2.5 mg/l for the more resistant species such as minnows (U.S. Environmental Protection Agency, 1975). In flowing water exposures, Spacie (1975) obtained 96-hour LC_{50} values of 0.5 mg/l, 1.6 mg/l, and 1.76 mg/l for bluegills, Lepomis macrochirus, fathead minnows, Pimephales promelas, and brook trout, Salvelinus fontinalis, respectively. Korn and Earnest (1974) found a 96-hour LC_{50} of 18 ug/l for juvenile freshwater and estuarine striped bass Morone saxatilis, in a flowing water system.

Few chronic exposure data are available for aquatic organisms. Brown bullheads, Ictalurus nebulosus, exposed to 30 ug/l parathion for 30 days exhibited tremors; at 60 ug/l they convulsed and were found to have developed a deformed vertebral column (Mount and Boyle, 1969). In a 23-month exposure of bluegills, Spacie (1975) observed deformities (scoliosis and a characteristic protrusion in the throat region) at 0.34 ug/l, but not at 0.16 ug/l. Tremors, convulsions, hypersensitivity, and hemorrhages also were evident at higher concentrations.

NMED Exhibit 83

Reproductive impairment and deformities were observed in fathead minnows exposed to 4.0 ug/l for 8 1/2 months. Development of brook trout, S. fontinalis embryos exposed to 32 ug/l was abnormal and mortalities associated with premature hatching were observed. Embryos at 10 ug/l appeared normal. No adverse effect on juveniles and adults was evident during 9 months exposure to 7 ug/l.

Inhibition of cholinesterase enzymes is the well established mode of physiological action of parathion and other organic phosphorous pesticides (Weiss, 1958). The degree of inhibition of brain acetylcholinesterase (AChE) activity has been the most frequently used measure of effect of these pesticides. Various studies (Weiss, 1958, 1959, 1961; Murphy et al., 1968; Gibson et al., 1969) have shown the degree of inhibition to be dependent upon toxicant concentration, length of exposure, and species sensitivity. The results of these studies have also indicated that death results from AChE inhibition ranging from 25 to 90 percent of normal. Weiss (1959) also showed that susceptibility depended upon the extent of recovery of AChE activity following prior exposure and that the recovery period for fish exposed to parathion was relatively long. In bluegills, AChE activity was only 50 percent recovered 30 days after exposure to 1 mg/l for 6 to 7 hours (Weiss, 1961).

Some of the other physiological effects observed to result from exposure of fish to parathion have been inhibition of spermatogenesis in guppies Poecilia reticulata, at 10 ug/l (Billard and deKinkelin, 1970), alternation of oxygen consumption rate in bluegills, Lepomis macrochirus at 100 ug/l (Dowden, 1966), and liver enlargement associated with increased pesticide-hydrolizing capability in mosquitofish, Gambusia affinis, (Ludke, 1970).

NMED Exhibit 83

Parathion has been found acutely toxic to aquatic invertebrates at under one microgram per liter, e.g., a 50-hour LC_{50} of 0.8 ug/l for Daphnia magna, 48-hour LC_{50} of 0.6 ug/l for Daphnia pulex, and 48-hour LC_{50} of 0.37 for Simocephalus serrulatus (a daphnid) (Sanders and Cope, 1966); a 5-day LC_{50} of 0.93 ug/l for the larval stonefly, Acroneuria pacifica (Jensen and Gaufin, 1964); and a 96-hour LC_{50} of 0.43 ug/l for the larval caddisfly, Hydropsyche californica (Gaufin et al., 1965). Mulla and Khasawinah (1969) obtained a 24-hour LC_{50} of 0.5 ug/l for 4th instar larvae of the midge Tanypus grodhausi. Spacie (1975) obtained 96-hour LC50's in flow-through bioassays of 0.62 ug/l for Daphnia magna, 0.40 ug/l for the scud, Gammarus fasciatus, and 31.0 ug/l for 4th instar of Chironomous tentans, a midge. Other invertebrates have been found acutely sensitive to parathion in concentrations of from 1 to 30 ug/l in water (U. S. Environmental Protection Agency, 1975).

Few longer exposures have been conducted. Jensen and Gaufin (1964) obtained 30-day LC50's for Pteronarcys californica and Acroneuria pacifica of 2.2 and 0.44 ug/l, respectively. Spacie (1975) found the three-week LC_{50} for Daphnia magna to be 0.14 ug/l. Statistically significant reproductive impairment occurred at concentrations above 0.08 ug/l. A 43-day LC_{50} of 0.07 ug/l was reported for Gammarus fasciatus and a concentration of 0.04 ug/l produced significantly greater mortality than among controls.

Limited information is available on persistence of parathion in water. Eichelberger and Lichtenberg (1971) determined the half-life in river water (pH 7.3 - 8.0) to be one week. Using AChE inhibitory capacity as the indicator, Weiss and Gakstatter (1964) found the half-life of parathion

NMED Exhibit 83

or its active breakdown products to be 40, 35, and 20 days in "natural" waters having a pH of 5.1, 7.0, and 8.4, respectively. The possibility of breakdown resulting in compounds more toxic than parathion was suggested by Burke and Ferguson (1969) who determined that the toxicity of this pesticide to mosquitofish, Gambusia affinis, was greater in static than in flowing water test systems. Sanders (1972), in 96-hour bioassays with the scud, Gammarus fasciatus, and glass shrimp, Palaemonetes kadiakensis, also observed greater toxicity under static than in flow-through conditions.

Tissue accumulations of parathion by exposed aquatic organisms are not great and do not appear to be very persistent. Mount and Boyle (1969) observed concentrations in the blood of bullhead, Ictalurus melas, up to about 50 times water concentrations. Spacie (1975) found muscle concentrations in chronically exposed brook trout, S. fontinalis to be several hundred times water concentrations; bluegills, Lepomis macrochirus, had about 25 times water concentrations in their bodies. Leland (1968) demonstrated a biological half-life of parathion in rainbow trout, Salmo gairdneri, exposed and then placed in fresh water to be only 30 to 40 hours. It is not expected that parathion residues in aquatic organisms exposed to the recommended criterion concentrations will be a hazard to consumer organisms.

Weiss and Gakstatter (1964) have shown that 15-day continuous exposure to parathion (1.0 ug/l) can produce progressively greater (i.e., cumulative) brain AChE inhibition in a fish species. After substantial inhibition by parathion exposure, it takes several weeks for brain AChE of exposed fishes to return to normal even though exposure is discontinued (Weiss 1959, 1961). Inhibition of brain AChE of fishes by 46 percent or

NMED Exhibit 83

more has been associated with harmful effects in exposures to organophosphate pesticides for one life cycle (Eaton, 1970) and for short periods (Carter, 1971; Coppage and Duke, 1971; Coppage, 1972; Coppage and Matthews, 1974; Post and Leasure, 1974; Coppage et al., 1975). It has been shown that a concentration of 10 ug parathion/l of flowing sea water kills 40 to 60 percent of the marine fishes Lagodon rhomboides (pinfish) and Leostomus xanthurus (spot) in 24 hours and causes about 87 to 92 percent brain AChE inhibition (Coppage and Matthews, 1974). Similar inhibition of AChE and mortality were caused in sheepshead minnows, Cyprinodon variegatus, in 2, 24, 48, and 72 hours at concentrations of 5000, 2000, 100, and 10 ug/l, respectively in static tests (Coppage, 1972). These data indicate that reductions of brain AChE activity of marine fishes by 70 to 80 percent or more in short-term exposures to parathion may be associated with some deaths.

Other estimates of parathion toxicity to marine organisms follow. The 48-hour EC_{50} for parathion to Penaeus duorarum was found to be 0.2 ug/l (Lowe et al., 1970). Lahav and Sarig (1969) reported the 96-hour LC_{50} for mullet, Mugil cephalus, to be 125 ug/l. The shell growth of the oyster, Crassostrea virginica, was found by Lowe et al. (1970) to be decreased by 22 percent after 96 hours in 1.0 mg/l.

An application factor of 0.1 is applied to the 96-hour LC50 data for invertebrates which range upward from 0.4 ug/l. A criteria of 0.04ug/l is recommended for marine and freshwater aquatic life.

NMED Exhibit 83

TOXAPHENE

CRITERIA:

5 ug/l for domestic water supply (health);

0.005 ug/l for freshwater and marine aquatic life.

RATIONALE:

The highest level of toxaphene found to have minimal or no long-term effects in the most sensitive mammal tested, the dog, is 10.0 mg/kg in the diet or 1.7 mg/kg of body weight/day (Lehman, 1965). Where adequate human data are not available for corroboration of the animal results, the total "safe" intake level is assumed to be 1/500 of the "no effect" or "minimal effect" level reported for the most sensitive animal tested.

Applying the available data and based upon the assumption that 20 percent of the total intake of toxaphene is from drinking water, that the average person weighs 70 kg and consumes 2 liters of water per day, the formula for calculating a criterion is 1.7 mg/kg X 0.2 X 70 kg X 1/500 X 1/2 =0.024 mg/l. However, at 0.024 mg/l there is an organoleptic effect which has been shown to occur at the level of 0.005 mg/l (Cohen, et al., 1961). Thus the criterion is set at 5 ug/l.

Macek and McAllister (1970) reported 96-hour LC50 values for 12 fish species ranging from 2 ug/l for largemouth bass, Micropterus

NMED Exhibit 83

salmoides, to 18 ug/l for bluegill, Lepomis macrochirus. Mahdi (1966) reported 96-hour LC50 values as low as 1.8 ug/l for black bullhead, Ictalurus melas, and as high as 50 ug/l for goldfish, Carrassius auratus, and Henderson, et al. (1959) reported 96-hour TLm values from 3.5 ug/l for bluegill to 20 ug/l for guppies, Poecilia reticulata. The 96-hour LC_{50} values for three stonefly species, Pteronarcys californica, Pteronarcella badia, and Claassenia sabulosa, were reported by Sanders and Cope (1968) to range from 1.3 to 3.0 ug/l.

In a chronic continuous flow bioassay with brook trout, Salvelinus fontinalis, Mayer, et al. (1975) found that toxaphene in water at a level of 0.039 ug/l adversely affected the growth and development of brook trout fry. The mortality of fish at this level was significantly greater than the controls, indicating a no-effect level of less than 0.039 ug/l. The 96-hour LC_{50} of toxaphene for 16-month-old trout was 10.8 ug/l. Mehrle and Mayer (1975) conducted a series of long-term studies on the fathead minnow, Pimephales promelas, exposing the organisms for 150 days to concentrations of toxaphene as low as 0.055 ug/l in a flow-through system. Their results confirmed the Mayer, et al.,(1975) work, showing that growth of all fish exposed to concentrations of 0.055 ug/l was significantly reduced. A no-effect level for this freshwater fish would be less than 0.055 ug/l.

NMED Exhibit 83

Hughes (1968) reported that lakes treated with toxaphene concentrations ranging from 40 to 150 ug/l remained toxic to fish for periods of a few months to five years. Terriere, et al. (1966) reported that a lake treated with toxaphene as a piscicide remained toxic to fish for at least five years. Bioconcentration factors of toxaphene were 500 for aquatic plants, 1,000 to 2,000 for aquatic animals other than fish, and 10,000 to 20,000 for rainbow trout in the lake. Mayer, et al. (1975) observed accumulations of 5,000 to 21,000 times water concentrations in brook trout exposed only through the water. Accumulation factors of 3,400 to 17,000 from aqueous solution have been reported for bacteria, algae and fungi (Paris, et al., 1975).

