Black-spotted pond frog (adult), *Pelophylax nigromaculatus* (formerly, *Rana nigromaculatus*)	S, U	21 days	PFOA >98%	-	-	LOEC (gene expression)	-	0.01	Non-apical endpoint	Lin et al. 2022a
Black-spotted pond frog, *Pelophylax nigromaculatus*	R, U	21 days	PFOA >98%	6.5	20	LOEC (cholesterol and triglyceride levels)	-	0.0025	Non-apical endpoint	Lin et al. 2022b
Black-spotted pond frog (adult), *Pelophylax nigromaculatus*	S, U	21 days	PFOA >98%	6.5	20	LOEC (reduced glutathione)	-	0.91	Non-apical endpoint	Lin et al. 2022c
Black-spotted pond frog, *Pelophylax nigromaculatus*	S, U	21 days	PFOA >98%	6.5	20	MATC (biochemical, genetic and immunological effects)	0.00111-0.01094	0.003485	Non-apical endpoint	Liu et al. 2023c
Gray treefrog (larva, Gosner 40), *Hyla versicolor*	S, U	96 hours	PFOA Unreported	-	21	LC_{50}	-	191	Poor control survival, low number of individuals per treatment.	Tornabene et al. 2021
Tiger salamander (larva, Harrison stage 46), *Ambystoma tigrinum*	R, M	30 days	PFOA ≥96%	-	20	NOEC (snout-vent length, weight, and mortality)	0.8677->0.8667	0.8677	Highly variable dose-response	Flynn et al. 2022
American toad (larva, Gosner stage 25), *Anaxyrus americanus*	R, M	26-45 days	PFOA ≥96%	-	20	MATC (days to metamorphosis)	0.09403-0.8728	0.2865	Highly variable dose-response	Flynn et al. 2022
American toad (larva, Gosner stage 25), *Anaxyrus americanus*	R, M	26-45 days	PFOA ≥96%	-	20	NOEC (growth, mortality)	0.8728->0.8728	0.8728	Highly variable dose-response	Flynn et al. 2022
Asiatic toad (tadpole, 1.8 cm, 0.048 g), *Bufo gargarizans*	R, M	96 hours	PFOA 99%	7	22	LC_{50}	-	114.74	Atypical source of organisms	Yang et al. 2014

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Effect	Chronic Limits (NOEC-LOEC) (mg/L)	Reported Effect Conc. (mg/L)	Deficiencies	Reference
Asiatic toad (tadpole, 1.8 cm, 0.048 g), *Bufo gargarizans*	R, M	30 days	PFOA 99%	7	22	EC_{10} (survival)	-	5.89	Not a true ELS test, atypical source of organisms	Yang et al. 2014

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

[b] C1 year corresponds to the total duration of the 10-generations study. Most generations did not show statistically significant effects.

[c] Reported in moles converted to milligram based on a molecular weight of 414.07 g/mol PFOA or 431.1 g/mol APFO.

[d] Chemical concentrations made in a side-test representative of exposure and verified stability of concentrations of PFOA in the range of concentrations tested under similar conditions. Daily renewal of test solutions.

[e] Concentration of APFO determined as the anion (PFO-).

NMED Exhibit 63

Appendix H Other Estuarine/Marine PFOA Toxicity Studies

H.1 Summary Table of Qualitative Estuarine/Marine PFOA Toxicity Studies

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Effect	Chronic Limits (NOEC-LOEC) (mg/L)	Reported Effect Conc. (mg/L)	Deficiencies	Reference
Bacterium, *Vibrio fischeri*	S, M	15 minutes	PFOA 96%	-	18	-	EC_{50} (bioluminescence inhibition)	-	524	Duration too short for a plant test, missing some exposure details, non-apical endpoint	Rosal et al. 2010
Cyanobacterium, *Anabaena sp.*	S, M	24 hours	PFOA 96%	-	28	-	EC_{50} (bioluminescence inhibition)	-	72.3	Duration too short for a plant test, missing some exposure details, non-apical endpoint	Rosal et al. 2010
Cyanobacterium, *Geitlerinema amphibium*	S, U	72 hours	PFOA Unreported	7.6-7.8	20	8	EC_{50} (growth)	-	248.4[b]	Duration too short for a plant test, missing some exposure details	Latala et al. 2009
Dinoflagellate, *Pyrocystis lunula*	S, M	24 hours	PFOA 95%	-	19	-	EC50 (bioluminescence inhibition)	-	18	Duration too short for a plant test, atypical endpoint	Hayman et al. 2021
Golden brown alga, *Isochrysis galbana*	S, U	72 hours	PFOA 96%	-	20	-	EC_{50} (growth inhibition)	-	163.6	Duration too short for a plant test, missing some exposure details	Mhadhbi et al. 2012
Green alga, *Chlorella vulgaris*	S, U	72 hours	PFOA Unreported	7.6-7.8	20	8	EC_{50} (growth)	-	977.2[b]	Duration too short for a plant test, missing some exposure details	Latala et al. 2009
Diatom, *Skeletonema marinoi*	S, U	72 hours	PFOA Unreported	7.6-7.8	20	8	EC_{50} (growth)	-	368.5[b]	Duration too short for a plant test, missing some exposure details	Latala et al. 2009
Purple sea urchin (fertilized eggs), *Paracentrotus lividus*	S, U	48 hours	PFOA 96%	-	20	-	EC_{50} (growth inhibition)	-	110.0	Duration too short for an acute test	Mhadhbi et al. 2012
Blue mussel, *Mytilus edulis*	R, U	21 days	PFOA Unreported	-	16-19	-	LOEC (catalase activity)	<0.2-0.2	0.2	Atypical endpoint	Li et al. 2021a

NMED Exhibit 63

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Effect	Chronic Limits (NOEC-LOEC) (mg/L)	Reported Effect Conc. (mg/L)	Deficiencies	Reference
Mediterranean mussel (adult), *Mytilus galloprovincialis*	R, U	16 days	PFOA ≥98%	7.98	15.2	37.9	NOEC (biochemistry, enzymatic changes)	0.100->0.100	0.100	Duration too short for a chronic exposure, non-apical endpoints	Geng et al. 2021
Green mussel (60-65 mm), *Perna viridis*	R, M	7 days	PFOA 96%	-	25	25	MATC (relative condition factor)	0.0114-0.099	0.03359	Exposure duration too short for chronic test and too long for acute test, non-apical endpoint	Liu et al. 2013; 2014c
Green mussel (adult), *Perna viridis*	R, M	7 days + 7 days observation	PFOA 96%	-	25	30	EC_{50} (integrative genotoxicity)	0.093-0.950	0.5940	Exposure duration too short for chronic test and too long for acute test, non-apical endpoint	Liu et al. 2014a
Green mussel (adult), *Perna viridis*	R, M	7 days	PFOA 96%	-	25	25	MATC (CAT and SOD activity)	0.099-1.12	0.3330	Exposure duration too short for chronic test and too long for acute test, non-apical endpoint	Liu et al. 2014b
Green mussel, *Perna viridis*	R, M	7 days + 7 days observation	PFOA 96%	8	25	30	MATC (hemocyte cell viability)	0.0114-0.099	0.03359	Exposure duration too short for chronic test and too long for acute test, non-apical endpoint	Liu and Gin 2018
Manila clam (3.64 cm), *Ruditapes philippinarum*	R, M	21 days	PFOA Unreported	-	12	35	NOEC (mortality)	0.00093->0.00093	0.00093	Only one exposure concentration, apical endpoints are not the focus of study	Bernardini et al. 2021
Manila clam, *Ruditapes philippinarum*	R, M	21 days	APFO >98%	-	12	35	NOEC (biochemistry, cell diameter, cell volume, hematocyte count)	0.00093->0.00093	0.00093	Only one exposure concentration, non-apical endpoints	Fabrello et al. 2021
Dolphinfish (embryo, <8 hr post spawn), *Coryphaena hippurus*	S, M	48 hours	PFOA 96%	-	27	-	LC_{50}	-	4	Duration too short for an acute test, high control mortality	Gebreab et al. 2022
Japanese medaka (adult), *Oryzias latipes*	R, U	7 days	PFOA ammonium salt 98%	-	25	-	NOEC (survival, condition factor)	100->100	100	Exposure duration too short for chronic test and too long for acute test	Yang 2010

NMED Exhibit 63

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Effect	Chronic Limits (NOEC-LOEC) (mg/L)	Reported Effect Conc. (mg/L)	Deficiencies	Reference
Dusky rockcod (adult), *Trematomus newnesi*	S, U	10 days	PFOA Unreported	-	-1	-	LOEC (gene expression)	-	1.5	Duration too long for an acute test and too short for a chronic test, atypical endpoint	Pacchini et al. 2023
Marbled flounder (adult), *Pseudopleuronectes yokohamae*	R, M	14 days	PFOA Unreported	-	15	37	LOEC (vitellogenin levels)	<0.197-0.197	0.197	Atypical duration, non-apical endpoint	Li et al. 2018b
Turbot (embryo), *Scophthalmus maximus* (formerly, *Psetta maxima*)	R, U	6 days	PFOA 96%	-	18	-	LC_{50}	-	11.9	Exposure duration too short for chronic test and too long for acute test	Mhadhbi et al. 2012

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

[b] Reported in moles converted to milligram based on a molecular weight of 414.07 mg/mmol.

NMED Exhibit 63

Appendix I Acute-to-Chronic Ratios

I.1 Acute-to-Chronic Ratios from Quantitatively Acceptable Tests.

Species	Chemical / Purity	Acute Test Duration	Chronic Test Duration	Acute Effect	Chronic Effect	Acute Effect Conc. (mg/L)	Chronic Effect Conc. (mg/L)	ACR	SMACR	Reference
Rotifer, *Brachionus calyciflorus*	PFOA 96%	24 hours	Up to 200 hours	LC_{50}	EC_{10} (intrinsic rate of natural increase)	150	0.5015	299.1	299.1	Zhang et al. 2013a
Water flea, *Daphnia carinata*	PFOA 95%	48 hours	21 days	EC_{50}	MATC (# of average number of offspring per brood and total # of living offspring)	66.8	0.03162	2,113	2,113	Logeshwaran et al. 2021
Cladoceran, *Daphnia magna*	APFO 99.7%	48 hours	21 days	EC_{50}	EC_{10} (average # of live young)	480	20.26	23.69	-	Colombo et al. 2008
Cladoceran, *Daphnia magna*	PFOA Unreported	48 hours	21 days	EC_{50} (immobility)	EC_{10} (# young/starting female)	542.5	7.853	69.08	-	Ji et al. 2008
Cladoceran, *Daphnia magna*	PFOA >98%	48 hours	21 days	LC_{50}	EC_{10} (# young/starting female)	193.3[a]	12.89	15.00	-	Li 2009, 2010
Cladoceran, *Daphnia magna*	PFOA 99%	48 hours	21 days	LC_{50}	EC_{10} (survival)	222.0	5.458	40.67	-	Yang et al. 2014
Cladoceran, *Daphnia magna*	PFOA 98%	48 hours	21 days	EC_{50}	MATC (growth and reproduction)	114.6	0.07155	1,602[b]	-	Lu et al. 2016
Cladoceran, *Daphnia magna*	PFOA Unreported	48 hours	21 days	LC_{50}	EC_{10} (# of offspring)	117.2	8.084	14.50	27.05	Yang et al. 2019

NMED Exhibit 63

Species	Chemical / Purity	Acute Test Duration	Chronic Test Duration	Acute Effect	Chronic Effect	Acute Effect Conc. (mg/L)	Chronic Effect Conc. (mg/L)	ACR	SMACR	Reference
Cladoceran, *Moina macrocopa*	PFOA Unreported	48 hours	7 days	EC_{50} (immobility)	EC_{10} (mean young/adult)	166.3	2.194	75.80	75.80	Ji et al. 2008
Mayfly, *Neocloeon triangulifer*	PFOA 95%	96 hours	23 days	LC_{50}	NOEC (survival, weight, emergence)	13.05	>3.085	<4.229	<4.229	Soucek et al. 2023
American bullfrog, *Lithobates catesbeiana*	PFOA Unreported	96 hours	72 days	LC_{50}	LOEC (snout vent length)	1,006	0.288	3,493	3,493	Flynn et al. 2019

a Geometric mean of three LC50 values.

b Value not used in the SMACR calculation, because the value is an order of magnitude greater than other ACRs for the species.

NMED Exhibit 63

Appendix J Unused PFOA Toxicity Studies

J.1 Summary of Unused PFOA Toxicity Studies

Author	Citation	Reason Unused
Arukwe, A. and A.S. Mortensen	2011. Lipid peroxidation and oxidative stress responses of salmon fed a diet containing perfluorooctane sulfonic- or perfluorooctane carboxylic acids. Comp. Biochem. Physiol. Part C 154: 288-295.	Force-fed (oral gavage); only one exposure concentration
Consoer, D.M.	2017. A mechanistic investigation of perfluoroalkyl acid kinetics in rainbow trout (*Oncorhynchus mykiss*). A dissertation submitted to the faculty of the University of Minnesota.	Injected toxicant; only one exposure concentration
Consoer, D.M., A.D. Hoffman, P.N. Fitzsimmons, P.A. Kosian and J.W. Nichols	2014. Toxicokinetics of perfluorooctanoate (PFOA) in rainbow trout (*Oncorhynchus mykiss*). Aquat. Toxicol. 156: 65-73.	All fish were surgically altered (dorsal aortic cannula, plus a urinary catheter); no controls; non-apical endpoints only
Cui, Y., W. Liu, W. Xie, W. Yu, C. Wang and H. Chen	2015. Investigation of the effects of perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS) on apoptosis and cell cycle in a zebrafish (*Danio rerio*) liver cell line. Int. J. Environ. Res. Public Health 12(12): 15673-15682.	Excised cells (liver cell line)
De Silva, A.O., P.J. Tseng and S.A. Mabury	2009. Toxicokinetics of perfluorocarboxylate isomers in rainbow trout. Environ. Toxicol. Chem. 28(2): 330-337.	Study involved a mixture of ECF PFOA, linear PFNA, and isopropyl PFNA added to diet
Dragojevic, J., P. Maric, J. Loncar, M. Popovic, I. Mihaljevic, and T. Smital	2020. Environmental Contaminants Modulate Transport Activity of Zebrafish Organic Anion Transporters Oat1 and Oat3. Comp. Biochem. Physiol. C Toxicol. Pharmacol.231:8 p.	The test duration was extremely brief (~10 mins), the exposure was in vitro, and no apical effects were evaluated.
Elnabarawy, M.T.	1980. Aquatic Toxicity Testing: FC-143 (Lot-37) L.R. 5626 S. Report No. 037; OPPT Administrative Record AR226-0504:3780-3786.	Results reported in another publication
Fernández-Sanjuan, M., M. Faria, S. Lacorte and C. Barata	2013. Bioaccumulation and effects of perfluorinated compounds (PFCs) in zebra mussels (*Dreissena polymorpha*). Environ. Sci. Pollut. Res. 20:2661–2669.	Mixture
Garoche, C., A. Boulahtouf, M. Grimaldi, B. Chiavarina, L. Toporova, M.J. Den Broeder, J. Legler, W. Bourguet and P. Ba.	2021. Interspecies differences in activation of peroxisome proliferator-activated receptor gamma by pharmaceutical and environmental chemicals. Environ. Sci. Technol. 55(24): 16489-16501.	In vitro
Gonzalez-Naranjo, V. and K. Boltes	2014. Toxicity of ibuprofen and perfluorooctanoic acid for risk assessment of mixtures in aquatic and terrestrial environments. Int. J. Environ. Sci. Technol. 11: 1743-1750.	Severe lack of exposure details (cannot judge against data quality objectives)
Gorrochategui, E., S. Lacorte, R. Tucker and F.L. Martin	2016. Perfluoroalkylated substance effects in *Xenopus laevis* A6 kidney epithelial cells determined by ATR-FTIR spectroscopy and chemometric analysis. Chem. Res. Toxicol. 29: 924-932.	The tests were performed on cell cultures obtained from an outside source; whole organisms were not investigated
Holth, T.F., M. Yazdani, A. Lenderink and K. Hyllan	2012. Effects of fluoranthene and perfluorooctanoic acid (PFOA) on immune functions in Atlantic cod (*Gadus morhua*). Abstracts Comp. Biochem. Physiol. Part A. 163: S39-S42.	Abstract only; cannot judge against data quality objectives

NMED Exhibit 63

Author	Citation	Reason Unused
Hoover, G.M.	2018. Effects of Per/Polyfluoroalkyl Substance Exposure on Larval Amphibians. Ph.D.Thesis, Purdue University, West Lafayette, IN	Test is unused because the source material is a PhD Thesis and has not undergone peer review. Only peer-reviewed data are considered in deriving aquatic life criteria
Hoover, G., S. Kar, S. Guffey, J. Leszczynski, and M.S. Sepulveda	2019. In Vitro and In Silico Modeling of Perfluoroalkyl Substances Mixture Toxicity in an Amphibian Fibroblast Cell Line. Chemosphere233:25-33.	In vitro exposure
Jantzen, C.E., K.M. Annunziato and K.R. Cooper	2016. Behavioral, morphometric, and gene expression effects in adult zebrafish (*Danio rerio*) embryonically exposed to PFOA, PFOS, and PFNA. Aquatic Toxicology. 180:123–130.	Single concentration test where exposure to PFOA was of an acute (117-hours) duration but endpoints were measured at 6 months of age
Jantzen, C.E., F. Toor, K.M. Annunziato and K.R. Cooper	2017b. Effects of chronic perfluorooctanoic acid (PFOA) at low concentration on morphometrics, gene expression, and fecundity in zebrafish (*Danio rerio*). Reproduct. Toxicol. 69: 34-42.	Unable to determine dietary exposure concentration
Khan, E.A., X. Zhang, E.M. Hanna, F. Yadetie, I. Jonassen, A. Goksoyr and A. Arukwe	2021. Appendix K EPA Methodology for Fitting Concentration-Response Data and Calculating Effect Concentrations

Toxicity values, including LC_{50} and EC_{10} values, were independently calculated from the data presented in the toxicity studies meeting the inclusion criteria described above (see Section 2.10.3.3) and when adequate concentrations-response data were published in the study or could be obtained from authors. When concentration-response data were not presented in toxicity studies, concentration-response data were requested from study authors to independently calculate toxicity values. In cases where study authors did not respond to the EPA's request for data or were unable to locate concentration-response data, the toxicity values were not independently calculated by the EPA, and the reported toxicity values were retained for criteria deviation. The EPA also retained author-reported effect concentrations when data availability did not support effect concentration calculation by the EPA. This retention was done to be consistent with use of author-reported toxicity values in previous criteria documents and retain informative toxicity values (that would have otherwise not been used only on the basis of lacking the underlying C-R data). Where concentration-response data were available, they were analyzed using the statistical software program R (version 3.6.2) and the associated dose-response curve (drc) package.

In some cases, the author-reported toxicity values were different than the corresponding effect concentrations calculated by the EPA. Overall, the magnitude of such discrepancies was limited and largely occurred for several potential reasons such as: (1) instances where authors were presumed to calculate effect concentrations using replicate level data, but the EPA only had access to treatment mean data; (2) the model selected to fit a particular set of C-R data, and; (3) the software used to fit a model to C-R data and calculate an effect concentration.

NMED Exhibit 63

K.1 Fitting Concentration Response Data in R

Concentration-response data were obtained from quantitatively-acceptable toxicity studies when reported data were available. In many scenarios, toxicity studies report treatment-level mean concentrations and mean organismal responses; however, individual-replicate data may also be reported. When fitting C-R curves, replicate-level data were preferred over treatment-level data, if both types of data were available. Within R, the drc package can fit a variety of mathematical models to each set of C-R data.

K.1.1 Fitting Acute Mortality Data

K.1.1.1 Dichotomous Data

Dichotomous data are binary in nature (e.g., live/dead or 0/1) and are typical of survival experiments. They are usually represented as a proportion survived.

K.1.2 Fitting Chronic Growth, Reproduction, and Survival Data

K.1.2.1 Continuous Data

Continuous data take on any value along the real number line (e.g., biomass).

K.1.2.2 Count Data

Count data take on only integer values (e.g., number of eggs hatched).

K.1.2.3 Dichotomous Data

Dichotomous data are binary in nature (e.g., live/dead or 0/1) and are typical of survival experiments. They are usually represented as a proportion survived.

K.2 Determining Most Robust Model Fit for Each C-R curve

The R drc package was used to fit a variety of models to each individual C-R dataset. A single model was then selected from these candidate models to serve as the representative C-R model. The selected model represented the most statistically-robust model available. To

NMED Exhibit 63

determine the most-statistically-robust model for a C-R dataset, all individual model fits were assessed on a suite of statistical metrics.

K.2.1 Selecting Candidate Models

Initially, models were ranked according to the Akaike information criteria (AIC). The AIC provides a measure of the amount of information lost for a given model by balancing goodness of fit with model parsimony. The models with the lowest AIC, relative to other models based on the same data, tend to be optimal. In some instances, however, the model with the lowest AIC possessed a questionable characteristic that suggested said model was not the most appropriate. Rather than selecting a model based solely on the lowest AIC, the initial ranking step was only used to identify a subset of candidate models that were more closely examined before selecting a model fit for each C-R dataset.

K.2.2 Assessment of Candidate Models to Determine the Most Appropriate Model

Candidate models (i.e., models with low AIC scores relative to other models produced for a particular C-R dataset) were further evaluated based on additional statistical metrics to determine a single, statistically robust curve for each quantitatively-acceptable toxicity test. These additional statistical metrics were evaluated relative to the other candidate curve fits produced for each C-R dataset. Of these statistical metrics, residual standard errors, confidence intervals relative to effects concentration estimates, and confidence bands carried the most weight in determining the most appropriate model to be representative of an individual C-R dataset. These additional statistical metrics included:

K.2.2.1 Comparison of residual standard errors

As with AIC, smaller values were desirable. Residual standard errors were judged relative to other models.

NMED Exhibit 63

K.2.2.2 Width of confidence intervals for EC estimates

Confidence intervals were assessed on standard error relative to estimate and confirming that the intervals were non-negative. Judged in absolute and relative to other models.

K.2.2.3 Width of confidence bands around the fitted model

A general visual inspection of the confidence bands for the fitted model. Wide bands in the area of interest were undesirable. Judged in absolute and relative to other models.

K.2.2.4 P-values of parameters estimates and goodness of fit tests

Hypothesis tests of parameter values to determine whether an estimate is significantly different from zero. Goodness of fit tests were used to judge the overall performance of the model fit. Typically, the level of significance was set at 0.05. There may have been occasional instances where the 0.05 criterion may not be met, but there was little recourse for choosing another model. Judged in absolute terms.

K.2.2.5 Residual plots

Residuals were examined for homoscedasticity and biasedness. Judged in absolute and relative to other models.

K.2.2.6 Overly influential observations

Observations were judged based on Cook's distance and leverage. When an observation was deemed overly influential, it was not reasonable to refit the model and exclude any overly influential observations given the limited data available with typical C-R curves. Judged in absolute terms.

K.3 Determining Curve Acceptability for use in Criteria Derivation

The final curve fits selected for each of the quantitatively-acceptable toxicity tests were further evaluated and classified to determine whether the curves were: 1) quantitatively-

NMED Exhibit 63

acceptable for use, 2) qualitatively acceptable for use, or 3) unacceptable. To determine curve acceptability for use in deriving an effect concentration, each individual curve was considered based on the statistical metrics described above and assessed visually to compare how the calculated effect concentration aligned with the underlying raw C-R data. Instead of evaluating curves fits relative to other curve fits for the same data (as was previously described to select the most-robust curve for each test), curve fit metrics were used to assign each curve a score:

- **Quantitatively Acceptable Model**. Model performed well on most/all statistical metrics and resultant effect concentrations were typically used in a quantitative manner.
- **Qualitatively Acceptable Model**. Model generally performed well on statistical metrics; however, the model presented some characteristic(s) that called estimates into question. Such models were considered with caution. These problems may have consisted of any number of issues such as a parameter with a high p-value, poor goodness of fit p-value, wide confidence bands for fit or estimate interval, or residuals that indicate model assumptions are not met. Broadly, effect concentrations from models that were deemed qualitatively acceptable were not used numerically in criteria derivation if quantitatively acceptable models for different endpoints or tests from the same publication were available. If quantitatively acceptable models for different endpoints or tests from the same publication were not available, effect concentrations from the qualitatively acceptable model were used numerically in criteria derivation on a case-by-case basis.
- **Unacceptable Model**. Model poorly fit the data. These models were not used for criteria derivation.

NMED Exhibit 63

No single statistical metric can determine a given model's validity or appropriateness. Metrics should be considered as a whole. As such, there is a slightly subjective component to these evaluations. That said, this assessment methodology was developed to aid in evaluating models as to their quantitative or qualitative attributes in a transparent and relatively repeatable manner.

NMED Exhibit 63

Appendix L Derivation of Acute Protective PFOA Benchmarks for Estuarine/Marine Waters through a New Approach Method (NAM)

L.1 Background

The 1985 *Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses* (U.S. EPA 1985) recommend that data for a minimum of eight families be available to fulfill taxonomic minimum data requirements (MDRs) to calculate criteria values, including to calculate estuarine/marine aquatic life criteria. Acute estuarine/marine test data are currently available for only three families, a mysid (*Siriella* and *Americamysis*), a sea urchin (*Strongylocentrotus*), and a mussel (*Mytilus*), addressing only three of the eight MDRs; thus, the EPA was not able to derive an acute estuarine/marine criterion element for PFOA based on the 1985 Guidelines MDR specifications (Section 2.10.1). However, the EPA was able to develop an acute PFOA protective benchmark using a New Approach Methods (NAMs) process, via the application of Interspecies Correlation Estimation (ICE) models (Raimondo et al. 2010). Although not a criterion based on 1985 Guidelines specifications, because of gaps in available data for several of the taxonomic MDRs listed in the 1985 Guidelines for the derivation of aquatic life criteria, this benchmark represents an aquatic life value derived to be protective of aquatic communities. The ICE model predictions supplement the available test dataset to help fill missing MDRs and allow the derivation of acute an estuarine/marine benchmark for aquatic life using procedures consistent with those in the 1985 Guidelines. This is important as it provides an approach by which values that are protective of aquatic life communities can be developed, even when MDRs are not fulfilled by direct PFOA test data. This approach is consistent with both the 1985 Guidelines "good science" clause, the EPA's interest in providing useful information to states and Tribes regarding protective values

NMED Exhibit 63

for aquatic life, and the EPA's intention to reduce the use of animal testing via application of NAMs (https://www.epa.gov/chemical-research/epa-new-approach-methods-work-plan-reducing-use-animals-chemical-testing).

L.1.1 Introduction to Web-ICE

ICE models, developed by the EPA's Office of Research and Development, are log-linear regressions of the acute toxicity (EC_{50}/LC_{50}) of two species across a range of chemicals, thus representing the relationship of inherent sensitivity between those species (Raimondo et al. 2010). Each model is derived from an extensive, standardized database of acute toxicity values by pairing each species with every other species for which acceptable toxicity data are available. Once developed, ICE models can be used predict the sensitivity of an untested taxon (predicted taxa are represented by the y-axis) from the known, measured sensitivity of a surrogate species (represented by the x-axis; Figure L-1).

ICE models have been developed for a broad range of different chemicals (e.g., metals and other inorganics, pesticides, solvents, and reactive chemicals) and across a wide range of toxicity values. There are approximately 3,400 significant ICE models for aquatic animal and plant species in the most recent version of web-ICE (v3.3, https://www3.epa.gov/webice/, last updated June 2016; Raimondo et al. 2015).

Models were validated using leave-one-out cross validation, which formed the basis for the analyses of uncertainty and prediction robustness. For this process, each datapoint within the model (representing the relative sensitivity of two species for a particular chemical) is systematically removed, one at a time. The model is then redeveloped with the remaining data (following each removal) and the removed value of the surrogate species is entered into the model. The estimated value for the predicted species is then compared to the measured value for that species (Raimondo et al 2010; Willming et al. 2016).

NMED Exhibit 63

ICE models have high prediction accuracy when values are derived from models with robust parameters (e.g., mean square error, R^2), that fall within a defined range of acceptability, and with close prediction confidence intervals that facilitate evaluating the fit of the underlying data (Brill et al. 2016; Raimondo et al. 2010; Willming et al. 2016). Results of these analyses provide the basis of the user guidance for selecting ICE predicted toxicity with high confidence (Box 1).

ICE models have undergone extensive peer review and their use has been supported for multiple applications, including direct toxicity estimation for endangered species (NRC 2013; Willming et al. 2016) and development of Species Sensitivity Distributions (SSDs) (Awkerman et al. 2014; Bejarano et al. 2017; Dyer et al. 2006, 2008; Raimondo et al. 2010, 2020). The application of ICE-predicted values to develop protective aquatic life values by multiple independent, international groups confirms that values developed from ICE-generated SSDs provides a level of protection that is consistent with using measured laboratory data (Dyer et al. 2008; Feng et al. 2013; Fojut et al. 2012a, 2012b; Palumbo et al. 2012; Wu et al. 2015, 2016; Wang et al. 2020; Zhang et al. 2017). A recent external review of ICE models additionally supports their use in regulatory applications based on the reliability of underlying data, model transparency, statistical robustness, predictive reliability, proof of principle, applicability to probabilistic approaches, and reproducibility of model accuracy by numerous independent research teams (Bejarano and Wheeler 2020).

NMED Exhibit 63

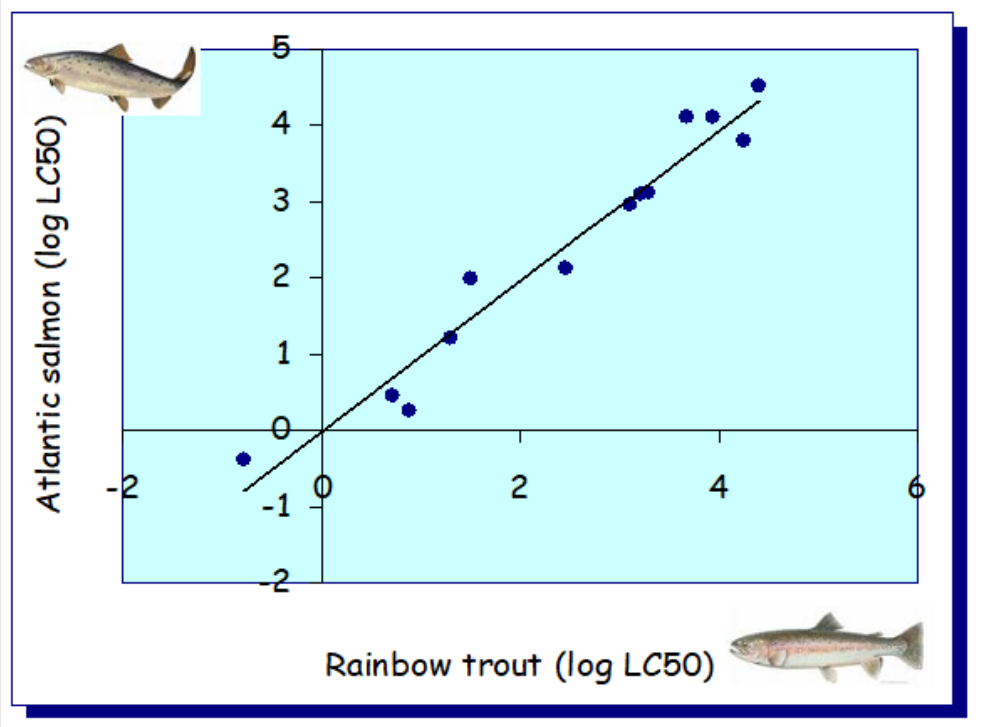

Figure L-1. Example ICE Model for Rainbow Trout (surrogate) and Atlantic Salmon (predicted).
Each model datapoint is a common chemical that was tested in both species to develop a log-linear regression.

Box 1. ICE Model User Guidance Recommended for Listed Species (Willming et al. 2016):

- Close taxonomic distance (within class)
- Low Mean Squared Error (<~ 0.95)
- High R^2 (>~ 0.6)
- High slope (>~ 0.6)
- Prediction confidence intervals should be used to evaluate the prediction using professional judgement for the application (Raimondo et al. 2024).
- For models between vertebrates and invertebrates, using those with lower MSE or MOA-specific models (not available for PFAS) has been recommended for listed species predictions (Willming et al. 2016).

L.1.2 Application of Web-ICE with PFOA

As previously discussed, ICE models have been developed using a diversity of compounds (e.g., metals and other inorganics, pesticides, solvents, and reactive chemicals)

NMED Exhibit 63

across a wide range of toxicity values; however, PFAS are not included in Web-ICE v3.3 due to the lack of available toxicity data at that time. PFAS acute values (typically reported as mg/L) can be greater than those used to develop an ICE model (ICE database toxicity range $1E^{-4}$ to $1E^{8}$ µg/L) such that the input PFAS value of the surrogate would be outside the model domain. In these cases, a user can either enter the value as µg/L and allow the model to extrapolate beyond its range or enter the toxicity as a "scaled" value (i.e., estimate the value as mg/L). The principal assumptions of ICE models are: 1) they represent the relationship of inherent sensitivity between two species, which is conserved across chemicals, mechanisms of action, and ranges of toxicity and; 2) the nature of a contaminant that was tested on the surrogate reflects the nature of the contaminant in the predicted species (e.g., effect concentration [EC_{50}] or lethal concentration [LC_{50}]), percentage of active ingredient, technical grade (Raimondo et al. 2010). While neither of these assumptions are violated by either extrapolating beyond the range of the model or using scaled toxicity data, the uncertainty of using ICE models in either manner had not been thoroughly evaluated. Additionally, since PFAS were not included in the database used to develop Web-ICE v3.3, the validation of ICE models to accurately and specifically predict to these compounds has not been previously explored. We address both these topics in the sections below.

L.2 Prediction Accuracy of Web-ICE for Scaled Toxicity and Values Beyond the Model Domain

The accuracy of using scaled toxicity data as input into ICE models was evaluated using an analysis with the existing ICE models and is described in detail in Raimondo et al. (2024). Briefly, ICE models containing a minimum of 10 datapoints and spanning at least five orders of magnitude were separated into two subsets: 1) a lower subset that contained all paired chemical data corresponding to values below the 75^{th} percentile of surrogate species values and; 2) an

NMED Exhibit 63

upper subset containing paired chemical data above the 75th percentile of surrogate values. The lower subset was used to develop "truncated" ICE models. The surrogate species values in the upper subset were converted to mg/L and entered into the truncated ICE models. The predicted mg/L value was compared to the respective value of the measured predicted species. Prediction accuracy was determined as the fold difference (maximum of the predicted/measured and measured/predicted) between the predicted and the measured value, consistent with previously published evaluations of ICE models (Raimondo et al. 2010; Willming et al. 2016). Accuracy of using scaled toxicity as input into ICE models was compared to overall ICE prediction accuracy as previously reported and prediction accuracy of the respective upper subset data points that were entered into the models as µg/L (i.e., values beyond the model domain). A total of 3,104 datapoints from 398 models were evaluated. A match-paired comparison showed that the average fold differences of toxicity values predicted using scaled toxicity was not significantly different than the respective average fold differences of all cross-validated data points reported in Willming et al. (2016) (Wilcoxon paired rank sum test, V = 42741, p-value 0.11). Additionally, Raimondo et al. (2010) and Willming et al (2016) showed a consistent and reproducible relationship between the taxonomic distance of the predicted and surrogate species, which was also reproduced using scaled values; the percentage of datapoints predicted using scaled toxicity was within five-fold of the measured value for over 94% of all validated datapoints for species pairs within the same order, with a reduction in accuracy coinciding with decreasing taxonomic relatedness (Raimondo et al. 2024). Comparison of scaled values with those predicted from µg/L values beyond the model domain showed that predicted values varied by a factor of 10 for models with slopes ranging from 0.66 – 1.33. Toxicity values predicted from models with slopes within this range had a median fold difference of 2.4 using mg/L values and 2.8 using µg/L

NMED Exhibit 63

values (Wilcoxon paired rank sum test, V = 1334749, p-value 0.77). These results and a detailed review of ICE model assumptions are provided in Raimondo et al. (2024)[2].

L.3 Direct Comparison of Web-ICE and Measured Toxicity Values

Since limited PFOA toxicity test data are available for estuarine/marine species, the ability of ICE models to predict PFOA toxicity was evaluated using direct comparisons of freshwater species sensitivity as reported in the criteria document and predicted by Web-ICE. In this comparison, the measured SMAVs for PFOA reported in Appendix A.1 and Appendix B.1 were used as values for surrogate species to predict to all possible species that also had a measured PFOA SMAV reported. The available SMAVs for PFOA that could be used as ICE surrogate values, along with the number of ICE models corresponding to each surrogate, are shown in Table L-1.