Heath, et al. (1972) reported the 5-day dietary LC_{50} to be 96 to 142 ppm for young birds of four species. No reproductive impairment occurred in mallards resulting from a long-term dietary dosage of 7 ppm and starlings tolerated 45 ppm for long periods (Patuxent Wildlife Research Center, Laurel, Maryland, unpublished data). At water levels known to affect fish (0.04 ug/l, Mayer, et al., 1975) and with accumulation factors similar to those cited above (20,000 times), resulting residue levels (0.04 x 20,000= 0.8 ppm) would not be expected to approach dosage levels known to be a hazard to birds.

No guideline for toxaphene has been set by the U.S. Food and Drug Administration as a residue limit for edible tissues of fish for human consumption.

NMED Exhibit 83

Lowe (1964) reported a 24-hour LC_{50} of 3.2 ug/l, a 48-hour LC_{50} of 1.0 ug/l, and a 144-hour LC_{50} of 0.5 ug/l for the spot, Leiostomus xanthurus. Butler (1963) reported a 90.8 percent decrease in productivity of natural phytoplankton communities during a 4-hour exposure to a concentration of 1,000 ug/l of toxaphene. Lowe also reported a 48-hour EC_{50} of 4.9 ug/l for the brown shrimp, Penaeus aztecus; and a 48-hour EC_{50} of 330 ug/l for juvenile blue crabs, Callinectes sapidus. A concentration of 57 ug/l resulted in a 50 percent decrease in oyster, Crassostrea virginica, shell growth after 96 hours of exposure at a water temperature of 31° C and 24 o/oo salinity, whereas 63 ug/l produced the same effect at 19° C and 19 o/oo salinity. The 48-hour LC_{50} for the juvenile white mullet, Mugil curema, was 5.5 ug/l.

Korn and Earnest (1974) report a 96-hour LC_{50} for the striped bass, Morone saxatilis of 4.4 ug/l. The 96-hour LC_{50} for the pinfish, Lagodon rhomboides, an organism of wide geographic distribution and ecological importance (Caldwell, 1957), has been reported as 0.5 ug/l (Schimmel, et al., in preparation). While the use of an application factor of 0.01 has been recommended by the NAS-NAE (NAS, 1974) its use is especially appropriate in the case of toxaphene because long-term studies with fathead minnows, Pimephales promelas (Mehrle and Mayer, 1975), and brook trout, Salvelinus fontinalis (Mayer, et al., 1975), have failed to establish a no-effect level. Application of the 0.01 factor to the 96-hour LC_{50} for the pinfish yields a marine criterion of 0.005 ug/l.

NMED Exhibit 83

A no-effect level was not achieved in the studies using freshwater organisms. Mortality and adverse physiological and physical effects were detected at the lowest concentration used, 0.039 ug/l. Hence, for toxaphene, the use of the same criterion for both marine and freshwater is recommended.

NMED Exhibit 83

pH

CRITERIA:

Range	
5 - 9	Domestic water supplies (welfare);
6.5 - 9.0	Freshwater aquatic life;
6.5 - 8.5*	Marine aquatic life.

INTRODUCTION:

"pH" is a measure of the hydrogen ion activity in a water sample. It is mathematically related to hydrogen ion activity according to the expression: $pH = - \log 10 (H^+)$, where (H^+) is the hydrogen ion activity.

The pH of natural waters is a measure of acid-base equilibrium achieved by the various dissolved compounds, salts and gases. The principal system regulating pH in natural waters is the carbonate system which is composed of carbon dioxide (CO_2), carbonic acid (H_2CO_3), bicarbonate ion (HCO_3^-), and carbonate ions ($CO_3^=$). The interactions and kinetics of this system have been described by Stumm and Morgan (1970).

pH is an important factor in the chemical and biological systems of natural waters. The degree of dissociation of weak acids or bases is affected by changes in pH. This effect is important because the toxicity of many compounds is affected by the degree of dissociation. One such

---

*. . . but not more than 0.2 units outside of normally occurring range.

NMED Exhibit 83

example is hydrogen cyanide (HCN). Cyanide toxicity to fish increases as the pH is lowered because the chemical equilibrium is shifted toward an increased concentration of HCN. Similar results have been shown for hydrogen sulfide (H_2S) (Jones, 1964).

The solubility of metal compounds contained in bottom sediments or as suspended material also is affected by pH. For example, laboratory equilibrium studies under anaerobic conditions indicated that pH was an important parameter involved in releasing manganese from bottom sediments (Delfino and Lee, 1971).

The pH of a water does not indicate ability to neutralize additions of acids or bases without appreciable change. This characteristic, termed "buffering capacity," is controlled by the amounts of alkalinity and acidity present.

RATIONALE:

Knowledge of pH in the raw water used for public water supplies is important because without adjustment to a suitable level, such waters may be corrosive and adversely affect treatment processes including coagulation and chlorination.

Coagulation for removal of colloidal color by use of aluminum or iron salts generally has an optimum pH range of 5.0 to 6.5 (Sawyer, 1960). Such optima are predicated upon the availability of sufficient alkalinity to complete the chemical reactions.

NMED Exhibit 83

The effect of pH on chlorine in water principally is on the equilibrium between hypochlorous acid (HOCl) and the hypochlorite ion (OCl^-) according to the reaction:

$$HOCl = H^+ + OCl^-$$

Butterfield (1948) has shown that chlorine disinfection is more effective at values less than pH 7. Another study (Reid and Carlson, 1974) has indicated, however, that in natural waters no significant difference in the kill rate for Escherichia coli was observed between pH 6 and pH 8.

Corrosion of plant equipment and piping in the distribution system can lead to expensive replacement as well as the introduction of metal ions such as copper, lead, zinc and cadmium. Langelier (1936) developed a method to calculate and control water corrosive activity that employs calcium carbonate saturation theory and predicts whether the water would tend to dissolve or deposit calcium carbonate. By maintaining the pH at the proper level, the distribution system can be provided with a protective calcium carbonate lining which prevents metal pipe corrosion. Generally, this level is above pH 7 and frequently approaches pH 8.3, the point of maximum bicarbonate/carbonate buffering.

Since pH is relatively easily adjusted prior to and during water treatment, a rather wide range is acceptable for waters serving as a source of public water supply. A range of pH from 5.0 to 9.0 would provide a water treatable by typical (coagulation, sedimentation, filtration and chlorination) treatment plant processes. As the range is extended, the cost of neutralizing chemicals increases.

NMED Exhibit 83

A review of the effects of pH on freshwater fish has been published by the European Inland Fisheries Advisory Commission (EIFAC, 1969). The Commission concluded: "There is no definite pH range within which a fishery is unharmed and outside which it is damaged, but rather, there is a gradual deterioration as the pH values are further removed from the normal range. The pH range which is not directly lethal to fish is 5 - 9; however, the toxicity of several common pollutants is markedly affected by pH changes within this range, and increasing acidity or alkalinity may make these poisons more toxic. Also, an acid discharge may liberate sufficient CO_2 from bicarbonate in the water either to be directly toxic, or to cause the pH range 5 - 6 to become lethal."

Mount (1973) performed bioassays on the fathead minnow, Pimephales promelas, for a 13-month, one generation time period to determine chronic pH effects. Tests were run at pH levels of 4.5, 5.2,

pH Range	Effect on Fish*
5.0 - 6.0	Unlikely to be harmful to any species unless either the concentration of free CO_2 is greater than 20 ppm, or the water contains iron salts which are precipitated as ferric hydroxide, the toxicity of which is not known.
6.0 - 6.5	Unlikely to be harmful to fish unless free carbon dioxide is present in excess of 100 ppm.
6.5 - 9.0	Harmless to fish, although the toxicity of other poisons may be affected by changes within this range.

* EIFAC, 1969.

NMED Exhibit 83

5.9, 6.6, and a control of 7.5. At the two lowest pH values (4.5 and 5.2) behavior was abnormal and the fish were deformed. At pH values less than 6.6, egg production and egg hatchability were reduced when compared with the control. It was concluded that a pH of 6.6 was marginal for vital life functions.

Bell (1971) performed bioassays with nymphs of caddisflies (two species), and stoneflies (four species), dragonflies (two species), and mayflies (one species). All are important fish food organisms. The 30-day TL_{50} values ranged from 2.45 to 5.38 with the caddisflies being the most tolerant and the mayflies the least tolerant. The pH values at which 50 percent of the organisms emerged ranged from 4.0 to 6.6 with increasing percentage emergence occurring with the increasing pH values.

Based on present evidence, a pH range of 6.5 to 9.0 appears to provide adequate protection for the life of freshwater fish and bottom dwelling invertebrate fish food organisms. Outside of this range, fish suffer adverse physiological effects increasing in severity as the degree of deviation increases until lethal levels are reached.

NMED Exhibit 83

Conversely, rapid increases in pH can cause increased NH_3 concentrations which are also toxic. Ammonia has been shown to be ten times as toxic at pH 8.0 as at pH 7.0 (EIFAC, 1969).

The chemistry of marine waters differs from that of fresh water because of the large concentration of salts present. In addition to alkalinity based on the carbonate system, there is also alkalinity from other weak acid salts such as borate. Because of the buffering system present in sea water, the naturally occurring variability of pH is less than in fresh water. Some marine communities are more sensitive to pH change than others (NAS, 1974). Normal pH values in sea water are 8.0 to 8.2 at the surface decreasing to 7.7 to 7.8 with increasing depth (Capurro, 1970). The NAS Committee's review (NAS, 1974) indicated that plankton and benthic invertebrates are probably more sensitive than fish to changes in pH and that mature forms and larvae of oysters are adversely affected at the extremes of the pH range of 6.5 to 9.0. However, in the shallow, biologically active waters in tropical or subtropical areas, large diurnal pH changes occur naturally because of photosynthesis. pH values may range from 9.5 in the daytime to 7.3 in the early morning before dawn. Apparently these communities are adapted to such variations or intolerant species are able to avoid extremes by moving out of the area.

For open ocean waters where the depth is substantially greater than the euphotic zone, the pH should not be changed more than 0.2 units

NMED Exhibit 83

outside of the naturally occurring variation or in any case outside the range of 6.5 to 8.5. For shallow, highly productive coastal and estuarine areas where naturally occurring pH variations approach the lethal limits for some species, changes in pH should be avoided but in any case not exceed the limits established for fresh water, i.e., pH of 6.5 to 9.0. As with the freshwater criteria, rapid pH fluctuations that are due to waste discharges should be avoided. Additional support for these limits is provided by Zirino and Yamamoto (1972). These investigators developed a model which illustrates the effects of variable pH on copper, zinc, cadmium, and lead; small changes in pH cause large shifts in these metallic complexes. Such changes may affect toxicity of these metals.

For the industrial classifications considered, the NAS report (NAS, 1974) tabulated the range of pH values used by industry for various process and cooling purposes. In general, process waters used varied from pH 3.0 to 11.7, while cooling waters used varied from 5.0 to 8.9. Desirable pH values are undoubtedly closer to neutral to avoid corrosion and other deleterious chemical reactions. Waters with pH values outside these ranges are considered unusable for industrial purposes.

The pH of water applied for irrigation purposes is not normally a critical parameter. Compared with the large buffering capacity of the soil matrix, the pH of applied water is rapidly changed to approximately that of the soil. The greatest danger in acid soils is that metallic ions such as iron, manganese or aluminum may be dissolved

NMED Exhibit 83

in concentrations which are subsequently directly toxic to plants. Under alkaline conditions, the danger to plants is the toxicity of sodium carbonates and bicarbonates either directly or indirectly (NAS, 1974).

To avoid undesirable effects in irrigation waters, the pH should not exceed a range of 4.5 to 9.0.

NMED Exhibit 83

PHENOL

CRITERION:

1 ug/l for domestic water supply (welfare), and
to protect against fish flesh tainting.

INTRODUCTION:

Phenolic compounds include a wide variety of organic chemicals. The phenols may be classified into monohydric, dihydric, and polyhydric phenols depending upon the number of hydroxyl groups attached to the aromatic ring. Phenol itself, which has but one hydroxyl group, is the most typical of the group and is often used as a model compound. The properties of phenol, with certain modifications depending on the nature of the substituents on the benzene ring, are shared by other phenolic compounds. Phenolic compounds arise from the distillation of coal and wood; from oil refineries; chemical plants; livestock dips; human and other organic wastes; hydrolysis, chemical oxidation and microbial degradation of pesticides; and from naturally occurring sources and substances. Some compounds are refractory to biological degradation and can be transported long distances in water.

RATIONALE:

Phenolic compounds can affect freshwater fishes adversely by direct toxicity to fish and fish-food organisms; by lowering the amount of available oxygen because of the high oxygen demand of the compounds and by tainting of fish flesh (EIFAC, 1973). Shelford (1917) observed

NMED Exhibit 83

that a concentration of 1 cc per liter (purity of compound and concentration are unknown) was rapidly fatal to fish but solutions of one half to three quarters of this amount (i.e., .5 to .75 cc) would require up to one hour to kill fish. Subsequent studies have confirmed the toxicity of phenol to both adult and immature organisms (EIFAC, 1973). Decreased egg development in the oyster, Crassostrea virginica, has been found to occur at levels of 2 mg/l phenol (Davis and Hidu, 1969).

Various environmental conditions will increase the toxicity of phenol. Lower dissolved oxygen concentrations, increased salinity and increased temperature all enhance the toxicity of phenol (EIFAC, 1973). It has been shown that phenol and o-cresol have 24-hour LC50's of 5 and 2 mg/l respectively for trout embryos (Albersmeyer and von Erichsen, 1959). Rainbow trout were killed in 7.3 mg/l phenol in 2 hours and in 6.5 mg/l phenol in 12 hours; at these concentrations there was rapid damage to gills and severe pathology of other tissues (Mitrovic, et al., 1968). Pathologic changes in gills and in fish tissues were found at concentrations in the range of 20 to 70 ug/l phenol (Reichenback-Klinke, 1965).

McKee and Wolf (1963), following a review of world literature, concluded that phenol in a concentration of 1 ug/l would not interfere with domestic water supplies, 200 ug/l would not interfere with fish and aquatic life, 50 mg/l would not interfere with irrigation, and 1,000 mg/l would not interfere with stock watering.

A major aesthetic problem associated with phenolic compounds is their organoleptic properties in water and fish flesh. Threshold odor levels range from 55 ug/l for p-cresol (Rosen, et al., 1962) to

NMED Exhibit 83

2 ug/l for 2-chlorophenol (Burttschell, et al., 1959). The chlorinated phenols present problems in drinking water supplies because phenol is not removed efficiently by conventional water treatment and can be chlorinated during the final water treatment process to form persistent odor-producing compounds. Thus, odor problems are created in the distribution system. Boetius (1954), Fetterolf (1962), Schulze (1961), and Shumway (1966) estimated threshold fish flesh tainting concentrations for o-chlorophenol, p-chlorophenol, and 2, 4-dichlorophenol to range from 0.1 ug/l to 15 ug/l. The O-chlorophenol produced tainting at the lower concentration.

A criterion of 1 ug/l phenol, which is about half of the chlorophenol odor effect level for a water supply and near the threshold fish flesh tainting concentration, should protect the freshwater environment for such users.

NMED Exhibit 83

PHOSPHORUS

CRITERION:

0.10 ug/l yellow (elemental) phosphorus for marine or estuarine waters.

INTRODUCTION

Phosphorus in the elemental form is particularly toxic and is subject to bioaccumulation in much the same way as mercury. Phosphorus as phosphate is one of the major nutrients required for plant nutrition and is essential for life. In excess of a critical concentration, phosphates stimulate plant growths. During the past 30 years, a formidable case has developed for the belief that increasing standing crops of aquatic plants, which often interfere with water uses and are nuisances to man, frequently are caused by increasing supplies of phosphorus. Such phenomena are associated with a condition of accelerated eutrophication or aging of waters. Generally, it is recognized that phosphorus is not the sole cause of eutrophication but there is substantiating evidence that frequently it is the key element of all of the elements required by freshwater plants, and generally, it is present in the least amount relative to need. Therefore, an increase in phosphorus allows use of other already present nutrients for plant growth. Further, of all of the elements required for plant growth in the water environment, phosphorus is the most easily controlled by man.

Large deposits of phosphate rock are found near the western shore of Central Florida, as well as in a number of other States. Deposits in Florida are found in the form of pebbles which vary in size from fine sand to about the size of a human foot. These pebbles are embedded in a matrix of clay and

NMED Exhibit 83

and sand. The phosphate rock beds lie within a few feet of the surface and mining is accomplished by use of hydraulic water jets and a washing operation that separates the phosphate from waste materials. The process is similar to that of strip-mining. Florida, Idaho, Montana, North Carolina, South Carolina, Tennessee, Utah, Virginia, and Wyoming share phosphate mining activities.

Phosphates enter waterways from several different sources. The human body excretes about one pound per year of phosphorus expressed as "P." The use of phosphate detergents and other domestic phosphates increases the per capita contribution to about 3-1/2 pounds per year of phosphorus as P. Some industries, such as potato processing, have wastewaters high in phosphates. Crop, forest, idle, and urban land contribute varying amounts of phosphorus diffused sources in drainage to watercourses. This drainage may be surface runoff of rainfall, effluent from tile lines, or return flow from irrigation. Cattle feedlots, concentrations of domestic duck or wild duck populations, tree leaves, and fallout from the atmosphere all are contributing sources.

Evidence indicates that: (1) high phosphorus concentrations are associated with accelerated eutrophication of waters, when other growth-promoting factors are present; (2) aquatic plant problems develop in reservoirs and other standing waters at phosphorus values lower than those critical in flowing streams; (3) reservoirs and lakes collect phosphates from influent streams and store a portion of them within consolidated sediments, thus serving as a phosphate sink; and, (4) phosphorus concentrations critical to noxious plant growth vary and nuisance growths may result from a particular concentration of phosphate in one geographical area but not in another. The amount or percentage of inflowing nutrients that may be retained by a lake or reservoir is variable and will depend upon: (1) the nutrient loading to the lake or reservoir; (2) the volume of the euphotic zone; (3) the extent of biological activities;

NMED Exhibit 83

(4) the detention time within the lake basin or the time available for biological activities; and, (5) the level of discharge from the lake or of the penstock from the reservoir.

Once nutrients are combined within the aquatic ecosystem, their removal is tedious and expensive. Phosphates are used by algae and higher aquatic plants and may be stored in excess of use within the plant cell. With decomposition of the plant cell, some phosphorus may be released immediately through bacterial action for recycling within the biotic community, while the remainder may be deposited with sediments. Much of the material that becomes combined with the consolidated sediments within the lake bottom is bound permanently and will not be recycled into the system.

RATIONALE

Elemental Phosphorus

Isom (1960) reported an LC50 of 0.105 mg/l at 48 hours and 0.025 mg/l at 160 hours for bluegill sunfish, Lepomis macrochirus, exposed to yellow phosphorus in distilled water at 26° C and pH 7. The 125- and 195-hour LC50's of yellow phosphorus to Atlantic cod, Gadus morhua, and Atlantic salmon, Salmo salar smolts in continuous-exposure experiments was 1.89 and 0.79 ug/l, respectively.(Fletcher and Hoyle, 1972). No evidence of an incipient lethal level was observed since the lowest concentration of P_4 tested was 0.79 ug/l. Salmon that were exposed to elemental phosphorus concentrations of 40 ug/l or less developed a distinct external red color and showed signs of extensive hemolysis. The predominant features of P_4 poisoning in salmon were external redness, hemolysis, and reduced hematocrits.

NMED Exhibit 83

Following the opening of an elemental phosphorus production plant in Long Harbour, Placentia Bay, Newfoundland, divers observed dead fish upon the bottom throughout the Harbour (Peer, 1972). Mortalities were confined to a water depth of less than 18 meters. There was visual evidence of selective mortality among benthos. Live mussels were found within 300 meters of the effluent pipe, while all scallops within this area were dead.

Fish will concentrate elemental phosphorus from water containing as little as 1 ug/l (Idler, 1969). In one set of experiments, a cod swimming in water containing 1 ug/l elemental phosphorus for 18 hours concentrated phosphorus to 50 ug/kg in muscle, 150 ug/kg in fatty tissue, and 25,000 ug/kg in the liver (Idler, 1969 ; Jangaard, 1970). The experimental findings showed that phosphorus is quite stable in the fish tissues.

The criterion of 0.10 ug/l elemental phosphorus for marine or estuarine waters is 1/10 of demonstrated lethal levels to important marine organisms and of levels that have been found to result in significant bioaccumulation.

Phosphate Phosphorus

Although a total phosphorus criterion to control nuisance aquatic growths is not presented, it is believed that the following rationale to support such a criterion, which currently is evolving, should be considered.

Total phosphate phosphorus concentrations in excess of 100 ug/l P may interfere with coagulation in water treatment plants. When such concentrations exceed 25 ug/l at the time of the spring turnover on a volume-weighted basis in lakes or reservoirs, they may occasionally stimulate excessive or nuisance

NMED Exhibit 83

growths of algae and other aquatic plants. Algal growths impart undesirable tastes and odors to water, interfere with water treatment, become aesthetically unpleasant and alter the chemistry of the water supply. They contribute to the phenomenon of cultural eutrophication.

To prevent the development of biological nuisances and to control accelerated or cultural eutrophication, total phosphates as phosphorus (P) should not exceed 50 ug/l in any stream at the point where it enters any lake or reservoir, nor 25 ug/l within the lake or reservoir. A desired goal for the prevention of plant nuisances in streams or other flowing waters not discharging directly to lakes or impoundments is 100 ug/l total P (Mackenthun, 1973). Most relatively uncontaminated lake districts are known to have surface waters that contain from 10 to 30 ug/l total phosphorus as P (Hutchinson, 1957).

The majority of the Nation's eutrophication problems are associated with lakes or reservoirs and currently there are more data to support the establishment of a limiting phosphorus level in those waters than in streams or rivers that do not directly impact such water. There are natural conditions, also, that would dictate the consideration of either

NMED Exhibit 83

a more or less stringent phosphorus level. Eutrophication problems may occur in waters where the phosphorus concentration is less than that indicated above and, obviously, there would be a need in such waters to have nutrient limits that are more stringent. Likewise, there are those waters within the Nation where phosphorus is not now a limiting nutrient and where the need for phosphorus limits is substantially diminished. Such conditions are described in the last paragraph of this rationale.

There are two basic needs in establishing a phosphorus criterion for flowing waters: one is to control the development of plant nuisances within the flowing water and, in turn, to control and prevent animal pests that may become associated with such plants; the other is to protect the downstream receiving waterway, regardless of its proximity in linear distance. It is evident that a portion of that phosphorus that enters a stream or other flowing waterway eventually will reach a receiving lake or estuary either as a component of the fluid mass, as bed load sediments that are carried downstream, or as floating organic materials that may drift just above the stream's bed or float on its water's surface. Superimposed on the loading from the inflowing waterway, a lake or estuary may receive additional phosphorus as fallout from the air shed or as a direct introduction from shoreline areas.

NMED Exhibit 83

Another method to control the inflow of nutrients, particularly phosphates, into a lake is that of prescribing an annual loading to the receiving water. Vollenweider (1973) suggests total phosphorus (P) loadings in grams per square meter of surface area per year that will be a critical level for eutrophic conditions within the receiving waterway for a particular water volume where the mean depth of the lake in meters is divided by the hydraulic detention time in years. Vollenweider's data suggest a range of loading values that should result in oligotrophic lake water quality.