[2] Use of scaled toxicity values and the use of surrogate toxicity values beyond the bounds of the ICE model that are input as µg/L are two approaches that both make extrapolations beyond the bounds of the underlying data. Actual predictions resulting from the two approaches from the same ICE model begin to deviate from one another the further the slope of the ICE model deviates from 1.0 (which is a primary reason why scaled toxicity data were only employed on ICE models with slopes ranging from 0.66 – 1.33). Overall, use of the scaled approach compared to direct extrapolation results a negligible change in the final estuarine/marine benchmark, primarily because the four most sensitive estuarine/marine GMAVs were based on direct toxicity test results, and secondarily, because only a subset of ICE models required use of scaled toxicity data to account for predicting beyond the bounds of the underlying ICE model. For example, the final acute PFOA estuarine/marine benchmark was 7.0 mg/L (see section L.5). Had the values in Table L-4 been predicted using unscaled data that were input as µg/L only (and the model slope requirement of 0.66 -1.33 been retained), the final acute estuarine/marine benchmark would remain unchanged at 7.0 mg/L. Had the values in Table L-4 been predicted using unscaled data input as µg/L only (and the model slope requirement of 0.66 -1.33 was removed), the final acute estuarine/marine benchmark would increase slightly to 7.5 mg/L. While both approaches contain uncertainty, use of the scaled approach resulted in a more protective acute PFOA estuarine/marine benchmark (i.e., CMC = 7.0 mg/L) than an exploratory benchmark that used acute toxicity data estimated through direct extrapolation, with the model slope requirement of 0.66 -1.33 removed (i.e., exploratory CMC = 7.5 mg/L).

NMED Exhibit 63

Table L-1. Surrogate Species Measured Values for PFOA and Corresponding Number of ICE Models for Each Surrogate.

For example, there are 53 species for which *Daphnia magna* can predict toxicity.

Broad Taxon	Species		PFOA SMAV (mg/L)	Number of ICE Models
	Common Name	Scientific		
Amphibian	Bullfrog	*Lithobates catesbeiana* [a]	1,020	9
Amphibian	Clawed frog	*Xenopus sp.* [b]	377	2
Crustacean	Mysid	*Americamysis bahia*	24	28
Crustacean	Water flea	*Daphnia magna*	220[c]	53
Fish	Zebrafish	*Danio rerio*	450.4	2 (juvenile models) 6 (embryo models)
Fish	Bluegill	*Lepomis macrochirus*	664	68
Fish	Rainbow trout	*Oncorhynchus mykiss*	4,001	77
Fish	Fathead minnow	*Pimephales promelas*	593.6	74
Mollusc	Fatmucket	*Lampsilis siliquoidea*	164.4	29
Mollusc	Black sandshell	*Ligumia recta*	161	1

[a] *Lithobates catesbeianus* was used in Web-ICE

[b] *Xenopus laevis* was used in Web-ICE

[c] *D.magna* species mean acute value used in Appendix L is 220.0 mg/L, which differs slightly from the *D. magna* species mean acute value reported in Appendix A.1 (i.e., 213.9 mg/L). This discrepancy was the result of including late-breaking data ahead for the release of the 2024 Final PFOA Aquatic Life Criteria document. The discrepancy in the *D. magna* SMAV used here vs. Appendix A.1 has no influence on the 2024 PFOA acute estuarine/marine benchmark (7.0 mg/L) because the four most sensitive genera used to derive the PFOA acute estuarine/marine are based entirely on empirical, laboratory-based toxicity data.

Table L-2 shows direct comparisons for PFOA measured and ICE-predicted values. The regressions for these comparisons are provided in Section L.6. Comparisons are limited by the number of measured toxicity values and models available. To be included in this comparison, a measured value was needed for both species in an ICE model pair. For direct comparison of predicted and measured PFOA values, the measured SMAV of the surrogate species is entered into a model for which the measured SMAV for the intended predicted species is also known. The PFOA toxicity predicted to this model is then compared to the measured SMAV for the predicted species listed in Appendix A.1, Appendix B.1 and Table L-1. This allows both species of an ICE model to serve as either the predicted or surrogate species. The exception to this was in cases involving zebrafish embryos, as web-ICE v3.3 only included models for which zebrafish embryos were used as surrogates. Accuracy of ICE predictions are presented as the "fold-

NMED Exhibit 63

difference" between the measured and the predicted species, such that fold difference is the maximum of the ratio of the predicted LC_{50}/measured LC_{50} or measured LC_{50}/predicted LC_{50}. Analyses of ICE prediction accuracy have shown that ICE models over- and under-estimate toxicity values randomly, i.e., there is no systematic bias associated with the models (Table L-2, Raimondo et al. 2010; Raimondo et al. 2024). For accuracy assessments, the fold difference provides a simplified metric to easily see how close predictions are to measured values at a glance. A five-fold difference has been demonstrated to be the average interlaboratory variability of acute aquatic toxicity tests and represents a conservative amount of variance under standardized test conditions for a given life stage (Fairbrother 2008; Raimondo et al. 2010). This inter-test variation can increase significantly where experimental variables differ between tests; however, all ICE models are based on standardized life stages to minimize extraneous variability (Raimondo et al. 2010).

NMED Exhibit 63

Table L-2. Comparison of ICE-predicted and measured values of PFOA for species using both scaled values (entered as mg/L) and values potentially beyond the model domain (entered as µg/L).

Measured SMAVs are for the predicted species as listed in Appendix A.1, Appendix B.1 and Table L-1. Footnotes indicate where predictions or models do not meet one or more of the user guidance criteria. Footnotes also indicate any differences between species mean acute values here that differ from species mean acute values reported in Appendix A.1.

		Toxicity Values Potentially Beyond Model Domain				Scaled Toxicity Values			
Predicted Species	**Surrogate Species**	**Measured SMAV (µg/L)**	**Web-ICE Predicted (µg/L)**	**Confidence Interval (µg/L)**	**Fold Difference**	**Measured SMAV (mg/L)**	**Web-ICE Predicted (mg/L)**	**Confidence Interval (mg/L)**	**Fold Difference**
Bullfrog (*Lithobates catesbeianus*)	Bluegill (*Lepomis macrochirus*)	1020000	351962.71	47028.33 – 2634108.91	2.9[ab]	1020	1085.27	358.55 – 3284.91	1.06

Predicted Species	Surrogate Species	Toxicity Values Potentially Beyond Model Domain				Scaled Toxicity Values			
		Measured SMAV (µg/L)	Web-ICE Predicted (µg/L)	Confidence Interval (µg/L)	Fold Difference	Measured SMAV (mg/L)	Web-ICE Predicted (mg/L)	Confidence Interval (mg/L)	Fold Difference
	Rainbow trout (*Oncorhynchus mykiss*)		41091.9	3178.59 – 531223.75	4[abc]		1143.35	381.34 – 3428.01	6.95[cd]
Black sandshell (*Ligumia recta*)	Fatmucket (*Lampsilis siliquoidea*)	161000	171536.98	34311.02 – 857594.23	1.07	161	237.72	25.46 – 2219.07	1.48[a]

[a] Confidence interval >1.5 order magnitude.

[b] Input data outside model range.

[c] Guidance for model mean square error, R^2, and/or slope not met.

[d] Does not meet slope criteria for using scaled toxicity (0.66-1.33).

[e] *D.magna* species mean acute value used in Appendix L is 220.0 mg/L, which differs slightly from the *D. magna* species mean acute value reported in Appendix A.1 (i.e., 213.9 mg/L). This discrepancy was the result of including late-breaking data ahead for the release of the 2024 Final PFOA Aquatic Life Criteria document. The discrepancy in the *D. magna* SMAV used here vs. Appendix A.1 has no influence on the 2024 PFOA acute estuarine/marine benchmark (7.0 mg/L) because the four most sensitive genera used to derive the PFOA acute estuarine/marine are based entirely on empirical, laboratory-based toxicity data.

NMED Exhibit 63

These comparisons are consistent with web-ICE user guidance, previously published reports on ICE model accuracy (Raimondo et al. 2010; Willming et al. 2016), and the above described uncertainty analysis of using scaled toxicity as model input. ICE models predict with acceptable accuracy for PFOA when invertebrates were used to predict to invertebrate species and vertebrates were used to predict to vertebrate species in these comparisons. Models validated across a wide range of species, chemicals, and toxicity values show an acceptable level of prediction accuracy (>90% values predicted within five-fold of measured value) when adhering to the model guidance listed in Box 1 (Raimondo et al. 2010; Willming et al. 2016). The results summarized in Sections L.1 and L.2 demonstrate that the relationship of inherent sensitivity is preserved across taxa, chemicals, and range of toxicity values when using robust ICE models. While the current analysis uses freshwater species to predict to estuarine/marine species, previous model validation and uncertainty analyses did not indicate the habitat of the species to be an influential source of ICE model uncertainty (Raimondo et al. 2010; Willming et al. 2016).

L.4 Prediction of Estuarine/Marine Species Sensitivity to PFOA

A value of PFOA sensitivity was predicted with web-ICE v3.3 for all possible species using all available surrogate species (Table L-1). Predicted values were obtained by entering all available surrogate species into the web-ICE SSD generator, which predicts to all possible species from all available surrogates simultaneously and exports results into an excel spreadsheet. Web-ICE results were generated using both mg/L and µg/L values to evaluate the full set of possible predictions using both units of measure against the model domain, confidence intervals, and model parameters. First, all available models were evaluated based on the parameter (MSE, R^2, slope) guidance in Box 1, which are the same for an ICE species pair regardless of input value (Table L-3). Models that did not meet the parameter criteria in Box 1

NMED Exhibit 63

were rejected in this first pass. In the next step, values that were predicted using µg/L were evaluated against the model domain and selected for the next tier of evaluation when the surrogate value was within the range of data used to develop the model. If the surrogate value reported as µg/L was beyond the model domain, the mg/L value was evaluated if it was within the model domain and if the model slope was between 0.66-1.33 (Raimondo et al. 2024). Cases in which both units were outside the model domain were not included quantitatively, but the value with the narrowest confidence intervals was included for qualitative considerations. Values (using either µg/L or mg/L input value) were excluded quantitatively from the SMAVs but retained for qualitative consideration if an evaluation of confidence intervals, model parameters, and the model domain indicated the relationship between surrogate and predicted species was not informed by robust underlying data. At this stage, specific predictions should be based on holistic evaluation of all available information provided by the model, confidence interval, and data used to develop the model. Decisions to exclude a prediction from the SMAV are clarified in footnotes. Because the sensitivity of a single species can be predicted by multiple surrogates, we calculated the SMAV where multiple robust models were available for a predicted species. Each predicted species was then assigned to the appropriate saltwater MDRs as defined in the 1985 Guidelines:

a) Family in the phylum Chordata
b) Family in the phylum Chordata
c) Either the Mysidae or Penaeidae family
d) Family in a phylum other than Arthropoda or Chordata
e) Family in a phylum other than Chordata
f) Family in a phylum other than Chordata
g) Family in a phylum other than Chordata
h) Any other family

NMED Exhibit 63

The acute sensitivity of estuarine/marine species to PFOA is presented in Table L-4. A total of 48 models representing 21 estuarine/marine species were available in Web-ICE to predict the toxicity of PFOA to saltwater species (Table L-4). Of these, 14 models were initially rejected based on model parameters not meeting the guidance in Box 1, reducing the number of predicted species to 19 represented by 34 models. Further evaluation of ICE predictions resulted in 13 SMAVs representing crustaceans, molluscs, and fish and demonstrated the potential to meet the saltwater MDRs. The range of sensitivity for the predicted taxa is consistent with the range of sensitivity of freshwater species for this compound.

NMED Exhibit 63

Table L-3. All ICE Models Available in Web-ICE v3.3 for Saltwater Predicted Species Based on Surrogates with Measured PFOA.

Model parameters are used to evaluate prediction robustness. Cross-validation success is the percentage of all model data that were predicted within 5-fold of the measured value through leave-one-out cross-validation (Willming et al. 2016). Taxonomic distance describes the relationship between surrogate and predicted species (e.g., 1 = shared genus, 2 = shared family, 3 = shared order, 4 = shared class, 5 = shared phylum, 6 = shared kingdom).

L.5 Derivation of Acute Water Benchmark for Estuarine/Marine Water

The Web-ICE predicted acute data set for PFOA contains 10 genera representing the eight MDR groups that would be necessary for developing an estuarine/marine criterion. However, the EPA supplemented this dataset with acceptable quantitative study data (discussed in Section 3.1.1.2). In scenarios where both empirical LC_{50} values and estimated LC_{50} values were available for the same species, only the empirical data were used to derive the species mean acute value. The ranked GMAVs for these combined data along with the MDR met by each GMAV is summarized in Table L-5. From this dataset, an acute benchmark was calculated using procedures consistent with the 1985 Guidelines and with those used for the derivation of freshwater criterion values for PFOA. GMAVs for the four most sensitive genera were within a factor of 1.5 of each other (Table L-5). The estuarine/marine FAV (the 5^{th} percentile of the genus sensitivity distribution) for PFOA is 14.07 mg/L (Table L-6). The FAV was lower than all of the GMAVs for both the tested species and for values derived using Web-ICE. The FAV is then divided by two to obtain a concentration yielding a minimal effects acute effect value. Based on the above, the FAV/2, which is the estuarine/marine acute water column benchmark magnitude, is 7.0 mg/L PFOA (rounded to two significant figures) and is expected to be protective of 95% of saltwater genera potentially exposed to PFOA under short-term conditions of one-hour of duration, if the one-hour average magnitude is not exceeded more than once in three years (Figure L-2).

NMED Exhibit 63

Table L-5. Ranked Estuarine/Marine Genus Mean Acute Values.

Values in bold are derived from empirical PFOA toxicity tests with the species.

MDR Group[1]	Common Name	Species	SMAV (mg/L)	GMAV (mg/L)	Rank	Percentile

Figure L-2. Ranked Estuarine/Marine Acute PFOA GMAVs Used for the Aquatic Life Acute Benchmark Calculation.

L.5.1 Estuarine Marine/Benchmark Uncertainty

The epistemic uncertainty of individual ICE estimates used for SMAV calculation was quantified through the calculation of corresponding 95% confidence intervals for each ICE estimate. Of the individual models and resultant ICE-estimated LC_{50} values from the available and quantitatively acceptable models (see bolded and underlined values in Table L-4; n =21), the range of individual 95% CIs (i.e., 95% CI range = upper 95% CI – lower 95% CI) as a percent of the corresponding LC_{50} estimate (i.e., = [95% CI range/LC50 estimate]*100) ranged from 69.01% to 626.49%. The ICE model with the lowest 95% CI range relative to the LC_{50} estimate (i.e., 69.01%) employed *Lepomis macrochirus* as the predictor species and *Cyprinodon variegatus* as the predicted species. The ICE model with the largest 95% CI range relative to the LC_{50} estimate (i.e., 626.49%) employed *Daphnia magna* as the predictor species and *Fenneropenaeus merguiensis* as the predicted species. Nineteen of the 21 ICE-predicted values in Table L-4 that were used for SMAV calculation had 95% CI ranges that were greater than the corresponding LC_{50} estimate (i.e., 95% CI range was >100% of the LC_{50} estimate). The relatively wide ranging 95% CIs demonstrate the underlying uncertainty in the PFOA estuarine/marine benchmark.

Four of the 13 GMAVs used to derive the acute PFOA estuarine/marine benchmark were based on empirical toxicity tests. The four GMAVs based on empirical data were also the four most sensitive GMAVs in the GSD (Figure L-2), meaning final estuarine/benchmark magnitude was primarily based on relatively certain empirical toxicity tests and the inherent uncertainty in the ICE models had little influence on the final acute estuarine/marine benchmark magnitude.

The estuarine/marine benchmark appears adequately protective based on the available high quality empirical data (Appendix B.1). The acute PFOA estuarine/marine benchmark (i.e., 7.0) is more than two times lower than the lowest GMAV (i.e., 15.5 mg/L), which was based on

NMED Exhibit 63

empirical data for *Siriella*. The EPA further evaluated the appropriateness of the estuarine/marine benchmark by comparing it to empirical, but qualitatively acceptable, data for estuarine/marine species. The EPA specifically focused on qualitatively-acceptable estuarine/marine tests reported in Table H.1 that (1) tested an animal species, (2) exposed test organisms to PFOA for a duration that was reasonably similar to standard acute exposures (e.g., 48 hours to seven days), (3) reported acute apical effects, and (4) reported effect concentrations that were lower than the acute estuarine/marine benchmark final acute value (i.e., 14 mg/L). The EPA identified three individual tests in Table H.1 as meeting the previous criteria:

1. Liu et al. (2013, 2014c) evaluated the chronic effects of PFOA (96% purity, purchased from Sigma-Aldrich) on green mussels, *Perna viridis*, via a seven-day measured, static-renewal study. A NOEC of 0.0114 mg/L and a LOEC of 0.099 mg/L was determined for a decrease in the relative condition factor (RCF). The study was acceptable for qualitative use only because of the atypical test duration, which is too long for an acute test and too short for a chronic test. Additionally, the PFOA test displayed a questionable concentration-response patten where there was no difference between the RCF at the LOEC (i.e., 0.099 mg/L) and the highest test concentration, which contained a PFOA concentration that was more than 10X greater (i.e., 1.120 mg/L). The large magnitude between these two concentrations in combination with the lack of effects to the RCF observed between the LOEC and the highest treatment concentration suggests a true concentration-response relationship was not observed for PFOA in this test.
2. Bernardini et al. (2021) reported the results of a 21-day chronic study with the Manila clam, *Ruditapes philippinarum*. Subsamples of clams (n=20) were also

NMED Exhibit 63

collected on test day seven. No significant effects of mortality were observed in the single treatment group throughout the exposure, including at test day seven. The seven-day NOEC, based on mortality, was 0.00093 mg/L PFOA. Although the seven-day NOEC is less than the acute estuarine/marine benchmark, the authors did not report any significant effects to mortality and this study was not useful in understanding the relative protectiveness of the acute PFOA estuarine/marine benchmark.

3. Mhadhbi et al. (2012) conducted a six-day acute test on the turbot, *Scophthalmus maximus* (a non-North American species). Endpoints included dead embryos, malformation, hatch success at 48-hours and larvae survival (missing heartbeat and a non-detached tail) at six days. The reported six-day LC_{50} of 11.9 mg/L PFOA was not used quantitatively because the test duration was longer than the standard 96 hour acute exposure. Nevertheless, this six-day test suggests early life stages of *S. maximus* may be sensitive to acute PFOA exposures. The EPA concluded the acute PFOA estuarine/marine benchmark to be protective on the six-day LC_{50} reported by Mhadhbi et al. (2012) because (1) it was reasonably similar to the most sensitive GMAV used to derive the acute estuarine/marine benchmark (i.e., *Siriella* GMAV = 15.5 mg/L) and (2) the 96-hour LC_{50} that corresponds to the six-day LC_{50} reported by Mhadhbi et al. (2012) was hypothesized to be greater than or equal to the six-day LC_{50} under the premise that acute effect concentrations typically decrease with exposure time (until an incipient lethal concentration is reached).

NMED Exhibit 63

4. Gebreab et al. (2022) exposed the marine mahi-mahi fish, *Coryphaena hippurus* to PFOA in a 48-hour static acute test with measured PFOA treatments. Authors stated that the test followed a new embryotoxicity assay for mahi mahi that was adapted from assays previously developed and validated for zebrafish embryotoxicity (Berry et al. 2007; Gebreab et al. 2020; Weiss-Errico et al. 2017). The author-reported 48-hour LC_{50} (i.e., 4 mg/L; 95% C.I. = 2-6 mg/L) was less than the acute estuarine/marine FAV of 14 mg/L. Results of this test were not used quantitatively primarily because there was 20-30% mortality in the negative control at the end of the exposure period. The high control mortality suggests the exposed organisms were stressed in the laboratory setting, which compounded any effects of PFOA and likely produced an artificially low LC_{50} value. Therefore, this qualitatively acceptable test did not provide sufficient evidence to conclude the estuarine/marine benchmark was underprotective of *C. hippurus*.

Overall, results of quantitatively- and qualitatively- acceptable empirical toxicity studies with estuarine/marine organisms do not provide any evidence that the aquatic estuarine/marine community will experience unacceptable chronic effects at the acute estuarine/marine PFOA benchmark.

[1] Reported as ng/g by study authors.

M.1.1 PFOA Occurrence and Concentrations in the Great Lakes Region

The Great Lakes are among the most widely studied waterbodies in the U.S. for PFOA occurrence; however, data remain relatively limited in this system. Comparisons across the Great Lakes system indicate PFOA concentrations are higher in Lakes Erie and Ontario than in Lakes Huron, Michigan, and Superior (Figure M-1). For example, mean PFOA concentrations in Lake Erie and Lake Ontario from several studies ranged from 1.9 to 35.75 ng/L and 3.7 to 44.7 ng/L, respectively (Boulanger et al. 2004; Furdui et al. 2008), while the range of reported mean PFOA concentrations in Lake Superior, Lake Huron, and Lake Michigan were comparatively lower. The mean PFOA concentration range was 1.8 to 4.1 ng/L in Lake Michigan and 0.59 to 3.2 ng/L

NMED Exhibit 63

in Lake Huron (Furdui et al. 2008; De Silva et al. 2011; Simcik et al. 2005). The most western and upstream lake within the great lakes system, Lake Superior, consistently had lower PFOA concentrations than the other Great Lakes, with mean concentrations reported in the literature ranging from 0.23 to 0.25 ng/L (Furdui et al. 2008; Scott et al. 2010; De Silva et al. 2011).

The higher PFOA concentrations in Lakes Erie and Ontario are likely due to higher levels of urbanization around these lakes (Boulanger et al. 2004; Remucal 2019). A mass balance constructed for Lake Ontario by Boulanger et al. (2005) indicated that surface water and wastewater effluent are the major sources of PFOA to the lake. In contrast, inputs from Canadian tributaries and atmospheric deposition of PFAS were the major contributing sources of PFOA to Lake Superior. Inputs from Canadian tributaries and atmospheric deposition were estimated to contribute 59% and 35% of PFOA inputs into Lake Superior, respectively (Scott et al. 2010).

Within the Great Lakes, Remucal (2019) noted there were limited PFOA data to evaluate temporal trends in surface waters. If the dataset was limited to Lake Ontario, which is one of the most well-studied waterbodies for PFOA occurrence in the U.S. (with data from 2002 to 2010) there appears to be a mild decrease in PFOA concentrations over time. This decrease was likely due to the reduction in PFOA manufacturing; however, the downward PFOA trend in Lake Ontario was statistically insignificant, with authors noting additional data over longer time scales were needed to fully inform conclusions (reviewed in Remucal 2019).

NMED Exhibit 63

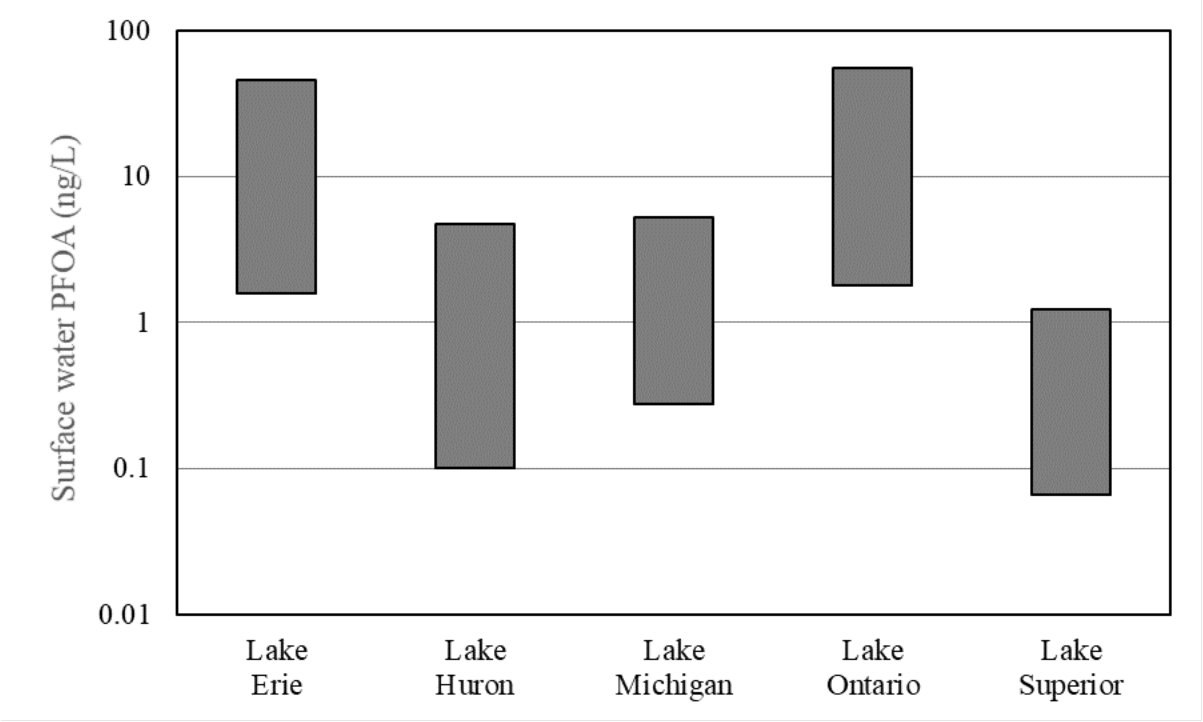

Figure M-1. Distribution of the minimum and maximum concentrations (ng/L) of Perfluorooctanoic acid (PFOA) measured in surface water samples collected from the Great Lakes as reported in the publicly available literature.
This distribution is arranged alphabetically by waterbody.

M.1.2 PFOA Occurrence and Concentrations in the Midwestern U.S.

Similar PFOA concentrations are reported in the publicly available literature for waterbodies in urban areas across the Midwest and northeastern U.S. along with lower PFOA concentrations associated with remote areas in the same states (Newsted et al. 2017; NJ DEP 2019; Simcik and Dorweiler 2005; Sinclair et al. 2006). In Minnesota, Simcik and Dorweiler (2005) observed PFOA concentrations ranging between 0.46 and 19 ng/L in urban areas near Minneapolis and concentrations ranging between 0.14 to 0.7 ng/L in remote areas in northern Minnesota.

M.1.3 PFOA Occurrence and Concentrations in the Northeastern U.S.

In New York, Sinclair et al. (2006) quantified (limit of quantification = 2 ng/L) PFOA in all waters sampled across the state. Unlike PFOS, PFOA was detected at relatively elevated

concentrations across all sites with comparatively little variability (median PFOA concentrations across nine sites ranged from 14 to 49 ng/L) (Sinclair et al. 2006). Additionally, the New Jersey Department of Environmental Protection (NJ DEP) measured PFOA in surface water samples collected from 14 different sites across the state. PFOA concentrations ranged from 1.9 ng/L to a high of 33.9 ng/L, which was quantified in the Metedeconk River downstream of a wastewater treatment plant. NJ DEP (2019) also indicated the Metedeconk River is impacted by PFOA-contaminated groundwater originating from an industrial source. Zhang et al. (2016) reported the surface water median PFOA concentration was 4.05 ng/L (n = 9; Zhang et al. 2016) in 2014 in the New York City Metropolitan area, including sites in New Jersey.

M.1.4 PFOA Occurrence and Concentrations in the Southeastern U.S.

Measured PFOA concentrations in surface waters among southeastern states of the U.S. are highly variable with some of the highest observed concentrations occurring in specific waterbodies near areas with PFOA manufacturing. In 2001 the 3M Company conducted a multi-city study measuring PFOA concentrations across waterbodies with known manufacturing and/or industrial uses of PFOA. In the 3M Company's 2001 report, PFOA concentrations from sites with known PFOA manufacturing uses were compared to PFOA concentrations in waterbodies with no known sources of any PFAS (3M Company 2001). In this comparison study, cities with PFOA manufacturing uses included Mobile and Decatur, Alabama, Columbus, Georgia, and Pensacola, Florida. Measured PFOA concentrations in surface waters, including lentic systems, ranged from not detected (with a detection limit of 7.5 ng/L stated in the report; 3M Company 2001) to 83 ng/L in the cities with known PFOA use in manufacturing processes. These PFOA concentrations were compared to those measured in control cities with no known PFOA applications in manufacturing. These control cities were Cleveland, Tennessee and Port St. Lucie, Florida. PFOA concentrations ranged from not detected to not quantified (limit of

NMED Exhibit 63

quantification = 25 ng/L; 3M Company 2001) in flowing surface waters. PFOA concentrations, however, ranged from 97 ng/L to 748.5 ng/L in lentic systems (i.e., ponds, lakes, and reservoirs; 3M Company 2001) in St. Lucie, Florida. Lentic water samples were not collected at the other city described as a "control," Cleveland, Tennessee. At the time of the report from the 3M Company, the source of PFOA in lentic waters near Port St. Lucie, Florida was unknown; however, the report noted the presence of visible litter, a greenish film on the water, and contributions from a culvert creating a grayish plume as it entered the waterbody (3M Company 2001). Aside from the samples collected in Port St. Lucie, Florida, this report demonstrated that measured PFOA concentrations in surface waters tend to be higher in areas with PFOA manufacturing and/or industrial use (3M Company 2001).

In separate studies, PFOS and PFOA concentrations were measured in surface waters by Hansen et al. (2002) near Decatur, Alabama and Konwick et al. (2008) in Georgia. Hansen et al. (2002) studied a stretch of the Tennessee river near Decatur, Alabama and Konwick et al. (2008) focused on the Conasauga River in Georgia as areas with known PFOA exposure and use. Hansen et al. (2002) reported discharge from a fluorochemical manufacturing facility entered the Tennessee River towards the middle of the sampling area of the study, allowing for a comparison of PFOA concentrations in relation to the fluorochemical manufacturing facility. In contrast, Konwick et al. (2008) compared the PFOA concentrations measured in the Conasauga River with those from reference sites (i.e., not impacted) along the Altamaha River. In both studies, mean PFOA concentrations were higher in the study areas near manufacturing sources of organic fluorochemicals. Specifically, Hansen et al. (2002) did not detect PFOA above the limit of quantification (i.e., 25 ng/L) upstream of the fluorochemical manufacturing facility. Downstream of the facility, PFOA concentrations ranged from below the limit of quantification at two sites

NMED Exhibit 63

immediately downstream of the facility to 598 ng/L with a mean concentration of 335.2 ng/L. Similarly, Konwick et al. (2008) observed higher measured PFOA concentrations in the Conasauga River, which ranged from 32.4 to 1,150 ng/L, compared to those in the Altamaha River, ranging between 3.0 and 3.1 ng/L. Consistent with the report from the 3M Company summarized above, the effluent from manufacturing facilities were determined to be the source of increased PFOA concentrations in both the Tennessee and Conasauga rivers (Hansen et al. 2002; Konwick et al. 2008). PFOA concentrations in contaminated areas of the Conasauga River and Altamaha River were relatively consistent with those measured in Alabama and Georgia (3M Company 2001).

Similarly, Nakayama et al. (2007) and Cochran (2015) measured PFAS, including PFOA, in the Cape Fear Drainage Basin in North Carolina and waterbodies on Barksdale Air Force Base in Bossier City, Louisiana; respectively. PFOA and PFOS were found to be the dominant PFAS detected in both studies. Nakayama et al. (2007) reported PFOA exceeded the level of quantification (i.e., 1 ng/L) in 82.3% of samples. PFOA concentrations in the Cape Fear Drainage Basin ranged between < 1 (the lower limit of quantification) and 287 ng/L with a mean concentration of 43.4 ng/L. Cochran (2015) detected PFOA in 64% of all water samples collected with an average concentration of 62.67 ng/L. As in other studies summarized above, lower PFAS concentrations were found in the smallest upland tributaries and highest in the middle reaches of the Cape Fear River. WWTP effluents were identified as the source of PFAS in the study area (Nakayama et al. 2007).

M.1.5 PFOA Occurrence and Concentrations in the Western U.S.

PFOA concentrations in urbanized areas of western U.S. states were consistent with concentrations measured in northeastern states (Sinclair et al. 2006; Zhang et al. 2016) but remained lower than contaminated areas of southeastern states (3M Company 2001). Plumlee et

NMED Exhibit 63

al. (2008) measured PFOA in surface water samples collected from Coyote Creek and a tributary of Upper Silver Creek in San Jose, California. PFOA concentrations in Coyote Creek ranged from below the detection limit (4 ng/L) to 13 ng/L and from 10 ng/L to 36 ng/L in Upper Silver Creek. Plumlee et al. (2008) postulated a combination of atmospheric deposition of volatile precursors and surface runoff are likely sources of PFOA to both Coyote and Upper Silver Creeks.

Dinglasan-Panlilio et al. (2014) measured PFOA concentrations along the Puget Sound in Washington, as well as Clayoquot and Barkley Sounds in British Columbia, Canada. Broadly, sampling locations spanned these inland marine systems and included freshwaters and estuarine/marine waters. Overall, PFOA was detected at all sampling locations (PFOA concentration range = 0.16 ng/L – 8.2 ng/L), but concentrations were lower than those observed from sites with known manufacturing and/or industrial PFOA uses. These concentrations were consistent with those reported in the publicly available literature for remote areas, such as the northern Great Lakes and rural Minnesota (Simcik and Dorweiler 2005). Dinglasan-Panlilio et al. (2014) speculate these specific regional sources as well as atmospheric deposition are likely contributors of PFOA to these remote areas (Dinglasan-Panlilio et al. 2014).

M.1.6 Summary of PFOA Occurrence and Concentrations across the U.S.

Despite the wide use and persistence of PFOA in aquatic ecosystems, current information on the environmental distribution of PFOA in surface waters across the U.S. remains limited. Present data are largely focused from freshwater systems collected along the east coast, southeast, and upper Midwest, focusing primarily on study areas with known manufacturing or industrial uses of PFAS. Current data indicate that PFOA concentrations measured in U.S. surface waters vary widely across five orders of magnitude (Figure M-2). Additional data,

NMED Exhibit 63

particularly in saltwater systems, are needed to better understand PFOA occurrence in aquatic ecosystems.

NMED Exhibit 63

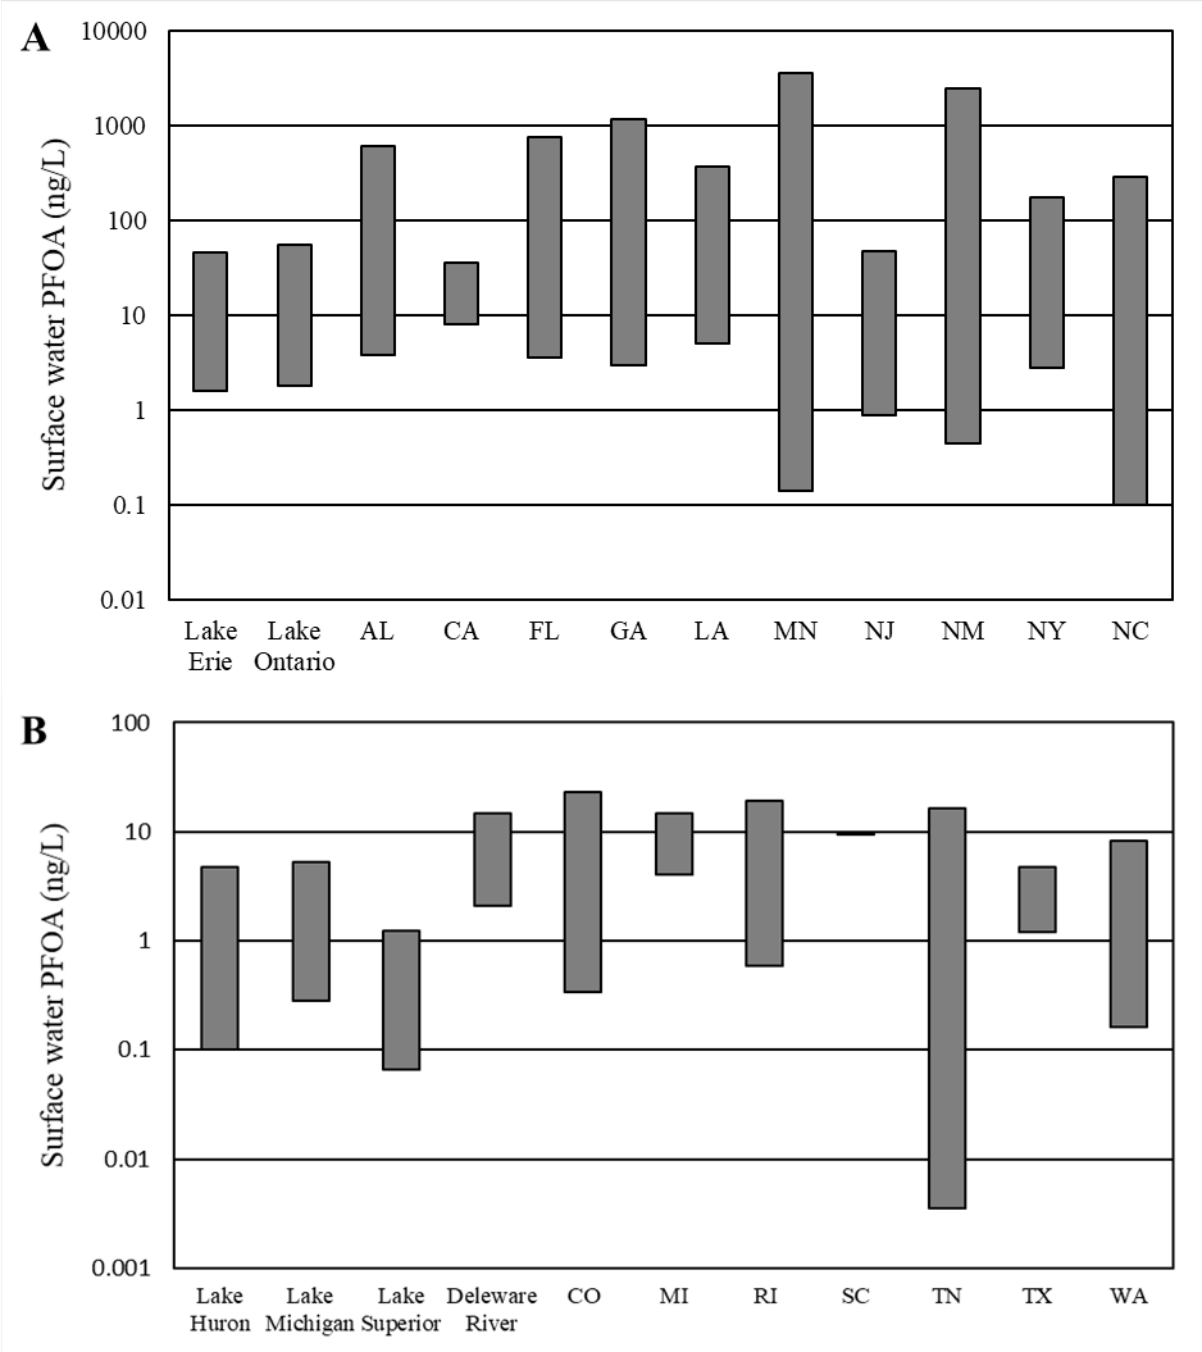

Figure M-2. Comparison of relatively high (A; greater than 30 ng/L) and low (B; less than 30 ng/L) maximum Perfluorooctanoic acid (PFOA) concentrations (ng/L) measured in surface water samples collected across the United States (U.S.) as reported in the publicly available literature.