Mean Depth/Hydraulic Detention Time (meters/year)	Oligotrophic or Permissible Loading (grams/meter^2/year)	Eutrophic or Critical Loading (grams/meter^2/year)
0.5	0.07	0.14
1.0	0.10	0.20
2.5	0.16	0.32
5.0	0.22	0.45
7.5	0.27	0.55
10.0	0.32	0.63
25.0	0.50	1.00
50.0	0.71	1.41
75.0	0.87	1.73
100.0	1.00	2.00

There may be waterways wherein higher concentrations or loadings of total phosphorus do not produce eutrophy, as well as those waterways wherein lower concentrations or loadings of total phosphorus may be associated with popula-

NMED Exhibit 83

tions of nuisance organisms. Waters now containing less than the specified amounts of phosphorus should not be degraded by the introduction of additional phosphates.

It should be recognized that a number of specific exceptions can occur to reduce the threat of phosphorus as a contributor to lake eutrophy. Often, naturally occurring phenomena limit the development of plant nuisances; often there are technological or cost-effective limitations to the control of introduced pollutants. Exceptions to the threat of phosphorus in eutrophication occur in waters highly laden with natural silts or colors which reduce the penetration of sunlight needed for plant photosynthesis; in those waters whose morphometric features of steep banks, great depth, and substantial flows contribute to a history of no plant problems; in those waters that are managed primarily for waterfowl or other wildlife; in those waters where an identified nutrient other than phosphorus is limiting to plant growth and the level and nature of such limiting nutrient would not be expected to increase to an extent that would influence eutrophication; and in those waters where phosphorus control cannot be sufficiently effective under present technology to make phosphorus the limiting nutrient. No national criterion is presented for phosphate phosphorus for the control of eutrophication.

NMED Exhibit 83

PHTHALATE ESTERS

CRITERION:

3 ug/l for freshwater aquatic life.

INTRODUCTION:

Phthalate esters are organic compounds extensively used as plasticizers, particularly in polyvinyl chloride plastics. The function of a plasticizer is to change the characteristics of the plastic resin by making them more flexible or to improve their workability. Some plastic formulations may contain up to 60 parts per hundred of a phthalate ester. Several phthalate esters are synthesized and vary in the side chain length and structure attached to the parent benzene ring. Certain esters, the di-2-ethylhexyl and di-n-butyl phthalates, are used as an orchard acaricide and insect repellent, respectively.

Occurrence of the phthalate residues has been demonstrated in fresh (Mayer, et al., 1971), marine (Morris, 1970), industrial and heavily populated waters (Stalling, 1972). No well documented information exists on the fate of the phthalate compounds in aquatic environments (Mayer, et al., 1972).

RATIONALE:

Acute toxicity of the phthalate esters tested has been shown to be quite low (Sanders et al., 1973). Mayer and Sanders (1973) determined the 96-hour LC_{50} of di-n-butyl phthalate to be 1.3 mg/l for the fathead minnow, Pimephales promelas; 0.73 mg/l for the bluegill, Lepomis macrochirus; 2.91 mg/l for channel catfish, Ictalurus punctatus; 6.47 mg/l for rainbow trout, Salmo gairdneri; 2.10 mg/l for the scud, Gammarus pseudolimnaeus; and >10 mg/l for the crayfish, Orconectes nais. Daphnia magna, when exposed to the di-2-ethylhexyl phthalate at

NMED Exhibit 83

levels of from 3 ug/l to 30 ug/l for 21 days, exhibited a decrease in the numbe of young produced of 60 to 83 percent, respectively.

Ability of aquatic organisms to accumulate various phthalate residues depend upon the ester, concentration and time of exposure. Concentration factors up to 6,600 have been reported for di-n-butyl phthalate in midge larva, Chironomus plumosus, after seven days exposure to 0.18 ug/l. Amphipods, Gammarus pseudolimnaeus, were found to concentrate the di-2-ethylhexyl phthalate 13,400 times in water containing 0.1 ug/l after 14 days exposure (Sanders et al., 1973). Daphnia magna were exposed to 0.1 ug/l of radioactively labeled phthalate for 7 days and then transferred to fresh flowing water to determine the time required for elimination of phthalate residues (Mayer and Sanders, 1973). After 3 days, 50 percent of the total radioactivity remained; 25 percent of the activity was still present after 7 days in fresh water.

Phthalate esters can be detrimental to aquatic organisms at low water concentrations. Ability to concentrate high levels from water and reproductive impairment in certain species are suggestive of potential environmental damage. While the fate of these compounds remains obscure, their presence in water affects successful growth and reproduction essential for maintenance of animal populations. A freshwater criterion of 3 ug/l is recommended even though some reproductive impairment was seen in daphnids, since all other species tested were so much more resistant. Until additional effect data become available this criterion should be a goal for marine waters.

NMED Exhibit 83

POLYCHLORINATED BIPHENYLS

CRITERION:

.001 ug/l for freshwater and marine aquatic life and for consumers thereof.

Every reasonable effort should be made to minimize human exposure.

INTRODUCTION:

Polychlorinated biphenyls (PCB's) are a class of compounds produced by the chlorination of biphenyls and are registered in the United States under the trade name, Aroclor (R) . The degree of chlorination determines their chemical properties, and generally their composition can be identified by the numerical nomenclature, e.g., Aroclor 1242, Aroclor 1254, etc. The first two digits represent the molecular type and the last two digits the average percentage by weight of chlorine (NTIS, 1972).

Identification of PCB's in the presence of organochlorine pesticides such as DDT and DDE has been difficult in the past because of their similar chromatographic characteristics (Risebrough, et al., 1968).

NMED Exhibit 83

In PCB analysis today, the interference of organochlorine hydrocarbons is overcome by sequential column chromatography on Florisil and silica gel (Armour and Burke, 1970; FDA, 1971). Gas-liquid chromatography with highly sensitive and selective detectors has been employed successfully in the detection of PCB's at low levels (Nebeker and Puglisi, 1974).

PCB compounds are slightly soluble in water (25-200 ug/l at 25°C), soluble in lipids, oils, organic solvents, and resistant to both heat and biological degradation (NTIS, 1972; Nisbet, et al., 1972). Typically, the specific gravity, boiling point, and melting point of PCB's increase with their chlorine content. PCB's are relatively non-flammable, have useful heat exchange and dielectric properties, and now are used principally in the electrical industry in capacitors and transformers.

RATIONALE:

The acute and chronic effects of PCB's have been determined on a number of aquatic organisms.

NMED Exhibit 83

Ninety-six-hour LC50 values for newly hatched fathead minnows, Pimephales promelas, were 15 ug/l for Aroclor 1242 and 7.7 ug/l for Aroclor 1254. In 60-day continuous flow bioassays 50 percent of the fathead minnows were killed in 8.8 ug/l Aroclor 1242 and in 4.6 ug/l Aroclor 1254 (Nebeker, et al., 1974). Nine-month continuous flow bioassay tests were conducted in the same series of experiments reported by Nebeker, et al. (1974). The spawning of fathead minnows was significantly affected at concentrations of 1.8 ug/l Aroclor 1254; concentrations of Aroclor 1242 above 10 ug/l were lethal to newly hatched fry. Defoe, et al. (In Press) conducted similar flow-through acute and chronic studies with fathead minnows using Aroclor 1248 and 1260. The calculated 30-day TL50 for newly hatched fathead minnows was 4.7 ug/l for Aroclor 1248 and 3.3 ug/l for Aroclor 1260. Fathead minnows were able to reproduce successfully at PCB concentrations which were acutely lethal to the larvae.

Stalling and Mayer (1972) determined 96-hour LC50 values ranging from 1,170 to 50,000 ug/l for cutthroat trout, Salmo clarki, using Aroclors 1221-1268. With rainbow trout, Salmo gairdneri, and Aroclors 1242-1260 the acute toxicity was

NMED Exhibit 83

greater than 1500 mg/l. Fifteen-day intermittent-flow bioassays carried out with bluegills, Lepomis macrochirus, and Arcclors 1242, 1248 and 1254 resulted in LC50 values of 54, 76 and 204 ug/l, respectively.

Johnson (1973), Mayer (1975) and Veith (1975) conducted bioassays which showed that the toxicity of Aroclor 1016, introduced recently to replace PCB's of the Aroclor 1200 series in many applications, was similar to that of Aroclor 1242.

Nebeker and Puglisi (1974) conducted bioassays with Daphnia magna exposed to concentrations of Aroclors 1221-1268. In continuous flow tests Aroclor 1254 was the most toxic with a 3-week LC50 of 1.3 ug/l; 100 percent mortality occurred at 3.5 ug/l and 100 percent reproductive impairment occurred at 3.8 ug/l. Stalling and Mayer (1972) and Mayer et al. (1975) conducted flow-through and static bioassay tests on freshwater invertebrates which likewise indicated that these organisms are generally more susceptible to acute toxic effects of PCB's than fish.

NMED Exhibit 83

Studies of the Milwaukee River (Wisconsin) revealed PCB concentrations in ambient water of 2.0 to 2.8 ug/l and residues in fish as high as 405 ug/g (Veith and Lee, 1971). Open water Lake Michigan PCB concentrations have been reported to be less than 0.01 ug/l; mean residues in coho salmon, Oncorhynchus kisutch, were about 15 ug/g (Veith, 1973). Veith (1973) found that goldfish, Carassius auratus, in the lower Milwaukee River accumulated Aroclor 1248 approximately 0.7×10^5 to 2×10^5 times depending upon the ambient water concentration. From both laboratory and river system studies, many aquatic organisms appear to bioaccumulate PCB mixtures containing 3, 4, 5, and 6 chlorine atoms per molecule approximately 3×10^3 to 2×10^5 times the concentration in the water. Tissue residues in fathead minnows, Pimephales promelas, ranged from 0.7 ug/g of Aroclor 1248 in control fish to 1036 ug/g of Aroclor 1254 in fish held for 8 months in water containing 4.0 ug/l of Aroclor 1254 (Nebeker, et al., 1974). The latter case indicates a bioaccumulation factor of 2.3×10^5, which is essentially independent of the PCB concentration in the water.

NMED Exhibit 83

Bluegill sunfish, Lepomis macrochirus, exposed to Aroclors 1248 and 1254 exhibited a bioaccumulation factor of 7.1×10^4 (Stalling and Mayer, 1972). The bioaccumulation factor for gizzard shad, Dorosoma cepedianum, in the Saginaw River (Michigan) varied between 0.6×10^5 and 1.5×10^5 for Aroclor 1254 (Michigan Water Resource Commission, 1973).

On the basis of the FDA action level of 5 ug/g in fish tissue, and both laboratory and field derived bioaccumulation levels for fathead minnows, Pimephales promelas, and goldfish, Carassius auratus, in the range of 0.7×10^3 to 2.3×10^5 , an ambient water concentration of no more than 0.022 ug/l would be permissible. However, lake trout from the Great Lakes larger than 12 inches in length generally contain more than 5 ug/g of PCB's and chub from the Great Lakes generally contain PCB's in amounts approaching or slightly exceeding 5 ug/g. Since monitoring data on the Great Lakes' waters consistently indicate concentrations equal to or less than .01 ug/l, a criterion of less than 0.01 ug/l for all fishes appears necessary.

NMED Exhibit 83

A residue level of 2 ug/g in fish consumed by commercial ranch mink has been shown to preclude survival of mink offspring (Ringer, et al., 1972). Reproduction was nearly eliminated in ranch mink fed a beef diet containing 0.64 ug/g of Aroclor 1254 (Platonow and Kalstad, 1973). This suggests that a tissue level limit of not more than 0.5 ug/g would be required to protect ranch mink, and by implication, other carnivorous mammals. These data, plus the fact that lake trout from the Great Lakes (in water with PCB levels equal to or less than 0.01 ug/l) already exceed the 5 ug/g FDA limit, justify a fresh water criterion of not greater than 0.001 ug/l.

Median PCB concentrations in whole fish of eight species from Long Island Sound obtained in 1970 were reported to be on the order of 1 ug/g, as were comparable concentrations found in fish off the coast of Southern California (Hays and Risebrough, 1972; Risebrough, 1969). Generally, residues in ocean fish have been below 1 ug/g (Risebrough, 1970).

Surveys of Escambia Bay (Florida) during the period September 1969 to December 1971 produced data on the

NMED Exhibit 83

pathways and effects of PCB's in the estuarine and marine environments. The sediment reservoir of Aroclor 1254 is thought to be a continuing source of PCB's to aquatic biota. The initial survey of Escambia Bay biota revealed fish, shrimp, and crabs with levels as high as 12 ug/g. Higher levels of PCB's were detected in higher trophic levels than shrimp, which could implicate a chain transfer from sediment to large animals (Duke, 1974).

From the Escambia Bay data, which include flow-through bioassays with residue analyses where possible, the following conclusions were reached: (1) all of the Aroclors tested are acutely toxic to certain estuarine organisms; (2) bioassays lasting longer than 96 hours demonstrated that Aroclor 1254 is toxic to commercial shrimp at less than 1 ug/l; (3) fish, particularly sheepshead minnows, Cyprinodon variegatus, are extremely sensitive to Aroclor 1254 with 0.1 ug/l lethal to fry; and, (4) acute toxicity of Aroclor 1016 to estuarine organisms is similar to that of other Aroclors but it appears less toxic to marine fish in long-term exposures than does Aroclor 1254 (Duke, 1974; Schimmel, et al., 1974).

NMED Exhibit 83

Oysters, Crassostrea virginica, were sensitive to Aroclor 1260 with growth diminished by 44 percent in concentrations of 10 ug/l and by 52 percent in 100 ug/l. Approximately 10 percent of the pink shrimp, Penaeus duorarum, died in 100 ug/l, but no apparent effects on pinfish, Lagodon rhomboides, were noted at that concentration. Aroclor 1254 had no apparent effect on juvenile pinfish at 100 ug/l in 48-hour flow-through tests, but killed 100 percent of the pink shrimp. At 100 ug/l of Aroclor 1254 for 96 hours, shell growth of oysters was inhibited and was decreased 41 percent at levels of 10 ug/l. The toxicity of Aroclor 1248 and 1242 to shrimp and pinfish was similar to that of Aroclor 1254. Aroclor 1242 was toxic to oysters at 100 ug/l. Killifish, Fundulus heteroclitus, exposed to 25 ug/l of Aroclor 1221 suffered 85 percent mortality. In 96-hour bioassays, Aroclor 1016 was toxic to an estimated 50 percent of the oysters, Crassostrea virginica; brown shrimp, Penaeus aztecus; and grass shrimp, Palecmonetes pugio, at 10 ug/l; it was lethally toxic to 18 percent of the pinfish at 100 ug/l (Duke, 1974).

NMED Exhibit 83

Young oysters, Crassostrea virginica, exposed to Aroclor 1254 in flowing sea water for 24 weeks experienced reduction in growth rates at 4.0 ug/l, but apparently were not affected by 1.0 ug/l. Oysters accumulated as much as 100,000 times the test-water concentration of 1.0 ug/l. General tissue alterations in the vesicular connective tissue around the diverticula of the hepatopancreas were noted in the oysters exposed to 5.0 ug/l. No significant mortality was observed in oysters exposed continuously to 0.01 ug/l of Aroclor 1254 for 56 weeks (Duke, 1974).

Blue crabs, Callinectes sapidus, apparently were not affected by 20 days' exposure to 5.0 ug/l of Aroclor 1254. Pink shrimp exposed under similar conditions experienced a 72 percent mortality. In subsequent flow-through bioassays, 51 percent of the juvenile shrimp were killed by Aroclor 1254 in 15 days and 50 percent of the adult shrimp were killed at 3.0 ug/l in 35 days. From pathological examinations of the exposed pink shrimp, it appears that Aroclor 1254 facilitates or enhances the susceptibility to latent viral infections. Aroclor 1254 was lethal to grass shrimp, Paleomonetes pugio, at 4.0 ug/l in 16 days, to

NMED Exhibit 83

amphipods at 10 ug/l in 30 days, and to juvenile spot, Leiostomus xanthurus, at 5.0 ug/l after 20 to 45 days. Sheepshead minnows, Cyprinodon variegatus, were the most sensitive estuarine organisms to Aroclor 1254 with 0.8 ug/l lethal to the fry within 2 weeks. Aroclor 1016, in two different 42-day flow-through bioassays, caused significant mortalities of pinfish at 32 ug/l and 21 ug/l. Pathological examination of those exposed to 32 ug/l revealed several liver and pancreatic alterations. Sheepshead minnows in 28-day Aroclor 1016 flow-through bioassays were not affected by concentrations of 10 ug/l or less, but died at 32 and 100 ug/l (Duke, 1974). The bioaccumulation factors determined by the flow-through bioassays are:

Aroclor	Organism	Time	Accumulation Factors (as a multiplier of test water concentrations)
1254	Oyster (Crassostrea virginica)	30 days	1.01×10^5
1254	Blue crab (Callinectes sapidus)	20 days	4×10^3
1254	Grass shrimp (Paleomonetes pugio)	7 days	3.2×10^3 to 11×10^3
1254	Spot (Leiostomus xanthurus)	14-28 days	37×10^3

NMED Exhibit 83

1254	Pinfish (Lagodon rhomboides)	35 days	21.8×10^3
1016	Pinfish (Lagodon rhomboides)	42 days	11×10^3 to 24×10^3
1016	Sheepshead minnow (Cyprinodon variegatus)		2.5×10^3 to 8.1×10^3

Based upon an accumulation factor of 100,000 in the oyster, it is necessary to limit the marine water concentration of PCB's to a maximum of 0.01 ug/l to protect the human consumer. However, data on the toxicity of Aroclor 1254 to sheepshead minnow fry mentioned earlier (Schimmel, et al., 1974), which indicate lethality at 0.1 ug/l, justify lowering the latter concentration by a factor of 0.01 to obtain a marine criterion of 0.001 ug/l. This level is further supported by the evidence cited earlier suggesting that a food tissue level of 0.5 ug/g, or 0.1 times the FDA level for human consumption, is necessary to protect carnivorous mammals.

Evidence is accumulating that PCB's do not contribute to shell thinning of bird eggs (NAS, 1974). Dietary PCB's produced no shell thinning in eggs of mallard ducks (Heath, et al., 1972). PCB's may increase susceptibility to

infectious agents such as viral diseases (Friend and Trainer, 1970), and increase the activity of liver enzymes that degrade steroids, including sex hormones (Risebrough, et al., 1968; Street, et al., 1968). Laboratory studies have indicated that PCB's with their derivatives or metabolites, cause embryonic death of birds (Voss and Koeman, 1970). Feeding PCB's to White Leghorn pullets at a level of 20 ppm caused a significant decrease in hatchability of the eggs and viability of the surviving progeny (Lillie, et al., 1974; Lillie, et al., 1975); in many cases, the cause of embryo mortality was attributed to gross abnormalities which ranged from edema to malformed appendages (Cecil, et al., 1974).

Exposure to PCB's is known to cause skin lesions (Schwartz and Peck, 1943) and to increase liver enzyme activity that may have a secondary effect on reproductive processes (Risebrough, 1969; Street, et al., 1968; Wasserman, et al., 1970). It is not clear whether the effects are due to the PCB's or their contaminants, the chlorinated dibenzofurans, which are highly toxic (Bauer, et al., 1961; Schultz, 1968; Varrett, 1970). While chlorinated

NMED Exhibit 83

dibenzofurans are a by-product of PCB production, it is not known whether they are also produced by the degradation of PCB's (NAS, 1974).

NMED Exhibit 83

SELENIUM

CRITERIA:

10 ug/l for domestic water supply (health);

For marine and freshwater aquatic life; 0.01 of the 96-hour LC_{50} as determined through bioassay using a sensitive resident species.

INTRODUCTION:

Biologically, selenium is an essential, beneficial element recognized as a metabolic requirement in trace amounts for animals but toxic to them when ingested in amounts ranging from about 0.1 to 10 mg/kg of food. The national levels of selenium in water are proportional to the selenium in the soil. In low selenium areas, the content of water may be well below 1 ug/l (Lindberg, 1968). In water from seleniferous areas, levels of selenium of 50 to 300 ug/l have been reported (WHO, 1972). Selenium appears in the soil as basic ferric selenite, calcium selenate, and as elemental selenium. Elemental selenium must be oxidized to selenite or selenate before it has appreciable solubility in water.

RATIONALE:

Selenium is considered toxic to man. Symptoms appear similar to those of arsenic poisoning (Keboe, et al., 1944; Fairhill, 1941). Any consideration of the toxicity of selenium to man must take into consideration the dietary requirement for the element in amounts estimated to be 0.04 to .10 mg/kg of food. Considering this requirement in conjunction with evidence that ingestion of selenium in amounts as low

NMED Exhibit 83

as .07 mg per day has been shown to give rise to signs of selenium toxicity, selenium concentrations above 10 ug/l should not be permitted in drinking water (Smith, et al., 1936; Smith and West, 1937). The USPHS drinking water standards recommend that drinking water supplies contain no more than 0.01 mg/l of selenium (USPHS, 1962).

As sodium selenite, 2.0 mg/l of selenium has been demonstrated to be lethal to goldfish, Carassius auratus, in 18 to 46 days (Ohio River Valley Water Sanitation Commission, 1950). Bringmann and Kuhn (1959) demonstrated the threshold effect of selenium as sodium selenite on a freshwater crustacean, an alga and a bacterium. In two days the median threshold effect occurred at 2.5 mg/l with Daphnia; in 4 days the median threshold effect was 2.5 mg/l with Scenedesmus, at 90 mg/l with Escherichia coli:, and 183 mg/l for the protozoan, Microregma.

Selenium in water apparently is toxic at concentrations of 2.5 mg/l or less to those few species tested. Animals can beneficially metabolize ingested selenium in amounts of 0.01 to 0.10 mg/kg of food.

Based on the data available, freshwater fish should not be exposed to water containing more than 0.01 of the 96-hour LC50 as determined through bioassay using a sensitive resident species.

NMED Exhibit 83

SILVER

CRITERIA:

50 ug/l for domestic water supply (health).

For marine and fresh water aquatic life 0.01 of the 96-hour LC_{50} as determined through bioassay using a sensitive resident species.

INTRODUCTION:

Biologically, silver is a non-essential, non-beneficial element recognized as causing localized skin discoloration in humans, and as being systemically toxic to aquatic life. Ingestion of silver or silver salts by humans results in deposition of silver in skin, eyes and mucous membranes that causes a blue-gray discoloration without apparent systemic reaction (Hill, 1957). Because of its strong bactericidal action, silver has been considered for use as a water disinfectant. Dosages of 0.001 to 500 ug/l of silver have been reported sufficient to sterilize water (McKee and Wolf, 1963). At these concentrations, the ingestion of silver has no obvious detrimental effect on humans.