M.1.7 Comparison to Global Occurrence of PFOA in Surface Waters

Similar to PFAS occurrence in surface waters in the U.S., generally PFOS and PFOA were the dominant PFAS detected in surface waters around the world (Ahrens 2011). On a global scale, concentrations of PFOA measured in surface waters generally range between pg/L and ng/L with some concentrations in the µg/L range. PFOA concentrations measured in the U.S. appear to be similar to those detected in studies with sampling sites in other countries. Global surface water PFOA concentrations reported in the public literature range between not detected and 11,300 ng/L near a PFAS spill site (as summarized below), and Zareitalabad et al. (2013) reported a median PFOA concentration in surface water of 24 ng/L across Canada, Europe, and Asia.

In Canada elevated concentrations of PFOA in surface waters were generally distributed among urbanized areas, suggesting that urban and industrial areas with high population densities contributed to the elevated concentrations of PFOA in surface waters (Gewurtz et al. 2013; Scott et al. 2009). In a systematic, cross-Canada study of PFAS in surface waters, Scott et al. (2009) observed that PFOS and PFOA were the predominant PFAS detected and that generally PFOS concentrations were higher overall, ranging between < 0.02 and 34.6 ng/L, than PFOA concentrations, which ranged between 0.044 and 9.9 ng/L. From the systems sampled in Canada, Scott et al. (2009) indicated that PFOA concentrations measured in Canadian surface waters were lower than those measured in the U.S., Europe, and Asia. However, elevated PFOA concentrations were observed in Etobicoke Creek, a tributary to Lake Ontario, after an accidental spill of a fire-retardant foam containing perfluorinated surfactants at L.B. Pearson International Airport in Toronto, Ontario in June 2000. The measured concentrations of PFOA ranged between not quantified (with a quantification limit of 9 ng/L) to 11,300 ng/L (Moody et al. 2002).

NMED Exhibit 63

PFOA concentrations measured in surface waters across Europe are similar to those observed in the U.S. Specifically, in a European Union (EU)-wide study of polar organic persistent pollutants, Loos et al. (2009) detected PFOA in 97% of samples with a median concentration of 3 ng/L in surface waters sampled across a wide range of sampling sites (including contaminated and pristine rivers and streams of various sizes). However, relatively high PFOA concentrations of nearly 200 ng/L were detected in the Po River, Italy. Mean PFOA concentrations observed by Pan et al. (2018) were similar to those reported in Loos et al. (2009) and across the U.S. with mean surface water concentrations from waterbodies across western Europe, specifically the Thames River, Mälaren Lake, and Rhine River, ranging between 2.31 ng/L to 8.51 ng/L, with a maximum concentration of 11.7 ng/L detected in the Thames River. Kwadijk et al. (2010) detected PFOA in all surface water samples collected from 20 locations across the Netherlands, with concentrations ranging from 6.5 to 43 ng/L. Huset et al. (2008) measured similar PFOA concentrations in three rivers in the Glatt Valley Watershed, Switzerland, and reported averages from three rivers ranging from 7.0 to 7.6 ng/L. Like in the U.S. and Canada, elevated concentrations of PFOA in surface waters across Europe are higher in urbanized areas and sources have been attributed to waste water treatment plant effluent, AFFF spills, and fluorochemical manufacturing facilities (Ahrens 2011; Huset et al. 2008; Kwadijk et al. 2010; Loos et al. 2007 and 2009).

PFOA concentrations observed in surface waters across eastern Asia were broadly similar to the U.S., Canada, and Europe. In Japan, Saito et al. (2003) observed PFOA concentrations ranging between 0.1 and 456 ng/L in surface waters samples collected from various locations. Similarly, Nguyen et al. (2011) reported PFOA concentrations ranging between 5 and 31 ng/L collected from an urbanized section of the Marina catchment in Singapore. Pan et al. (2018)

NMED Exhibit 63

reported PFOA concentrations from 112 samples across eastern Asia ranging from 0.15 ng/L to 52.8 ng/L. These 112 samples were collected from eight different water bodies, including; the Yangtze River (median PFOA = 12.2 ng/L; n = 35), Yellow River (median PFOA = 2.45 ng/L; n = 15), Pearl River (median PFOA = 1.82 ng/L; n = 13), Liao River (median PFOA = 9.39 ng/L; n = 6), Huai River, (median PFOA = 6.01 ng/L; n = 9), Han River (median PFOA = 3.69 ng/L; n = 6), Chao Lake (median PFOA = 8.17 ng/L; n = 13) and Tai Lake (median = 17.95 ng/L; n = 15).

Overall, these studies show the widespread distribution and variability of PFOA concentration in surface waters around the world and that surrounding land use and urbanization with high population densities have a large influence on the overall occurrence of PFOA in surface waters (Ahrens 2011; Gewurtz et al. 2013; Loos et al. 2007; Loos et al. 2009; Scott et al. 2009).

M.2 PFOA Occurrence and Detection in Aquatic Sediments

Although aquatic sediments are not anticipated to be a major PFOA sink (Ahrens 2011; Ahrens et al. 2009), PFOA has been detected in aquatic sediments in relatively remote regions. For example, maximum PFOA concentrations of 1.7 µg/kg dry weight (dw) were detected in lake sediments in the Canadian Artic (Butt et al. 2010). Typically, in the U.S., soil and sediment measurements of PFOA near contaminated sites and manufacturing plants occur in the µg/kg dry weight range. For example, PFOA ranged from below the limit of detection (0.017 µg/kg) to 700 µg/kg in sediments near a fluorochemical manufacturer in West Virginia (Lau et al. 2007).

Across ten U.S. Air Force bases where there is a known historic use of AFFF, Anderson et al. (2016) measured sediment (0-1 foot below top of the sediment) samples between March-September of 2014 at the ten locations with PFOA concentrations detected in 67% of samples.

NMED Exhibit 63

The median concentration of PFOA across all sites was 2.45 µg/kg, with a maximum concentration of 950 µg/kg (Anderson et al. 2016). Lasier et al. (2011) measured PFOA in sediment from the Coosa River, Georgia watershed, upstream and downstream of a land-application site of municipal/industrial wastewater, at concentrations ranging from 0.06-1.97 µg/kg dry weight. Values reported in various locations across San Francisco Bay ranged from below detection to 0.292 µg/kg dry weight (San Francisco Bay RWQCB 2020, Sedlak et al. 2017). Internationally, values ranged from below detection in areas with relatively low population density to µg/kg wet weight in areas of higher human population density, including <LOQ, Gufunes Bay, Iceland (Butt et al. 2010); <LOQ, Faroe Islands (Butt et al. 2010); 0.96 µg/kg wet weight, Tidal Flats of Ariake Sea, Japan (Nakata et al. 2006); 0.29-0.36 µg/kg dry weight, Tokyo Bay, Japan (Ahrens et al. 2010) and <0.05-0.2 µg/kg wet weight, Toronto, Ontario (Vedagiri et al. 2018).

M.3 PFOA Occurrence and Detection in Groundwater

Similar to surface water, PFOS and PFOA are the dominant PFAS detected in groundwater. Subsurface soil samples in Minnesota indicated PFOA concentrations increase with depth, suggesting the migration of PFOA from the surface, through soils, and into groundwaters (Xiao et al. 2015). Generally, PFOA concentrations tend to range in the ng/L range, with some elevated occurrences in µg/L (Ahrens 2011; Xiao 2017). Previous detections of PFOA in groundwater have been associated with the use of AFFF and fire-training locations (Ahrens 2011; Xiao 2017). For example, a maximum PFOA concentration of 105 µg/L was quantified in Michigan groundwater near a site formerly used for military fire-training operations that had been decommissioned for nearly five years prior to sampling (Moody et al. 2003). Similarly, the Minnesota Pollution Control Agency (MPCA) detected PFOA concentrations as

NMED Exhibit 63

high as ~ 23 µg/L in ground water near a PFAS disposal site, with concentrations decreasing to < 0.1 µg/L 1.4 km from the PFAS disposal site (Xaio et al. 2015). Despite not having been an active-fire training area, PFOA was still present on various U.S. Air Force Installations where there is a known history of use of AFFF to extinguish hydrocarbon-based fires. Anderson et al. (2016) measured groundwater samples between March and September of 2014 at the ten locations with PFOA concentrations detected in 90% of samples. The median concentration of PFOA across all sites was 0.41 µg/L, with a maximum concentration of 250 µg/L (Anderson et al. 2016). These concentrations are consistent with groundwater samples from Holloman Air Force Base in New Mexico measured in 2017 with PFOA groundwater concentrations in evaporation ponds and fire training areas ranging from 0.746 -254 µg/L (NMED 2021).

PFOA was detected in groundwater samples across Minnesota in 2006/2007, approximately five years after the 3M Corporation phased out PFOS production in Minnesota in 2002 (MPCA 2008). Analyses of samples collected from vulnerable, shallow aquifers in both urban and agricultural areas across Minnesota, with a variety of potential contamination sources (i.e., industrial and municipal stormwater, pesticides, land application of contaminated biosolids and atmospheric deposition), indicated that perfluorinated chemicals were present in concentrations of potential concern in areas beyond the disposal sites and aquifers associated with them (MPCA 2008). Groundwater samples ranged from <0.001 to 0.0324 µg/L with a reporting limit of 0.025 µg/L.

M.4 PFOA Occurrence and Detection in Air and Rain

Air concentrations of PFOA in the atmosphere is widely distributed globally. In an urban area in Albany, NY perfluorinated acids were measured in air samples in both the gas and particulate phase in May and July 2006 (Kim and Kannan 2007). PFOA in the gas phase had a

NMED Exhibit 63

mean concentration of 3.16 pg/m^3 (range: 1.89-6.53) and in the particulate phase had a mean concentration of 2.03 pg/m^3 (range: 0.76-4.19) (Kim and Kannan 2007). Kim and Kanaan (2007) also reported mean PFOA concentrations of 2.53 ng/L and 4.89 ng/L in rain and snow, respectively. In an urban area in Minneapolis, MN, PFOA was measured in both the particulate and gas phase. PFOA in the particulate phase ranged from 1.6-5.1 pg/m^3 and from 1.7-16.1 pg/m^3 in the gas phase across the five samples (MPCA 2008). The mean concentration value reported from a location in Resolute Bay, Nunavut, Canada was 1.4 pg/m^3 (Stock et al. 2007). These concentrations are greater than PFOA concentrations measured in the particle phase of air samples measured in Zeppelinstasjonen, Svalbard (Butt et al. 2010). PFOA was measured in September and December of 2006 and August and December of 2007, with mean concentrations of 0.44 pg/m^3 (Norwegian Institute for Air Research, 2007a,b).

M.5 PFOA Occurrence and Detection in Ice

Very little information is provided about PFOA concentrations in ice. The PFOA concentration from a Russian Arctic ice core sampled in 2007 was 131 pg/L (Saez et al. 2008; Martin et al. 2010). During the spring of 2005 and 2006 surface snow was collected and the following values were reported for the Canadian Arctic and Greenland, respectively: 13.1-53.7 pg/L and 50.9-520 pg/L (Young et al. 2007).

NMED Exhibit 63

Appendix N Translation of The Chronic Water Column Criterion into Other Fish Tissue Types

The PFOA freshwater aquatic life criteria (summarized in Section 3.3) includes chronic tissue criteria for fish whole body, fish muscle, and invertebrate whole-body tissues. Additional values for fish liver, fish blood, and fish reproductive tissues were also calculated by transforming the freshwater chronic water column criterion (i.e., 0.10 mg/L) into representative tissue concentrations using tissue-specific bioaccumulation factors (BAFs). Fish liver, fish blood, and fish reproductive BAFs were identified following the same approaches used to identify fish wholebody, mush muscle, and inverterbrate whole body BAFs, which are described in detial in section 2.11.3.1. Briefly, BAFs were determined from field measurements and calculated using the equation:

$$BAF = \frac{C_{biota}}{C_{water}} \qquad \text{(}\textit{Equation N-1}\text{)}$$

Where:

C_{biota} *= PFOA concentration in organismal tissue(s)*
C_{water} *= PFOA concentration in water where the organism was collected*

To identify the representative BAFs, a literature search for reporting on PFOA bioaccumulation was implemented by developing a series of chemical-based search terms to identify studies that were reviewed for reported BAFs and/or reported concentrations in which BAFs could be calculated for both freshwater and estuarine/marine species. BAFs from both freshwater and estuarine/marine species were considered because; (1) inclusion of estuarine/marine BAFs expanded the relatively limited PFOA BAF dataset and (2) Burkhard (2021) did not specifically observe notable differences in PFAS BAFs between freshwater and estuarine/marine systems, instead stating additional research is needed to formulate conclusions.

NMED Exhibit 63

Sources with relevant BAF information were further screened to determine if the reported BAF information from each source was of low, medium, or high quality. Only BAFs of high and medium quality were used to derive the tissue-specific BAFs and corresponding tissue-based values described below.

BAFs based on reproductive tissues identified by Burkhard (2021) were further screened to ensure only BAFs based on adult females were considered, because female reproductive tissues are most relevant to potential maternal transfer to offspring. This subset of reproductive-based BAFs and corresponding species and sampling locations are described in Table N-1.

Table N-1. Characteristics of adult fish sampled for the calculation of PFOA reproductive tissue BAFs.

All sampled fish were adults, and all reproductive tissues identified as gonad. Weights, lengths, and BAFs are averages.

Author	Species	Collection Date	n	Sex	Age (yr.)	Weight (g-ww)	Length (cm)	BAF (L/kg)

N.R. = Not Reported

[1] Range.

Additional details on BAF compilation and ranking can be found in Section 2.11.3.1 and Burkhard (2021). The distributions of fish liver, fish blood, and fish reproductive BAFs identified in the literature used to calculate tissue-specific BAFs were determined in the same manner as invertebrate, fish muscle, and fish whole body BAFs (Section 3.2.2). Briefly, distributions of BAFs used to derive additional tissue values were based on the lowest species-level BAF reported within a waterbody. When more than one BAF was available for the same

NMED Exhibit 63

species at the same site, the species-level BAF was calculated as the geometric mean of all BAFs for that species at that site. Summary statistics for the PFOA BAFs used in the derivation of the additional tissue-based values are presented below (Table N-2) and individual BAFs are provided in Appendix O.

Table N-2. Summary Statistics for PFOA Freshwater BAFs in Additional Fish Tissues[1].

Category	n	Geometric Mean BAF (L/kg-wet weight)	Median BAF (L/kg-wet weight)	20th Centile BAF (L/kg-wet weight)	Minimum (L/kg-wet weight)	Maximum (L/kg-wet weight)
Liver	13	15.59	10	2.349	0.732	1,109
Blood	5	80.71	34.1	14.90	14	636
Reproductive Tissue	4	9.488	5.62	3.1	3.1	85.41

[1] Based on the lowest species-level BAF measured at a site (i.e., when two or more BAFs were available for the same species at the same site, the species-level geometric mean BAF was calculated, and the lowest species-level BAF was used).

Equation N-2 was used to transform the chronic freshwater column criterion (see Section 3.2.1.3) into tissue values using the 20th centile BAFs from the distributions of BAFs described above and summarized in Table N-2:

$$Tissue\ Value = Chronic\ Water\ Column\ Criterion\ \times 20th\ Centile\ BAF \qquad (Equation\ N\text{-}2)$$

The resulting tissue values that correspond to the 20th centile tissue-specific BAFs used in Equation N-2 are reported in Table N-3. The values reported in Table N-3 represent tissue-based concentrations that offer a level of protection that is equal to the magnitude components of the chronic water column criterion as well as the fish whole body, fish muscle, and invertebrate whole body tissue-based criteria; however, the tissue-based values reported in Table N-3 are only presented for comparative purposes and are not recommended criteria.

NMED Exhibit 63

Table N-3. PFOA Concentrations for Additional Fish Tissue Values.[1, 2]

Category	PFOA Concentration (mg/kg ww)
Liver	0.2349
Blood	1.490
Reproductive Tissue	0.3100

[1] These PFOA concentrations are provided as supplemental information and are not recommended criteria.
[2] Tissue concentrations are expressed as wet weight (ww) concentrations.

a – WB (Fish whole body); Invert (Invertebrate whole body)
b – Lowest species level BAF (highlighted in bold) at each site represents the site-level BAF
c – One site level BAF represented by four species tied for lowest species level BAF

O.2 Summary of PFOA BAFs used to calculate tissue criteria and supplemental fish tissue values

Field measured BAFs used to calculate fish and invertebrate PFOA tissue criteria (fish muscle, fish whole body, invertebrate whole body) and supplemental fish tissue values (blood, reproductive tissue, liver) are shown in Appendix O.1. Summary statistics for the BAFs from this table used to derive tissue criteria and additional tissue values (i.e., lowest species-level BAF from each site) are reported in Table 3-11 and Table N-2, respectively. Rankings for individual BAFs were determined by Burkhard (2021), who devised a ranking system based on five characteristics: 1) number of water samples; 2) number of tissue samples; 3) spatial coordination of water and tissue samples; 4) temporal coordination of water and tissue samples; and 5) general experimental design. For the first four characteristics, a score of one to three was assigned, based on number of samples or how closely the water and tissue measurements were paired. For the experimental design characteristic, a default value of zero was assigned; unless the measured tissues were composites of mixed species, in which case it was assigned a three (Burkhard 2021). These sub-scores were then summed and assigned a rank based on the final score. Studies with high quality rankings had scores of four or five, studies with medium quality rankings had scores of five or six, and studies with low quality rankings had scores of seven or higher (Burkhard 2021). Parameters for the scores assigned to the five characteristics are listed in Table 2-2, and additional details can be found in Burkhard (2021). Only BAFs from studies with high or medium quality rankings were included for the final BAF geometric mean calculations used to derive tissue criteria (Table 3-12) and supplemental tissue values (Table N-3).

Appendix P Example Data Evaluation Records (DERs)

Background: This set of published literature was identified using the ECOTOXicology database (ECOTOX; https://cfpub.epa.gov/ecotox/) as meeting data quality standards. ECOTOX is a source of high-quality toxicity data for aquatic life, terrestrial plants, and wildlife. The database was created and is maintained by the EPA, Office of Research and Development, Center for Computational Toxicology and Exposure. The ECOTOX search generally begins with a comprehensive chemical-specific literature search of the open literature conducted according to ECOTOX Standard Operating Procedures (SOPs). The search terms are often comprised of chemical terms, synonyms, degradates and verified Chemical Abstracts Service (CAS) numbers. After developing the literature search strategy, ECOTOX curators conduct a series of searches, identify potentially applicable studies based on title and abstract, acquire potentially applicable studies, and then apply the applicability criteria for inclusion in ECOTOX. Applicability criteria for inclusion into ECOTOX generally include:

1. The toxic effects are related to single chemical exposure (unless the study is being considered as part of a mixture effects assessment);
2. There is a biological effect on live, whole organisms or *in vitro* preparation including gene chips or omics data on adverse outcome pathways potentially of interest;
3. Chemical test concentrations are reported;
4. There is an explicit duration of exposure;
5. Toxicology information that is relevant to OW is reported for the chemical of concern;
6. The paper is published in the English language;
7. The paper is available as a full article (not an abstract);
8. The paper is publicly available;
9. The paper is the primary source of the data;
10. A calculated endpoint is reported or can be calculated using reported or available information;
11. Treatment(s) are compared to an acceptable control;
12. The location of the study (*e.g.*, laboratory vs. field) is reported; and
13. The tested species is reported (with recognized nomenclature).

NMED Exhibit 63

Following inclusion in the ECOTOX database, toxicity studies are subsequently evaluated by the Office of Water. All studies were evaluated for data quality generally as described by U.S. EPA (1985) in the 1985 Guidelines and in the EPA's Office of Chemical Safety and Pollution Prevention (OCSPP)'s Ecological Effects Test Guidelines (U.S. EPA 2016b), and EPA OW's internal data quality SOP, which is consistent with OCSPP's data quality review approach (U.S. EPA 2018). These toxicity data were further screened to ensure that the observed effects could be primarily attributed to PFOA exposure. Office of Water completed a DER for each species by chemical combination from the PFOA studies identified by ECOTOX. Example DERs are presented here to convey the meticulous level of evaluation, review, and documentation each PFOA study identified by ECOTOX was subject to. Appendix P.1 shows an example fish DER and Appendix P.2 shows an example aquatic invertebrate DER.

NMED Exhibit 63

P.1 Example Fish DER

Part A: Overview

I. Test Information

Chemical name:

CAS name: CAS Number:
Purity: Storage conditions:
Solubility in Water (units):

____ **Controlled Experiment** (*manipulated*) ____ **Field Study/Observation** (*not manipulated*) (*Place X by One*)

Primary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)

Secondary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)
(*At least one reviewer should be from EPA for sensitive taxa*)

Citation: *Indicate: author(s), year, study title, journal, volume, and pages*.
(e.g., Slonim, A.R. 1973. Acute toxicity of beryllium sulfate to the common guppy. J. Wat. Pollut. Contr. Fed. 45(10): 2110-2122)

Companion Papers: *Identify any companion papers associated with this paper using the citation format above.*

-

Were other DERs completed for Companion Papers? ____ **Yes** ____ **No** (*If yes, list file names of DERs below*)

Study Classification for Aquatic Life Criteria Development: *Place X by One Based on Highest Use*

_____ Acceptable for Quantitative Use
_____ Acceptable for Qualitative Use
_____ Not Acceptable for Use/Unused

General Notes: *Provide any necessary details regarding the study's use classification for all pertinent endpoints, including non-apical endpoints within the study (e.g., note all study classifications for each endpoint if the use varies)*

Major Deficiencies (note any stated exclusions): *Check all that apply. Checking any of these items make the study "**Not Acceptable for Use**"*

_____ Mixture (for controlled experiments only)
_____ No Controls (for controlled experiments only)
_____ Excessive Control Mortality (> 10% for acute and > 20% for chronic)
_____ Dilution water not adequately characterized
_____ Bioaccumulation: steady state not reached
_____ Dermal or Injection Exposure Pathway
_____ Review paper or previously published without modification
_____ Other: *(if any, list here*)

NMED Exhibit 63

POTENTIAL CHEMICAL MIXTURES: *Describe any potential chemicals mixtures as characterized by study authors (including any confirmation of chemical mixtures).*

DESCRIPTION OF DILUTION WATER: *Describe concerns with characterization of and/or major deficiencies with dilution water.*

General Notes:

Minor Deficiencies: *List and describe any minor deficiencies or other concerns with test. These items may make the study "**Acceptable for Qualitative Use**"* **(exceptions may apply as noted)**

***For Field Studies/Observations**: A field study/observation may be considered "**Acceptable for Quantitative Use**" if it consisted of a range of exposure concentrations and the observed effects are justifiably contributed to a single chemical exposure*

_____ Mixture (observed effects not justifiably contributed to single chemical exposure)
_____ Uncharacterized Reference Sites/Conditions

POTENTIAL CHEMICAL MIXTURES PRESENT AT SITE: *Describe any potential chemicals mixtures present at the site as characterized by study authors (including any confirmation of chemicals present at study site).*

EXPOSURE VARIABILITY ACROSS STUDY SITE(S): *Describe any exposure variability across study site(s) as characterized by study authors (i.e., description of study design with reference and contaminated sites).*

General Notes:

Reviewer's Comments: *Provide additional comments that do not appear under other sections of the DER.*

ABSTRACT: *Copy and paste abstract from publication.*

SUMMARY*: Fill out and modify as needed.*

Acute:

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Hardness (mg/L as $CaCO_3$) or Salinity (ppt)	DOC (mg/L)	Effect	Reported Effect Concentration (mg/L)	Verified Effect Concentration (mg/L)	Classification
											Quantitative / Qualitative / Unused

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

Chronic:

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Hardness (mg/L as $CaCO_3$) or Salinity (ppt)	DOC (mg/L)	Chronic Limits	Reported Chronic Value (mg/L or µg/g)	Verified Chronic Value (mg/L or µg/g)	Chronic Value Endpoint	Classification
												Quantitative / Qualitative / Unused

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

II. Results *Provide results as reported in the publication (including supplemental materials). Include screen shots of tables and/or figures reporting results from the article following tabulated data table in each associated results section for all studies. Complete tabulated data tables for all studies for studies marked "**Acceptable for Quantitative Use"** and **"Acceptable for Qualitative Use**".*

Water Quality Parameters: *If only general summary data of water quality parameters is provided by study authors (i.e., no specific details of water quality parameters on a treatment level is provided), summarize any information regarding water quality parameters under General Notes below and indicate data not provided in* Table A.II.1.

General Notes: *For aquatic life criteria development, measured water quality parameters in the treatments nearest the toxicity test endpoint(s), e.g., LC_{50}, EC_{20}, etc., are most relevant.*

-

Table A.II.1. Measured Water Quality Parameters in Test Solutions.

Dissolved oxygen, temperature, pH and [other parameters (hardness, salinity, DOC)] in test solutions during the *[X]*-day exposure of *[test organism]* to *[concentration of treatment(s)]* of *[test substance]* under *[static renewal/flow-through]* conditions.

Parameter	Treatment	Mean	Range
Dissolved Oxygen (% saturation or mg/L)	*[1]*		
	[2]

Part B: Detailed Review

I. Materials and Methods

Protocol/Guidance Followed: *Indicate if provided by authors.*

Deviations from Protocol: *If authors report any deviations from the protocol noted above indicate here.*

Study Design and Methods: *Copy and paste methods section from publication.*

TEST ORGANISM: *Provide information under Details and any relevant or related information or clarifications in Remarks.*

Parameter	Details	Remarks
Species:	Common Name: Scientific Name:	North American species? ____ Surrogate for North American Taxon? ____ *(Place X if applicable)*

Strain/Source:
• Wild caught from unpolluted areas [1]
  o Quarantine for at least 14 days or until they are disease free, before acclimation [1]
• Must originate from same source and population [1]
• Should not be used:
  o If appeared stressed, such as discoloration or unusual behavior [1]
  o If more than 5% die during the 48 hours before test initiation [1]
  o If they were used in previous test treatments or controls [2]
• No treatments of diseases may be administered:
  o Within 16 hour of field collection [1]
  o Within 10 days or testing or during testing [1]		

Age at Study Initiation:
Acute:
• Juvenile stages preferred [1]
Chronic:
• Life-cycle test:
  o Embryos or newly hatched young < 48 hours old [2]
• Partial life-cycle test:
  o Immature juveniles at least 2 months prior to active gonad development [2]
• Early life-stage test:
  o Shortly after fertilization [2]		

Was body weight or length recorded at test initiation?	____ Yes ____ No	
Was body weight or length recorded at regular intervals?	____ Yes ____ No *If yes, describe regular intervals:*	

STUDY PARAMETERS: *Provide information under Details and any relevant information of deficiencies in Remarks. Complete for both Controlled Experiments and Field Studies/Observations.*

	Parameter	Details	Remarks
For Both Controlled Experiments and Field Observations	**Number of Replicates per Treatment Group:** • At least 2 replicates/treatment recommended for acute tests [1] • At least 2 replicates/treatment recommended for chronic tests [3]	Control(s): Treatment(s):	
	Number of Organisms per Replicate/ Treatment Group: • At least 10 organisms/treatment recommended [3] • At least 7 organisms/treatment acceptable [4]	Control(s): Treatment(s):	
	Exposure Pathway: *(i.e., water, sediment, gavage, or diet).* *Note: all other pathways (e.g., dermal, single dose via gavage, and injection) are unacceptable.*		
	Exposure Duration: **Acute** • Should be 96 hours [2] **Chronic** • Life-cycle tests: o Ensure that all life stages and life processes are exposed [2] o Begin with embryos (or newly hatched young), continue through maturation and reproduction, and should end not less than 24 days (90 days for salmonids) after the hatching of the next generation [2] • Partial life-cycle tests: o Allowed with species that require >1 year to reach sexual maturity, so that all major life stages can be exposed to the test material in <15 months [2] o Begin with immature juveniles at least 2 months prior to active gonad development, continue through maturation and reproduction, and end not less than 24 days (90 days for salmonids) after the hatching of the next generation [2] • Early life-cycle tests: o 28 to 32 day (60 day post hatch for salmonids) exposures from shortly after fertilization through embryonic, larval, and early juvenile development [2]	____ Acute ____ Partial Life Cycle ____ Early Life Stage ____ Full Life Cycle ____ Other *(please remark):*	
	Test Concentrations (remember units): *Recommended test concentrations include at least three concentrations other than the control; four or more will provide a better statistical analysis* [3]	Nominal: Measured: Media measured in:	
	Observation Intervals: • Should be an appropriate number of observations over the study to ensure water quality is being properly maintained [4]		

CONTROLLED EXPERIMENT STUDY PARAMETERS: *Provide information under Details and any relevant information of deficiencies in Remarks. Complete for Controlled Experiments only.*

For Controlled Experiments Only

Parameter	Details	Remarks
Acclimation/Holding: • Should be placed in a tank along with the water in which they were transported o Water should be changed gradually to 100% dilution water (usually 2 or more days) [1] o For wild-caught animals, test water temperature should be within 5°C of collection water temperature [1] o Temperature change rate should not exceed 3°C within 72 hours [1] • To avoid unnecessary stress and promote good health: o Organisms should not be crowded [1] o Water temperature variation should be limited [1] o Dissolved oxygen: ▪ Maintain between 60 – 100% saturation [1] ▪ Continuous gentle aeration if needed [1] o Unionized ammonia concentration in holding and acclimation waters should be < 35 µg/L [1]	Duration: Feeding: Water type: Temperature (°C): Dissolved Oxygen (mg/L): Health (*any mortality observed?*):	*Identify number of individuals excluded from testing and/or analysis (if any):*
Acclimation followed published guidance? *Describe, if any*	____ Yes ____ No *If yes, indicate which guidance:*	
Test Vessel: • Test chambers should be loosely covered [1] • Test chamber material: o Should minimize sorption of test chemical from water [1] o Should not contain substances that can be leached or dissolved in solution and are free of substances that could react with exposure chemical [1] o Glass, No. 316 stainless steel, nylon screen and perfluorocarbon (e.g. Teflon) are acceptable [1] o Rubber, copper, brass, galvanized metal, epoxy glues, lead and flexible tubing should not come into contact with test solution, dil. Water, or stock [1] • Size/volume should maintain acceptable biomass loading rates (see Biomass Loading Rate below) [1]	Material: Size: Fill Volume:	*Briefly describe the test vessel:*
Test Solution Delivery System/Method: • Flow-through preferred for some highly volatile, hydrolysable or degradable materials [2] o Concentrations should be measured often enough using acceptable analytical methods [2] • Chronic exposures: o Flow-through, measured tests required [2]	Test Concentrations Measured ____ Yes ____ No Test Solution Delivery System: ____ Static ____ Renewal *Indicate Interval:* ____ Flow-through *Indicate Type of Diluter:*	
Source of Dilution Water: • Freshwater hardness range should be < 5 mg/L or < 10% of the average (whichever is greater) [1] • Saltwater salinity range should be < 2 g/kg or < 20% of the average (whichever is greater) [1] • Dilution water must be characterized (natural surface water, well water, etc.) [3] o Distilled/deionized water without the addition of appropriate salts should not be used [2] • Dilution water in which total organic carbon or particulate matter >5 mg/L should not be used [2] o Unless data show that organic carbon or particulate matter do not affect toxicity [2]		
Dilution Series (*e.g., 0.5x, 0.6x, etc.*):		

	Parameter	Details	Remarks
For Controlled Experiments Only	**Dilution Water Parameters:** *Measured at the beginning of the experiment or averaged over the duration of the experiment (details of water quality parameters measured in test solutions should be included under the results section)*	Dissolved Oxygen (mg/L): pH: Temperature (°C): Hardness (mg/L as $CaCO_3$): Salinity (ppt): Total Organic Carbon (mg/L): Dissolved Organic Carbon (mg/L):	
	Aeration: • Acceptable to maintain dissolved oxygen at 60 – 100% saturation at all times [1] • Avoid aeration when testing highly oxidizable, reducible and volatile materials [1] • Turbulence should be minimized to prevent stress on test organisms and/or re-suspend fecal matter [1] • Aeration should be the same in all test chambers at all times [1]	____ Yes ____ No	
	Describe Preparation of Test Concentrations (e.g., water exposure, diet):		
	Test Chemical Solubility in Water: *List units and conditions (e.g., 0.01% at 20ºC)*		
	Were concentrations in water or diet verified by chemical analysis? *Measured test concentrations should be reported in* Table A.II.2 *above.*	__Yes __No *Indicate media:*	
	Were test concentrations verified by chemical analysis in tissue? *Measured test concentrations can be verified in test organism tissue (e.g., blood, liver, muscle) alone if a dose-response relationship is observed.* *Measured test concentrations should be reported in* Table A.II.2 *above.*	__Yes __No *Indicate tissue type:*	*If test concentrations were verified in test organism tissue, was a dose-response relationship observed?*
	Were stability and homogeneity of test material in water/diet determined?	__Yes __No	
	Was test material regurgitated/avoided?	__Yes __No	
	Solvent/Vehicle Type (Water or Dietary): • When used, a carrier solvent should be kept to a minimum concentration [1] • Should not affect either survival or growth of test organisms [1] • Should be reagent grade or better [1] • Should not exceed 0.5 ml/L (static) or 0.1 ml/L (flow through) unless it was shown that higher concentrations do not affect toxicity [3]		
	Negative Control:	____ Yes ____ No	
	Reference Toxicant Testing:	____ Yes ____ No	*If Yes, identify substance:*
	Other Control: *If any (e.g. solvent control)*		

NMED Exhibit 63

	Biomass Loading Rate: • Loading should be limited so as not to affect test results. Loading will vary depending on temperature, type of test (static vs. flow-through), species, food/feeding regime, chamber size, test solution volume, etc. [1] • This maximum number would have to be determined for the species, test duration, temperature, flow rate, test solution volume, chamber size, food, feeding regime, etc. • Loading should be sufficiently low to ensure: o Dissolved oxygen is at least 60% of saturation (40% for warm-water species) [1,5] o Unionized ammonia does not exceed 35 µg/L [1] o Uptake by test organisms does not lower test material concentration by > 20% [1] o Growth of organisms is not reduced by crowding • Generally, at the end of the test, the loading (grams of organisms; wet weight; blotted dry) in each test chamber should not exceed the following: o Static tests: > 0.8 g/L (lower temperatures); > 0.5 g/L (higher temperatures) [1] o Flow through tests: > 1 g/L/day or > 10 g/L at any time (lower temperatures); > 0.5 g/L/day or > 5 g/L at any time (higher temperatures) [1] • Lower temperatures are defined as the lower of 17˚C or the optimal test temperature for that species [1]		

NMED Exhibit 63

	Parameter	Details	Remarks

For Controlled Experiments Only	**Feeding:**
	• Unacceptable for acute tests [2]
	  o Exceptions:
	  ▪ Data indicate that the food did not affect the toxicity of the test material [2]
	  ▪ Test organisms will be severely stressed if they are unfed for 96 hours [2]
	  ▪ Test material is very soluble and does not sorb or complex readily (e.g., ammonia) [2]
		____ Yes ____ No	

	Lighting:
	• Depends on the type of test (acute or chronic) and endpoint (e.g., reproduction) of interest.
	  o Embryos should be incubated under dim incandescent lighting (≤ 20 fc) or total darkness during early life-stage toxicity testing
	  o Embryos must not be subjected to prolonged exposure to direct sunlight, fluorescent lighting, or high intensity incandescent lighting
	• Generally, ambient laboratory levels (50-100 fc) or natural lighting should be acceptable, as well as a diurnal cycle consisting of 50% daylight or other natural seasonal diurnal cycle.
	• Artificial light cycles should have a 15 – 30-minute transition period to avoid stress due to rapid increases in light intensity [1]		

Study Design/Methods Classification: *(Place X by One Based on Overall Study Design/Methods Classification)*
Provide details of Major or Minor Deficiencies/Concerns with Study Design in Associated Sections of Part A: Overview
This classification should be taken into consideration for the overall study classification for aquatic life criteria development in Part A.

_____ Study Design Acceptable for Quantitative Use
_____ Study Design Acceptable for Qualitative Use
_____ Study Design Not Acceptable for Use

Additional Notes: *Provide additional considerations for the classification of study use based on the study design.*

OBSERVATIONS: *Provide information under Details and any relevant information in Remarks. This information should be consistent with the Results Section in Part A.*

Parameter	Details	Remarks

Parameters measured including sublethal effects/toxicity symptoms:
Common Apical Parameters Include:
Acute
• EC_{50} based on percentage of organisms exhibiting loss of equilibrium plus the percentage of organisms immobilized plus percentage of organisms killed [2]
  ○ If not available, the 96-hr LC_{50} should be used [2]
Chronic
• Life-cycle/Partial Life-cycle test:
  ○ Survival and growth of adults and young, maturation of males and females, eggs spawned per female, embryo viability (salmonids only), and hatchability [2]
• Early life-cycle test:
  ○ Survival and growth [2]
	List parameters:	

Was control survival acceptable? **Acute** • > 90% control survival at test termination [2] **Chronic** • > 80% control survival at test termination [2]	____ Yes ____ No Control survival (%):	
Were individuals excluded from the analysis?	____ Yes ____ No *If yes, describe justification provided:*	
Was water quality in test chambers acceptable? • If appropriate, describe any water quality issues (e.g., dissolved oxygen level below 60% of saturation)	____ Yes ____ No	
Availability of concentration-response data: • Were treatment level concentration-response data included in study publication (can be from tables, graphs, or supplemental materials)? *Specify endpoints in remarks* • Were replicate level concentration-response data included in study publication (can be from tables, graphs, or supplemental materials)? *specify endpoints in remarks* • If treatment and/or replicate level concentration-response data were included, how was data presented? *(check all that apply)* • Were concentration-response data estimated from graphs study publication or supplemental materials? • Should additional concentration-response data be requested from study authors? *If concentration-response data are available, complete **Verification of Statistical Results (Part C)** for sensitive species.*	____ Yes ____ No ____ Yes ____ No ____ Tables ____ Graphs ____ Supplemental Files ____ Yes ____ No *If yes, indicate software used:* ____ Yes ____ No Requested by: Request date: Date additional data received:	

Part C: Statistical Verification of Results

I. Statistical Verification Information: *Report the statistical methods (e.g., EPA TRAP, BMDS, R, other) used to verify the reported study or test results for the five (5) most sensitive genera and sensitive apical endpoints (including for tests where such estimates were not provided). If values for the LC_{50}, LT_{50} and NOEC are greater than the highest test concentration, use the ">" symbol.*

Primary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)

Secondary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)
(*At least one reviewer should be from EPA for sensitive taxa*)

EC_{50} or LC_{50}

Dose-Response Curve Classification: *(Place X by One)*
This classification should be taken into consideration for the overall study classification for aquatic life criteria development in Part A

_____ Dose-Response Curve Acceptable for Quantitative Use
_____ Dose-Response Curve Acceptable for Qualitative Use
_____ Dose-Response Curve Not Acceptable for Use

Summary of Statistical Verification: *Provide summary of methods used in statistical verification.*

Additional Notes:

Attachments:

1. *Provide attachments to ensure all data used in Part C are captured, whether from study results reported in the publication and/or from additional data requested from study authors*
    - *Data from study results of the publication should be reported in Results section of Part A*
    - *Additional data provided upon request from study authors should be reported in Table C.II.1 below and original correspondence with study authors should be included as attachments*
2. *Model assessment output (including all model figures, tables, and fit metrics)*
3. *Statistical code used for curve fitting*

NMED Exhibit 63

III. Attachments: *Include all attachments listed above after the table below.*

Additional Data Used in Response-Curve: *Provide all data used to fit dose-response curve not captured in Results section of DER above in Part A. Add rows as needed. First row in italicized text is an example.*

Table C.II.1 Additional Data Used in Dose-Response Curve.

Curve ID	Species	Endpoint	Treatment	Replicate	[Standard Deviation or Standard Error]	# of Survivors	N[a]	k[a]	n[a]	Response	Response Unit	Conc	Conc units
Alchronic1	*Ceriodaphnia dubia*	*# of young/female*	*0*	*6*			*10*	*10*	*1*	*18*	*count*	*0.03*	*mg/L*

[a] N = number of individuals per treatment; k = number of replicates per treatment level; n = number of individuals per replicate

Part A: Overview

I. Test Information

Chemical name:

CAS name: CAS Number:
Purity: Storage conditions:
Solubility in Water (units):

____ **Controlled Experiment** (*manipulated*) ____ **Field Study/Observation** (*not manipulated*) (*Place X by One*)

Primary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)

Secondary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)
(*At least one reviewer should be from EPA for sensitive taxa*)

Citation: *Indicate: author(s), year, study title, journal, volume, and pages.*
(e.g., Keller, A.E and S.G. Zam. 1991. The acute toxicity of selected metals to the freshwater mussel, *Anodonta imbecilis*. Environ. Toxicol. Chem. 10(4): 539-546.)

Companion Papers: *Identify any companion papers associated with this paper using the citation format above.*

Were other DERs completed for Companion Papers? ____ **Yes** ____ **No** (*If yes, list file names of DERs below*)

Study Classification for Aquatic Life Criteria Development:

_____ Acceptable for Quantitative Use
_____ Acceptable for Qualitative Use
_____ Not Acceptable for Use/Unused

General Notes: *Provide any necessary details regarding the study's use classification for all pertinent endpoints, including non-apical endpoints within the study (e.g., note all study classifications for each endpoint if the use varies)*

Major Deficiencies (note any stated exclusions): *Check all that apply. Checking any of these items make the study "**Not Acceptable for Use**"*

_____ Mixture (for controlled experiments only)
_____ No Controls (for controlled experiments only)
_____ Excessive Control Mortality (> 10% for acute and > 20% for chronic)
_____ Dilution water not adequately characterized
_____ Bioaccumulation: steady state not reached
_____ Dermal or Injection Exposure Pathway
_____ Review paper or previously published without modification
_____ Other: *(if any, list here)*

POTENTIAL CHEMICAL MIXTURES: *Describe any potential chemicals mixtures as characterized by study authors (including any confirmation of chemical mixtures).*

DESCRIPTION OF DILUTION WATER: *Describe concerns with characterization of and/or major deficiencies with dilution water.*

General Notes:

Minor Deficiencies: *List and describe any minor deficiencies or other concerns with test. These items may make the study "**Acceptable for Qualitative Use**"* **(exceptions may apply as noted)**

***For Field Studies/Observations**: A field study/observation may be considered "**Acceptable for Quantitative Use**" if it consisted of a range of exposure concentrations and the observed effects are justifiably contributed to a single chemical exposure*

_____ Mixture (observed effects not justifiably contributed to single chemical exposure)
_____ Uncharacterized Reference Sites/Conditions

POTENTIAL CHEMICAL MIXTURES PRESENT AT SITE: *Describe any potential chemicals mixtures present at the site as characterized by study authors (including any confirmation of chemicals present at study site).*

EXPOSURE VARIABILITY ACROSS STUDY SITE(S): *Describe any exposure variability across study site(s) as characterized by study authors (i.e., description of study design with reference and contaminated sites).*

General Notes:

Reviewer's Comments: *Provide additional comments that do not appear under other sections of the template*.

ABSTRACT: *Copy and paste abstract from publication.*

SUMMARY*: Fill out and modify as needed.*

Acute:

Species (lifestage)	Method[a]	Test duration	Chemical / Purity	pH	Temp. (°C)	Hardness (mg/L as $CaCO_3$) or Salinity (ppt)	DOC (mg/L)	Effect	Reported Effect Concentration (mg/L)	Verified Effect Concentration (mg/L)	Classification
											Quantitative / Qualitative / Unused

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

Chronic:

Species (lifestage)	Method[a]	Test duration	Chemical / Purity	pH	Temp. (°C)	Hardness (mg/L as $CaCO_3$) or Salinity (ppt)	DOC (mg/L)	Chronic Limits	Reported Chronic Value (mg/L or µg/g)	Verified Chronic Value (mg/L or µg/g)	Chronic Value Endpoint	Classification
												Quantitative / Qualitative / Unused

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

II. Results *Provide results as reported in the publication (including supplemental materials). Include screen shots of tables and/or figures reporting results from the article following tabulated data table in each associated results section for all studies. Complete tabulated data tables for all studies for studies marked "**Acceptable for Quantitative Use**" and "**Acceptable for Qualitative Use**".*

Water Quality Parameters: *If only general summary data of water quality parameters is provided by study authors (i.e., no specific details of water quality parameters on a treatment level is provided), summarize any information regarding water quality parameters under General Notes below and include data not provided in* Table A.II.1.

General Notes: *For aquatic life criteria development, measured water quality parameters in the treatments nearest the toxicity test endpoint(s), e.g., LC_{50}, EC_{20}, etc., are most relevant.*

Table A.II.1. Measured Water Quality Parameters in Test Solutions.

Dissolved oxygen, temperature, pH and [other parameters (hardness, salinity, DOC)] in test solutions during the *[X]*-day exposure of *[test organism]* to *[concentration of treatment(s)]* of *[test substance]* under *[static renewal/flow-through]* conditions.

Parameter	Treatment	Mean	Range
Dissolved oxygen (% saturation or mg/L)	*[1]*		
	[2]

	j		

Chemical Concentrations: *Summarize the concentration verification data from test solutions/media. Expand table to include each measured concentration data for each media type (i.e., muscle, liver, blood, etc.).*

General Notes: *Provide any necessary detail regarding the measured concentrations, including any identified cause for substantial differences between nominal and measured concentrations, if samples were collected on separate days (and if so provide details), and any potential cross contamination.*

Table A.II.2. Measured (and Nominal) Chemical Concentrations in Test Solutions/Media.

[Analytical Method] verification of test and control concentrations during an [X]-day exposure of [test organism] to [test substance] under [static renewal/flow-through] conditions.

Treatment	Nominal Concentration (units)	[Mean] Measured Concentration (units)	Number of Samples	Non-Detect[a]	Number of Samples Below Non-Detect	[Standard Deviation or Standard Error]	Range
Control							
[1]							
[2]							
[3]							
[4]							
[5]							
[6]							
j							

[a]Non-Detect: 0 = measured and detected; 1=measured and not detected; if not measured or reported enter as such

Mortality: *Briefly summarize mortality results (if any).*

General Notes: *Comment on concentrations response relations and slope of response if provided. Compare mortality with control treatment and/or the reference chemical.*

Table A.II.3. Mean Percent [Mortality or Survival].

Mean percent mortality [or number of immobilized] or survival of [test organism] exposed to [test substance] for [test duration] under [static/renewal/flow-through] conditions.

Treatment	[Mean % Mortality]	[Standard Deviation or Standard Error]

Part B: Detailed Review

I. Materials and Methods

PROTOCOL/GUIDANCE FOLLOWED: *Indicate if provided by authors.*

DEVIATIONS FROM PROTOCOL: *If authors report any deviations from the protocol noted above indicate here.*

Study Design and Methods: *Copy and paste methods section from publication.*

TEST ORGANISM: *Provide information under Details and any relevant or related information or clarifications in Remarks.*

Parameter	Details	Remarks
Species:	Common Name: Scientific Name:	North American species? ____ Surrogate for North American Taxon? ____ *(Place X if applicable)*

Strain/Source:
• Wild caught from unpolluted areas [1]
  o Quarantine for at least 7 days or until they are disease free, before acclimation [1]
• Must originate from same source and population [1]
• Should not be used:
  o If appeared stressed, such as discoloration or unusual behavior [1]
  o If more than 5% die during the 48 hours before test initiation [1]
  o If they were used in previous test treatments or controls [2]
• No treatments of diseases may be administered:
  o Within 16 hours of field collection [1]
  o Within 10 days of testing or during testing [1]		

Age at Study Initiation:
Acute:
• Larval stages preferred [1]
• Mayflies and Stoneflies
  o Early instar [1]
• Daphnids/cladocerans:
  o < 24-hr old [1]
• Midges:
  o 2nd or 3rd instar larva [1]
• *Hyalella azteca* (chronic exposure)
  o Generally, 7 - 8 days old [3]
• Freshwater mussels (chronic exposure)
  o Generally, 2 month old juveniles [4]
• Mysids (chronic exposure)
  o < 24-hr old [1]		

Was body weight or length recorded at test initiation and/or at regular intervals?	____ Yes ____ No	
Was body weight or length recorded at regular intervals?	____ Yes ____ No *If yes, describe regular intervals:*	

STUDY PARAMETERS: *Provide information under Details and any relevant information of deficiencies in Remarks. Complete for both Controlled Experiments and Field Studies/Observations.*

For Both Controlled Experiments and Field Observations

Parameter	Details	Remarks
Number of Replicates per Treatment Group: • At least 2 replicates/treatment recommended for acute tests [1] • At least 2 replicates/treatment recommended for chronic tests [5]	Control(s):	
	Treatment(s):	
Number of Organisms per Replicate/ Treatment Group: • At least 10 organisms/treatment recommended.	Control(s):	
	Treatment(s):	
Exposure Pathway: *(i.e., water, sediment, or diet). Note: all other pathways (e.g., dermal, injection) are unacceptable.*		
Exposure Duration: **Acute** • Cladocerans and midges should be 48 hours [2] o Longer durations acceptable if test species not fed and had acceptable controls [2] • Freshwater mussel glochidia should be a maximum of 24 hours [4] o Shorter durations (6, 12, 18 hours) acceptable so long as 90% survival of control animals achieved (see below) [4] • Embryo/larva (bivalve mollusks, sea urchins, lobsters, crabs, shrimp and abalones) should be 96 hours, but at least 48 hours [2] • Other invertebrate species should be 96 hours **Chronic** • Daphnids/cladocerans should be 21 days (3-brood test) [2] o Exception 7 days acceptable for *Ceriodaphnia dubia* [2] • Freshwater juvenile mussels should be at least 28 days [4] • *Hyalella azteca* should be at least 42 days o Beginning with 7 - 8 day old animals [3] • Mysids should continue until 7 days past the median time of first brood release in the controls [4]	____ Acute ____ Chronic ____ Other *(please remark):*	
Test Concentrations (remember units): *Recommended test concentrations include at least three concentrations other than the control; four or more will provide a better statistical analysis.*	Nominal:	
	Measured:	
	Media measured in:	
Observation Intervals: • Should be an appropriate number of observations over the study to ensure water quality is being properly maintained [1]		

CONTROLLED EXPERIMENT STUDY PARAMETERS: *Provide information under Details and any relevant information of deficiencies in Remarks. Complete for Controlled Experiments only.*

For Controlled Experiments Only

Parameter	Details	Remarks
Acclimation/Holding: • Should be placed in a tank along with the water in which they were transported [1] o Water should be changed gradually to 100% dilution water (usually 2 or more days) [1] o For wild-caught animals, test water temperature should be within 5°C of collection water temperature [1] o Temperature change rate should not exceed 3°C within 72 hours [1] • To avoid unnecessary stress and promote good health: o Organisms should not be crowded [1] o Water temperature variation should be limited o Dissolved oxygen: ▪ Maintain between 60 - 100% saturation [1] ▪ Continuous gentle aeration if needed [1] o Unionized ammonia concentration in holding and acclimation waters should be < 35 µg/L [1]	Duration: Feeding: Water: Temperature (°C): Dissolved Oxygen (mg/L): Health (*any mortality observed?*):	*Identify number of individuals excluded from testing and/or analysis (if any):*
Acclimation followed published guidance? *Describe, if any*	____ Yes ____ No *If yes, indicate which guidance:*	
Test Vessel: • Test chambers should be loosely covered [1] • Test chamber material: o Should minimize sorption of test chemical from water [1] o Should not contain substances that can be leached or dissolved in solution and free of substances that could react with exposure chemical [1] o Glass, No. 316 stainless steel, nylon screen and perfluorocarbon (e.g. Teflon) are acceptable [1] o Rubber, copper, brass, galvanized metal, epoxy glues, lead and flexible tubing should not come into contact with test solution, dilution water or stock [1] • Size/volume should maintain acceptable biomass loading rates (see below) [1] • Substrate: o Required for some species (e.g., *Hyalella azteca*) [3] o Common types: stainless steel screen, nylon screen, quartz sand, cotton gauze and maple leaves [3] o More inert substances preferred over plant material, since plants may break down during testing and promote bacterial growth [3] o Consideration should be given between substrate and toxicant [3] ▪ Hydrophobic organic compounds in particular can bind strongly to Nitex® screen, reducing exposure concentrations, especially for studies using static or intermittent renewal exposure methods [3]	Material: Size: Fill Volume: Substrate Used *(if applicable)*:	*Briefly describe the test vessel here*

	Parameter	Details	Remarks

For Controlled Experiments Only	**Test Solution Delivery System/Method:**
	• Flow-through preferred for some highly volatile, hydrolyzable or degradable materials [2]
	  o Concentrations should be measured often enough using acceptable analytical methods [2]
	• Chronic exposures:
	  o Flow-through, measured tests required [2]
	  o Exception: renewal is acceptable for daphnids [2]
		Test Concentrations Measured
		____ Yes ____ No
		
		Test Solution Delivery System:
		____ Static
		____ Renewal
		Indicate Interval:
		
		____ Flow-through
		Indicate Type of Diluter:	

	Source of Dilution Water:
	• Freshwater hardness range should be < 5 mg/L or < 10% of the average (whichever is greater) [1]
	• Saltwater salinity range should be < 2 g/kg or < 20% of the average (whichever is greater) [1]
	• Dilution water must be characterized (natural surface water, well water, etc.) [2]
	  o Distilled/deionized water without the addition of appropriate salts should not be used [2]
	• Dilution water in which total organic carbon or particulate matter exceed 5 mg/L should not be used
	  o Unless data show that organic carbon or particulate matter do not affect toxicity [2]
	• Dilution water for tests with *Hyalella azteca*
	  o Reconstituted waters should have at least 0.02 mg bromide/L; natural ground or surface water presumed to have sufficient bromide [3]
	  o Recommended that control/dilution waters have chloride concentrations at or above 15 mg/L [3]		

	Dilution Series (*e.g., 0.5x, 0.6x, etc.*):		
	Dilution Water Parameters: *Measured at the beginning of the experiment or averaged over the duration of the experiment (details of water quality parameters measured in test solutions should be included under the results section)*	Dissolved Oxygen (mg/L): pH: Temperature (°C): Hardness (mg/L as $CaCO_3$): Salinity (ppt): Total Organic Carbon (mg/L): Dissolved Organic Carbon (mg/L):	
	Aeration: • Acceptable to maintain dissolved oxygen at 60 - 100% saturation at all times [1] • Avoid aeration when testing highly oxidizable, reducible and volatile materials • Turbulence should be minimized to prevent stress on test organisms and/or re-suspend fecal matter [1] • Aeration should be the same in all test chambers at all times [1]	____ Yes ____ No	
	Describe Preparation of Test Concentrations (e.g., water exposure, diet):		

	Parameter	Details	Remarks
For Controlled Experiments Only	**Test Chemical Solubility in Water:** • List units and conditions (e.g., 0.01% at 20ºC)		
	Were concentrations in water or diet verified by chemical analysis? *Measured test concentrations should be reported in* Table A.II.2 *above.*	____ Yes ____ No *Indicate media:*	
	Were test concentrations verified by chemical analysis in tissue? *Measured test concentrations can be verified in test organism tissue (e.g., blood, liver, muscle) alone if a dose-response relationship is observed.* *Measured test concentrations should be reported in* Table A.II.2 *above.*	____ Yes ____ No *Indicate tissue type:*	*If test concentrations were verified in test organism tissue, was a dose-response relationship observed?*
	Were stability and homogeneity of test material in water/diet determined?	____ Yes ____ No	
	Was test material regurgitated/avoided?	____ Yes ____ No	
	Solvent/Vehicle Type: • When used, a carrier solvent should be kept to a minimum concentration [1] • Should not affect either survival or growth of test organisms [1] • Should be reagent grade or better [1] • Should not exceed 0.5 ml/L (static), or 0.1 ml/L (flow through) unless it was shown that higher concentrations do not affect toxicity [5]		
	Negative Control:	____ Yes ____ No	
	Reference Toxicant Testing:	____ Yes ____ No *If yes, identify substance:*	
	Other Control: *If any (e.g. solvent control)*		
	Biomass Loading Rate: • Loading should be limited so as not to affect test results. Loading will vary depending on temperature, type of test (static vs. flow-through), species, food/feeding regime, chamber size, test solution volume, etc. [1] • This maximum number would have to be determined for the species, test duration, temperature, flow rate, test solution volume, chamber size, food, feeding regime, etc. • Loading should be sufficiently low to ensure: o Dissolved oxygen is at least 60% of saturation (40% for warm-water species) [1,6] o Unionized ammonia does not exceed 35 µg/L [1] o Uptake by test organisms does not lower test material concentration by > 20% [1] o Growth of organisms is not reduced by crowding • Generally, at the end of the test, the loading (grams of organisms; wet weight; blotted dry) in each test chamber should not exceed the following: o Static tests: > 0.8 g/L (lower temperatures); > 0.5 g/L (higher temperatures) [1] o Flow through tests: > 1 g/L/day or > 10 g/L at any time (lower temperatures); > 0.5 g/L/day or > 5 g/L at any time (higher temperatures) [1] o Lower temperatures are defined as the lower of 17˚C or the optimal test temperature for that species. [1]		

For Controlled Experiments Only	**Feeding:**
	• Unacceptable for acute tests [2]
	  o Exceptions:
	  ▪ Data indicate that the food did not affect the toxicity of the test material [2]
	  ▪ Test organisms will be severely stressed if they are unfed for 96 hours [2]
	  ▪ Test material is very soluble and does not sorb or complex readily (e.g., ammonia) [2]
		____ Yes ____ No	

	Lighting: • No specific requirements for lighting • Generally, ambient laboratory levels (50 - 100 fc) or natural lighting should be acceptable, as well as a diurnal cycle consisting of 50% daylight or other natural seasonal diurnal cycle • Artificial light cycles should have a 15 - 30 minute transition period to avoid stress due to rapid increases in light intensity [1] • Depends on the type of test (acute or chronic) and endpoint (e.g., reproduction) of interest.		

Study Design/Methods Classification: *(Place X by One Based on Overall Study Design/Methods Classification)*
Provide details of Major or Minor Deficiencies/Concerns with Study Design in Associated Sections of Part A: Overview
This classification should be taken into consideration for the overall study classification for aquatic life criteria development in Part A.

_____ Study Design Acceptable for Quantitative Use
_____ Study Design Acceptable for Qualitative Use
_____ Study Design Not Acceptable for Use

Additional Notes: *Provide additional considerations for the classification of study use based on the study design.*

OBSERVATIONS: *Provide information under Details and any relevant information in Remarks. This information should be consistent with the Results Section in Part A.*

Parameter	Details	Remarks

Parameters measured including sublethal effects/toxicity symptoms:
Common Apical Parameters Include:
Acute
• Daphnids/cladocerans:
  ○ EC_{50} based on percentage of organisms immobilized plus percentage of organisms killed [2]
• Embryo/larva (bivalve molluscs, sea urchins, lobsters, crabs, shrimp, and abalones):
  ○ EC_{50} based on the percentage of organisms with incompletely developed shells plus the percentage of organisms killed [2]
  ▪ If not available, the lower of the 96 hour EC_{50} based on the percentage of organisms with incompletely developed shells and the 96-hr LC_{50} should be used [2]
• Freshwater mussel (glochidia and juveniles):
  ○ Glochidia: EC_{50} based on 100 x number closed glochidia after adding NaCl solution - number closed glochidia before adding NaCl solution) / Total number open and closed glochidia after adding NaCl solution [4]
  ○ Juvenile: EC_{50} based on percentage exhibiting foot movement within a 5-min observation period [4]
• All other species and older life stages:
  ○ EC_{50} based on the percentage of organisms exhibiting loss of equilibrium plus the percentage of organisms immobilized plus the percentage of organisms killed [2]
  ▪ If not available, the 96 hour LC_{50} should be used [2]
Chronic
• Daphnid:
  ○ Survival and young per female [2]
• Mysids:
  ○ Survival, growth and young per female [2]
	List parameters:	

Was control survival acceptable?
Acute
• > 90% control survival at test termination [2]
  ○ Glochidia 90% after 24 hours, or, the next longest duration less than 24 hours that had at least 90% survival [4]
Chronic
• > 80% control survival at test termination [2]
  ○ 80% in 42 day test with *Hyalella azteca*, slightly lower in tests substantially longer than 42 days [3]
	_____ Yes _____ No
	Control survival (%):	

Parameter	Details	Remarks
Were individuals excluded from the analysis?	____ Yes ____ No *If yes, describe justification provided:*	
Was water quality in test chambers acceptable? • If appropriate, describe any water quality issues (e.g., dissolved oxygen level below 60% of saturation)	____ Yes ____ No	
Availability of concentration-response data: • Were treatment level concentration-response data included in study publication (can be from tables, graphs, or supplemental materials)? *specify endpoints in remarks* • Were replicate level concentration-response data included in study publication (can be from tables, graphs, or supplemental materials)? *specify endpoints in remarks* • • If treatment and/or replicate level concentration-response data were included, how was data presented? *(check all that apply)* • Were concentration-response data estimated from graphs study publication or supplemental materials? Should additional concentration-response data be requested from study authors? *If concentration-response data are available, complete **Verification of Statistical Results (Part C)** for sensitive species.*	____ Yes ____ No ____ Yes ____ No ____ Tables ____ Graphs ____ Supplemental Files ____ Yes ____ No *If yes, indicate software used:* ____ Yes ____ No Requested by: Request date: Date additional data received:	

Part C: Statistical Verification of Results

I. Statistical Verification Information: *Report the statistical methods (e.g., EPA TRAP, BMDS, R, other) used to verify the reported study or test results for the five (5) most sensitive genera and sensitive apical endpoints (including for tests where such estimates were not provided). If values for the LC_{50}, LT_{50} and NOEC are greater than the highest test concentration, use the ">" symbol.*

Primary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)

Dose-Response Curve Classification: *(Place X by One)*
This classification should be taken into consideration for the overall study classification for aquatic life criteria development in Part A

_____ Dose-Response Curve Acceptable for Quantitative Use
_____ Dose-Response Curve Acceptable for Qualitative Use
_____ Dose-Response Curve Not Acceptable for Use

Summary of Statistical Verification: *Provide summary of methods used in statistical verification.*

Additional Notes:

-

Attachments:

1. *Provide attachments to ensure all data used in Part C is captured, whether from study results reported in the publication and/or from additional data requested from study authors*
    - *Data from study results of the publication should be reported in Results section of Part A*
    - *Additional data provided upon request from study authors should be reported in Table C.II.1 below and original correspondence with study authors should be included as attachments*
2. *Model assessment output (including all model figures, tables, and fit metrics)*
3. *Statistical code used for curve fitting*

III. Attachments: *Include all attachments listed above after the table below.*

Additional Data Used in Response-Curve: *Provide all data used to fit dose-response curve not captured in Results section of DER above in Part A, rows as needed. First row in italicized text is an example.*

Table C.II.1 Additional Data Used in Dose-Response Curve.

Curve ID	Species	Endpoint	Treatment	Replicate	[Standard Deviation or Standard Error]	# of Survivors	N[a]	k[a]	n[a]	Response	Response Unit	Conc	Conc units
Alchronic1	*Ceriodaphnia dubia*	*# of young/female*	*0*	*6*			*10*	*10*	*1*	*18*	*count*	*0.03*	*mg/L*

[a] N = number of individuals per treatment; k = number of replicates per treatment level; n = number of individuals per replicate

TECHNICAL AND REGULATORY GUIDANCE

Per-and Polyfluoroalkyl Substances (PFAS)

Prepared By
The Interstate Technology & Regulatory Council (ITRC)
PFAS Team

EXECUTIVE SUMMARY

ABOUT ITRC

ITRC is a national coalition focused on developing tools and strategies to reduce interstate barriers to the deployment of innovative environmental technologies. ITRC produces documents and training to improve technical knowledge and expedite quality regulatory decision making while protecting human health and the environment. With private and public sector members from all 50 states and the District of Columbia, ITRC truly provides a national perspective. More information on ITRC is available at **https://www.itrcweb.org**.

ITRC is a program of the Environmental Research Institute of the States (ERIS), a 501(c)(3) organization incorporated in the District of Columbia and affiliated with the Environmental Council of the States (ECOS). ECOS is the national, nonprofit, nonpartisan association representing the state and territorial environmental commissioners. About ITRC info here.

DISCLAIMER

This material was prepared as an account of work sponsored by an agency of the United States Government. Neither the United States Government nor any agency thereof, nor any of their employees, makes any warranty, express or implied, or assumes any legal liability or responsibility for the accuracy, completeness, or usefulness of any information, apparatus, product, or process disclosed, or represents that its use would not infringe privately owned rights. Reference herein to any specific commercial product, process, or service by trade name, trademark, manufacturer, or otherwise does not necessarily constitute or imply its endorsement, recommendation, or favoring by the United States Government or any agency thereof. The views and opinions of authors expressed herein do not necessarily state or reflect those of the United States Government or any agency thereof and no official endorsement should be inferred.

The information provided in documents, training curricula, and other print or electronic materials created by the Interstate Technology & Regulatory Council ("ITRC" and such materials are referred to as "ITRC Materials") is intended as a general reference to help regulators and others develop a consistent approach to their evaluation, regulatory approval, and deployment of environmental technologies. The information in ITRC Materials was formulated to be reliable and accurate. However, the information is provided "as is" and use of this information is at the users' own risk.

ITRC Materials do not necessarily address all applicable health and safety risks and precautions with respect to particular materials, conditions, or procedures in specific applications of any technology. Consequently, ITRC recommends consulting applicable standards, laws, regulations, suppliers of materials, and material safety data sheets for information concerning safety and health risks and precautions and compliance with then-applicable laws and regulations. ITRC, ERIS and ECOS shall not be liable in the event of any conflict between information in ITRC Materials and such laws, regulations, and/or other ordinances. The content in ITRC Materials may be revised or withdrawn at any time without prior notice.

ITRC, ERIS, and ECOS make no representations or warranties, express or implied, with respect to information in ITRC Materials and specifically disclaim all warranties to the fullest extent permitted by law (including, but not limited to, merchantability or fitness for a particular purpose). ITRC, ERIS, and ECOS will not accept liability for damages of any kind that result from acting upon or using this information.

ITRC, ERIS, and ECOS do not endorse or recommend the use of specific technology or technology provider through ITRC Materials. Reference to technologies, products, or services offered by other parties

does not constitute a guarantee by ITRC, ERIS, and ECOS of the quality or value of those technologies, products, or services. Information in ITRC Materials is for general reference only; it should not be construed as definitive guidance for any specific site and is not a substitute for consultation with qualified professional advisors.

TABLE OF CONTENTS

1 PFAS PRIORITY TOPICS 1
1.1 Priority Topics For History, Uses, and Naming Conventions 1
1.1.1 Semiconductor Industry Uses 1
1.1.2 Less-publicized PFAS Sources 3
1.1.3 Less-studied PFAS 10
1.2 Priority Topics for Firefighting Foams 16
1.2.1 Firefighting Foam Inventory 16
1.2.2 Firefighting Foam Ecotoxicity 17
1.2.3 Transition Planning and Guidance 17
1.3 Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization 21
1.3.1 Vadose Zone Characterization and Transport 22
1.3.2 Septic Systems 27
1.3.3 Perfluoroalkyl Acids Precursor Biotransformation 28
1.3.4 Groundwater Partitioning, Colloidal Transport, GW-SW Interactions 32
1.3.5 Understanding PFAS in Marine Environments 38
1.3.6 Effects of Suspended Sediment on Surface Water Sampling and Measurement of PFAS 44
1.3.7 Source ID, Differentiation, and Forensics 51
1.3.8 Site Characterization Tools and Techniques 67
1.4 Priority Topics for Human and Ecological Health Effects 77
1.4.1 Potential Human Health Effects of PFAS Exposure Arising from AFFF in Drinking Water 77
1.4.2 Potential PFAS Exposures from Consumer Products 81
1.4.3 Dermal Uptake of PFAS in the Environment 85
1.4.4 Health Effects of Ultra-short-chain PFAS 91
1.4.5 New Information on Considerations for Addressing PFAS as a Class 103
1.4.6 Potential PFAS Exposures in Occupational Settings 107
1.4.7 Evaluating Risk to Livestock from PFAS Exposure 113
1.4.8 Reptiles Toxicity Data 121
1.5 Priority Topics for Sampling and Analysis 122
1.5.1 Leaching Methods 123
1.5.2 Fish Sampling and Laboratory Homogenization 124
1.5.3 Ultrashort-chain PFAS Analysis 127
1.5.4 Consumer Product Testing 130
1.5.5 ISM for PFAS Sampling 134
1.5.6 Concrete and Asphalt Sampling and Analysis 135

1.5.7 Field Screening Tools 138
1.6 Priority Topics for Treatment Technologies 139
1.6.1 Thermal Treatment Update 139
1.6.2 Supercritical Water Oxidation 144
1.6.3 Investigation-derived Waste 148
1.6.4 Treatment of Sediment 150
1.6.5 Treatment of Biosolids 151
1.6.6 Updated and Recent and Relevant Technology Review Papers 157
1.7 Priority Topics for Biosolids Land Application 157
1.7.1 Introduction: Application of Biosolids to Lands Supporting Animals and Crops 159
1.7.2 Conceptual Site Model 160
1.7.3 Assessing Potential Risk from Agricultural Impacts 168
1.7.4 Plant Uptake 169
1.7.5 Uptake by Animals 173
1.7.6 Conclusion 174
1.8 Priority Topics for PFAS and Microplastics 175
1.8.1 Composition and Definitions 175
1.8.2 Co-sources of PFAS and Microplastics 177
1.8.3 Sampling and Analysis 177
1.8.4 Fate and Transport 178
1.8.5 Risk Assessment 181
1.8.6 Treatment 183
1.8.7 Regulatory and Guidance Considerations 185
1.8.8 Changing Weather Patterns 186
2 PFAS CHEMISTRY AND NAMING CONVENTIONS, HISTORY AND USE OF PFAS, AND SOURCES OF PFAS RELEASES TO THE ENVIRONMENT 187
2.1 Environmental Significance 188
2.2 Chemistry, Terminology, and Acronyms 190
2.2.1 Naming Convention Considerations 194
2.2.2 Introduction to the PFAS Family 196
2.2.3 Perfluoroalkyl Substances 201
2.2.4 Polyfluoroalkyl Substances 207
2.2.5 Chemical Manufacturing 210
2.3 Emerging Health and Environmental Concerns 213
2.3.1 Awareness of Potential Health Impacts 213
2.3.2 Analytical Developments 214
2.3.3 Detection in the Environment 216
2.3.4 Growing Awareness and Concern 216

2.4 PFAS Reductions and Alternative PFAS Formulations....217
2.4.1 3M Voluntary Phaseout of Certain Long-Chain PFAS....217
2.4.2 USEPA Significant New Use Rules (SNURs)....218
2.4.3 USEPA PFOA Stewardship Program....219
2.4.4 Stockholm Convention on Persistent Organic Pollutants....219
2.4.5 Global Manufacture and Use of PFAS....220
2.4.6 PFAS-Based Replacement Chemistry....221
2.5 PFAS Uses and Products....222
2.5.1 PFAS Uses....223
2.5.2 Potential PFAS Use or Occurrence....226
2.5.3 PFAS Certification and Acceptability of Products....227
2.6 PFAS Releases to the Environment....229
2.6.1 Major Manufacturing and Industry Sources....229
2.6.2 Class B Fluorine-Containing Firefighting Foams....235
2.6.3 Solid Waste Management Facilities....235
2.6.4 Wastewater Treatment and Wastewater Treatment Residuals and Biosolids....238
3 FIREFIGHTING FOAMS....243
3.1 Foam Formulations....243
3.2 AFFF Characteristics....247
3.3 Mechanisms for Release to the Environment....248
3.4 AFFF Fate and Transport....249
3.4.1 Physical and Chemical Characteristics....249
3.4.2 Fate and Transport Processes....250
3.4.3 Fate and Transport Considerations for AFFF Remediation....250
3.5 Forensic Analysis of AFFF....251
3.5.1 Manufacturing and Chemistry....252
3.5.2 Factors Affecting the PFAS Fate and Fractionation....253
3.5.3 Summary of Forensic Analysis of AFFF....254
3.6 AFFF Procurement and Inventory....256
3.6.1 Foam Selection and Requirements....256
3.6.2 AFFF Storage and Handling....256
3.7 Foam Systems and Operations....257
3.7.1 Fixed System Testing....257
3.7.2 Mobile Firefighting Equipment Testing....258
3.7.3 Training Exercises....258
3.8 Emergency Firefighting Operations....259
3.8.1 Best Management Practices (BMPs)....260