RATIONALE:

The 1962 USPHS Drinking Water Standards contained a limit for silver of 0.05 mg/l. This limit was established because of the evidence that silver, once absorbed, is held indefinitely in tissues, particularly the skin, without evident loss through usual channels of elimination or reduction by transmigration to other body sites, and because of the probable high absorbability of silver bound to sulfur components of food cooked in silver-containing water (Aub and Fairhall, 1942). A study of the toxic

NMED Exhibit 83

effects of silver added to drinking water of rats showed pathologic changes in kidneys, liver and spleen at concentrations of 400, 700, and 1,000 ug/l (Just and Szniolis, 1936).

Using silver nitrate, Coleman and Clearly (1974) demonstrated that juvenile largemouth bass, Micropterus salmoides, and bluegill, Lepomis macrochirus exposed to silver in concentrations of 0.3 to 70 ug/l accumulated the metal, especially in the internal organs and gills. The quantity of accumulated silver increased as exposure concentrations increased with a subsequent equilibrium developing between the water and tissue concentrations. After two months' exposure to 7 ug/l silver, the concentration of silver in gills exceeded that in the gills of the control fish by 200-fold. The 70 ug/l concentration of silver was lethally toxic to bass.

Data compiled by Doudoroff and Katz (1953) show that sticklebacks were killed by a 20 ug/l concentration of silver nitrate in two days. Anderson (1948) reported that the toxic threshold of silver nitrate for sticklebacks, Gasterosteus aculeatus, was 3.0 ug/l as silver. He also found that Daphnia magna were immobilized by 3.2 ug/l as silver. Jones (1939) found the lethal concentration of silver nitrate for sticklebacks was 3.0 ug/l as silver. In differing concentrations the average survival times of the fish were; one week at 4.0 ug/l, four days at 10.0 ug/l, and only one day at 100.0 ug/l.

NMED Exhibit 83

In a 10-month bioassay on rainbow trout, Salmo gairdneri, exposed to silver nitrate, Geottl, et al. (1974) determined that no significant number of test fish died when exposed to silver concentrations of .09 and 0.17 ug/l as silver. The results did not reflect possible effects of silver on spawning behavior or reproduction.

Using silver thiosulfate, silver nitrate, silver carbonate and silver chloride, Terhaar, et al. (1972) reported that all of a test group of 20 fathead minnows, Pimephales promelas, survived exposure for 96 hours to 5,000 ug/l silver as silver thiosulfate; at 250,000 ug/l 15 of 20 fish died. Silver nitrate in concentrations of 1,000 and 100.0 ug/l as silver killed 16 out of 20 and 12 out of 20 fish, respectively. Silver carbonate killed all 20 test fish at concentrations of 1,000 ug/l.

In marine waters a concentration of 400 ug/l as silver killed 90 percent of test barnacles, Balanus balanoides (Clarke, 1947). Silver nitrate effects on the development of sea urchin, Arbacia, have been reported at approximately 0.5 ug/l (Wilber, 1969). Calabrese, et al. (1973) reported an LC_{50} (48-hour) of 5.8 ug/l as silver for oyster larvae, Crassostrea virginica, and an LC_{50} (48-hour) of 21.0 ug/l as silver for larvae of the hard-shell clam, Mercenaria mercenaria. Jackim, et al. (1970) reported a sublethal enzyme effect at a concentration of 20.0 ug/l as silver for Fundulus heteroclitus.

NMED Exhibit 83

It is apparent that there is a wide variation in the toxicity of silver compounds to aquatic life and that the degree of dissociation characteristic of these compounds affects toxicity. Since little information is available on the movement and chemical stability of these compounds in the aquatic environment, a silver criterion must be based on the total silver concentration.

The silver criterion should be established at 0.01 of the 96-hour LC_{50} as determined through bioassay using a sensitive resident species. This application factor has been recommended (NAS, 1974) for persistent or cumulative toxicants.

NMED Exhibit 83

SOLIDS (DISSOLVED) AND SALINITY

CRITERION:

250 mg/l for chlorides and sulfates
in domestic water supplies (welfare).

INTRODUCTION:

Dissolved solids and total dissolved solids are terms generally associated with freshwater systems and consist of inorganic salts, small amounts of organic matter and dissolved materials (Sawyer, 1960). The equivalent terminology in Standard Methods is filtrable residue (Standard Methods, 1971). Salinity is an oceanographic term, and although not precisely equivalent to the total dissolved salt content it is related to it (Capurro, 1970). For most purposes, the terms total dissolved salt content and salinity are equivalent. The principal inorganic anions dissolved in water include the carbonates, chlorides, sulfates and nitrates (principally in ground waters); the principal cations are sodium, potassium, calcium, and magnesium.

RATIONALE:

Excess dissolved solids are objectionable in drinking water because of possible physiological effects, unpalatable mineral tastes and higher costs because of corrosion or the necessity for additional treatment.

The physiological effects directly related to dissolved solids include laxative effects principally from sodium sulfate and magnesium sulfate and the adverse effect of sodium on certain patients afflicted with cardiac disease and women with toxemia associated with pregnancy. One study was made

NMED Exhibit 83

using data collected from wells in North Dakota. Results from a questionnaire showed that with wells in which sulfates ranged from 1,000 to 1,500 mg/l, 62 percent of the respondents indicated laxative effects associated with consumption of the water. However, nearly one-quarter of the respondents to the questionnaire reported difficulties when concentrations ranged from 200 to 500 mg/l (Moore, 1952). To protect transients to an area, a sulfate level of 250 mg/l should afford reasonable protection from laxative effects.

As indicated, sodium frequently is the principal component of dissolved solids. Persons on restricted sodium diets may have an intake restricted from 500 to 1,000 mg/day (Nat. Res. Coun., 1954). That portion ingested in water must be compensated by reduced levels in food ingested so that the total does not exceed the allowable intake. Using certain assumptions of water intake (e.g., 2 liters of water consumed per day) and sodium content of food, it has been calculated that for very restricted sodium diets, 20 mg/l in water would be the maximum, while for moderately restricted diets, 270 mg/l would be maximum. Specific sodium levels for entire water supplies have not been recommended but various restricted sodium intakes are recommended because: (1) the general population is not adversely affected by sodium, but various restricted sodium intakes are recommended by physicians for a significant portion of the population, and; (2) 270 mg/l of sodium is representative of mineralized waters that may be aesthetically unacceptable, but many domestic water supplies exceed this level. Treatment for removal of sodium in water supplies is costly (NAS, 1974).

A study based on consumer surveys in 29 California water systems was made to measure the taste threshold of dissolved salts in water (Bruvold et al., 1969) Systems were selected to eliminate possible interferences from other taste-causing substances than dissolved salts. The study revealed that consumers rated waters with 319 to 397 mg/l dissolved solids as "excellent" while those with 1283 to

NMED Exhibit 83

1333 mg/l dissolved solids were "unacceptable" depending on the rating system used. A "good" rating was registered for dissolved solids less than 658 to 755 mg/l. These results should be interpreted with consideration of consumer acclimation to such waters. The PHS Drinking Water Standards (1962) recommended a maximum dissolved solids concentration of 500 mg/l unless more suitable supplies were unavailable.

Specific constituents included in the dissolved solids in water may cause mineral taste at lower concentrations than other constituents. Chloride ions have frequently been cited as having a low taste threshold in water. Data from Ricter and MacLean (1939) on a taste panel of 53 adults indicated that. 61 mg/l NaCl was the median level for detecting a difference from distilled water. At a median concentration of 395 mg/l chloride a salty taste was distinguishable, although the range was from 120 to 1215 mg/l. Lockhart, et al. (1955) evaluated the effect of chlorides on water used for brewing coffee. Threshold concentrations for chloride ranged from 210 mg/l to 310 mg/l depending on the associated cation. These data indicate that a level of 250 mg/l chlorides is a reasonable maximum level to protect consumers of drinking water.

The causation of corrosion and encrustation of metallic surfaces by water containing dissolved solids is well known. In water distribution systems corrosion is controlled by insulating dissimilar metal connections by non-metallic materials, use of pH control and corrosion inhibitors, or some form of galvanic or impressed electrical current systems (Lehmann, 1964). Damage in household systems occurs to water piping, wastewater piping, water heaters, faucets, toilet flushing mechanisms, garbage grinders and both clothes and dishwashing machines.

NMED Exhibit 83

By use of water with 1,750 mg/l dissolved solids as compared with 250 mg/l, service life reductions ranged from 70 percent for toilet flushing mechanisms to 30 percent for washing equipment. Such increased corrosion was calculated in 1968 to cost the consumer an additional $0.50 per 1,000 gallons used (Patterson and Banker, 1968).

All species of fish and other aquatic life must tolerate a range of dissolved solids concentrations in order to survive under natural conditions. Based on studies in Saskatchewan it has been indicated that several common freshwater species survived 10,000 mg/l dissolved solids, that whitefish and pike-perch survived 15,000 mg/l, but only the stickleback survived 20,000 mg/l dissolved solids. It was concluded that lakes with dissolved solids in excess of 15,000 mg/l were unsuitable for most freshwater fishes (Rawson and Moore, 1944). The NTAC Report (1968) also recommended maintaining osmotic pressure levels of less than that caused by a 15,000 mg/l solution of sodium chloride.

Marine fishes also exhibit variance in ability to tolerate salinity changes. However, fishkills in Laguna Madre off the Texas coast have occurred with salinities in the range of 75 to 100 o/oo. Such concentrated sea water is caused by evaporation and lack of exchange with the Gulf of Mexico (Rounsefell and Everhart, 1953).

Estuarine species of fish are tolerant of salinity changes ranging from fresh to brackish to sea water. Anadromous species likewise are tolerant although evidence indicates that the young cannot tolerate the change until the normal time of migration (Rounsefell and Everhart, 1953). Other aquatic species are more dependent on salinity for protection from predators or require

NMED Exhibit 83

certain minimal salinities for successful hatching of eggs. The oyster drill cannot tolerate salinities less than 12.5 o/oo. Therefore, estuarine segments containing salinities below about 12.5 o/oo produce most of the seed oysters for planting (Rounsefell and Everhart, 1953). Based on similar examples, the NTAC Report (1968) recommended that to protect fish and other marine animals no changes in hydrography or stream flow should be allowed that permanently change isohaline patterns in the estuary by more than 10 percent from natural variation.

Many of the recommended game bird levels for dissolved solids concentrations in drinking water have been extrapolated from data collected on domestic species such as chickens. However, young ducklings were reported poisoned in Suisan Marsh by salt when maximum summer salinities varied from 0.55 to 1.74 o/oo with means as high as 1.26 o/oo (Griffith, 1963).

Indirect effects of excess dissolved solids are primarily the elimination of desirable food plants and other habitat forming plants. Rapid salinity changes cause plasmolysis of tender leaves and stems because of changes in osmotic pressure. The NTAC Report (1968) recommended the following limits in salinity variation from natural to protect wildlife habitats:

Natural Salinity (o/oo)	Variation Permitted (o/oo)
0 to 3.5	1
3.5 to 13.5	2
13.5 to 35	4

NMED Exhibit 83

Agricultural uses of water are also limited by excessive dissolved solids concentrations. Studies have indicated that chickens, swine, cattle and sheep can survive on saline waters up to 15,000 mg/l of salts of sodium and calcium combined with bicarbonates, chlorides and sulfates but only 10,000 mg/l of corresponding salts of potassium and magnesium. The approximate limit for highly alkaline waters containing sodium and calcium carbonates is 5,000 mg/l (NTAC, 1968).

Irrigation use of water is not only dependent upon the osmotic effect of dissolved solids, but also on the ratio of the various cations present. In arid and semiarid areas general classification of salinity hazards has been prepared (NTAC, 1968) (see Table 9).