3.8.2 Personal Protective Equipment....262
3.8.3 Initial Mitigation Efforts for Firefighting Foam....263
3.9 Immediate Investigative and Cleanup Actions....264
3.9.1 Visual Site Delineation....264
3.9.2 The Shake Test....265
3.9.3 Initial Investigative Sampling....265
3.9.4 Interim Removal....265
3.9.5 Confirmation Samples....265
3.10 AFFF Disposal....265
3.10.1 Stabilization and Landfill Disposal....266
3.10.2 Incineration....267
3.10.3 Deep Well Injection....267
3.10.4 Potential Future Disposal Technologies....268
3.10.5 Fire Water and Flush Water Containing PFAS....269
3.11 Firefighting Foam System Replacement....270
3.11.1 Replacement Products....270
3.11.2 System Decontamination and Sampling During Foam Replacement....272
3.11.3 AFFF Transition Planning....273
3.12 Federal, State, and International Regulations and Guidance....275
3.12.1 Overview....275
3.12.2 Take-Back Programs....276
3.12.3 Federal Guidance....276
3.12.4 International Guidance on AFFF....277
3.13 Foam Research and Development....278
3.13.1 Research on Current AFFF....278
4 PHYSICAL AND CHEMICAL PROPERTIES....281
4.1 Challenges and Limitations Related to PFAS Physical and Chemical Properties....281
4.2 Physical Properties....281
4.2.1 Physical State/Appearance....282
4.2.2 Density....282
4.2.3 Melting/Boiling Points....282
4.2.4 Solubility....282
4.2.5 Vapor Pressures (V_p)....283
4.2.6 Henry's Law Constant (K_h)....283
4.2.7 Critical Micelle Concentration....284
4.2.8 Partitioning to Fluid-Fluid Interfaces....284
4.2.9 Octanol/Water Partition Coefficient (K_{ow})....286

4.2.10 Organic Carbon/Water Partition Coefficient (K_{oc}) 286
4.2.11 Partitioning to Biota 286
4.3 Chemical Properties 287
4.3.1 Carbon-Fluorine (C-F) Bond Properties 288
4.3.2 Functional Group Properties 288
4.3.3 Thermal Stability 290
4.3.4 Chemical Stability 291
5 ENVIRONMENTAL FATE AND TRANSPORT PROCESSES 292
5.1 Fate and Transport Introduction 292
5.1.1 Overview of PFAS Fate and Transport 292
5.1.2 Factors Affecting PFAS Fate and Transport 293
5.1.3 Section Organization 293
5.2 Phase Partitioning 295
5.2.1 Introduction 295
5.2.2 Considerations for PFAS Partitioning 295
5.2.3 Partitioning to Solid Phases 297
5.2.4 Partitioning to Air 300
5.2.5 Partitioning into NAPL Co-Contaminants 302
5.3 Media-Specific Migration Processes 303
5.3.1 Diffusion In and Out of Lower Permeability Materials 303
5.3.2 PFAS Transport via Air 303
5.3.3 Leaching 306
5.3.4 Transfer of PFAS between groundwater, surface water, porewater, and sediment 307
5.4 Transformations 310
5.4.1 Introduction 310
5.4.2 PFAA Precursors 310
5.4.3 Atmospheric Transformations 311
5.4.4 In Situ Transformations 312
5.4.5 Polymer Transformation 313
5.4.6 Practical Implications 314
5.5 PFAS Uptake into Aquatic Organisms 315
5.5.1 Bioconcentration 317
5.5.2 Bioaccumulation 317
5.5.3 Biomagnification 319
5.5.4 Characterization of Bioaccumulation in Criteria Development and Risk Assessments 320
5.6 PFAS Uptake into Plants 321
5.6.1 Uptake Pathways 321

5.6.2 Bioconcentration/Bioaccumulation 322
6 MEDIA-SPECIFIC OCCURRENCE 325
6.1 Air 326
6.1.1 Outdoor Air 326
6.1.2 Indoor Air 327
6.1.3 Settled Dust 328
6.1.4 Precipitation 329
6.2 Soil, Sediment, and Biosolids 330
6.2.1 Soil 330
6.2.2 Sediment 332
6.2.3 Biosolids 333
6.3 Groundwater 335
6.4 Surface Water 336
6.5 Biota 337
6.5.1 Plants 337
6.5.2 Invertebrates 338
6.5.3 Fish 338
6.5.4 Vertebrates 339
7 HUMAN AND ECOLOGICAL HEALTH EFFECTS OF SELECT PFAS 340
7.1 Human Health Effects 340
7.1.1 Human Biomonitoring and Sources of Exposure 342
7.1.2 Toxicokinetics 344
7.1.3 Human Epidemiology Studies 345
7.1.4 Animal Toxicology Studies 346
7.1.5 PFAS Mixtures 348
7.1.6 Evaluating PFAS using New Approach Methodologies 350
7.1.7 Regulation of PFAS as a Class 350
7.1.8 PFAS Inhalation Toxicity 353
7.1.9 Data Gaps and Research Needs 355
7.2 Ecological Toxicology 356
7.2.1 Introduction 356
7.2.2 Invertebrates 357
7.2.3 Vertebrates 360
7.2.4 Plants 364
7.2.5 Uncertainties and Conclusions 365
8 BASIS OF REGULATIONS 366
8.1 Introduction 366

8.2 Regulatory Programs....366
8.2.1 Background to Regulation of PFAS....366
8.2.2 Federal PFAS Regulations....367
8.2.3 State PFAS Regulations and Guidance....375
8.3 Differences in the Available Regulations, Advisories, and Guidance....377
8.3.1 Toxicity Values....378
8.3.2 Exposure Assumptions....379
9 SITE RISK ASSESSMENT....380
9.1 Human Health Risk Assessment....380
9.1.1 Toxicity Assessment....380
9.1.2 Exposure Assessment....384
9.1.3 Risk Characterization....387
9.2 Ecological Risk Assessment....389
9.2.1 Ecological Effects Assessment....390
9.2.2 Ecological Exposure Assessment....398
9.2.3 Risk Characterization....399
9.3 Uncertainty....400
9.3.1 Fate and Transport....400
9.3.2 Human Toxicity....401
9.3.3 Ecological Toxicity....401
9.3.4 Accounting for Nonsite-Related PFAS....401
10 SITE CHARACTERIZATION....402
10.1 Site Characterization Issues Relevant to PFAS....403
10.1.1 Evolving Science and Regulations....403
10.1.2 Source, Fate, and Transport Properties....403
10.2 Initial Steps....404
10.3 Site Investigation....405
10.3.1 Development of Site Investigation Work Plan....405
10.3.2 Nature of PFAS Sources....408
10.3.3 Extent of PFAS....409
10.3.4 Investigation-Derived Waste (IDW)....410
10.4 Data Analysis and Interpretation....413
10.4.1 Vadose Zone Leaching....413
10.4.2 Retardation Coefficients and Travel Time in Groundwater....415
10.4.3 Matrix-Diffusion....417
10.4.4 Mass Flux/Mass Discharge....417
10.4.5 Contributions from Different Sources....418

10.4.6 Transformation Pathways and Rates 419
10.4.7 Assessing Retention, Migration, and Attenuation Processes 420
10.4.8 Assessing Plume Stability 422
10.4.9 Modeling PFAS Fate and Transport 422
10.5 Forensics and Source Identification 427
10.5.1 Source Identification Tools 428
11 SAMPLING AND ANALYSIS 434
11.1 Sampling 435
11.1.1 General 435
11.1.2 Equipment and Supplies 437
11.1.3 Bottle Selection 438
11.1.4 Sample Preservation, Shipping, Storage, and Holding Times 438
11.1.5 Decontamination Procedures 439
11.1.6 Field QC Samples 440
11.1.7 Sampling Procedures 443
11.2 Analytical Methods/Techniques 454
11.2.1 Quantitative Techniques 454
11.2.2 Qualitative Techniques 463
11.3 Data Evaluation 469
11.3.1 Pre-sampling Planning 469
11.3.2 Overall Usability of the Data 470
11.3.3 Sensitivity 471
11.3.4 Target Analyte Lists 472
11.3.5 Linear and Branched Isomers 472
11.3.6 Isotope Dilution Standard Results and Surrogates 474
11.3.7 Blank Contamination 475
11.3.8 Duplicate Results 475
11.3.9 Acid Versus Anion Form of PFAAs 476
11.4 Source Identification 477
11.4.1 Extended Target Lists 477
11.4.2 Linear/Branched Speciation 477
11.4.3 Non Targeted Analysis (NTA) 477
12 TREATMENT TECHNOLOGIES 480
12.1 Overview 480
12.1.1 Factors Affecting Technology Selection 482
12.1.2 Tiered Remedial Approach 483
12.1.3 Section Organization 484

12.1.4 Considerations for Specific Environmental Media 484
12.2 Field-Implemented Liquids Treatment Technologies 486
12.2.1 Sorption Technologies 486
12.2.2 High-Pressure Membranes 497
12.2.3 Foam Fractionation 500
12.2.4 In Situ Remediation with Colloidal Activated Carbon 503
12.2.5 Supercritical Water Oxidation 505
12.3 Field-Implemented Solids Treatment Technologies 505
12.3.1 Sorption and Stabilization 506
12.3.2 Excavation and Disposal 508
12.3.3 Soil Washing 509
12.4 Incineration 511
12.5 Air Treatment Technologies 513
12.5.1 Conventional Air Pollution Control (APC) Technologies 513
12.6 Limited Application and Developing Liquids Treatment Technologies 515
12.6.1 Sorption Technologies 516
12.6.2 Precipitation/Coagulation/Flocculation 518
12.6.3 Redox Manipulation 519
12.6.4 Biodegradation 528
12.6.5 Alkaline Hydrothermal Reaction 529
12.6.6 Deep Well Injection 529
12.6.7 Monitored Natural Attenuation 530
12.7 Limited Application and Developing Solids Treatment Technologies 531
12.7.1 Sorption and Stabilization/Solidification 532
12.7.2 Thermal Treatment 532
12.8 Integrated Water Treatment Solutions 534
12.8.1 Development of Alternative Water Treatment Trains 534
12.9 Sustainability of PFAS Treatment 536
12.10 Improving Evaluation of PFAS Treatment Technologies 537
13 STAKEHOLDER PERSPECTIVES 538
13.1 Stakeholder Concerns 540
13.1.1 Lack of Comprehensive Regulatory Standards or Advisories for Thousands of PFAS 540
13.1.2 Desire for One Standard or Screening Level for PFAS 542
13.1.3 Lack of Occupational Standards 542
13.1.4 Lack of Comprehensive Monitoring Information 542
13.1.5 Need to Apply a Precautionary Approach in Decision Making 543
13.1.6 Safety of Short-chain Substitutes 543

13.1.7 Contamination from AFFF Release Sites 544
13.1.8 Contamination from Unused AFFF Disposal....544
13.1.9 Duty to Warn AFFF First Responders....545
13.1.10 Limitations in Sampling and Analysis Methods 545
13.1.11 Limited Programs for Health Monitoring and Blood Testing....546
13.1.12 PFAS in Food Packaging....546
13.1.13 Potential PFAS Contamination in Recycling, Compost, and Fertilizer 547
13.1.14 Lack of Disclosure by Product Manufacturers 547
13.1.15 Limited Availability on Information on the Health Effects of PFAS....547
13.1.16 Responsibility for Sampling and Treatment on Private Property 547
13.1.17 Potential PFAS Emissions from Cleanup Methods....547
13.1.18 Lack of Scientific Evidence that Some PFAS Treatment and Disposal Methods and Remedies Are Fully Protective of Human and Ecological Health and Prevent Toxic Emissions....548
13.1.19 Stormwater and PFAS Manufacturing Discharges that May Contain PFAS....549
13.1.20 Psychological Effects....549
13.1.21 Economic Consequences of Local PFAS Contamination....549
13.1.22 Remediation of PFAS With Other Contaminants Especially Chlorinated Solvents 549
13.1.23 Pesticides containing PFAS....550
13.1.24 Artificial Turf 550
13.1.25 Semiconductor Manufacturing....550
13.1.26 Monitored Natural Attenuation (MNA) for PFAS....550
13.2 Specific Tribal Stakeholder Concerns 552
13.3 Stakeholder Resources 553
14 RISK COMMUNICATION 554
14.1 Role of Risk Perception: Public Stakeholders and Decision Makers....554
14.1.1 Role of Risk Perception and Public Stakeholders....555
14.1.2 Role of Risk Perception and Decision Makers 556
14.2 Risk Communication Challenges....556
14.2.1 Regulatory....557
14.2.2 Fate and Transport....557
14.2.3 Toxicological/Epidemiological Information and Risk Assessment....558
14.2.4 Technical 559
14.2.5 Analytical Ability....559
14.2.6 Challenges to Risk Communication around Health Risks....559
14.3 Risk Communication Planning and Engagement Tools....560
14.3.1 Risk Communication Planning Model....560
14.3.2 PFAS Risk Communication SMART Goals and Objectives....562
14.3.3 Community Identification and Mapping Tools....563

14.3.4 Social Factors Vision Board Tool....565
14.3.5 PFAS Key Messages....566
14.3.6 Communication and Engagement Tools....567
15 CASE STUDIES....570
15.1 Site Characterization Case Studies....570
15.1.1 Data Visualization at an AFFF Release Site (2020)....570

1 PFAS PRIORITY TOPICS

These topics were identified by both regulators and the scientific community as ones for which more information is needed. The Priority Topics are published as part of the ITRC PFAS Technical and Regulatory Guidance Document (PFAS-1) (https://pfas-1.itrcweb.org).

Section Number	Topic
1.1	**Priority Topics for History, Use, and Naming Conventions**
1.2	**Priority Topics for Firefighting Foams**
1.3	**Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization**
1.4	**Priority Topics for Human and Ecological Health Effects**
1.5	**Priority Topics for Sampling and Analysis**
1.6	**Priority Topics for Treatment Technologies**
1.7	**Priority Topics for Biosolids Land Application**
1.8	**Priority Topics for PFAS and Microplastics**

1.1 Priority Topics For History, Uses, and Naming Conventions

Section Number	Topic
1.1.1	**Semiconductor Industry Uses**
1.1.2	**Less-publicized PFAS Sources**
1.1.3	**Less-studied PFAS**

Information in these Priority Topics was prepared to supplement the information published in **Section 2**, which covers PFAS chemistry and naming conventions, history and use of PFAS, and sources of PFAS releases to the environment.

1.1.1 Semiconductor Industry Uses

This section provides more information on the uses of PFAS in the semiconductor industry and expands on the information presented in **Section 2.6.1.6**.

1.1.1.1 Background

Semiconductors, or chips, are small electronic devices used in a vast array of industries, including consumer electronics, manufacturing, medicine, commerce, military, artificial intelligence, and others. With the advent of artificial intelligence, data centers, and ever-expanding computational needs, chip manufacturing in the United States and around the world will continue to grow (SIA 2024). Many chip manufacturing processes rely on PFAS, some of which are proprietary, and other chemicals (for example, N-methylpyrrolidone, hydrochloric acid, and hydrofluoric acid) (NIST 2024), which may result in potential risks to workers and the environment. **Figure 2-20** provides an example conceptual site model for industrial sites and can be useful in the evaluation of semiconductor PFAS uses and releases.

1.1.1.2 PFAS Uses

Because of the unique properties of PFAS (see **Section 2**), many PFAS from multiple classes are used during semiconductor manufacturing. For example, fluoropolymers are used to filter out small particles from fluids during chip production and are an important component during the photolithography process. No known alternatives exist for many of the industry's uses of fluorocarbon-containing materials (SIA 2023, p. 3.), and once an alternative is invented, the process to qualify it for use is complex and may require many years to deploy for high-volume manufacturing (SIA 2023, p. 3.). Therefore, continued access to PFAS is currently a prerequisite for high-volume and advanced semiconductors. Given this, the focus on preventing exposures and the buildup of PFAS in the environment lies in materials management, particularly the management of wastes from semiconductor manufacturing, and perhaps even in the management of chips and semiconductor manufacturing equipment at the end of their service life.

When the bipartisan CHIPS and Science Act of 2022 was signed into law, it provided the Department of Commerce with $50 billion for a suite of programs to strengthen and revitalize the US position in semiconductor research, development, and manufacturing. The CHIPS Program Office's Final Programmatic Environmental Assessment contains tables describing the uses of PFAS in semiconductor manufacturing, Table C-4, (NIST 2024), and a list of chemicals used by the industry, Appendix D, (NIST 2024). The following subclasses, groups, or subgroups of PFAS were included on this list:

- fluorinated polymers, including polymeric perfluoropolyethers (PFPE), side-chain fluorinated polymers, and perfluoroalkoxy alkanes
- perfluoroalkane sulfonic acids (PFSAs) (for example, perfluorobutane sulfonic acid [PFBS], perfluorooctane sulfonic acid [PFOS])
- perfluoroalkane sulfonamides (FASAs) (for example, perfluorobutane sulfonamide [FBSA])
- perfluoroalkyl dicarboxylic acids (PFdiCAs) (for example, perfluorobutyl dicarboxylic acid [PFBdiCA])
- perfluoroalkane sulfonamido ethanols (FASEs) (for example, FBSE)
- perfluoroalkane sulfonamido acetic acids (FASAAs) (for example, perfluorobutane sulfonamido acetic acid [FBSAA])

More information about PFAS subclasses, groups, and subgroups is included in **Section 2.2.2** and **Figure 2-4**.

The industry phased out the use of legacy PFAS, such as PFOS and perfluorooctanoic acid (PFOA), years ago, replacing them typically with C4-short chain replacement compounds (see bulleted list above), including PFBS (SIA 2023). These shorter chain compounds are now found in the wastewater from semiconductor fabrication plants (Chen et al. 2024; Jacob, Barzen-Hanson, and Helbling 2021; Jacob and Helbling 2023). In addition, fluorinated gases (see **Section 1.1.3.4**) are used as a plasma etchant in semiconductor manufacturing.

1.1.1.3 Exposure Pathways

In general, potential PFAS release mechanisms and pathways at semiconductor facilities include wastewater and stormwater discharges; on- and off-site disposal of solid wastes; accidental releases; and stack and fugitive emissions. Refer to **Figure 2-20**. The conceptual site model presents exposure routes and receptors that may be associated with semiconductor facilities. Semiconductor manufacturing is typically completed in a closed loop, where clean-room facilities may limit worker

exposure. However, electronic waste recycling facilities may not provide such safeguards. Additional exposure pathways may include processing steps during materials recovery and scavenging during electronic waste recycling, including collection, processing, and disposal sites (Tansel 2022). Fluorinated gases (see **Section 1.1.3.4**) that are used in plasma etching processes are the largest source of greenhouse gas emissions from semiconductor production, and perfluorocarbons (PFCs) make up most of those releases (USEPA 2025).

Although often the focus is on industrial releases to wastewater treatment plants, the same chemicals could be released directly to land, surface water, groundwater, or air from leaks and spills. For example, GlobalFoundries' Essex Junction, Vermont, plant has a National Pollutant Discharge Elimination System (NPDES) permit to discharge directly into the Winooski River (Vermont DEC 2021). Although there are no regulations specific to discharges of PFAS from semiconductor wastewater, many states have regulations on industries or facilities with significant PFAS sources to perform and report discharge monitoring. Some of these states include Virginia, New Hampshire, and West Virginia. Missouri has a voluntary PFAS sampling program for facilities renewing existing wastewater or stormwater permits. Additional information is available in the **Regulatory Programs Table** and refer to the topic/focus area "Wastewater."

Many different types of solutions, rinses, inert equipment (such as molds and piping), and components are used in semiconductor manufacturing processes and have the potential to end up in waste streams. Studies have documented semiconductor waste streams containing PFAAs, including PFBS, perfluorohexane sulfonic acid (PFHxS), PFOS, perfluorohexanoic acid (PFHxA), PFOA, perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA), perfluoroundecanoic acid (PFUnA), and perfluorododecanoic acid (PFDoA) (see **Section 2.6.1.6**). A 2024 study identified effluent sample data from wastewater treatment plants associated with semiconductor facilities and identified perfluorobutane sulfonamido derivatives and ultra-short-chain PFAS (ultrashort PFAS) (see **Section 1.1.3.1**) as new trends associated with the semiconductor manufacturing industry (Chen et al. 2024). However, it should be noted that many of these newly identified PFAS are not included in typical commercial analytical laboratory PFAS methods; in addition, the toxicity or potential risk of these compounds is not known at this time.

Wastewater from processes that use wet chemical formulations (for example, chip production) containing PFAS may be discharged to the publicly owned treatment works (POTWs) without substantive PFAS removal, and generally, treatment works are not typically equipped to measure or remove PFAS from their effluent or biosolids. However, some companies are considering segregating, storing, and sending PFAS-containing process wastes off-site for treatment (NIST 2024; NIST 2024).

Fluorinated gases (see **Section 1.1.3.4**) that are used in plasma etching processes are the largest source of greenhouse gas emissions from semiconductor production, and PFCs make up most of those releases (USEPA 2025). Some of the more common PFCs used in the semiconductor industry include trifluoromethane (HFC-23), difluoromethane (HFC-32), tetrafluoromethane (PFC-14), hexafluoroethane (PFC-116), and octafluoropropane (PFC-218) (SIA 2023).

Semiconductor factories conduct wastewater pretreatment for other substances, such as acids, under wastewater discharge permits from POTWs. Pretreatment for PFAS at the end of a pipe, before the PFAS waste stream mixes with other wastes, could be an important component in addressing PFAS used in the production process.

1.1.2 Less-publicized PFAS Sources

As noted in **Section 2.5.2**, growing awareness of PFAS has led to both research and speculation about the use and occurrence of PFAS associated with an increasing number of products, and whether such occurrences may constitute a risk to human health and the environment. Although PFAS have been

previously identified in applications mentioned in **Section 2.5.1**, this section expands on the knowledge of the application and use of PFAS in these areas. In addition, some other potential less-publicized sources are discussed.

1.1.2.1 Hydraulic Fluids

Hydraulic fluid has many purposes, including transferring forces, lubricating surfaces, and acting as a sealant and coolant. PFAS are used in these applications primarily for their unique combination of properties that are beneficial in high performance and extreme condition environments. Two important criteria for hydraulic fluids are viscosity and additives that provide resistance to corrosion. Hydraulic fluids use PFAS for corrosion, chemical, temperature, and wear resistance for machines to operate smoothly.

The Organisation for Economic Co-operation and Development (OECD) (2025) report on PFAS in hydraulic oils and lubricants provided a comprehensive overview of the use of PFAS in hydraulic fluids and lubricants, emphasizing their technical functions and the challenges of substitution. Although comprehensive, the authors noted that the report is not exhaustive or definitive. For example, hydraulic oil and lubricant formulations are typically considered confidential business information, often limiting the available details, such as the percent of PFAS in each formulation (see the example safety data sheets below).

PFAS are "notable for their oil- and water-repellent characteristics and high thermal stability, have effectively reduced friction and wear in diverse mechanical systems" (Dias et al. 2024). Tribology is the study of friction which "most often involves the control and reduction of friction" (Watterson 2019). "A popular use of PFAS in tribological applications is the use of polytetrafluoroethylene (PTFE) in coatings and lubricants, renowned for its lubricity, resilience at high temperatures, and resistance to chemical attacks" (Dias et al. 2024) and referenced therein as Yeo et al. (2012), Dubey et al. (2015), and Zheng et al. (2023). In lubricants, PFAS are used in base oils (for example, PFPEs, polychlorotrifluoroethylenes [PCTFEs]), additives (for example, micropowder PTFE), and solvents, contributing to durability, reduced maintenance, and compatibility with various materials (OECD 2025). Table 2.1 in the OECD report summarizes the PFAS used in specific functions and in which applications this use may apply.

Glüge et al. (2020) further stated: "anionic PFAS (largely those with a sulfonic acid group) are used as additives in brake and hydraulic fluids due to their ability to alter the electrical potential of the metal surface and thus, protect the metal surface from corrosion through electrochemical oxidation."

Automotive Applications

In the automotive industry, PFAS-based lubricants are valued for their durability, low friction, and compatibility with diverse materials. They help reduce maintenance frequency and extend the lifespan of components such as gears and bearings. PFAS additives also support performance in high-temperature and high-load conditions (OECD 2025).

Zhu and Kannan (2020) stated that PFAS have been used as additives in automotive lubricant oils and hydraulic fluids, to reduce surface tension, and to prevent fires and evaporation. In the automotive sector, the use of PFAS has been noted in the development of some lubricants, engine oils, and hydraulic fluids (Wang et al. 2010; Rico et al. 2007). PFAS play a crucial role in supplying essential features such as anti-wear, anticorrosion, and antifoaming capabilities. The annual demand for vehicle lubricating oils in the United States is estimated at approximately 2.4 billion gallons (Research and Markets 2019).

Zhu and Kannan (2020) analyzed 18 lubricants purchased in the United States for PFAS; however, they noted that seven of the 18 lubricants were explicitly for use in aircraft applications. Several perfluoroalkyl carboxylic acids (PFCAs) and PFSAs were detected in the lubricants. They were analyzed before and after

oxidation using the total oxidizable precursor (TOP) assay. Following oxidation, lubricant extracts yielded total perfluoroalkyl acid (PFAA) concentrations up to two orders of magnitude higher than before oxidation, as high as 8,300 nanogram/gram (ng/g) mean. Long-chain PFCAs were the majority of PFAS detected prior to oxidation; however, variable and poor recoveries were noted for some of the volatile precursors during the TOP assay procedure.

Aviation Applications

PFAS additives have been used in aircraft hydraulic fluids due to their flame resistance, and erosion- and corrosion-inhibiting properties, which are essential for maintaining system integrity under extreme temperatures and pressures (OECD 2025). Applications in the aviation industry may include flight control systems and landing gear (OECD 2025). In broader aerospace applications, PFAS-containing hydraulic fluids maintain performance at a broader range of temperatures, where petroleum-based fluids may underperform at either temperature extreme (OECD 2025).

One PFAS cited in papers as being used in hydraulic fluids is perfluoroethylcyclohexane sulfonate (PFECHS) (MPART 2020) (see **Section 2.2.3.3**). Multiple reports have linked the use of PFECHS in aviation applications to environmental contamination. PFAS have been used in aircraft hydraulic fluids since the mid-1960s (De Silva et al. 2011; de Solla et al. 2012; MacInnis et al. 2017). For more information on PFECHS, see **Section 1.1.3.2**.

Examples of Corrosion-inhibitor Safety Data Sheets (SDS)

Corrosion inhibitors typically consist of fluorochemical surfactants which include PFAS. They may be used as additives to the acid media, or they may be applied as a thin, protective film on the metal prior to contact with the acid. Historical examples of fluorochemical surfactants used as corrosion inhibitors include FC-95, FC-98, FC-128, FC-134, and FX-161, FC-170, and FX-172 (3M Company 1963), and FC-5120 (3M Company 2012).

Safety Data Sheets reviewed (see call-out boxes) denote that the PFAS reported in fluorochemical surfactants used as corrosion inhibitors include salts of PFOS or PFECHS as more prevalent components, along with salts of other perfluoroalkyl sulfonates (for example, C4 through C7), including linear or cyclic isomers as minor components. More recently, PFBS-based surfactants are also reported, such as fluorosurfactant FC-5120 (3M Company 2012). Apart from salts of perfluoroalkylsulfonates, salts of perfluoroalkylcarboxylates appear to have also been used in some formulations of fluorochemical surfactants (see FC-118 example).

SDS for FC-118 FLUORAD Brand Fluorochemical surfactant

Issue Date: May 20, 1996

Source: **Specialty Chemicals Division, 3M Company**

The SDS includes the following ingredients:

- water (80%)
- ammonium perfluorooctanoate (18%–21%)
- ammonium perfluoroheptanoate (0.1%–1%)
- ammonium perfluorohexanoate (0–0.1%)
- ammonium perfluoropentanoate (0.1%–1%)

SDS for FC-135™ FLUORAD Brand Fluorochemical surfactant

Issue date: December 12, 2012

Source: **Environmental Health and Safety Services Department, 3M Canada Company**

The SDS includes the following ingredients:

- perfluoroalkylsulfonyl quaternary ammonium iodide (C8), which in water may produce PFOS (40%–44%)
- isopropyl alcohol (33%)
- fluoroalkyl quaternary ammonium iodides (C4, C5, C6, and C7) (0.1%–5%)
- methyl iodide (0.1%)

Cases for Continued Use

Despite the identification of several nonfluorinated chemical and technical alternatives, including

silicone oils, esters, graphite, molybdenum disulfide, and boron nitride, none fully replicate the multifunctional performance of PFAS. The OECD (2025) report highlighted that while alternatives may be viable for some uses, they often require reformulation, increased maintenance, or compromise on performance. Moreover, no commercially viable alternatives are known to currently exist for PFAS in aviation hydraulic fluids. The report concluded that substitution is technically and economically challenging, and that regulatory drivers, rather than market forces, are likely to be the primary catalyst for change. Table 2.2 of the OECD report (2025) provides a list of silicone-based alternatives and which PFAS they would be intended to replace.

In Canada and the United States, use of FC-98 is permitted in the aviation industry based on the lack of alternatives, its critical role in the safe performance of aircraft, and anticipated minimal environmental release (USEPA 2005).

In the USEPA Docket control number OPPTS-50639, the Boeing Company submitted comments to USEPA's PFAS proposed Significant New Use Rule, Supplemental Proposed Rule, published in the Federal Register on March 11, 2002 (67 Fed. Reg. 11014). Boeing mentioned the variety of commercial and military aircraft they manufacture and how many people they employ. They wrote in support of USEPA's proposal to exclude from the definition of significant new use, "1) the manufacture or import of certain PFAS chemicals for use as an anti-erosion additive (i.e., FC-95 and FC-98) in fire-resistant phosphate ester aviation hydraulic fluids; and 2) the use of these PFAS chemicals as intermediates to produce other chemicals used solely for the excluded aviation hydraulic uses."

In other sectors, the Association of Equipment Manufacturers (AEM) (**www.aem.org**) indicates PFAS are needed to meet objectives such as air quality, climate, safety, and sustainability and alternative power goals (AEM, 2024). The applications include such uses in seals, hoses, hydraulic systems, refrigerant, and alternative power technologies. Examples of machines and systems that use hydraulic power include excavators, cranes, forklifts, lifts, dozers, graders, loaders, shovels, trenchers, and concrete pumping systems, among others. Pinhole leaks, sudden drops in pressure, or contamination of the fluid can all cause serious safety issues for the operator or maintenance team (AEM 2024).

Additionally, the thinktank Industrial Resources Strategies issued a final report titled, "PFAS: Application, Technical Functions and Substitution Possibilities in the Industry" (Lang-Koetz, Hutschek, and Heil 2024), which examined suitable substitutes for various applications, including hydraulic fluids. To determine whether there are adequate substitutes that could replace PFAS, a specially developed artificial intelligence (AI) was used. Over 35,000 scientific documents were analyzed, and the AI-based system identified 420 materials and summarized them into 32 classes for five European companies. For the companies (which include an automobile company), the report claimed there were either none or only 2 to 3 identified materials that have the potential to replace PFAS in the future. "An adequate substitute that could be used immediately or in the near future was not found in any of the cases examined" (Lang-Koetz, Hutschek, and Heil 2024).

Canter (2024) provided information for companies involved in producing lubricants to minimize PFAS release and exposure. Canter (2024) recommended paying attention to the supply chain and establishing a system to determine the most likely source of PFAS. As well as a recommendation for a resource allocation plan, an assessment of all PFAS sources of contamination in water, fire suppression systems, and raw materials should be performed. Finally, Canter (2024) recommended that a lubricant manufacturer ask for a reformulated raw material without fluorine or find a supplier with a viable nonfluorine-containing alternative.

1.1.2.2 Pesticides

When identifying PFAS use in pesticides, it should be noted that organizations define PFAS differently. Refer to **Table 2-1** for more information on the various definitions of PFAS. Pesticides can contain

fluorinated compounds, but depending on what definition is used, they may or may not be identified as PFAS.

Two general categories of ingredients are used in pesticides: active and inert. Active ingredients are the primary elements that kill or suppress the targeted organisms, while the inert ingredients, including emulsifiers, fragrances, and dyes, are added to enhance the product and do not have to be disclosed (Donley et al. 2024). Donley et al. (2024) reported that several patents have identified fluorinated "inerts" as assisting with dispersal of spraying pesticides, preventing foaming, aiding in surfactancy, and penetrating organisms. Because the manufacturers of pesticides are not required to disclose when fluorinated substances are used as an inert ingredient, the full extent of PFAS in pesticides is uncertain.

Fluorination in pesticides can be used to modify chemical attributes such as stability and lipophilicity (Alexandrino et al. 2022). Active ingredients are often fluorinated in pesticides, with insecticides and acaricides (targeting ticks and mites) being highly fluorinated (Ogawa et al. 2020). Molecular stability can result from fluorination and can influence lipophilicity, allowing binding to target proteins (Alexandrino et al. 2022). The most common chemotype is a trifluoromethyl (CF3), followed by a monofluoromethyl group (CFH2) (Ogawa et al. 2020). Only a broad definition of PFAS would include these shorter chain chemicals under a PFAS classification. (Alexandrino et.al. 2022) discussed the increased use of fluorination in pesticides. It grew from 9% by the end of the twentieth century to over 50% between 2010 and 2020. Fluorinated pesticides made up nearly 70% of all new approved agrochemicals during the second half of 2010. Ogawa et al. (2020) said the difluoro[1]methyl group, CF2H, is emerging more rapidly than the CF3 group due to progress of synthetic methods.

Section 2.4.5 discusses the pesticide sulfluramid, which is manufactured in Brazil. The active ingredient in sulfluramid (a pesticide used for control of leaf-cutting ants) is n-ethyl perfluorooctane sulfonamide (EtFOSA), which is a direct precursor to PFOS. Although PFOS is listed under Annex B (restriction of use) in the UN Stockholm Convention on Persistent Organic Pollutants (POPs) (UNEP 2025), use of sulfluramid in insect bait has continued acceptable use in Argentina, Brazil, Costa Rica, and Vietnam from December 2020 onwards under the UN Stockholm Convention on POPs. Sulfluramid has prior registration for use in the United States in termite, ant, and roach bait stations (USEPA 2001). This may indicate prior potential for commercial and consumer use application both inside and outside of homes and buildings, as well as other locations.

A study in Denmark looked at worker exposure to PFAS-containing pesticides (including long-chain PFAS). This study, conducted between 1996 and 2001 on pregnant greenhouse workers, found elevated PFAS in their blood (Andersen et al. 2024), demonstrating higher exposure risk for this sector of people.

A study has identified PFAS as leaching from the coatings of pesticide containers (USEPA 2021). The practice of coating polyethylene plastic containers started as early as 1958 (Joffre 1957). Today this practice of coating agricultural containers continues (Rand and Mabury 2011). Often, molded plastic containers are treated under high temperature with fluorine gas (Kharitonov 2008). Recent activity includes:

- July 2024: EPA Grants Petition on 3 PFAS Found in Fluorinated Plastic Containers (USEPA 2024)
- October 2024: EPA Issued Test Order for PFAS Used in Manufacturing Under National Testing Strategy (USEPA 2024). This action orders Innovative Chemical Technologies, Chemours Company, Daikin America, Sumitomo Corporation of Americas, and DuPont to conduct and submit testing on 6:2 FTAc (6:2 fluorotelomer acrylate), which is used in manufacturing plastics, resins, textiles, apparel, leather, and other chemicals.

More work is needed to study fluorinated coated containers in the agricultural industry and containers used in other sectors to understand the impact on the environment and human health.

1.1.2.3 Other Less-publicized Sources

Table 1-1 provides less-publicized sources, in addition to those presented in Table 2-7 in **Section 2.5**.

Table 1-1. Additional examples of PFAS claims in other less-publicized sources.

Potential Use	Technical Basis	Documentation	Potential Conflicting Perceptions on Presence of PFAS and Significance of PFAS
Commercial Car Washes	Analysis of PFAS in car wash products and other consumer products.	Borg and Ivarsson (2017) Glüge et al. 2020	PFAS are used in some car wash products and may leach into wastewater. PFAS presence in such products can be significant, depending on their concentration and usage patterns.
Concrete Sealers	Review of different types of penetrating concrete sealers and their chemical composition.	Concrete Sealers USA (2016)	Concrete sealers may contain PFAS to enhance water resistance. The significance depends on the type of sealer and its PFAS content, which varies by manufacturer.
Toilet Paper	Analysis of PFAS presence in toilet paper and its contribution to wastewater.	Thompson et al. (2023)	Toilet paper can be a significant source of PFAS in wastewater. The level of PFAS varies, and its contribution to overall PFAS pollution depends on the volume of toilet paper used and its PFAS concentration.
Fracking Fluids	Media reports describe a review of publicly reported data (FracFocus database: **https://fracfocus.org/**) detailing the use of nonionic fluorosurfactants used in injection fluids for fracking of hydrocarbons. These reports indicate PFAS or PFAS precursors in thousands of wells across a handful of states. Colorado has banned the use of PFAS in fracking fluids as of January 1, 2024.	FracFocus (2025) Horwitt (2021) Friday (2022) Connor et al. (2021) Horwitt and Gottlieb (2023) Colorado General Assembly (2022) Murphy and Hewat (2008) Schramm (2000)	The use of PFAS in fracking fluids is likely; however, due to limited details in the database, the exact type of PFAS and extent of PFAS, or PFAS precursors used in current or historical specific fracking operations is unknown. PTFE (Teflon) is a potential concern with use in fracking operations.
Medical Devices	PFAS have widespread uses in medical devices and in vitro diagnostic reagents and instruments.[1] A consumer study[2] identified total organic fluorine content in 18 different soft contact lens products.	[1]PFAS Uses: Glüge et al. (2020) and Gaines (2022) [2]Contact Lenses Consumer Study: Segedie (2023) [3]Essential Uses, Patient Safety: Levy et al. (2023); Cousins et al. (2019); Spyrakis and Dragani (2023); Ozben et al. (2024); Rezvova et al. (2023) [4]Medical Testing and Safety: Henry et al. (2018); Maitz (2015); Ozben et al. (2024) [5]Polymer of Low Concern Analysis: Lohmann et al. (2020) [6]PFAS Serum Study: Kang et al. (2024)	Position papers[3] discuss the essential uses of some PFAS in medical devices (i.e., PTFE, polyvinylidene fluoride (PVDF) and volatile PFAS used as propellants in inhalers) and the impact that restrictions would have on patient safety. In a contact lens consumer study[2], organic fluorine levels ranged between 105 ppm to 20,700 ppm. Organic fluorine was detected in all 18 products; the study stated that the organic fluorine can be a marker for PFAS. Proponents[4] argue that PFAS—fluoropolymers in particular—are chemically and biologically inert and have a robust clinical history and testing of implanted medical devices supporting their safety in medical applications. However, others[5] point to new research in animals showing the potential for some fluoropolymers to be bioavailable. One US study[6] of young adults (aged 20—39 years) estimated a statistically significant increase in the body burden of PFAS in contact lens users as compared to non-contact lens users. No statistically significant difference in PFAS body

Potential Use	Technical Basis	Documentation	Potential Conflicting Perceptions on Presence of PFAS and Significance of PFAS
			burden was observed in a supplemental analysis of older adults aged 40–59 years. The study authors noted that not all potential confounders could be adjusted in the model and identified several limitations when interpreting the age-dependent observations.
Lithium-Ion Batteries	PFAS are widely reported components in lithium-ion batteries, including in the electrodes (cathode and anode), binder, electrolyte (main component and additives), and separator (porous membrane). The global clean energy sector may be an unrecognized and potentially growing source of international PFAS release into the environment, highlighting a need to evaluate clean energy impacts beyond just carbon dioxide emissions. A fire on Long Island at the largest utility-scale storage facility of lithium salt and battery cells burned on May 21, 2023. Elevated PFAS concentrations were detected in the extinguishing water concentrations. The concern over fluorinated compounds in lithium-ion batteries has led to research on fluorine-free batteries: Ma et al. (2024); Ma et al. 2024.	Vamosi (2023) Quant et al. (2023) Rensmo et al. (2023) Guelfo et al. (2024) Willstrand, Quant, and Hynynen (2025)	Savvidou et al. (2024) suggested PFAS-free alternatives are available in electrodes and electrolytes. PFAS-free lithium-ion batteries: Ma et al. (2024); Ma et al. 2024.
Dry Cleaners	PFAS may be used in dry-cleaning systems as replacements for tetrachloroethene-based systems. PFAS may also be in waste discharges from dry cleaners as a result of PFAS in the materials being laundered.	Gaines (2022) CA ARB (2006) FL DEP (2021)	Existing patents show the use of hydrofluoroethers with other PFAS as an alternative to tetrachloroethene or other solvents used in dry cleaning. Another patent mentions the use of carbon dioxide and a surfactant; fluoroalkyl substances are mentioned as a potential surfactant. The Zonyl series by DuPont is mentioned as a source of fluorinated compounds. California report discusses a replacement for tetrachloroethene called PureDry, which contains HFE-7200, FC-43, PF-5070, and PF-5060.
Explosives, Pyrotechnics, and Propellants	Published information on composition of explosives, propellants, and pyrotechnics is available.	Valluri, Schoenitz, and Dreizin (2019)	Although certain fluoropolymers are known to be components of some explosives, propellants, and pyrotechnics, data are not available on the fate and transport of fluoropolymers associated with these items. Research is underway to address data gaps.

1.1.3 Less-studied PFAS

Section 2 provides a summary of different PFAS classes, subclasses, and groups. This section expands on that discussion to provide information on some of the less-studied PFAS, including ultrashort PFAS, cyclic PFAS, volatile PFAS, and fluorinated gases.

1.1.3.1 Ultrashort PFAS

Ultra-short-chain PFAS (ultrashort PFAS) are generally described as having ≤3 carbons (Zheng, Eick, and Salamova 2023; Neuwald et al. 2022). Common examples of ultrashort PFAS include trifluoroacetic acid (TFA, C2), perfluoropropanoic acid (PFPrA, C3), perfluoropropanesulfonic acid (PFPrS, C3), and 1,1,1-trifluoro-N-[(trifluoromethyl)sulfonyl] methanesulfonamide (TFSI, C2) (**Table 1-2**). Some fluorinated gases may also be considered ultrashort PFAS (**Section 1.1.3.4**). Zhi et al. (2024) identified ultrashort PFAS found in environmental samples, including PFPrA, trifluoromethanesulfonic acid (TFMS, C1), perfluoroethane sulfonic acid (PFEtS, C2), and PFPrS. Ultrashort PFAS are known to be industrial chemicals used for a variety of direct applications or may be byproducts from the construction of complex chemicals. As examples, TFA and PFPrA are common reagents and catalysts used in laboratories (Zheng, Eick, and Salamova 2023), and TFSI is used in the production of lithium-ion batteries and as an additive to biodegradable natural rubber matrixes (Sowińska et al. 2021).

Existing studies have shown ultrashort PFAS tend to be as persistent as their longer chain homologues and are more mobile in the environment. In some cases, ultrashort PFAS may have higher acute ecological toxicity than short- and long-chain PFAS (Wang et al. 2014) and can be more difficult to remove from water (Ateia et al. 2019; Neuwald et al. 2022). Ultrashort PFAS are not typically included in studies focusing on capture and destruction of PFAS. Human health–related toxicological effects of ultrashort PFAS are discussed in **Section 1.4.4** on health effects of ultrashort PFAS.

Although TFA is a common example of a C2 ultrashort-chain PFAS, it is worth noting that under some existing definitions of PFAS, it would not be considered a PFAS (refer to **Section 2.2**). TFA has been found in the environment at concentrations orders of magnitude higher than other PFAS. TFA was found at higher occurrence in residential house dust and tap water in a study in Indiana (Zheng, Eick, and Salamova 2023). In Zhi et al. (2024), the authors noted the elevated TFA levels and that levels are increasing in the global environment. This paper also identified four additional ultrashort PFAS found in environmental samples, including PFPrA, TFMS, PFEtS, and PFPrS. In addition, large amounts of TFA are produced for use as an intermediate in chemical manufacturing and for other purposes (National Center for Biotechnology Information 2025, PubChem website).

Although TFA is extremely persistent, this ultrashort PFAS does not have well-established drinking water health advisories or regulatory limits (Arp et al. 2024). However, it should be noted that the Netherlands National Institute for Public Health and the Environment (RIVM) and the German Environment Agency (UBA) have developed drinking water guidelines for TFA of 2.2 ug/L (RIVM 2023) and 60 ug/L (UBA 2020), respectively.

Ultrashort PFAS are less studied than short- and long-chain PFAS and are often not included in analytical methods used for other PFAS because their highly polar characteristics make them difficult to analyze with current analytical methods (Björnsdotter et al. 2020; Liang, Steimling, and Chang 2023; Neuwald et al. 2022). Additional information about ultrashort PFAS analysis is found in **Section 1.5.3**. However, studies evaluating transformation of PFAA precursors suggest their contribution to human exposure to ultra-short-chain PFAS—specifically, polyfluoroalkyl carboxamides, polyfluorinated phosphate esters (PAP), FOSAs, FOSEs, FTOHs, and FTACs, among others (Zheng, Eick, and Salamova 2023).

TFA has been documented to form through the atmospheric degradation of several F-gases, including hydrofluorocarbons and hydrochlorofluorocarbons used in refrigerants (Jordan and Frank 1999; Liang,

Steimling, and Chang 2023). Similarly, ultrashort PFAS such as PFPrA and TFA can be produced through the breakdown of pharmaceuticals, pesticides, and polymers (Jordan and Frank 1999; Liang, Steimling, and Chang 2023). Ultrashort PFAS are also included in formulations of aqueous film-forming foam (AFFF) or are the result of the breakdown of other PFAS in AFFF. For example, PFPrA and TFA are breakdown products of perfluoro-2-methyl-3-pentanone (PFMP), which was marketed by 3M as a fire protection fluid replacement for chlorofluorocarbons and halons (Jackson et al. 2011), while other ultrashort PFAS (PFPrS and PFEtS) have been quantified in AFFF formulations manufactured between 1989 and 2001 (Barzen-Hanson and Field 2015). For additional examples and occurrences and health effects associated with ultrashort PFAS, see **Section 1.4.4**. In addition, see the updated **Table 4-1** for physical and chemical properties of some ultrashort PFAS.

Table 1-2 summarizes some ultrashort PFAS examples, with a notation of those covered in **Table 4-1** as well as those that can be currently analyzed by some environmental laboratories, see **Section 1.5.3** for more information about analysis of ultrashort PFAS. Note: The USEPA's CompTox Chemicals Dashboard (CompTox Chemicals Dashboard (epa.gov)) was used to standardize naming conventions and CAS numbers for ultrashort PFAS throughout the different sections of the Priority Topics documents.

Table 1-2. Ultrashort PFAS examples.

CAS No.	Chemical Name	Included in Table 4-1	Included on Current Commercial Lab Lists
381-73-7	Difluoroacetic acid (DFA)		
76-05-1	Trifluoroacetic acid (TFA)	X	X
422-64-0	Perfluoropropanoic acid (PFPrA)	X	X
421-85-2	Trifluoromethylsulfonamide		
78491-70-0	Perfluoroethanesulfonamide		
152894-03-6	Perfluoropropanesulfonamide		
423-41-6	Perfluoropropanesulfonic acid (PFPrS)	X	X
354-88-1	Perfluoroethanesulfonic acid (PFEtS)	X	X
1493-13-6	Trifluoromethanesulfonic acid (TFMS)	X	X
344324-36-3	Perfluoroethane-1-sulfinic acid		
359868-84-1	Perfluoropropane-1-sulfinic acid		
34642-42-7	Perfluoromethane-1-sulfinic acid		
674-13-5	Perfluoro-2-methoxyacetic acid (PFMOAA)	X	X
1036-91-3	Perfluoro-2-(trifluoromethoxy)ethanesulfonic acid		
374-09-4	Trifluoromethylphosphonic Acid		
103305-01-7	Pentafluoroethylphosphonic acid		
82113-65-3	1,1,1-trifluoro-N-[(trifluoromethyl)sulfonyl] methanesulfonamide (TFSI)	X	
90076-65-6	Lithium bis[(trifluoromethyl)sulfonyl]azanide (HQ-115)	X	X
34642-43-8	Perfluorobutane-1-sulfinic acid (PFBSi)		X
756-09-2	2,2,3,3-Tetrafluoropropanoic acid (2,2,3,3-TFPA)		X
359-49-9	2,3,3,3-Tetrafluoropropanoic acid (2,3,3,3-TFPA)		X

1.1.3.2 Cyclic PFAS

Cyclic PFAS include a carbon ring that may be partially or fully fluorinated or aromatic substances that have a fluorinated side chain. Although cyclic PFAS are not commonly tested for by USEPA standard test methods (for example, USEPA Method 1633A), some are included in ASTM methods such as D7979. Classification of these fluorinated compounds as PFAS is dependent on the definition of PFAS used. Examples of cyclic PFAS include:

- perfluorocycloalkyl sulfonates such as perfluoromethylcyclohexane sulfonate (PFMeCHS), perfluoropropylcyclopentanesulfonate (PFPCPeS), and perfluoroethylcyclohexane sulfonate (PFECHS)
- perfluorotoluene
- (perfluoropropyl)benzene
- fipronil

Certain cyclic structures can have much in common with noncyclic PFAS analogs and have been used in replacement chemistry. See **Section 2.2.3.3**.

Of the examples of cyclic PFAS, PFECHS is among those with the most available published peer-reviewed research. PFECHS is an 8-carbon cyclic PFAS that was produced by 3M and sold commercially as FC-98 as a corrosion inhibitor in some hydraulic fluid formulations (see **Section 1.1.2.1**) (de Silva et al. 2011). For example, PFECHS is considered an analog for PFOS and has been documented as a replacement compound for PFOS in some hydraulic fluids (O'Rourke et al. 2024). This is further supported by a multivariate statistical analysis demonstrating a positive correlation between PFECHS and PFOS (O'Rourke et al. 2024). In 2020, the Michigan PFAS Action Response Team (MPART), in conjunction with the Michigan Department of Health and Human Services, prepared a study noting occurrence of PFECHS in multiple media, including drinking water, surface water, sediment, marine organisms, and human blood (MPART 2020). Further, MPART noted the documented use of PFECHS and other perfluorocycloalkyl sulfonates in commercially available fluorochemical surfactants (MPART 2020). 3M phased out production of PFECHS and other perfluorooctyl-based compounds; however, it remains a permitted chemical in the United States and Canada due to "the lack of alternatives, its critical role in the safe performance of aircraft, and anticipated minimal environmental release" (de Silva et al. 2011).

SDS for FC-98 FLUORAD Brand Fluorochemical surfactant

Issue Date: September 10, 2002

The SDS includes the following ingredients:

- potassium perfluoroethyl cyclohexyl sulfonate (66%–70%)
- potassium perfluoromethyl cyclohexyl sulfonate (18%–22%)
- potassium perfluorodimethyl cyclohexyl sulfonate (9%–13%)
- potassium perfluorocyclohexyl sulfonate (1%–3%)
- residual organic fluorochemicals (not known)

Three studies cited by MPART (2020)—Wang et al. 2016, de Solla, De Silva, and Letcher (2012), and Letcher et al. (2015)—documented the greatest concentrations of PFECHS near airports. A review paper by Mahoney et al. (2022) discussed available information about PFECHS detection in environmental samples. PFECHS has been detected in surface water, herring gull eggs, and predator fish from the Great Lakes and other freshwater bodies (Mahoney et al. 2022; Muir et al. 2019; De Silva et al. 2011). Data reported by Szabo et al. (2022) indicate PFECHS in black swan serum and excrement and associated aquatic environmental media samples.

O'Rourke et al. (2024) noted that the similarity in persistence within living organisms to that of long-chain legacy PFAS may indicate that PFECHS and other replacement compounds such as F-53B are being used as substitutes for PFOS, suggesting comparable transportation pathways of environmental contamination in freshwater systems. Miaz et al. (2020) reported on analyses of serum samples from Swedish women collected from 1996 to 2017. Their study showed a declining trend in serum concentrations since 2000, with detectable concentrations of PFECHS of 0.06–0.28 ng/g. More research is needed to fully understand the toxicity and bioaccumulation properties of PFECHS.

PFECHS has biomagnification potential and is moderately bioaccumulative in the estuarine and marine food web (Wang et al. 2023). Although Mahoney et al. (2022) concluded PFECHS had a lower bioconcentration potential than PFOS in a trout cell assay, in 2023 Mahoney et al. (2023) found that PFECHS has potential to cause adverse effects at the cellular level in the marine system. Szabo et al. (2022) calculated a bioaccumulation factor for PFECHS of 593 L/kg versus the bioaccumulation factor for PFOS of 1,097 L/kg. In a study published by Wang et al. (2016), PFECHS and PFPCPeS were found to accumulate most significantly in the liver, kidney, blood, and bladder, with estimated average whole body bioaccumulation factors (log $BAF_{whole\text{-}body}$) of 2.7 and 1.9, respectively. Currently, PFECHS is thought to have a lower toxic potency than PFOS, but there is a need for additional research (Mahoney et al. 2023).

1.1.3.3 Volatile PFAS

Refer to the **PFAS-Vapor Intrusion Fact Sheet** for a discussion of the current state of the science for vapor-forming PFAS and their potential role in the vapor intrusion pathway. In addition, refer to **Section 4.2** for an introduction to the physical properties of volatile PFAS. USEPA vapor intrusion guidance (2015) considers a compound to be volatile if it has a vapor pressure greater than 1 millimeter of mercury (mm Hg) or a Henry's law coefficient greater than 10^{-5} atmosphere-meter cubed per mole (atm m^3 mol^{-1}). Numerous PFAS meet this volatility criteria, including both anionic and neutral PFAS (Abusallout et al. 2022; Schumacher et al. 2024).

As discussed in greater detail in **Section 4.2**, there are limited reliable data on the physical and chemical properties related to PFAS volatilization. For example, reported Henry's law coefficients can span multiple orders of magnitude for a single PFAS (see **Table 4-1**), making it difficult to know which values are most representative of the compound's behavior in the environment. Thus, it is not always clear whether certain compounds meet the USEPA volatility definition when the range of estimated or measured vapor pressures and/or Henry's law coefficients extends both below and above the thresholds. The PFAS listed in **Table 4-1** with sufficient vapor pressure and/or Henry's Law coefficient to be considered volatile are summarized in **Table 1-3**.

At this time, vapor-phase occurrence is mostly commonly associated with neutral PFAS, such as fluorotelomer alcohols (FTOHs), perfluorooctane sulfonamido ethanol (FOSE), perfluorooctane sulfonamide (PFOSA), and ultrashort-chain PFAS (considered to include 3 or fewer carbon atoms) (See **Section 1.1.3.1**). However, it should be noted that nonvolatile terminal PFAS, such as PFNA, PFOA, and perfluoroheptanoic acid (PFHpA), can also be formed from transformation of FTOHs, and PFOS can be released from transformation of FOSE. (See **Section 2.2.4** for more information about polyfluoroalkyl substances).

Some example uses of volatile PFAS include the following:

- fluorotelomer alcohols in paints (Cahuas et al. 2022).
- textile and leather production (MPCA 2023). FTOHs, N-EtFOSE, and MeFOSE are commonly used in textile manufacturing and in impregnation treatments for textiles and leather (MPCA 2023).
- medical industry as propellants in inhalers (Gaines 2022).

Table 1-3. PFAS listed in Table 4-1 with sufficient vapor pressure and/or Henry's law coefficient to be considered volatile.

PFAS	Sufficient Vapor Pressure per Table 4-1	Sufficient Henry's Law Coefficient per Table 4-1
Perfluorocarboxylic acids (PFCAs)		
Perfluorobutanoic acid (PFBA)	X	X
Perfluoropentanoic acid (PFPeA)	X	
Perfluoroalkane sulfonamides (FASAs)

PFMBA	X	X

1.1.3.4 Fluorinated Gases

Fluorinated gases (F-gases) are humanmade, include hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulfur hexafluoride, and other fluorinated compounds, and are used (both historically and currently) in a variety of industrial applications (**Table 1-4**). Under the very broad definition of PFAS recommended by the Organisation for Economic Co-operation and Development (OECD), fluorinated gases are considered PFAS (OECD 2021), fluorinated gases are considered PFAS. HFCs represent approximately 90% of all F-gases (European Commission n.d.). F-gases under the definition of PFAS typically contain between 1 and 7 carbons; some examples of F-gases are provided in **Table 1-4** (MPCA n.d.). The broad OECD PFAS definition encompasses many of the PFC and HFC gases used in semiconductor device manufacturing (see **Section 1.1.1**), as well as fluorinated heat transfer fluids (SIA 2023). As noted in **Section 1.1.3.1**, TFA has been documented to form through the atmospheric degradation of several F-gases, including hydrofluorocarbons and hydrochlorofluorocarbons used in refrigerants (Jordan and Frank 1999; Liang, Steimling, and Chang 2023).

Table 1-4. Examples of fluorinated gases.

F-Gas	CAS No.	Chemical Name	Use
HFC-23	75-46-7	Trifluoromethane	Refrigerant, fire extinguisher, semiconductor manufacturing
HFC-32	75-10-5	Difluoromethane	Refrigerant
HFC-41	593-53-3	Fluoromethane	
HFC-43-10mee	138495-42-8	Decafluoropentane	Cleaning solvent
HFC-125		Pentafluoroethane	Fire extinguisher
HFC-134	359-35-3	1,1,2,2-Tetrafluoroethane	
HFC-134a	811-97-2	1,1,1,2-Tetrafluoroethane	Refrigerant, fire extinguisher, foaming agent, medical propellants, aerosol propellants
HFC-143	430-66-0	1,1,2-Trifluoroethane	
HFC-143a	420-46-2	1,1,1-Trifluoroethane	Refrigerant
HFC-152	624-72-6	1,2-Difluoroethane	
HFC-152a	75-37-6	1,1-Difluoroethane	Refrigerant, foaming agent, aerosol propellant, temperature sensing agent
HFC-161	353-36-6	Fluoroethane	
HFC-227ea	431-89-0	Heptafluoropropane	Refrigerant, fire extinguisher, medical propellant
HFC-236cb	677-56-5	1,1,1,2,2,3-Hexafluoropropane	
HFC-236ea	431-63-0	1,1,1,2,3,3-Hexafluoropropane	
HFC-236fa	690-39-1	1,1,1,3,3,3-Hexafluoropropane	Refrigerant, fire extinguisher, foaming agent, medical propellant
HFC-245ca	679-86-7	1,1,2,2,3-Pentafluoroproane	Refrigerant
HFC-245fa	460-73-1	1,1,1,3,3-Pentafluoropropane	Refrigerant, foaming agent
HFC-365mfc	406-58-6	Pentafluorobutane	Refrigerant, foaming agent
PFC-14	75-73-0	Perfluoromethane; tetrafluoromethane	Plasma etchant, semiconductor manufacturing, refrigerant
PFC-116	76-16-4	Perfluoroethane; hexafluoroethane	Plasma etchant, semiconductor manufacturing
PFC-218	76-19-7	Perfluoropropane; octafluoropropane	Plasma etchant, semiconductor manufacturing, refrigerant, fire extinguisher
PFC-318	115-25-3	Perfluorocyclobutane; octafluorocyclobutane	Plasma etchant, cleaning agent, refrigerant, propellant in food industry
PFC-3-1-10	355-25-9	Perfluorobutane; decafluorobutane	Refrigerant, fire extinguisher
PFC-4-1-12	678-26-2	Perfluoropentane; dodecafluoropentane	Refrigerant, cleaning solvent
PFC-5-1-14	355-42-0	Perfluorohexane; tetradecane fluorohexane	Refrigerant, cleaning solvent, fire extinguisher
PFC-9-1-18	306-94-5	Perfluorodecalin	
c-C3F6	931-91-9	Perfluorocyclopropane	

Source: MPCA (n.d.) "Table of HFCs and PFCs and Pounds of Chemicals that Trigger Reporting Requirements."

F-gases are often used as replacements for ozone-depleting substances (such as halons), as these gases are not typically as harmful to the atmospheric ozone layer. However, F-gases are still highly regulated because they are strong greenhouses gases with a higher potential to contribute to global warming than carbon dioxide. Some of these regulations have banned F-gases such as HFC-23 due to their high potential to contribute to global warming (European Environment Agency 2025; EFCTC n.d.). F-gases are highly regulated by the US Clean Air Act, the Montreal Protocol for Greenhouse Gases, the Paris Agreement, and European Union air regulations. However, the World Meteorological Organization (UNEP 2018) estimates the global warming potential of some of these F-gases to be lower than carbon dioxide over a 100-year time horizon (it depends on the F-gas) and lists the ozone depletion potential of many F-gases to be 0. The atmospheric half-life of many of these compounds is on the order of days to years, depending on the chemical, via oxidation or photolysis in the atmosphere.

F-gases are used in many different products, equipment, and processes, such as refrigeration, air conditioning, heat pumps, insulation, fire protection, power lines, and aerosol propellants, as well as in industrial processes (European Commission n.d.; EFCTC n.d.). Electronics and aerospace industries use solvents containing F-gases to clean components (NetRegs n.d.). Several industries rely on F-gases for safe and reliable operations, including food storage, distribution to pharmaceutical production, and home heating and cooling. Benefits of F-gases include energy efficiency and less reliance on fossil fuels (Chemours n.d.).

Refer to EFCTC (n.d.) for additional information on the F-gases.

1.2 Priority Topics for Firefighting Foams

Section Number	Topic
1.2.1	**Firefighting Foam Inventory**
1.2.2	**Firefighting Foam Ecotoxicity**
1.2.3	**Transition Planning and Guidance**

Firefighting foam continues to be a driving concern as it relates to PFAS and potential impacts to the environment. Important considerations include management of the foam, mitigation once released, and elimination from use. These Priority Topics present updates to some of the information included in **Section 3**, including the existing Foam Inventory Table (**Table 3-1**), as well as recent updates on foam transition planning, guidance, and case studies, including updates to the existing Case Study Table (**Table 3-5**).

1.2.1 Firefighting Foam Inventory

ITRC continues to inventory both aqueous film-forming foam (AFFF) (foams with intentionally added PFAS) and fluorine-free foams (F3) to provide information regarding product name, manufacturer, and other relevant information. **Table 3-1** has been revised and now includes two tabs in the downloadable Table 3-1 Excel file. These include:

1. AFFF Inventory: A compilation of current and historical AFFFs from the DoD (Department of Defense) Qualified Product list (USDOD 2018), as well as state inventories.

2. F3 Inventory: A compilation of F3 foams from the Interstate Chemicals Clearinghouse (IC2) report titled “PFAS in Firefighting Foam” (IC2 2019) and GreenScreen for Safer Chemicals website (Clean Production Action 2024), as well as the DoD Military-Specification 32725 fluorine-free products (USDOD 2023).

1.2.2 Firefighting Foam Ecotoxicity

Recent tests reported in Fuller et al. (2024) on F3s show they are slightly more acutely toxic to aquatic organisms than AFFF, but their chronic toxicity is generally similar or less. The study analyzed the impact of six F3s on six aquatic species, finding that the acute toxicity of several of the F3s was greater than AFFFs with PFAS. Others had similar acute risks to AFFFs with PFAS. Chronic toxicity varied by species and formulation, with some F3s affecting growth and reproduction in specific species. In other testing, Hossain et al. (2024) conducted an acute avian study evaluating one short-chain PFAS-containing firefighting foam and six nonfluorinated firefighting foams. The results indicated that an analyzed F3 has less toxicity on chick growth than AFFF, but both the F3 and AFFF affected embryo development, leading to death of unhatched eggs. Work by Yeardley et al. (2024) compared the acute, chronic, and behavioral effects of two fluorine-free formulations with a PFAS-containing AFFF on two species of earthworms. The study indicated that F3s show varying acute toxicity to earthworms. Earthworms strongly avoided soils treated with F3 and AFFF; however, one F3 was much more acutely toxic than the compared AFFF. These three studies on ecological receptors and similar research provide essential data for selecting less environmentally toxic alternatives to AFFF. These findings, much like with AFFF, strongly suggest that thoughtful consideration should be taken with the selection of F3s and that best management practices (BMPs) continue to be used when handling, storing, applying, and remediating both AFFF and F3. See **Section 3.8.1** for more information about BMPs.

1.2.3 Transition Planning and Guidance

Section 3.11 includes information about firefighting foam system replacement. The following sections provide updates to the information about transition planning of foam systems from AFFF to F3 and available guidance.

1.2.3.1 State Activity

Several states are actively addressing AFFF, and specifically the transition of AFFF to F3. Many more states have initiated take-back programs or intend to initiate take-back programs. Some states have also developed or refreshed guidance to support foam transitions. According to Safer States (2025), at least seven states will consider policies to eliminate PFAS from firefighting foam, including phase-out, restrictions, or take-back programs. These include Connecticut, Maine, Montana, New Jersey, New York, Oregon, and Pennsylvania. A total of fifteen states has already adopted phaseouts of PFAS in firefighting foams.

State take-back program approaches have varied. According to the Environmental Council of States (ECOS 2025) compendium of States PFAS Action Report (April 2025), a total of nineteen states has completed take-back (or collection) programs. ECOS (2025) reported disposal of collected AFFF included hazardous waste landfills (10 states), incineration (three states), destruction technology using supercritical water oxidation (SCWO) (two states), and interim storage until a safe method is identified, or disposal method under development (three states). In addition, ECOS (2025) reported that states have collected over 1,672,500 pounds (which is approximately 167,250 gallons) of AFFF through take-back programs. Costs per gallon vary depending on what type of disposal/destruction method was chosen, as well as what other services may have been included (collection/storage, inventory activities, waste hauling, processing).

1.2.3.2 State Foam Transition Guidance

According to ECOS (2025), 32 states have already transitioned at least one fire department or airport from using AFFF to the use of F3, and 33 states have conducted outreach to fire departments, airports, and other users of AFFF ranging from surveying fire departments, coordinating with state fire marshals,

setting up informational web pages, developing fact sheets, and coordinating with their state Department of Transportation, among other efforts (ECOS 2025). States such as Washington and Minnesota have developed guidance to support foam transitions from AFFF to F3. A summary of each guidance document is below.

The Washington Department of Ecology's August 2024 interim guidance, "Best Management Practices for Deep Cleaning Fire Equipment Contaminated with PFAS-Containing Firefighting Foam in Washington State," outlines the following key practices (WA Dept. of Ecology 2024):

- **No PFAS cleaning standard** currently exists for firefighting equipment.
- **AFFF concentrate and rinsate** must be collected in labeled containers and **cannot** be disposed of in sanitary sewers, septic systems, storm drains, catch basins, or on the ground; disposal must go through a licensed hazardous waste hauler.
- **Foam replacement** should use only Green Screen-certified or DoD-specified F3 products.
- **Before replacement**, systems must be fully drained and dried; drained material should be stored in labeled containers.
- **Sampling of the new F3** at least 20 days after installation and keeping detailed cleaning and replacement records is recommended. PFAS is expected to be detected in the sample results, but it is not intentionally added, and should still be managed using BMPs.
- **Hot water rinsing (110°F–160°F)** of tanks and plumbing is recommended; use glycol-based detergents such as 20% butyl CARBITOL™, FluoroFighter™, or PerfluorAd®; circulate for at least 30 minutes.
- **A second rinse is recommended,** and an optional third rinse is suggested.
- **Sampling of rinsate** for halogenated organic compounds is recommended: if under 100 ppm, coordinate discharge with local publicly owned treatment works; if over 100 ppm, follow Washington State hazardous waste disposal rules.

The Minnesota Pollution Control Agency (MPCA) issued guidance in June 2023 and updated in December 2025 outlining the use and disposal of PFAS-containing firefighting foam (MPCA 2025). Key points include:

- **Phase-out deadlines**: Municipal and rural fire departments must stop using AFFF by the end of 2023; oil refineries have until the end of 2025 unless they have been explicitly granted a waiver to the end of 2027.
- **Airport requirements**: Airports and users at airports, except for fixed systems in hangars; must phase out PFAS-containing foam by the end of 2025 with fixed systems in airport hangars; by the end of 2027.
- **Usage and reporting**: All PFAS foam use or release must be reported within 24 hours and handled with full containment, collection, and disposal.
- **Disposal protocols**: Foam concentrate must be incinerated or solidified and landfilled as hazardous waste; runoff must be treated with granular activated carbon until PFAS levels meet Minnesota Department of Health guidance values and must be preapproved for sewer disposal.

- **F3 product standards**: Only Green Screen-certified or DoD-qualified F3 foams are permitted for replacement.

1.2.3.3 Federal Agency Guidance

Several federal agencies have published guidance pertaining to foam transitions. A summary of those follows:

DoD Guidance for Mobile Systems (March 2024) (USDOD 2024):

- **AFFF Phase-Out Deadline**: All land-based use of AFFF containing PFAS must stop by September 30, 2024.
- **Mobile System Requirements**: Mobile systems transitioning from AFFF must be fully drained, rinsed with water, and reconfigured for fluorine-free alternatives. Appropriate spill prevention and containment measures must be implemented.

DoD Guidance for Fixed Systems (July 2024) (USDOD 2024):

- **AFFF Phase-Out Deadline**: All land-based use of AFFF containing PFAS must cease by September 30, 2024.
- **Fixed System Transition**: Fixed systems must be drained, rinsed, and components drip-dried, with containment of foam and rinsate. Accidental releases must be reported if perfluorooctane sulfonic acid (PFOS) or perfluorooctanoic acid (PFOA) exceed 1 pound in a 24-hour period.
- **System Removal or Abandonment**: For abandoned or removed systems, a water rinse and drying process will be conducted before recycling or disposal.
- **Waste Disposal**: AFFF, rinsate, and impacted waste must be disposed of according to the Assistant Secretary of Defense (Energy, Installments, & Environment) ASD(EI&E) Interim Guidance on Destruction or Disposal of Materials Containing PFAS in the US (July 11, 2023)(USDOD 2023). Based on DoD analysis and consistent with USEPA guidance, four options are available including carbon reactivation, hazardous waste landfills, solid waste landfills, and hazardous waste incinerators. Hazardous waste storage may also be considered as well as underground injection control on a site-specific basis and existing or developing treatment or destruction technologies.

Federal Aviation Administration (FAA) Guidance:

- The FAA has published many documents to support airports with F3 transition planning and guidance. This includes an aircraft transition plan, four CertAlerts, and other materials. The FAA (2025) "Fluorine-Free Foam (F3) Transition for Aircraft Firefighting" website includes links for the documents:
    - **An FAA Aircraft Firefighting Foam Transition Plan (2023)** was published to support transition planning for FAA Part 139 airports. The plan was established in response to a December 2022 congressional directive for FAA to develop "a transition plan that would include all known legislative requirements, personnel training changes, and other operational aspects to be implemented for a certificate holder's transition to MILSPEC F3" (FAA 2023).
    - **Part 139 CertAlert 23-07** was published to describe availability of F3 on the Navy's Qualifed Products List (QPL)

- **Part 139 CertAlert 23-01** was published to describe new military specification for performance-based standards for F3s for aircraft fires.
- **Part 139 CertAlert 24-05** was published to describe rinsing procedures for cleaning out mobile systems transitioning from AFFF to F3.
- **Part 139 CertAlert24-11** was published to describe testing requirements and outputs after completion of F3 transitions.

Deadline Extension and Support:

- **Transition Deadline Extension**: The DoD has extended the AFFF transition deadline from September 30, 2024, to September 30, 2025, for both mobile and fixed systems due to the need for more time to replace AFFF with fluorine-free alternatives at 1,500 facilities and 6,000 mobile assets (USDOD 2024).
- **FAA Support for Airports**: The FAA is supporting airport transitions through the FAA Reauthorization Act of 2024 (FAA 2024), which includes funding and a PFAS replacement program for the switch to F3. As of September 2025, Congress had not appropriated funding for the PFAS replacement program. Section 767 of the act identifies the "PFAS-related resources for airports" (FAA 2024).

1.2.3.4 Other Guidance on Foam Transition

Other governments, as well as organizations representing foam users, have developed guidance on foam transition. Some additional representative guidance is presented below.

Queensland, Australia

The Queensland Department of Environment & Science released a 2021 policy for managing firefighting foam to minimize environmental harm, based on the precautionary principle. It outlines requirements for handling, transport, storage, use, release, treatment, and disposal of foam, emphasizing the need to assess environmental and health risks (Queensland Government 2021). Key points include:

- **Hazard assessment criteria**: All foams shall be evaluated for environmental persistence, bioaccumulation, toxicity (acute/chronic), mobility in soil and water, biodegradability, and biochemical oxygen demand.
- **Nonpersistent (fluorine-free) foams**: PFAS levels in systems shall be tested after 1 month of residence in existing system; limits are <10 mg/kg (combined specific PFAS compounds) and <6.4 mg/kg using total organic fluorine (TOF).
- **Management of fluorine-free foams**: Site managers shall take all reasonable and practical steps to contain, treat, or properly dispose of foam and runoff to avoid significant environmental harm.
- **Persistent foams (for example, AFFF)**: Concentrates must contain <10 mg/kg PFAS (specified compounds) and <50 mg/kg TOF. These foams must be fully contained on-site and disposed of as regulated waste.
- **Disposal planning**: A disposal plan shall be created within 3 months of the foam being removed from service or deemed surplus.

The Arctic Council

"The Arctic Council is the leading intergovernmental forum promoting cooperation, coordination and interaction among the Arctic States, Arctic Indigenous Peoples and other Arctic inhabitants on common Arctic issues, in particular on issues of sustainable development and environmental protection in the Arctic. It was formally established in 1996" (Arctic Council, 2025). In 2021, the Arctic Council initiated transition from AFFF to F3 foams (Arctic Council 2021), and a transition plan was finalized in August 2023 (Arctic Council 2023).

1.2.3.5 Transition from AFFF to F3 Case Studies

Case studies provide examples of AFFF transitions across industries and geographies globally. The case studies are intended to provide examples of the range of approaches to transition from AFFF to F3 and are not intended to be recommendations for specific approaches at other sites. **Table 3-5** includes the case studies collected to date.

Although there are commercial products available intended to clean residual PFAS from AFFF-impacted fire suppression systems, published literature evaluating the occurrence, duration, and concentrations of long-term PFAS rebound after the initial cleaning is lacking (Nguyen et al. 2025; Bonnet et al. 2025,; Vatankhah et al. 2025). PFAS rebound is when a PFAS-free foam is added to a system and PFAS remaining in the system infrastructure leaches back into the foam, making it a foam with PFAS in it. To date, no studies have published decontamination methods that fully remove residual PFAS from interior surfaces as indicated by PFAS rebound into replacement F3. Without aggressive surface agitation, postcleaning PFAS rebound is hard to avoid (Lang et al. 2022). To determine post-treatment efficiency of AFFF decontamination and before transitioning, swab samples are needed to assess PFAS remaining on surfaces (Bonnet et al. 2025).