Table 9 **Dissolved Solids Hazard for Irrigation Water (mg/l)**

Water from which no detrimental effects will usually be noticed	500
Water which can have detrimental effects on sensitive crops	500-1,000
Water that may have adverse effects on many crops and requires careful management practices	1,000-2,000
Water that can be used for tolerant plants on permeable soils with careful management practices	2,000-5,000

The amount of sodium and the percentage of sodium in relation to other cations are often important. In addition to contributing to osmotic pressure, sodium is toxic to certain plants, especially fruits, and frequently causes problems in soil structure, infiltration and permeability rates (Agriculture Handbook #60,

NMED Exhibit 83

1954). A high percentage of exchangeable sodium in soils containing clays that swell when wet can cause a soil condition adverse to water movement and plant growth. The exchangeable-sodium percentage (ESP)* is an index of the sodium status of soils. An ESP of 10 to 15 percent is considered excessive if a high percentage of swelling clay minerals is present (Agricultural Handbook #60, 1954).

For sensitive fruits, the tolerance for sodium for irrigation water is for a sodium adsorption ratio (SAR)** of about 4, whereas for general crops and forages a range of 8 to 18 is generally considered usable (NTAC, 1968). It is emphasized that application of these factors must be interpreted in relation to specific soil conditions existing in a given locale and therefore frequently requires field investigation.

Industrial requirements regarding the dissolved solids content of raw waters is quite variable. Table 10 indicates maximum values accepted by various industries for process requirements (NAS, 1974). Since water of almost any dissolved solids concentration can be de-ionized to meet the most stringent requirements, the economics of such treatment are the limiting factor for industry.

---

*$ESP = \frac{100[a + b(SAR)]}{1 \quad [a + b(SAR)]}$

where: a = intercept representing experimental error (ranges from -0.06 to 0.01)
b = slope of regression line (ranges from 0.014 to 0.016)

**SAR = sodium adsorption ratio = $\frac{Na}{[0.5(Ca + Mg)]^{0.5}}$

SAR is expressed as milliequivalents

NMED Exhibit 83

SOLIDS (SUSPENDED, SETTLEABLE) AND TURBIDITY

CRITERIA:

Freshwater fish and other aquatic life:

> Settleable and suspended solids should not reduce the depth of the compensation point for photosythetic activity by more then 10 percent from the seasonably established norm for aquatic life.

INTRODUCTION

The term "suspended and settleable solids" is descriptive of the organic and inorganic particulate matter in water. The equivalent terminology used for solids in Standard Methods (APHA, 1971) is total suspended matter for suspended solids, settleable matter for settleable solids, volatile suspended matter for volatile solids and fixed suspended matter for fixed suspended solids. The term "solids" is used in this discussion because of its more common use in the water pollution control literature.

RATIONALE:

Suspended solids and turbidity are important parameters in both municipal and industrial water supply practices. Finished drinking waters have a maximum limit of 1 turbidity unit where the water enters the distribution system. This limit is based on health considerations as it relates to effective chlorine disinfection. Suspended matter provides areas where micro-organisms do not come into contact with the chlorine disinfectant (NAS, 1974). The ability of common water treatment processes (i.e., coagulation, sedimentation, filtration and chlorination) to remove suspended matter to achieve acceptable

NMED Exhibit 83

final turbidities is a function of the composition of the material as well as its concentration. Because of the variability of such removal efficiency, it is not possible to delineate a general raw water criterion for these uses.

Turbid water interferes with recreational use and aesthetic enjoyment of water. Turbid waters can be dangerous for swimming, especially if diving facilities are provided because of the possibility of unseen submerged hazards and the difficulty in locating swimmers in danger of drowning (NAS, 1974). The less turbid the water the more desirable it becomes for swimming and other water contact sports. Other recreational pursuits such as boating and fishing will be adequately protected by suspended solids criteria developed for protection of fish and other aquatic life.

Fish and other aquatic life requirements concerning suspended solids can be divided into those whose effect occurs in the water column and those whose effect occurs following sedimentation to the bottom of the water body. Noted effects are similar for both fresh and marine waters.

The effects of suspended solids on fish have been reviewed by the European Inland Fisheries Advisory Commission (EIFAC, 1965). This review identified four effects on the fish and fish food populations, namely:

> "(1) by acting directly on the fish swimming in water in which solids are suspended, and either killing them or reducing their growth rate, resistance to disease, etc.;
> (2) by preventing the successful development of fish eggs and larvae;
> (3) by modifying natural movements and migrations of fish;
> (4) by reducing the abundance of food available to the fish; . . ."

NMED Exhibit 83

Settleable materials which blanket the bottom of water bodies damage the invertebrate populations, block gravel spawning beds, and if organic, remove dissolved oxygen from overlying waters (EIFAC, 1965; Edberg and Hofsten, 1973). In a study downstream from the discharge of a rock quarry where inert suspended solids were increased to 80 mg/l, the density of macroinvertebrates decreased by 60 percent while in areas of sediment accumulation benthic invertebrate populations also decreased by 60 percent regardless of the suspended solid concentrations (Gammon, 1970). Similar effects have been reported downstream from an area which was intensively logged. Major increases in stream suspended solids (25 ppm turbidity upstream vs. 390 ppm downstream) caused smothering of bottom invertebrates reducing organism density to only 7.3 per square foot versus 25.5 per square foot upstream (Tebo, 1955).

When settleable solids block gravel spawning beds which contain eggs, high mortalities result although there is evidence that some species of salmonids will not spawn in such areas (EIFAC, 1965).

It has been postulated that silt attached to the eggs prevents sufficient exchange of oxygen and carbon dioxide between the egg and the overlying water. The important variables are particle size, stream velocity and degree of turbulence (EIFAC, 1965).

Deposition of organic materials to the bottom sediments can cause imbalances in stream biota by increasing bottom animal density, principally worm populations, and diversity is reduced as pollution sensitive forms disappear (Mackenthun, 1973). Algae likewise fluorish in such nutrient rich areas although forms may become less desirable (Tarzwell and Gaufin, 1953).

NMED Exhibit 83

Plankton and inorganic suspended materials reduce light penetration into the water body reducing the depth of the photic zone. This reduces primary production and decreases fish food. The NAS committee recommended that the depth of light penetration not be reduced by more than 10 percent (NAS, 1974). Additionally, the near surface waters are heated because of the greater heat absorbency of the particulate material which tends to stabilize the water column and prevents vertical mixing (NAS, 1974). Such mixing reductions decrease the dispersion of dissolved oxygen and nutrients to lower portions of the water body.

One partially offsetting benefit of suspended inorganic material in water is the sorption of organic materials such as pesticides. Following this sorption process subsequent sedimentation may remove these materials from the water column into the sediments (NAS, 1974).

Identifiable effects of suspended solids on irrigation use of water include the formation of crusts on top of the soil which inhibits water infiltration, plant emergence and impedes soil aeration; the formation of films on plant leaves which blocks sunlight and impedes photosynthesis and which may reduce the marketability of some leafy crops like lettuce; and finally the adverse effect on irrigation reservoir capacity, delivery canals and other distribution equipment (NAS, 1974).

The criteria for freshwater fish and other aquatic life is essentially that proposed by the N.A.S. and the Great Lakes Water Quality Board.

SULFIDE - HYDROGEN SULFIDE

CRITERION:

2 ug/l undissociated H_2S for fish and other aquatic life, fresh and marine water

INTRODUCTION:

Hydrogen sulfide is a soluble, highly poisonous, gaseous compound having the characteristic odor of rotten eggs. It is detectable in air by humans at a dilution of 0.002 ppm. It will dissolve in water at 4000 mg/l at 20°C and one atmosphere of pressure. Hydrogen sulfide biologically is an active compound that is found primarily as an anaerobic degradation product of both organic sulfur compounds and inorganic sulfates. Sulfides are constituents of many industrial wastes such as those from tanneries, paper mills, chemical plants and gas works. The anaerobic decomposition of sewage, sludge beds, algae and other naturally deposited organic material is a major source of hydrogen sulfide.

When soluble sulfides are added to water they react with hydrogen ions to form HS^- or H_2S, the proportion of each

NMED Exhibit 83

depending on the pH. The toxicity of sulfides derives primarily from H_2S rather than from the hydrosulfide (HS^-) or sulfide ($S^=$) ions. When hydrogen sulfide dissolves in water it dissociates according to the reactions:

$$H_2S \rightleftharpoons HS^- + H^+ \text{ and } HS^- \rightleftharpoons S^= + H^+$$

At pH 9 about 99 percent of the sulfide is in the form of HS^-, at pH 7 the sulfide is equally divided between HS^- and H_2S and at pH 5 about 99 percent of the sulfide is present as H_2S (NAS 1974). The fact that H_2S is oxidized in well-aerated water by natural biological systems to sulfates or is biologically oxidized to elemental sulfur has caused investigators to minimize the toxic effects of H_2S on fish and other aquatic life.

RATIONALE:

The degree of hazard exhibited by sulfide to aquatic animal life is dependent on the temperature, pH and dissolved oxygen. At lower pH values a greater proportion is in the form of the toxic undissociated H_2S. In winter when the pH is neutral or below or when dissolved oxygen levels are low but not lethal to fish, the hazard from sulfides is exacerbated. Fish exhibit a strong avoidance reaction to sulfide. Based on data from experiments with the stickleback, Jones (1964) hypothesized that if fish

NMED Exhibit 83

encounter a lethal concentration of sulfide there is a reasonable chance they will be repelled by it before they are harmed. This of course assumes that an escape route is open.

Many past data on the toxicity of hydrogen sulfide to fish and other aquatic life have been based on extremely short exposure periods. Consequently these early data have indicated that concentrations between 0.3 and 0.4 mg/l permit fish to survive (Van Horn 1958, Boon and Follis 1967, Theede et al., 1969). Recent long-term data, both in field situations and under controlled laboratory conditions, demonstrate hydrogen sulfide toxicity at lower concentrations.

Colby and Smith (1967) found that concentrations as high as 0.7 mg/l existed within 20 mm of the bottom of sludge beds, and the levels of 0.1 to 0.02 mg/l were common within the first 20 mm of water above this layer. Walleye, Stizostedion vitreum, eggs held in trays in this zone did not hatch. Adelman and Smith (1970) reported that the hatchability of northern pike, Esox lucius, eggs was substantially reduced at 25 ug/l H_2S; at 47 ug/l mortality was almost complete. Northern pike fry had

NMED Exhibit 83

96-hour LC_{50} values that varied from 17 to 32 ug/l at normal oxygen levels of 6.0 mg/l. The highest concentration of hydrogen sulfide that had no observable effect on eggs and fry was 14 and 4 ug/l, respectively. Smith and Oseid (1972), working on eggs, fry and juveniles of walleyes and white suckers, Catostomus commersoni , and Smith (1971), working on walleyes and fathead minnows, Pimephales promelas , found that safe levels varied from 2.9 ug/l to 12 ug/l with eggs being the least sensitive and juveniles being the most sensitive in short-term tests. In 96-hour bioassays, fathead minnows and goldfish, Carassius auratus, varied greatly in tolerance to hydrogen sulfide with changes in temperature. They were more tolerant at low temperatures (6 to 10°C). Holland, et al. (1960) reported that 1.0 mg/l sulfide caused 100 percent mortality in 72 hours with Pacific salmon.

On the basis of chronic tests evaluating growth and survival, the safe H_2S level for bluegill, Lepomis macrochirus, juveniles and adults was 2 ug/l. Egg deposition in bluegills was reduced after 46 days in 1.4 ug/l H_2S (Smith and Oseid, 1974). White sucker eggs were hatched at 15 ug/l, but juveniles showed growth reductions at 1 ug/l. Safe levels for fathead minnows were between 2 and 3 ug/l. Studies showed that safe levels for Gammarus pseudolimnaeus and Hexagenia limbata were 2 and 15 ug/l, respectively (Oseid and Smith, 1974a, 1974b). Some species typical of normally stressed habitats, Asellus spp., were much more resistant (Oseid and Smith, 1974c).