More information pertaining to PFAS and AFFF can be found in **Section 3**.

1.3 Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization

Section Number	Topic
1.3.1	**Vadose Zone Characterization and Transport**
1.3.2	**Septic Systems**
1.3.3	**Perfluoroalkyl Acids Precursor Biotransformation**
1.3.4	**Groundwater Partitioning, Colloidal Transport, GW-SW Interactions**
1.3.5	**Understanding PFAS in Marine Environments**
1.3.6	**Effects of Suspended Sediment on Surface Water Sampling and Measurement of PFAS**
1.3.7	**Source ID, Differentiation, and Forensics**
1.3.8	**Site Characterization Tools and Techniques**

Information in these Priority Topics was prepared to supplement the information for Physical and Chemical Properties published in **Section 4**, Fate and Transport published in **Section 5**, Site Characterization published in **Section 10**, and Surface Water Quality in **Section 16**. Information about Strategic Environmental Research and Development Program (SERDP) and Environmental Security Technology Certification Program (ESTCP) projects for these topics can be found at **https://serdp-estcp.mil/**.

1.3.1 Vadose Zone Characterization and Transport

This section provides additional details on air-water partitioning behavior of PFAS and advances in vadose zone fate-and-transport modeling for PFAS. This content complements information in **Section 4**, **Section 5**, and **Section 10**. More specific references are provided for each subtopic.

1.3.1.1 Air-water Partitioning

Section 4.2.8, **Section 5.2.4.1**, and **Section 5.3.3** describe how competing hydrophobic and hydrophilic properties characteristic of surfactants, and specifically PFAS, result in complex transport dynamics. The presence of PFAS in porewater lowers interfacial tension and forms films at the air-water interface (AWI), with the hydrophobic carbon-fluorine tail oriented toward the air and the hydrophilic head group dissolved in water. AWI partitioning can retard PFAS migration and reduce leaching potential, with site-specific factors such as soil texture, salinity, and pH influencing the extent of retention. AWI can vary spatially in response to soil texture and heterogeneities, and temporally in response to saturation and recharge events. This behavior can significantly affect PFAS transport in the vadose zone (**Figure 1-1**).

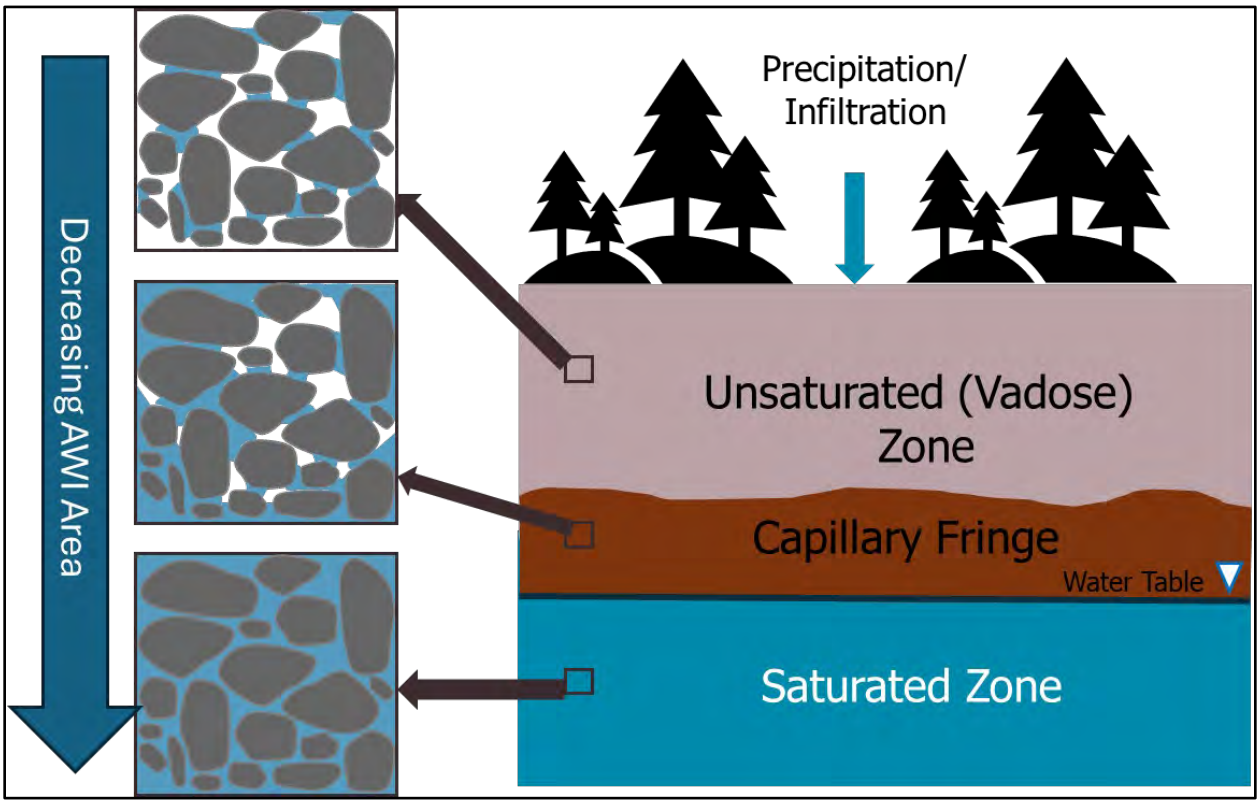

Figure 1-1. Partitioning and interfacial area. The degree of water saturation affects the amount of interfacial area in a nonlinear manner. Increased interfacial area increases retention. Factors that contribute to retention at the AWI include porewater ionic strength, PFAS concentration, and soil properties such as grain size, minerology, and moisture content, which affect the thickness of the capillary fringe.

Studies have shown that adsorption of PFAS such as perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) at the AWI can retard transport, contributing to around 50% of total retention under certain test conditions, depending on site-specific parameters (Brusseau 2018; Bigler et al. 2024). This adsorption to the AWI can be assumed to be instantaneous (Guo et al. 2022). This section primarily summarizes recent research on this rapidly evolving topic, emphasizing the need for continued

investigation and incorporation of AWI processes, in addition to vadose zone retention, into conceptual site models (CSMs) and, as the science advances, risk assessments.

Interrelated to vadose zone retention, AWI within the capillary fringe may also impact retention. Wallis et al. (2022) noted that prolonged periods of evapotranspiration exceeding rainfall result in periods of upward flux of PFAS mass, leading to evapoconcentration and associated persistence in the vadose zone. This process acts counter to downward flux to groundwater, as typically conceived. The capillary forces discussed above demonstrate the dynamic nature of the AWI and highlight factors to consider when evaluating PFAS retention in the vadose zone and capillary fringe.

The AWI area is influenced by both soil grain size and soil saturation. In particular, the AWI-saturation relationship is nonlinear, with high AWI at low saturation and zero AWI at full saturation (Guo, Zeng, and Brusseau 2020). For example, soils with higher percentages of silt and clay size particles typically support larger AWI areas than coarser grain soils for a given water saturation (Brusseau 2023). Brusseau noted that spatial variability in soil texture and soil moisture should be considered when evaluating AWI area. Similarly, temporal changes in soil saturation (from infiltration and drainage) also affect the AWI area and may be important to consider depending on the specific goals/objectives of the investigation. Specifically, Guo et al. (2022) showed that modeled long-term leaching of PFAS was adequately assessed assuming steady-state conditions. But modeling focused on short-term impacts of infiltration on AWI area and PFAS leaching should consider the dynamic nature of surfactant-induced flow, and rate-limited, nonlinear adsorption at solid-water and air-water interfaces. However, incorporating these factors comes with significant computational costs and the requirement for detailed input parameters. Last, it is noted that grain size also affects the extent of PFAS retention via conventional sorption methods, as discussed in **Section 5.2**.

Soil type (mineralogy, grain size, and surface area) and porewater ionic type and strength influence PFAS accumulation at the AWI. Coarser grain sizes having lower water content and more air-filled pore space can increase retention. The adsorption of PFAS at the AWI decreases with increasing concentration and increases with the number of perfluorinated carbons, indicating different retention behaviors for various PFAS (Silva, Martin, and McCray 2021). Additionally, Le et al. (2021) and Stults et al. (2023) both highlighted that increasing ionic strength significantly enhances PFAS accumulation and retention at the AWI. Le et al. (2021) demonstrated this effect through a mass-action model, showing orders-of-magnitude increases in adsorption with rising ionic strength. Stults et al. (2023) further emphasized the influence of ion type and concentration, refining predictive models by adding an empirical ionic strength correction factor accounting for these effects under environmentally relevant conditions. Both studies underscore the critical role of ionic strength in PFAS fate and transport. Note that tidally influenced sites could have significantly retarded PFAS transport due to a combination of higher ionic strengths in the vadose and saturated zones, as well as thickened capillary fringe. Understanding this retention behavior will support review of site-specific analytical results combined with soil profile data. Processes that contribute to retention of PFAS in the vadose zone are summarized in **Figure 1-2**. Refer to **Section 1.3.8.6**, and **Table 1-7** for sampling and analysis recommendations for grain size, soil classification, moisture content, and cation/anion exchange capacity that relate to vadose zone partitioning and leaching.

Research has shown significant variability in leaching behavior across different soils, emphasizing the need for site-specific assessment. Thompson et al. (2024) highlighted the benefits of site-specific leaching tests for PFAS risk assessment, demonstrating variability in leaching among five different soils compared to modeled data based on regulatory assumptions. Navarro et al. (2024) described how laboratory-scale leaching tests provide controlled insights into PFAS behavior but struggled to replicate in situ conditions, particularly for the AWI. Laboratory leaching methods, including synthetic precipitation leaching procedure (SPLP) tests, often rely on simplified, saturated conditions over extended periods. This can overestimate the leaching from soils collected from the water table interface, as fully saturated conditions do not reflect the reality of the vadose zone, where saturation is transient and varies in both

persistence and periodicity. Such methods overlook the important role of the AWI in PFAS accumulation and mobility, particularly for long-chain compounds. Ignoring adsorption to the AWI can result in soil screening levels that are significantly more stringent than otherwise (Brusseau and Guo 2023). As a result, standard tests may misrepresent leaching potential under field conditions. The observed variability in leaching behavior and the potential for laboratory studies to misrepresent leaching behavior together underscore the need for site-specific field validation approaches that account for climate, soil structure, wet-dry cycling, and variable saturation dynamics.

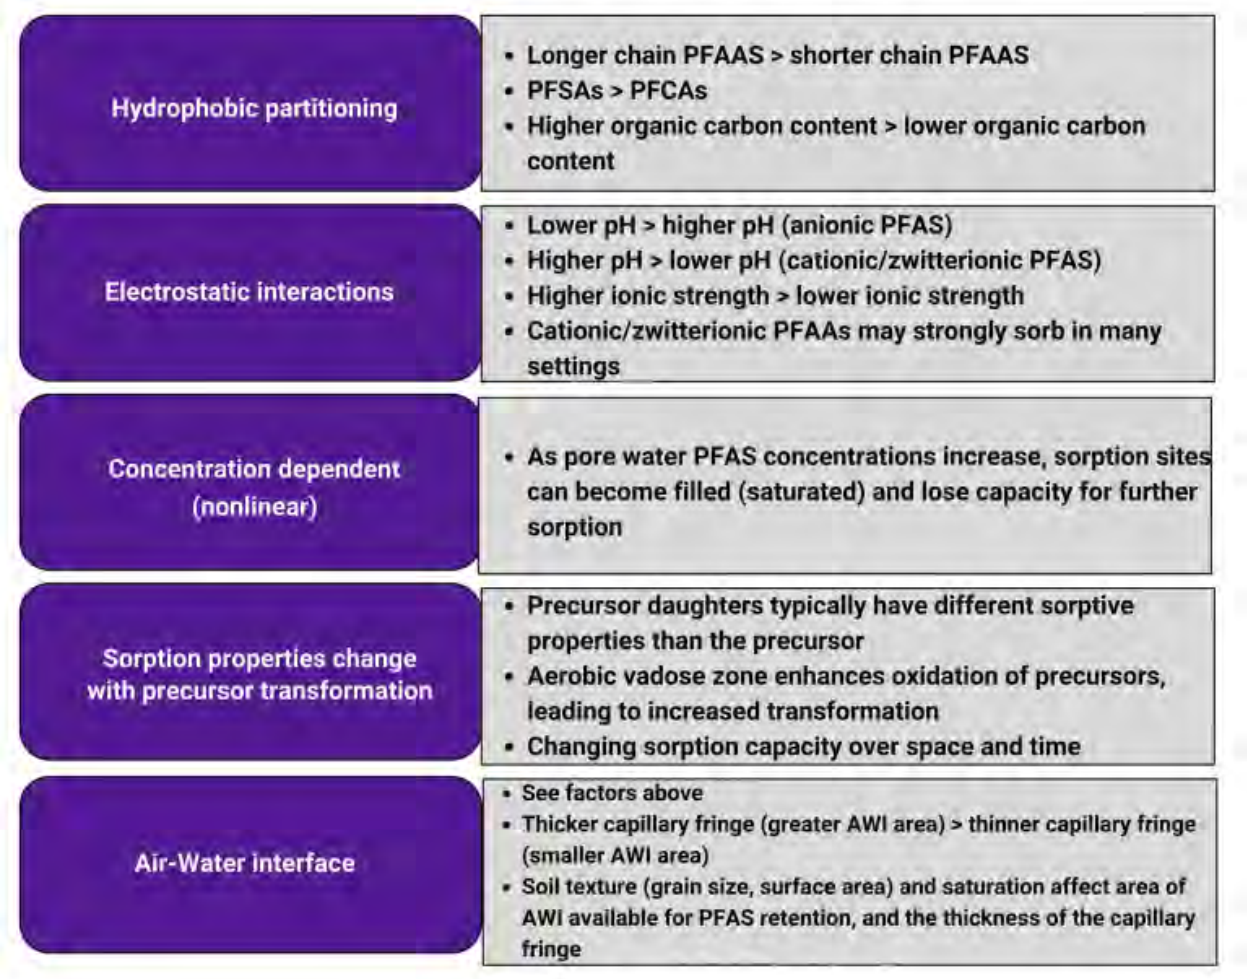

Figure 1-2. Factors influencing retention in the vadose zone.

Recent microscale modeling by Chen and Guo (2023) provided additional insight into PFAS transport through the vadose zone. Their work showed that although PFAS can move efficiently within individual pores, its movement slows down significantly in areas where water is held tightly between grains and connectivity is limited. These restricted zones can delay PFAS release and cause extended periods of low-level contamination after initial breakthrough. This research reinforces the importance of accounting for small-scale retention processes when predicting PFAS movement through unsaturated soils.

Arshadi et al. (2024) compared 1-D simulations of aqueous film-forming foam (AFFF) -associated PFAS transport in the vadose zone to field observations. The study indicated that a large portion of the mass of PFOA and PFOS exists at the solid phase and the AWI. This tends to limit transport in the vadose zone.

The rate of transport of PFAS in the aqueous phase is based on hydrogeologic properties, such as hydraulic conductivity and recharge rate. Their simulations also demonstrated the importance of considering the PFAS and other chemicals in the AFFF mixture because accumulation at interfaces is competitive and depends on the species present. Less surface–active PFAS (for example, shorter carbon chain length compounds such as perfluorohexane sulfonic acid (PFHxS), perfluorohexanoic acid (PFHxA), and perfluorobutane sulfonic acid (PFBS) (Guo, Saleem, and Brusseau 2023)) tend to have greater mobility when other chemicals are present.

Field studies also reveal gaps in our understanding of PFAS behavior at the AWI. Schaefer et al. (2024) used lysimeters to measure PFAS porewater concentrations at five AFFF-impacted sites, comparing field data with laboratory results from unsaturated soil cores and laboratory batch soil slurries. The study noted gaps in the scientific understanding of PFAS accumulation at the AWI. For instance, in the study PFAS accumulation at the AWI was orders of magnitude less than expected at two of the test sites. The research findings noted the potential importance of PFAS accumulation at the AWI in unsaturated soils and the impact of both soil texture and soil moisture content. The study also found that bench-scale testing of PFAS leaching and retention can be beneficial for understanding site-specific conditions but cautioned that improper accounting of AWI effects will result in misrepresentation of in situ leaching. The study noted significant concentrations of precursor compounds in 3 of 5 sites even after many years since original AFFF release. The authors stressed that sufficient understanding of precursor mass is essential for understanding long-term mass discharge and its role in the CSM. Last, the researchers noted that additional research is required to determine the extent to which their findings could be applied to more complex unsaturated zone conditions, such as dry and deep vadose zones with complex stratigraphy, and during extreme infiltration events. Disparities in field observations suggest a need to consider site-specific soil screening limits to account for wetting and drying cycles, soil texture, depth to water, and other parameters that may affect mass flux from the vadose zone. As such, vadose zone modeling techniques are being developed to define site-specific soil screening limits (Smith et al. 2024).

In a study of an AFFF-impacted site in a semi-arid region (27 cm average annual rainfall) where groundwater occurs at approximately 106 m below ground surface, researchers concluded that “99% of PFAS mass resided in the upper 3 m of the vadose zone” (Bigler et al. 2024). The researchers also noted that longer chain PFAS tended to remain within the uppermost (0–20 cm) portion of the vadose zone, while shorter chain PFAS accumulated at around approximately 1 m in depth, which is the top of a calcic horizon typically found in arid and semi-arid regions. PFAS of intermediate chain length were detected across the profile from surface to the calcic horizon (Bigler et al. 2024). It should also be noted that elevated PFAS concentrations (up to 40 ug/L) were observed along a 1- to 2-mile plume in deeper groundwater (water table at 100 m below land surface) in another portion of the site (USACE 2025), suggesting the importance of understanding subsurface heterogeneities that can affect PFAS in space and time.

1.3.1.2 Vadose Zone Modeling

Researchers from the University of Arizona have developed a comprehensive framework to model PFAS transport through the vadose zone (Brusseau and Guo 2023). Their research incorporated PFAS-specific retention mechanisms into the US Environmental Protection Agency’s (EPA’s) recommended process for determining migration to groundwater for soil screening levels (USEPA 1996); importantly, incorporation of these mechanisms can result in less stringent limits. Recently the Air Force Civil Engineer Center for Evaluation of Soil to Groundwater Leaching (AFCEC 2025) accepted this revised approach to developing the dilution attenuation factor. This does not necessarily imply regulatory acceptance, and practitioners should consult their specific regulators for guidance on how to determine a dilution attenuation factor and note that USEPA prefers multiple lines of evidence to support development of a site-specific dilution attenuation factor. The Smith, Brusseau, and Guo (2024) integrated modeling framework combines vadose-zone transport and groundwater dilution approaches, demonstrating that incorporating AWI

retention is essential to accurately characterize PFAS contamination risks, particularly for longer chain PFAS.

The role of the AWI in PFAS retention and leaching is important but complex. Zeng and Guo (2023) conducted systematic numerical simulations to test the hypothesis that subsurface heterogeneities, such as soil texture, accelerate the migration of PFAS in soils. Their evaluations predicted that longer chain PFAS would be strongly retained in shallow soils but could also migrate to deeper soils in response to subsurface heterogeneities, such that heterogeneity-generated preferential flow reduces the AWI area accessible to PFAS and may accelerate migration more for longer chain PFAS than for shorter chain PFAS. Overall, the study suggested that characterizing and representing soil heterogeneities is critical for determining the accessible AWI area and accurately quantifying PFAS migration. This finding aligns with Stults et al. (2024), who used laboratory column studies and the HYDRUS 1-D model to show that while equilibrium models could predict total mass leaching, they failed to accurately forecast effluent porewater concentrations. A novel two-site leaching model incorporating AWI partitioning and rate-limited desorption provided better predictions, particularly for long-chain PFAS such as PFOS and PFOA. The uncertainty in leaching rates is much higher for long-chain than short-chain PFAS. The short-chain PFAS exhibit less retention in the vadose zone and are more uniformly distributed with depth, in part because solid-phase adsorption and AWI retention are comparatively weak for short-chain PFAS. The differences in leaching between short- and long-chain PFAS imply that while short-chain PFAS mass discharge to groundwater will tend to occur relatively quickly, long-chain mass discharge to groundwater can persist for decades (Zeng, Brusseau, and Guo 2021).

Finally, Hort et al. (2024) examined PFOS retention above the water table in a marine setting using the MODFLOW-USG-Transport PFAS model, which includes AWI adsorption. Their findings indicated that recharge rates, recharge patterns, and sand grain size (fine versus coarse) significantly impact PFOS retention, with higher rates and more frequent recharge leading to less retention and coarse sands showing greater retention. The study explored inert gas sparging as a management strategy to concentrate PFOS in the vadose zone and simulated the effectiveness of retaining PFOS near the water table for extended periods. Additionally, the study results illustrated that long-term retention of PFOS in the vadose zone may be achieved by limiting or eliminating recharge via installation of an impermeable cap or cover. This suggests that effective management of soil to groundwater PFAS contamination can potentially be achieved by considering options that limit the downward flux to groundwater.

Recent advances in vadose zone modeling have improved our understanding of PFAS mobility, retention, and risk, particularly through the incorporation of AWI partitioning. Smith et al. (2024) developed an integrated vadose zone–groundwater framework that emphasized the importance of AWI retention, especially for long-chain PFAS. Subsequent modeling and laboratory studies (Zeng and Guo 2023; Stults et al. 2024) demonstrated how preferential flow, transient saturation, and nonequilibrium desorption contribute to the persistence of long-chain PFAS plumes, while short-chain PFAS concentrations tend to diminish more quickly. Hort et al. (2024) further highlighted the influence of recharge patterns and soil texture, with implications for both mass discharge and potential remedial strategies. Despite these advances, key uncertainties remain. Field-scale validation of AWI-inclusive models is limited, and model performance under transient conditions—especially wet–dry cycles and fluctuating recharge—remains poorly constrained (Stults et al. 2024; Zeng and Guo 2023). Site-specific factors such as climate variability, soil heterogeneity, and recharge dynamics are not yet fully integrated into most modeling efforts (Hort et al. 2024). Additionally, standard leaching tests such as SPLP may not reflect unsaturated conditions, potentially misrepresenting PFAS mobility (Stults et al. 2024). The interactive effects of PFAS mixtures and co-contaminants under dynamic flow conditions also require further investigation (Zeng, Brusseau, and Guo2021; Le et al. 2021). Additional information on co-contaminant effects on PFAS fate and transport may be found in **Section 1.3.4.1**.

1.3.2 Septic Systems

The following supplements **Section 2.6.4** (Wastewater Treatment and Wastewater Treatment Residuals and Biosolids), **Section 5.3** (Media-Specific Migration Processes), and **Section 10.3.2** (Nature of PFAS Sources) by further discussing the occurrence, fate and transport, and characterization of PFAS in groundwater at or near facilities with domestic septic systems (DSS) in proximity. In addition, a site characterization case study from the Raup et al. (2024) paper is presented in **Section 15.1.4**.

Several studies show that PFAS from DSS may be contributing to the contamination of private drinking water supply wells (Raup et al. 2024; Schaider et al. 2016; McMahon et al. 2022; Silver et al. 2023; Yang et al. 2017). Association with known septic contaminants is one line of evidence to determine if PFAS originate from a septic source (Raup et al. 2024; Silver et al. 2023). Common markers help determine whether a drinking water supply is contaminated by a septic system, including coliform and other bacteria. However, the minimum allowed distance between septic fields and downgradient private wells is designed specifically to prevent such bacteria from reaching neighboring water wells and is not designed to be protective of highly mobile PFAS that may be released from the septic system. Other chemical markers, such as caffeine, artificial sweeteners, or pharmaceuticals, are, like many PFAS, transported farther and at a faster rate than bacteria in groundwater and can be used in combination as first indicators of DSS influence on water sources (Raup et al. 2024, Silver et al. 2023).

Schaider et al. (2016) used sweeteners and pharmaceuticals and personal care products to establish a connection between DSS and PFAS contamination (**Figure 1-3**). Samples collected from five aquifer systems in the eastern United States in 2019 had a high co-occurrence of PFAS with VOCs and pharmaceutical chemicals, with higher pharmaceutical detections in an aquifer with a high abundance of septic systems relatively near water supply wells (McMahon et al. 2022). Silver et al. (2023) sampled 450 shallow wells from private residences throughout the state of Wisconsin and found that samples exceeding the EPA MCL for PFOA or PFOS tended to be associated with the presence of artificial sweeteners and pharmaceuticals, indicating a human waste source. Raup et al. (2024) sampled water supply wells near a superfund site in New York State and used the presence of septic tracers and multivariate statistics comparing PFAS composition to conclude that the probable source of PFAS to groundwater is the discharge of consumer products to septic systems.

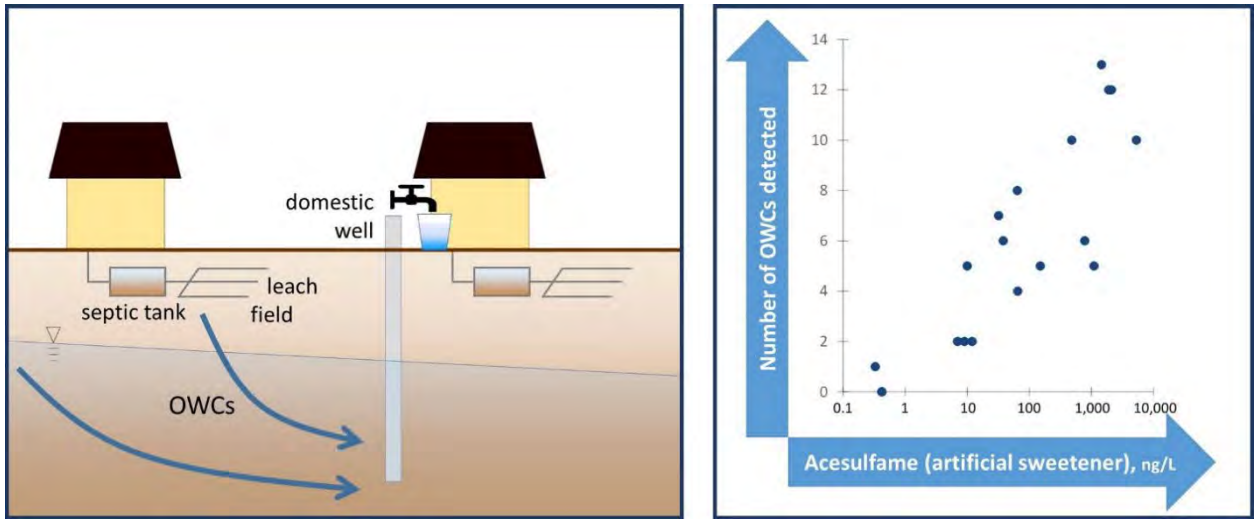

Figure 1-3. Conceptual model of drinking water contamination by neighboring organic wastewater compounds (OWCs) and use of sweetener as indicator of potential number of contaminants detected.

*Source: Schaider et al. 2016. Open Access, **https://creativecommons.org/licenses/by-nc-nd/4.0/**.*

Contamination of groundwater with PFAS from DSS is a challenge in site characterization projects given that the operation of domestic leach fields and the variety of consumer products that contain PFAS can lead to areas of diffuse contamination from wastewater sources. Examples of DSS can include leach fields and seepage pits, depending on local subsurface and environmental conditions. The presence of PFAS in consumer products, including cosmetics, cleaning products, cookware, carpets, upholstery, electronic products (Glüge et al. 2020), and certain foods (Hill et al. 2022; Lasters et al. 2022; Mikolajczyk et al. 2022; Ghisi et al. 2019; Lupton et al. 2014), can result in PFAS in household wastewater. Much like wastewater at public treatment plants, it should be expected for domestic wastewater to contain PFAS (MacMahon et al. 2022; Schaider et al. 2016).

It is important to emphasize that the existence of a significant statistical correlation between the levels of PFAS and markers such as sweeteners or pharmaceuticals and personal care products in private water supply wells does not eliminate the possibility that *other* sources of PFAS could also be contributing to the contamination. For example, Schaider et al. (2016) were not able to rule out potential influence from landfills in their conclusions. In fact, artificial sweeteners have been used to evaluate the impact of landfills on groundwater (Propp et al. 2022), and artificial sweeteners (Li et al. 2021) and pharmaceuticals (Kinney and Vanden Heuvel 2020) have been found in biosolids used on agricultural fields.

Other sources that could contribute to PFAS in groundwater or water supply wells have been documented. For example, Sivaram (2022) noted the presence of PFAS in commercially available garden soil mixes and composts, and at least one study documented downward migration of PFAS from compost (Saha et al. 2024), indicating that composts or other lawn and garden amendments have the potential to contribute PFAS to groundwater. PFAS contamination could also originate from a variety of diffuse sources such as wet precipitation (Pike et al. 2021) and dry deposition (Schroeder et al. 2021) that may infiltrate and percolate, transferring from the atmosphere into the vadose zone and groundwater (Guo, Zeng, and Brusseau. 2020). In addition, because the mix of consumer products used in a household or business can vary, the mixture of PFAS, or PFAS signature, should not be expected to be similar for all septic sources. Because of these potential complications and uncertainties, a multiple-lines-of-evidence approach should be used when investigating septic systems as potential PFAS sources.

1.3.3 Perfluoroalkyl Acids Precursor Biotransformation

This section presents information on precursor biotransformation to perfluoroalkyl acids (PFAAs). It builds upon **Section 5.4.2**, which introduced perfluoroalkyl acid (PFAA) precursors, and **Section 5.4.4.2** and **Section 5.4.4.3**, which discussed aerobic and anaerobic biological pathways, respectively. The introduction discusses why it is important to understand PFAA precursor biotransformation and provides background information on the process. This is followed by detailed information on the development of a precursor transformation database, and a short discussion on the application of PFAA precursor data.

1.3.3.1 Introduction

Some PFAS, commonly referred to as precursors, can undergo biotransformation processes, leading to the formation of degradation products and, ultimately, the terminal products of perfluoroalkyl acids (PFAAs). Understanding the transformation pathways and kinetics helps in predicting how PFAS mixtures change over time and how they travel and persist in different environmental media. This section describes PFAS biotransformation and the process of compilation of a database of precursor degradation rates. Please refer to **Section 2.2.2** for descriptions of PFAS nomenclature and PFAS groups and **Section 5.4** for discussion of transformation processes. Although **Table 4-1** is meant to be a compilation of biodegradation rates, not all studies described in **Table 4-1** have controls that definitively exclude the potential for *abiotic* transformation within the experiment. Additionally, not all studies had controls that excluded additional removal processes such as sorption.

Understanding the accumulation of PFAAs through biodegradation is important from a regulatory and risk assessment perspective. The mobility, toxicity, and bioaccumulation tendencies of terminal products appear to differ from the parent substances, and, as such, understanding the occurrence, diversity, and complexity of transformation pathways has become a priority in the assessment of PFAS risk. Consequently, documenting the current understanding of the number and types of transformation products, both terminal and intermediate, as well as the rates at which they are generated and transform, is an essential endeavor.

Additionally, the biological conversion of precursors can be impacted by remediation activities such as aeration in groundwater in the proximity of biosparging or air sparging wells (McGuire et al. 2014) or chemical oxidation (Houtz and Sedlak 2012). Understanding precursor transformations can also help in the assessment of appropriate remedial actions by enabling forecasts of transformation rates of various PFAS and enabling the quantification of "chemical retention" of PFAA precursors (future PFAAs) in a system alongside the geochemical retention of PFAAs through standard processes such as sorption or matrix diffusion (Newell et al. 2021). Collectively, the management of these retention processes is referred to as PFAS monitored retention (Adamson et al. 2025).

For further context, in most cases, cationic and zwitterionic PFAS tend to be retained in soil, whereas anionic PFAS exhibit greater mobility and are more likely to migrate into groundwater (see **Section 5**). Given that a significant proportion of zwitterionic and cationic PFAS are precursors—and considering that their retention in soil is not permanent—it is critically important to understand their transformation pathways and environmental fate. Further investigation into the fate and transport of zwitterionic and cationic PFAS is essential for assessing long-term contamination risks and developing effective remediation strategies (Tajdini et al. 2025)

Some studies of PFAS precursor biodegradation have focused specifically on PFAS present in AFFF. The study of PFAS transformation within AFFF sources has aided understanding of PFAS biodegradation pathways. Studies have shown that the pathways depend on the different source profiles produced by different AFFF production methods (for example, electrochemical fluorination [ECF] or fluorotelomerization, with precursors from these processes shown to degrade into perfluoroalkyl acids (PFAAs) as one of their terminal environmental products (Liu et al. 2021). To aid in general understanding of AFFF biodegradation pathways, some researchers have further classified precursors into primary and secondary ECF- or fluorotelomerization-based precursors. Primary precursors are those that were originally incorporated into AFFF formulations as intended PFAS components and are typically present at high concentrations. Secondary precursors, alternatively, are intermediate transformation products (excluding PFAAs) derived from primary precursors and are commonly detected in AFFF-impacted environments (Yan et al. 2024).

Awareness of complex PFAS precursor transformation pathways to intermediates and end products provides important context for understanding PFAS fate and transport. Development of reactive fate-and-transport models to predict the movement and behavior of PFAS in soil, water, air, and biota will require and benefit from enhanced understanding of biotransformation pathways and kinetics. By accounting for the diversity of transformation pathways and kinetic parameters, these models can provide more accurate assessments of PFAS behavior and environmental distribution.

1.3.3.2 Development of Precursor Transformation Database

The need for compilation of available precursor transformation kinetics was identified for practitioners to reference or use as guidance. A centralized table curated from peer-reviewed published literature was developed and presented as a tab named Biotransformation in **Table 4-1** to address this need.

Sources of data on transformation of PFAS in soil media were examined, giving priority to peer-reviewed scientific literature due to the vetted nature, traceability, and thus reliability of such data. All references

are included in the References tab of the table. While the data presented in **Table 4-1** are the current state of the science, the values are highly dependent on the experimental conditions. Study- or site-specific information extrapolated from **Table 4-1** to other situations may lead to erroneous assumptions of PFAS transformation rates and extent. Importantly, interested parties must be cautious about comparing half-lives or rate constants from different studies and using literature values from specific studies for other purposes. Additionally, some of the values are true biodegradation rates while others are based on source decay or release. For these reasons, the rate constants and related values presented in Table 4-1 should be considered estimates, since derivation of these parameters is sensitive to experimental conditions, substrates, and analytical error (since standards are not available for many precursors and daughter, intermediate, and downstream products).

Data Collection Method

Table 4-1 presents only papers in which a transformation rate or half-life was explicitly reported and thus does not represent the full extent of the published information on PFAS biotransformation. **Table 4-1** includes biotransformation pathways and kinetics for PFAS from a variety of sources, including AFFF. To access a detailed description of foam formulations and a compilation of PFAS frequently present in AFFF, please refer to **Section 3**. **Section 2.2.2**, and **Figure 2-5**, include information about the PFAS family and different groups and subgroups of PFAS.

The columns in **Table 4-1** include categories such as parent PFAS name, average atomic weight, primary daughter product(s), intermediate metabolites, downstream products (downstream metabolites, term defined and discussed below), the matrix in which the precursor transformation experiments or observations were completed, the period of observation (defined as assay length), geochemical condition under which the transformation rates were observed, the transformation kinetics information identifying if the values are half-lives or rate constants, and published literature references. Numerous studies in the scientific literature provide qualitative descriptions of transformation pathways and product accumulation; however, they were not included in this compilation because they do not explicitly report transformation rates or half-lives. Additionally, many studies present precursor transformation data—such as concentration versus time plots—without calculating or reporting a rate or half-life. These studies were also excluded from the database.

Perfluoroalkyl Acids Precursors in Table 4-1

The following 13 groups of PFAA precursors will be discussed for precursor transformation:

- fluorotelomer carboxylic acids (FTCAs)
- fluorotelomer sulfonic acids (FTSAs)
- perfluoroalkane sulfonamides (FASAs)
- perfluoroalkane sulfonamidoethanols (FASEs)
- perfluoroalkane sulfonamido acetic acids (FASAAs)
- fluorotelomer alcohols (FTOHs)
- polyfluoroalkyl phosphate esters (PAPs)
- polyfluoroalkyl amine oxides (PFNOs)
- perfluoroalkyl ether carboxylic acids (PFECAs)
- perfluoroalkyl ether sulfonic acids (PFESAs)
- other perfluoroalkyl compounds
- polyfluoroalkyl ether acids
- polymer mixtures

In addition to the above groups, there are some studies listed that report degradation of perfluoroalkyl acids, although most of these values are NDO (no degradation observed). The environmental matrix considered was primarily soil. However, if high-quality data were available in other media, including

activated sludge and sediment, they were also recorded. Experimental conditions included both aerobic and anaerobic systems, but most data were obtained under aerobic conditions.

Of the 13 different groups listed above, limited information was available for four groups, namely FASAs, FASAAs, FTOHs, and PAPs. Additional research is needed for precursor transformation rates.

Transformation Product Categories

The sequence or network of transformation products was split into different categories:

- intermediate products
- daughter products
- downstream products (downstream metabolites)
- terminal products

Intermediate products: Intermediate products were identified as detected compounds present in the transformation pathway between the parent and daughter product for which the reaction rate or half-life was reported. In cases where the intermediate product was reported, the authors determined the rate constant or half-life through the measured accumulation of the specified daughter product.