NMED Exhibit 83

Sulfide criteria for domestic or livestock use have not been established because the unpleasant odor and taste would preclude such use at hazardous concentrations.

It is recognized that the hazard from hydrogen sulfide to aquatic life is often localized and transient. Available data indicate that water containing concentrations of 2.0 ug/l undissociated H_2S would not be hazardous to most fish and other aquatic wildlife, but concentrations in excess of 2.0 ug/l would constitute a long-term hazard.

NMED Exhibit 83

TAINTING SUBSTANCES

CRITERION:

> Materials should not be present in concentrations that individually or in combination produce undesirable flavors which are detectable by organoleptic tests performed on the edible portions of aquatic organisms.

RATIONALE:

Fish or shellfish with abnormal flavors, colors, tastes or odors are either not marketable or will result in consumer complaints and possible rejection of the food source even though subsequent lots of organisms may be acceptable. Poor product quality can and has seriously affected or eliminated the commercial fishing industry in some areas. Recreational fishing also can be affected adversely by off-flavored fish. For the majority of sport fishermen, the consumption of their catch is part of their recreation and off-flavored catches can result in diversion of the sportsmen to other water bodies. This can have serious economic impact on the established recreation industries such as tackle and bait sales and boat and cottage rental.

Water Quality Criteria, 1972 (NAS, 1974) lists a number of wastewaters and chemical compounds that have been found to lower the palatability of fish flesh. Implicated wastewaters included those from 2,4-D manufacturing plants, kraft and neutral sulfite pulping processes, municipal wastewater treatment plants, oily wastes, refinery wastes, phenolic wastes, and wastes from slaughterhouses. The list of implicated chemical compounds is long; it includes cresol and phenol compounds, kerosene, naphthol, styrene, toluene, and exhaust outboard motor fuel. As little as 0.1 ug/l o-chlorophenol was reported to cause tainting of fish flesh.

Shumway and Palensky (1973) determined estimated threshold concentrations for

NMED Exhibit 83

twenty-two organic compounds. The values ranged from 0.4 ug/l (2,4-dichlorophenol) to 95,000 ug/l (formaldehyde). An additional twelve compounds were tested, seven of which were not found to impair flavor at or near lethal levels.

Thomas (1973) reviewed the literature on tainting substances and listed serious problems that have occurred; he detailed studies and methodology used in the evaluation of the palatability of fishes in the Ohio River as affected by various waste discharges. The susceptibility of fishes to the accumulation of tainting substances is variable and dependent upon the species, length of exposure, and the pollutant. As little as 5 ug/l of gasoline can impart off-flavors to fish (Boyle, 1967).

NMED Exhibit 83

TEMPERATURE

CRITERIA

Freshwater Aquatic Life

For any time of year, there are two upper limiting temperatures for a location (based on the important sensitive species found there at that time):

1. One limit consists of a maximum temperature for short exposures that is time dependent and is given by the species-specific equation:

$$\text{Temperature}_{(C^o)} = (1/b)(\log_{10}[\text{time}_{(\text{min})}] - a) - 2^oC$$

where: $\log_{10}$ = logarithm to base 10. (common logarithm)

a = intercept on the "y" or logarithmic axis of the line fitted to experimental data and which is available from Appendix II-C, NAS, 1974 for some species.

b = slope of the line fitted to experimental data and available from Appendix II-C, NAS, 1974 for some species.

and

2. The second value is a limit on the weekly average temperature that:

   a. in the cooler months (mid-October to mid-April in the north and December to February in the south) will protect against mortality of important species if the elevated plume temperature is suddenly dropped to the ambient temperature, with the limit being the acclimation temperature minus 2^oC when the lower lethal threshold temperature equals the ambient water temperature (in some regions this limitation may also be applicable in summer).

or

   b. In the warmer months (April through October in the north and March through November in the south) is determined by adding to the physiological optimum temperature (usually for growth) a factor calculated as one-third of the difference between the ultimate upper incipient lethal temperature and the optimum temperature for the most sensitive important species (and appropriate life state) that normally is found at that location and time.

NMED Exhibit 83

or

c. During reproductive seasons (generally April through June and September through October in the north and March through May and October through November in the south) the limit is that temperature that meets site-specific requirements for successful migration, spawning, egg incubation, fry rearing, and other reproductive functions of important species. These local requirements should supersede all other requirements when they are applicable.

or

d. There is a site-specific limit that is found necessary to preserve normal species diversity or prevent appearance of nuisance organisms.

Marine Aquatic Life

In order to assure protection of the characteristic indigenous marine community of a water body segment from adverse thermal effects:

a) the maximum acceptable increase in the weekly average temperature due to artificial sources is 1° C (1.8° F) during all seasons of the year, providing the summer maxima are not exceeded; and

b) daily temperature cycles characteristic of the water body segment should not be altered in either amplitude or frequency.

Summer thermal maxima, which define the upper thermal limits for the communities of the discharge area, should be established on a site-specific basis. Existing studies suggest the following regional limits:

	Short-term Maximum	Maximum True Daily Mean*
Sub-tropical Regions (south of Cape Canaveral and Tampa Bay, Florida, and Hawaii	32.2° C (90° F)	29.4°C (85°F)
Cape Hatteras, N.C., to Cape Canaveral, Fla.	32.2° C (90° F)	29.4° C (85° F)
Long Island (south shore) to Cape Hatteras, N.C.	30.6° C (87° F)	27.8° C (82° F)

(* True Daily Mean = average of 24 hourly temperature readings.)

NMED Exhibit 83

Baseline thermal conditions should be measured at a site where there is no unnatural thermal addition from any source, which is in reasonable proximity to the thermal discharge (within 5 miles) and which has similar hydrography to that of the receiving waters at the discharge.

INTRODUCTION

The uses of water by man in and out of its natural situs in the environment are affected by its temperature. Offstream domestic uses and instream recreation are both partially temperature dependent. Likewise, the life associated with the aquatic environment in any location has its species composition and activity regulated by water temperature. Since essentially all of these organisms are so called "cold blooded" or poikilotherms, the temperature of the water regulates their metabolism and ability to survive and reproduce effectively. Industrial uses for process water and for cooling is likewise regulated by the water's temperature. Temperature, therefore, is an important physical parameter which to some extent regulates many of the beneficial uses of water. To quote from the FWPCA (1967), "Temperature, a catalyst, a depressant, an activator, a restrictor, a stimulator, a controller, a killer, is one of the most important and most influential water quality characteristics to life in water."

RATIONALE

The suitability of water for total body immersion is greatly affected by temperature. In temperate climates, dangers from exposure to low temperatures is more prevalent than exposure to elevated water temperatures. Depending on the amount of activity by the swimmer, comfortable temperatures range from 20°C to 30°C. Short durations of lower and higher temperatures can be tolerated by most individuals. For example, for a 30-minute period, temperatures of 10°C or 35°C can be tolerated without harm by most individuals (NAS, 1974).

NMED Exhibit 83

Temperature also affects the self-purification phenomenon in water bodies and therefore the aesthetic and sanitary qualities that exist. Increased temperatures accelerate the biodegradation of organic material both in the overlying water and in bottom deposits which makes increased demands on the dissolved oxygen resources of a given system. The typical situation is exacerbated by the fact that oxygen becomes less soluble as water temperature increases. Thus, greater demands are exerted on an increasingly scarce resource which may lead to total oxygen depletion and obnoxious septic conditions. These effects have been described by Phelps (1944), Camp (1963), and Velz (1970).

Indicator enteric bacteria, and presumably enteric pathogens, are likewise affected by temperature. It has been shown that both total and fecal coliform bacteria die away more rapidly in the environment with increasing temperatures (Ballentine and Kittrell, 1968).

Temperature effects have been shown for water treatment processes. Lower temperatures reduce the effectiveness of coagulation with alum and subsequent rapid sand filtration. In one study, difficulty was especially pronounced below 5°C (Hannah, et al., 1967). Decreased temperature also decreases the effectiveness of chlorination. Based on studies relating chlorine dosage to temperature, and with a 30-minute contact time, dosages required for equivalent disinfective effect increased by as much as a factor of 3 when temperatures were decreased from 20° C to 10° C (Reid and Carlson, 1974). Increased temperature may increase the odor of water because of the increased volatility of odor-causing compounds (Burnson, 1938). Odor problems associated with plankton may also be aggravated.

NMED Exhibit 83

The effects of temperature on aquatic organisms have been the subject of several comprehensive literature reviews (Brett, 1956; Fry, 1967; FWPCA, 1967; Kinne, 1970) and annual literature reviews published by the Water Pollution Control Federation (Coutant, 1968, 1969, 1970, 1971; Coutant and Goodyear, 1972; Coutant and Pfuderer, 1973, 1974). Only highlights from the thermal effects on aquatic life are presented here.

Temperature changes in water bodies can alter the existing aquatic community. The dominance of various phytoplankton groups in specific temperature ranges has been shown. For example, from 20°C to 25°C, diatoms predominated; green algae predominated from 30°C to 35°C; and blue-greens predominated above 35°C (Cairns, 1956). Likewise, changes from a cold water fishery to a warm water fishery can occur because temperature may be directly lethal to adults or fry; cause a reduction of activity; or limit reproduction (Brett, 1960).

Upper and lower limits for temperature have been established for many aquatic organisms. Considerably more data exist for upper as opposed to lower limits. Tabulations of lethal temperatures for fish and other organisms are available (Jones, 1964: FWPCA, 1967; NAS, 1974). Factors such as diet, activity, age, general health, osmotic stress, and even weather contribute to the lethality of temperature. The aquatic species, thermal acclimation state and exposure time are considered the critical factors (Parker and Krenkel, 1969).

The effects of sublethal temperatures on metabolism, respiration, behavior, distribution and migration, feeding rate, growth and reproduction have been summarized by De Sylva (1969). Another study has illustrated that inside the tolerance zone there is encompassed a more restrictive temperature range in

NMED Exhibit 83

which normal activity and growth occur; and yet an even more restrictive zone inside that in which normal reproduction will occur (Brett, 1960).

De Sylva (1969) has summarized available data on the combined effects of increased temperature and toxic materials on fish. The available data indicate that toxicity generally increases with increased temperature and that organisms subjected to stress from toxic materials are less tolerant of temperature extremes.

The tolerance of organisms to extremes of temperature is a function of their genetic ability to adapt to thermal changes within their charactertistic temperature range, the acclimation temperature prior to exposure, and the time of exposure to the elevated temperature (Coutant, 1972). The upper incipient lethal temperature or the highest temperature that 50% of a sample of organisms can survive is determined on the organism at the highest sustainable acclimation temperature. The lowest temperature that 50% of the warm acclimated organisms can survive in is the ultimate lower incipient lethal temperature. True acclimation to changing temperatures requires several days (Brett, 1941). The lower end of the temperature accommodation range for aquatic life is $0^{o}C$ in fresh water and somewhat less for saline waters. However, organisms acclimated to relatively warm water, when subjected to reduced temperatures which under other conditions of acclimation would not be detrimental, may suffer a significant mortality due to thermal shock (Coutant, 1972).

Through the natural changes in climatic conditions, the temperatures of water bodies fluctuate daily, as well as seasonally. These changes do not eliminate indigenous aquatic populations, but affect the existing community structure and the geographical distribution of species. Such temperature changes are necessary to induce the reproductive cycles of aquatic organisms and to regulate other life factors (Mount, 1969).