Daughter products: The daughter products were those determined to represent the reported rate constant or half-life at the authors' discretion. Many papers were not explicit and reported the reaction rates in relation to the removal of the parent compound but not in relation to the formation of a specific daughter compound. In these instances, the first measured compound identified in the transformation pathway resulting from the measured decrease in concentration of the parent/precursor compound was considered a daughter product. In some cases, the metabolic pathways were not singular and multiple daughter products were possible. In these instances, more than one daughter product was listed.

Downstream products: Downstream metabolites were any compounds detected as degradation products further along the reported pathway than the daughter product. Some papers reported molar yields or relative concentrations of multiple metabolites detected. This information was included in the table where available. PFAAs were the most frequent terminal products. However, given that many of the studies did not continue until complete transformation of the parent compounds, the publications identified partial degradation of compounds at different points along the transformation pathway. Relative concentrations of downstream metabolites documented a time-specific extent of transformation in the degradation pathway.

Terminal products: Terminal products are a subset of downstream metabolites after which there is most likely no further transformation. They are most often PFAAs. A few studies that investigated PFAAs as parent compounds and observed no further degradation have also been included in **Table 4-1**, providing additional support for the characterization of PFAAs as terminal transformation products.

Transformation Kinetics

Transformation kinetics data for the precursor/parent PFAS and transformation products such as reaction rate constants and half-life estimates were mined from sources whenever available. Liu and Liu (2016) found a negative correlation between the half-lives and corresponding molecular weights of 11 PFAS that undergo biotransformation in aerobic soils. This indicates that molecular weight may serve as a reliable indicator of the overall stability of low molecular weight PFAS that have shorter carbon-fluorine chains in aerobic environments. To provide a standardized frame of reference, whenever only either the rate constants or the half-life values were provided, the other value was calculated assuming the transformation reaction followed a first-order kinetics model. This occurred unless otherwise indicated in the study. Additionally, a few studies reported no observable degradation for certain PFAS; in these cases,

the kinetic data were recorded as no degradation observed (NDO). Importantly, reaction rates depend on factors such as temperature, pH, oxidation-reduction potential, moisture content, and similar parameters. Kinetic values should be considered site-specific and may vary over time. The reaction rates presented in **Table 4-1** are intended to provide a general understanding of which products are likely to prevail during transformations.

Transformation Conditions

Most reported transformations occur under aerobic conditions, which favor oxidizing reactions. Under anaerobic conditions, PFAAs are not always formed (**Section 5**). Experimental (or field) conditions such as temperature, pH, test duration, soil type, and test settings (for example, microcosm, culture) are recorded in **Table 4-1**. Transformation has been observed with multiple soils (except for some sulfonamide precursors), usually in presence of alternate organic substrates (for example, glycols in AFFF, acetate, glucose), suggesting some of the transformations may be catalyzed by microorganisms using these primary substrates via nonspecific oxygenases with cometabolic pathways for PFAS transformation (Yang et al. 2022; Olivares et al. 2022; Ruyle et al. 2023). Some studies have also reported the role of sulfur limitation in fluorotelomer transformation (Van Hamme et al. 2013).

1.3.3.3 Applications

The present envisioned uses for this type of PFAA precursor transformation data include:

- mapping of observed and traceable degradation pathways for contaminant forensics and fingerprinting
- introduction of reliable input variables for reactive transport models
- PFAS exposure assessments in which both PFAA precursors and PFAAs are present in the environment or within organisms for bioaccumulations models (Glaser et al. 2021)
- development of a baseline for prioritization of exposure and toxicity studies
- development of site-specific degradation rate estimations

As regulations continue to evolve to address PFAS impacts, including diverse transformation pathways in risk assessments is important to ensure regulatory compliance and design effective mitigation strategies. Understanding the full spectrum of PFAS transformation pathways helps regulators, remediation practitioners, and local infrastructure decision makers and operators to set appropriate guidelines and timeframes for PFAS management and remediation efforts. Accurately clarifying the diversity and complexity of PFAS transformation pathways in fate-and-transport modeling is essential for a comprehensive understanding of the environmental impact, human exposure risks, and regulatory implications associated with these persistent chemicals.

1.3.4 Groundwater Partitioning, Colloidal Transport, GW-SW Interactions

The following supplements **Section 5.2.5** and **Section 5.3.4** by further discussing the fate and transport of PFAS in groundwater and the effects of co-contaminants, colloidal transport, and groundwater-surface water interactions.

1.3.4.1 Co-contaminant Effects on Fate and Transport

In addition to the effects of aqueous chemistry and soil interactions, PFAS fate and transport may be affected by the presence of co-contaminants. **Section 5.2.5** provides a discussion of interactions

between PFAS and co-contaminants, including light nonaqueous phase liquid (LNAPL). Key interactions are as follows:

- LNAPL may contribute to PFAS retention via phase partitioning or interface accumulation; where only residual (immobile) LNAPL is present, LNAPL may contribute to a reduction in PFAS flux.
- PFAS accumulation at the LNAPL/water interface is likely to be less than accumulation at the AWI.
- LNAPL biodegradation can deplete oxygen, causing a local transition from aerobic to anaerobic conditions, which may affect the transformation of PFAS precursors.

Ongoing research continues to provide additional insights into PFAS interactions with co-contaminants. Multiple studies have evaluated relative effects of phase partitioning and interface partitioning in water-LNAPL systems, and many of these studies have involved calculation of partition coefficients for both processes. These studies have generally involved only a single co-contaminant (or a small number), whereas real-world scenarios involving multicomponent mixtures of PFAS and LNAPL (or other co-contaminants) are limited. In general, PFAS retention due to interface partitioning is reported to be greater than retention due to partitioning into bulk nonaqueous phase liquid (NAPL) phases. An overview of these studies is provided in the remainer of this section.

It should be noted that the authors of these studies use slightly different definitions for the terms and coefficients they present. Generally, three terms are commonly used: solid-phase partition (absorption) coefficient, K_d; NAPL-water partition (absorption) coefficient, K_n; and NAPL-water interface adsorption coefficient, K_{nw}. Interface adsorption may also be referred to as interfacial adsorption or accumulation. "Partition coefficient" may be used as a general partitioning term (K) or may be used to describe media-specific partitioning (for example, K_d). In some instances, the term "sorption coefficient" is used to describe absorption or adsorption if the precise nature of the partitioning is not determined.

Christie et al. (2023) explored the need to account for residual LNAPLs at AFFF-impacted sites as potential sources of PFAS contamination. Though interface accumulation was not studied, insights into AFFF formulations and occurrence in groundwater were provided. The research group evaluated PFAS in bulk LNAPL from groundwater monitoring wells at military AFFF sites, using targeted and non-targeted analytical methods for anionic and neutral PFAS (that is, fluorotelomer alcohols). PFAS were detected in most LNAPL samples, with most frequently detected compounds including PFOS (nondetect to 11,100 ng/L) and perfluoroalkyl sulfonamides, such as perfluorohexanoic acid (PFHxSA) (nondetect to 67,700 ng/L). Insights were provided into the source AFFF, with some samples showing signatures of various AFFF formulations (for example, ECF versus fluorotelomerization). The analysis evaluated bulk LNAPL and did not evaluate interface accumulation. The presence of residual LNAPLs at AFFF-impacted sites should be factored into the planning and execution of remediation strategies.

Fang et al. (2024) explored the partitioning of PFAS in LNAPL; they found that PFAS partitioning was significantly influenced by both the structure of PFAS and the characteristics of LNAPL, with LNAPL potentially serving as a transport reservoir. The team investigated the partitioning of six PFAS (PFBA, PFOA, PFBS, PFOS, 6:2 FTS, and 8:2 FTS) into a weathered, field-collected LNAPL. Individual partition coefficient (K, defined as ratio of LNAPL concentration to aqueous concentration) values were determined via batch experiments. The study showed that 1) K values increase with increasing perfluorocarbon chain length; 2) K values increase with greater C-F to C-H bond ratios; and 3) the structure of the head group did not strongly affect the K values. In all cases, a higher initial aqueous concentration of LNAPL resulted in a greater K value. The study demonstrated that batch experiments may be useful for determining LNAPL/aqueous partition coefficients for PFAS. Similar to Christie et al. (2023), this analysis evaluated bulk LNAPL and did not evaluate interface accumulation.

Ding et al. (2022) evaluated interaction between PFAS and chlorinated volatile organic compound dense nonaqueous phase liquid (DNAPL) associated with a fluoropolymer manufacturing facility. Chlorinated volatile organic compounds present at the site include dichloromethane, trichloromethane, 1,1,2-trichloroethane, carbon tetrachloride, trichloroethene, and tetrachloroethene (PCE). Seventeen target PFAS were analyzed, including select PFCAs, PFSAs, and precursors. Laboratory experiments and field samples were evaluated to calculate sorption coefficients (referred to by the authors as K_d). In field samples, elevated PFAS concentrations were detected in groundwater, with PFOA as high as 204 µg/L. Laboratory experiments showed that the presence of DNAPL caused the K_d values for nearly all PFAS to increase. The values increased with an increase in carbon chain length, with the K_d for PFOA increasing by a factor of nearly 4 in the deep aquifer (where DNAPL was inferred to be present). Similar to the studies discussed above, no investigation was made between absorption of PFAS into the bulk DNAPL versus adsorption of PFAS to the water-DNAPL interface.

Liu et al. (2024) evaluated the impact of heterogeneous LNAPL on PFAS transport via a laboratory study comprising two-dimensional (2-D) flow cells. Decane and PFOS were used as model NAPL and PFAS, respectively. Two flow regimes were created, one with NAPL in residual saturation and a second with NAPL in greater than residual (pool) saturation. An influent PFOS concentration of 30 mg/L was used to represent concentrations found in source zones. The method of temporal moments, a commonly used method for analyzing concentration breakthrough curves by comparing theoretical moments of concentration to breakthrough data (Pang et al. 2003), was used to calculate retardation factors, including the effects of solid-phase adsorption, NAPL-water interfacial adsorption, and absorption into bulk NAPL. The K_n value for PFOS in decane was measured at 0.02. The retardation factor in the NAPL residual saturation flow cell measured by moment analysis was 1.7, with solid-phase adsorption, NAPL-water interfacial adsorption, and NAPL absorption being 0.56, 0.43, and 0.1, respectively. The retardation factor in the NAPL pool flow cell measured by moment analysis was 1.4, which was attributed to minimal contribution to retardation by NAPL-water interfacial adsorption due to flow bypass. In 3-D numerical simulations, the retardation factors varied from 1.13 to 2.65, with higher values being associated with closer proximity to the NAPL source zone. Therefore, the spatial distribution of LNAPL likely influences PFAS mobility, retardation, and occurrence of potential preferential pathways for PFAS transport.

Van Glubt and Brusseau (2021) studied PFAS retention by NAPL partitioning and interface adsorption, as well as the effect of PFAS on NAPL mobilization and distribution. PFAS aqueous solutions contained PFOS, PFOA, or PFPeA (perfluoropentanoic acid), while decane and trichloroethene (TCE) were used as NAPLs. Batch and column experiments were used to determine partitioning of PFAS into the bulk NAPL phase and PFAS transport in the presence of residual NAPL. Batch solubilization experiments were conducted to investigate the effect of PFOS concentrations on the aqueous concentration of TCE. Column experiments were also used to determine whether PFAS could cause NAPL mobilization. Batch experiment-derived K_n values for PFOS were 0.11 in TCE and 0.022 in decane, while batch experiment-derived K_n values for PFOA were 0.19 in TCE and 0.065 in decane. For NAPL-water interfacial tension, the activity was observed to increase with carbon chain length. Other factors influencing K_n values include the protonation/deprotonation status of the PFAS, as described by the pK_a value. Overall, the K_n values for PFOS and PFOA are small compared to other NAPLs. Retardation factors for PFOS in columns with TCE NAPL ranged from 2.5 to 3.3, while for decane NAPL they ranged from 1.7 to 2.6. The retardation factor for PFOA in a column with TCE NAPL was 1.5. However, the contribution of partitioning to the bulk NAPL phase was minimal for all these experiments, ranging from 0.5% to 19% of total retention. The results of Van Glubt and Brusseau (2021) also suggest that PFAS typically only significantly affect NAPL solubilization and mobilization when present at high concentrations (hundreds of milligrams per liter) that are rarely observed at legacy AFFF source-zone sites but may apply to both recent AFFF releases and historical-release situations.

Kosteleros et al. (2021) performed laboratory studies looking at the effects of LNAPL (jet fuel) on AFFF mobility in the vadose zone. These studies were conducted on five AFFFs and one fluorine-free foam using phase behavior and column experiments. The latter were performed to mimic AFFF migrating

through the soil column and encountering LNAPL. The outcomes found that there was the formation of a microemulsion that had a higher viscosity than either the LNAPL or the AFFF and was immobile and stable in the laboratory for at least one year. The result also showed that the LNAPL was a sink for the surfactants/PFAS associated with AFFFs. No conclusions were generated concerning the long-term stability in the environment of the microemulsion, including binding the PFAS/LNAPL in place. Nor was there an evaluation of impact on the biodegradation rate of the LNAPL.

Liao et al. (2022) investigated the effect of residual NAPL on transport and retention of individual PFAS and PFAS mixtures. The six PFAS employed were PFBS, PFHxS, perfluoroheptanoic acid (PFHpA), PFOA, PFOS, and perfluorononanoic acid (PFNA). Tetrachloroethene (PCE) was chosen as the NAPL. Interfacial tension measurements were conducted with PCE NAPL and aqueous-phase PFAS, and batch reactor experiments were used to assess PFAS partitioning into PCE NAPL and adsorption on the solid phase. Column experiments were performed to investigate the impact of residual PCE NAPL on PFAS transport in a quartz sand, and a mathematical model was developed to account for PFAS accumulation at the NAPL-water interface and partitioning into the NAPL and solid phases. PFAS partitioning into PCE NAPL was linear. The PFOS NAPL-water coefficient K_{nw} was 0.098, while the PFNA NAPL-water coefficient K_{nw} was 0.048. The NAPL-water coefficient K_{nw} for PFOA, PFHpA, PFHxS, and PFBS in a mixture ranged from 0.028 to 0.034. There was a minimal effect on partitioning values due to the PFAS being in a mixture. The sand mixture was found to have a low adsorption capacity for PFAS in column experiments. Column experiments were then performed with a residual PCE saturation of 16%, using PFOS and PFNA. These experiments showed a delay in peak arrival times, with NAPL-water interfacial accumulation accounting for 83% and 88% of the retardation for PFOS and PFNA, respectively. In contrast, PFBS, PFHpA, PFHxS, and PFOA were only slightly delayed in their breakthrough, showing that they minimally accumulate at the NAPL-water interface. Also, the effect of PFAS on PCE solubility was minimal over a PFAS concentration range from 0.01 to 10 mg/L.

Costanza et al. (2020) focused on NAPL-water and air-water interfacial tension values for PFOA, PFOS, perfluorooctane sulfonamide (FOSA), and AFFF formulations at concentrations from 0.1 to 1,000 mg/L. NAPLs tested included jet fuel, PCE, and dodecane. Interfacial tensions were measured for both air-water and NAPL-water experiments. Of note are the calculations performed for the mass of PFOA, PFOS, and FOSA in the aqueous phase, adsorbed to soil, and at the air-water and dodecane-water interfaces for a sandy soil. These results showed that for concentrations below 1 mg/L, most of the mass of PFOA, PFOS, and FOSA is at the AWI, and little is at the dodecane-water interface with a dodecane saturation of 2%. This study highlighted the importance of PFAS accumulation at the AWI in assessing mass transport of PFAS in aqueous systems.

Brusseau (2018) proposed a comprehensive conceptual model for PFAS retention and transport in porous media systems. Literature was searched for physicochemical property data, including phase-distribution coefficients, for PFOA and PFOS, which were then used to calculate retardation factors. Each of the phase-distribution coefficients contributes to the combined retardation factor in a porous media system, including air-water partitioning, adsorption at the AWI, adsorption to the solid phase, NAPL-water partitioning, and adsorption at the NAPL-water interface. Assumptions in the conceptual model included the insignificance of gas phase transport relative to aqueous-phase transport (thereby making volatilization to the gas phase a retention process), and that NAPL is immobile and has a minimal impact on solid surfaces in terms of blocking solid phase adsorption. A sandy quartz vadose zone soil with moderately low organic content, a water saturation of 78%, a NAPL saturation of 2%, and an air saturation of 20% was assumed. PFOA, PFOS, and 8:2 fluorotelomer alcohol (a precursor to PFOA and other PFCAs such as PFNA and PFHpA) were included. Partition coefficients were gathered from the literature. Notably, reported K_{ow} values were used as a surrogate for K_{nw} partition coefficients. For PFOA and PFOS, the contribution of NAPL-water partitioning was small: for PFOA, the total retardation factor was 14.1, with NAPL-water partitioning contributing 16%; for PFOS, the total retardation factor was 47.9, with NAPL-water partitioning contributing 8.2%. For both PFAS, the dominant contributor to retardation was air-water interfacial adsorption. For FTOH, however, NAPL-water partitioning contributed 98% to the total

retardation factor of 9,906. This study (Brusseau 2018) did not involve any laboratory or field aspects. It is important to note that the K_{ow} values used as surrogates for K_{nw} values ranged from 83 (PFOA) to 282 (PFOS) to 380,189 (FTOH). It is important to better understand the K_{nw} for FTOH given its role as a PFOA precursor. Last, because the model developed by Brusseau (2018) was based on the available literature at the time, more recent literature should be used for the partition coefficients of the subject PFAS if the model is to be used. **Table 1-6** summarizes the partition coefficients in this section.

Please note Table 1-5 was removed from the document and webpage.

Table 1-6. Summarized PFAS: NAPL partition coefficients (based on references in this section).

PFAS	Weathered LNAPL	Decane	TCE	PCE
PFBA	0.02 to 0.22			
PFBS	0.06 to 0.33			0.0291
PFOA	7.485 to 9.034	0.02 0.065[1]	0.19[1]	0.0321
PFOS	11.65 to 38.8	0.022[1]	0.11[1]	0.098
6:2 FTS	1.11 to 1.52			
8:2 FTS	18.69 to 19.10			
PFNA				0.048 0.0402
PFHpA				0.0276
PFHxS				0.0340

[1] Batch NAPL-partitioning experiment values from Van Glubt and Brusseau (2021).

1.3.4.2 Colloidal Transport of PFAS in Groundwater

Colloid and colloid-facilitated solute transport have been investigated in the subsurface in recent years. Deb and Chakma (2023) "identified fundamental mechanisms of colloid mobilization and the principal mathematical relationship describing colloid transport including attachment-detachment, size exclusion, and air-water interfacial area." The paper also considered mobile colloid attachment at the AWI and the air-water-solid contact line present during infiltration and water table fluctuations.

Bierbaum et al. (2023) investigated the sorption processes that affect PFAS transport during leaching by creating a continuum model and a particle tracking model and comparing results to data from previously conducted column and lysimeter experiments. The authors proposed that colloid-facilitated transport in column and lysimeter experiments resulted in "premature leaching" of PFOA and PFOS. Sorption processes investigated included equilibrium and rate-limited sorption to soil and AWIs, and colloid-facilitated transport. The study highlighted that precursor transformation may be more relevant for long-term leaching of PFAS in the environment compared to rate-limited sorption, and that AWI sorption has the potential to be the dominant retention mechanism at PFAS-contaminated sites. The authors also noted that results of the model simulations suggest that "premature leaching" may be a result of colloid-facilitated transport, and that this mechanism appears to be more significant for PFOS than PFOA, likely due to the increased sorption affinity of PFOS compared to PFOA.

Borthakur et al. (2021) noted that flow interruptions from groundwater injection in clay-rich soil caused increased leaching of PFBA and PFOA associated with increased soil colloid concentrations. Concentrations of PFOA were higher than PFBA in effluent samples, indicating that colloid transport is more significant for long-chain PFAS due to their higher sorption affinity. This was corroborated in a

series of column studies by Das et al. (2024) to simulate managed aquifer recharge, which showed that a greater fraction of PFOS in the effluent was associated with particulates compared to PFBS, which was predominantly in the dissolved phase. The authors noted that colloids may play a higher role in PFAS transport in conditions that release colloids (Borthakur et al. (2021), which could include natural fluctuations in groundwater flow, extreme precipitation events, or soil disturbance.

Microplastics are often associated with PFAS and can be transported as colloids (see **Section 1.8.4**).

1.3.4.3 Groundwater–Surface Water Interactions

Understanding the fate and transport of solute contaminants at the groundwater-surface water interface is an important component of site characterization and CSMs (see **Section 16.7**). This interface (also known as the hyporheic zone) consists of saturated sediments comprising streambeds, stream banks, and floodplains that exist between surface water and underlying/laterally adjacent aquifer materials. **Section 5.3.4.1** discusses PFAS in the hyporheic zone in the context of how changing redox conditions can affect biodegradation. This section provides information for additional topics and references.

Bed sediments often have different physical and chemical characteristics relative to the aquifer itself. These characteristics include:

- reduced hydraulic conductivity associated with silt and clay (discretized as a zone of reduced "conductance" in groundwater flow models)
- increased organic carbon content
- changes in geochemical parameters (redox, solute concentrations)
- presence of biota
- brackish, saline, and tidally influenced conditions in coastal areas

As discussed in **Section 5.2.3**, sorption of PFAS can be influenced by a variety of factors, including grain size, organic carbon (OC), presence of co-contaminants, and carbon chain length of the PFAS molecule. In general, the characteristics of the hyporheic zone would tend to inhibit PFAS flux in groundwater by reducing seepage and enhancing sorption to OC.

In coastal areas, PFAS sorption to the aquifer or sediment matrix is enhanced by the ionic strength of brackish or saline water. Early in the progression of PFAS research, Chen et. al (2012) noted that sorption of PFOS to marine sediments was strong—approximately 10 times higher than that in fresh water. The sorption affinity was well correlated with the sediment OC content, confirming the significance of hydrophobic interactions. This phenomenon is more recently referred to as "PFAS salting out," defined by Hort et al. (2024); (see **Section 1.3.5.1** for more details on the salting-out effect), which becomes an increasingly dominant process as "PFAS in fresh groundwater mixes with saline groundwater near marine shorelines, resulting in increased sorption to aquifer solids" (Hort et al. 2024).

Studies that directly explore PFAS behavior at the groundwater–surface water boundary are sparse, with some authors calling for more research in this area (Divine et al. 2023). Tokranov et al. (2021) examined the impact of groundwater–surface water boundaries on PFAS transport and transformation in a flow-through lake, fed by contaminated groundwater, and its downgradient surface water–groundwater boundary. PFAA precursors made up 45% of the total PFAS concentration in the oxic lake, which was impacted by a fire training area and historical wastewater discharges. In shallow porewater downgradient from the lake, the proportion of PFAA precursors decreased by 85%; the decrease was attributed to enhanced precursor transformation at the boundary between surface water and groundwater. Tokranov et al. (2021) also explored the effect of seasonality on both sorption capacity and transformation rates in the hyporheic zone. The study noted increased PFAA concentrations in the hyporheic zone and in groundwater downgradient of the lake in winter months, showing an inverse correlation with temperature (increased PFAA with decreased temperature) and a strong inverse correlation with nitrate. Seasonal

changes could not be explained by precursor transformation or AWI sorption. The authors noted large temporal variations in field-derived K_d values and suggested that future work should investigate whether there are biological mechanisms driving sorption. Tokranov et al. (2021) conclude that biogeochemical conditions at the groundwater-surface water interface result in complex and competing transport and transformation processes.

Given the large number of variables affecting PFAS interactions in the hyporheic zone, practitioners may find it advantageous to collect site-specific data. In these instances, several tools exist to characterize site-specific partitioning of PFAS to the range of media and phases and to measure flux of PFAS between groundwater and surface water. These include drive-point piezometers, porewater samplers (USEPA 2023), seepage meters, tide charts, stilling wells (gauged or with pressure transducers), sediment cores, and biological tissue sampling.

PFAS passive samplers are also becoming available for deployment in sediments at the groundwater-surface water interface that allow for discrete, time-weighted sampling and the assessment of PFAS distribution and flux (Eldridge et al. 2025; Carter et al. 2025). See also the ITRC "Passive Sampling Technology Update" (ITRC 2024).

1.3.5 Understanding PFAS in Marine Environments

This section describes some of the key factors affecting the fate of PFAS in transport from fresh water to the marine environment, in ocean spray via aerosolization and in ocean foam, as well as the bioaccumulation of PFAS to marine life. This topic supplements **Section 16** and **Section 5.3.4**, which address PFAS in a freshwater environment.

1.3.5.1 Salting-Out Effect

An important factor influencing the behavior of PFAS at the freshwater/marine water interface is the salting-out effect. As discussed below, the solubility of PFAS decreases in the presence of elevated salinity in water (that is, high cation and anion concentrations), and PFAS has a higher tendency to sorb to solid-phase materials. This process has the potential to increase retention of PFAS in saline environments. This phenomenon was observed by Munoz et al. (2017) in a survey of PFAS in an estuary discharging to the Atlantic Ocean in France. These authors observed an increase in the affinity of PFAA compounds to particulate matter in the presence of increasing saltwater concentrations. Using field data, these authors derived sorption coefficients based on both particle concentration and salting-out effects for C7–C9 PFCAs and C6–C8 (branched and linear) perfluoroalkane sulfonic acid (PFSA).

Yin et al. (2022) conducted a series of PFAS sorption/desorption studies at different salinities using marine sediment collected from the South China Sea. The results showed that the sorption coefficient increased with increasing PFAS chain length and salinity, indicating that hydrophobic and electrostatic processes are involved. In a literature-based study of PFAS in groundwater plumes discharging to sandy beaches, Hort et al. (2024) used a multivariate regression model developed from data at three PFAS sites to estimate the increased sorption of PFOS with ionic strengths as follows:

- low ionic strength (< 10 ppt), estimated a 1- to 2.5-fold increase in PFOS sorption
- medium ionic strength (10 to 20 ppt), a 2- to 6.4-fold increase in PFOS sorption
- higher ionic strength (> 20 ppt), a 3.8-fold to 25-fold increase in PFOS sorption

In an earlier study, López-Fontan et al. (2005) demonstrated the gradual micellization (self-aggregation) of sodium perfluorooctanoate (SPFO) in water with increasing ionic strength. At low ionic strength (0.01 mol decimeter^{-3} [dm]$^{-3}$), pre-micelles of perfluorooctanoate ions are formed. At 0.02 mol dm^{-3}, sodium ions (Na^+) are captured and form micelles at a critical micelle concentration of 0.03 mol dm^{-3}. At the

critical micelle concentration, the micelles are significantly ionized. At around 0.06 mol dm^{-3}, the degree of ionization was lower, suggesting the micelles are more compact.

Other studies have found that the type of cation present in the saltwater environment can influence the salting-out effect. In a series of isotherm studies, Steffens et al. (2021) found that divalent cations such as Ca^{2+} and Mg^{2+} resulted in more surface aggregation (accumulation at the air-water interface, see **Section 4.2.8**) and bulk aggregation (formation of micelles see **Section 4.2.7**) of PFOS at lower ionic concentrations compared to monovalent cations such as Na^{+} and K^{+}. Similarly, column experiments by Li et al. (2021) showed that an increase in ionic strength led to greater retardation of PFOA in unsaturated columns, and that Ca^{2+} resulted in greater retardation than Na^{+}. Using a mass-action model to determine the impact of monovalent versus divalent salts on the air-water partitioning coefficients for PFOA, Le et al. (2022) also found that divalent cations had a much larger impact on increasing the air-water distribution coefficient of PFOA than monovalent cations. An earlier column study by Lyu and Brusseau (2020) noted that while PFOA retardation was affected by changes in ionic strength under unsaturated conditions, the impact was minimal under saturated conditions—emphasizing the importance of the AWI to adsorption and retardation.

Based on literature, Hort et al. (2024) identified conceptual mechanisms for the retention of PFAS in groundwater and saturated soils with high salinity: neutralizing surface charge; salting out process leading to: increased sorption to solids and increased AWI sorption; bridging by divalent cations, leading to increased sorption to solids; and, increased formation of micelles from increased cation concentrations.

Last, several studies have shown that the type of PFAS also influences the salting-out effect and the retention of PFAS. For example, Yin et al. (2022) showed that the sorption of PFCAs on marine sediments was lower than PFSAs with the same chain length, and PFOS showed much stronger sorption than 6:2 FTSA. As discussed by Steffens et al. (2021), although the PFAS C-F bond exhibits low polarizability (see **Table 4-2**), the functional head of individual PFAS (for example, carboxyl, sulfonate) governs the extent of polarizability (see **Section 2.2.3**). Others cited by Steffens et al. (2021) have shown a higher polarizability of PFOS than of PFOA, resulting in greater increases in K_d values for PFOS compared to PFOA in increasingly saline solutions.

In a series of column leaching studies using different soils contaminated with AFFF, Tsou et al. (2024) demonstrated that the type of PFAS has an influence on its fate in a saltwater environment. These authors found that PFOA moved through the columns faster than other PFAS analytes tested (PFOS and two precursors) at all water salinities tested. However, zwitterionic PFAS moved through the columns at different rates depending on the charge of the terminal group (and the soil type tested). Salt water accelerated the transport of a positive terminal group zwitterion, N-dimethyl ammonio propyl perfluorohexane sulfonamide (AmPr-FHxSA), but slowed down zwitterions with a terminal negative charge, such as, 6:2 fluorotelomer sulfonamido betaine (6:2 FTAB). These authors also reported that salt water increased the mobility of the branched AmPr-FHxSA.

1.3.5.2 Hydrodynamic Effects

Hydrodynamic effects such as tidal currents, wind action, and wave action can influence the amount of mixing of groundwater and salt water and , in turn, the occurrence and distribution of PFAS in the marine environment. An example of this is the salting out effect discussed in **Section 1.3.5.1** which is driven by fresh water-salt water gradients that are influenced by currents and wind and wave actions (Santos et al. 2012; Robinson et al. 2018). As noted by Hort et al. (2024), based on Robinson et al. 2007), the extent of mixing is influenced by the magnitude of the groundwater influx, the tidal range, coastal topography, and the aquifer's hydrogeology. Of these, the groundwater flux and tidal amplitude were found to have the greatest influence. The relative strengths of these two forces will determine the extent of the mixing within a shallow coastal aquifer and subsequent discharge into an estuarine/marine environment.

For an aquifer with a low groundwater flux relative to the tidal amplitude, the saline water will be able to circulate through the nearshore shallow aquifer to a much greater extent. Under these circumstances (and depending on the PFAS present), the salting-out effect could be an important attenuation mechanism for PFAS in nearshore aquifers and limit the discharge of PFAS to the ocean (Newell et al. 2021; 2022). In a modeling study of groundwater dynamics in a coastal aquifer, Li et al. (2022) demonstrated that the salting-out effect reduced the peak PFOS discharge rate and its dispersion in a discharged plume. In addition, these authors observed that PFOS became concentrated at the center of the upper saline plume where salinity concentrations were higher, forming a lobe-shaped plume. Furthermore, these authors observed that the salting-out effect for PFOS was more pronounced at greater tidal amplitudes, particularly at tidal amplitudes > 0.25 meters (no impacts observed at tidal amplitudes of < 0.25 meters or for small solid-water sorption coefficients of around 0.1 L/kg). Last, as noted by Hort et al. (2024), the sorption of PFAS to beach sediment means there is also the potential for the PFAS to be remobilized should salinity change, which could be an important factor to consider in beach/estuary environments. which could be an important factor to consider in beach/estuary environments.

Other factors such as the concentration of suspended particulates, sediment OC, and biogeochemical factors have been reported to influence the fate and transport of PFAS in the freshwater environment (see **Section 5.3.4**) and are likely to also play a role in the fate of PFAS in the marine environment.

1.3.5.3 Aerosolization and Ocean Foam

This section presents the causes of aerosolization and the formation of foam in oceanic environments, as well as how those two processes affect PFAS in the environment.

Aerosolization

Aerosolization is the process whereby air trapped below the water surface due to wave action scavenges particles such as salt and PFAS from the water and releases them to the atmosphere as bubbles burst. This was described in a study by McMurdo et al. (2008) regarding the aerosol enrichment of the anionic perfluorooctanoate (PFOA). In a series of laboratory studies, these authors demonstrated that wave-induced aerosols had significantly higher concentrations of PFOA than the source water body. In addition, these authors speculated that the PFOA on the droplet surface is protonated, which is the acid form of PFOA that is released to the atmosphere. In a 2021 paper regarding sampling of sea spray aerosol and PFAS in Norway, the authors stated that there are three main sources of PFAS to the atmosphere: "(1) direct emission from manufacturing sources such as fluoropolymer plants, (2) formation in the atmosphere via degradation from volatile precursors such as fluorotelomer alcohols (FTOHs), and (3) water-to-air transfer via sea spray aerosol (SSA) emission" (Sha et al. 2021). SSA emissions occur at the shoreline and away from shore following wave and wind action. The following focuses on this third source because of wave action at the shoreline and what it means for aerial transport of PFAS.

According to a study published by de Leeuw et al. (2011), SSA consists mainly of liquid droplets suspended in air that are generated at the surface of the sea. The radii of the droplets range from around 10 nanometers to at least several millimeters, but most are less than 1 micrometer (µm). The residence time of the SSA in the atmosphere ranges from seconds to minutes for the larger droplets (removal by gravitational force) to days for the smaller particles (removal primarily by rainfall). The longer the residence time, the greater the potential distance that SSA particles can travel. It is estimated that SSA particles that are 1 µm in size (at 80% humidity) can travel up to 1,000 kilometers (Radoman et al. 2022).

The formation of SSA is not complicated. As waves crash upon the ocean surface, air becomes entrained in water in a cloud of bubbles. These bubbles work their way upward to the surface and burst. When a bubble bursts, upward of 1,000 droplets are released into the atmosphere. The number and size of droplets released from each bubble depend primarily on the size of the bubble (**Figure 1-4**).

As air is entrained below the sea surface, surface-active substances such as PFAAs and decaying organic matter can be captured at the AWI of the bubbles. As the bubbles burst, the SSA released to the atmosphere will include the PFAS, along with organic matter, salt ions, and similar substances found in ocean water. Sha et al. (2021) used laboratory-derived enrichment factors, along with measured concentrations of PFOS and PFOA in seawater. They concluded that the fluxes of PFOS and PFOA to the atmosphere provided by SSA "were comparable with the other two sources of atmospheric PFAAs (that is, direct emission from manufacturing sources and degradation from volatile precursors), suggesting the potential of SSA as an important source of PFAAs to the atmosphere" (Sha et al. 2021).

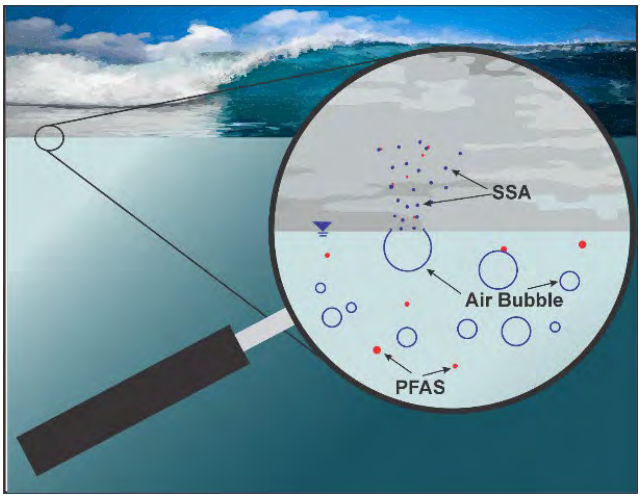

Figure 1-1. Illustration of air trapped below the water surface.

Source: A. MacDonald, used with permission.

Casas et al. (2020) sampled seawater, the surface microlayer (SML), and SSA simultaneously. Results were compared to determine SML and SSA enrichment factors. The calculated enrichment factors ranged from 1.2 to 5 for the SML and 522 to 4,690 for the SSA, the latter of which was estimated by normalizing atmospheric PFAS in SSA based on measurements of Na^{+} as a representation of the amount of seawater released during bubble bursting and wind driven SSA formation. Casas et al. (2020) concluded that "the amplification of concentrations in the SML is consistent with the surfactant properties of PFAS, while the large enrichment of PFAS in atmospheric SSA may be facilitated by the large surface area of SSA and the sorption of PFAS to aerosol organic matter." In addition, as discussed in **Section 1.3.5.1**, Steffens et al. (2021) found that the presence of seawater ions such as Ca^{+2} and Mg^{+2} enhanced the enrichment of some long-chain PFAS. Casas et al. (2020) noted that the implications of these findings include interactions with microorganisms inhabiting the surface layer as well as SSA playing a role in the global transport of PFAS.

Studies by McMurdo et al. (2008), Sha et al. (2021), and Casas et al. (2020) support the conclusion that aerosolization in seawater scavenges PFAS from oceanwater and releases it to the atmosphere, where it can potentially be transported long distances. Aerosolization can therefore be a cause of potential exposure, primarily via the inhalation route, from the shoreline to potentially considerable distances inland. The concentrations of PFAS found in the SSA depend on the concentration in the ocean during formation of the SSA. Outside of areas of PFAS sources, those concentrations can be relatively low but may still result in continuous loading of PFAS to inland soil, surface water, and groundwater.

Sha et al. (2021) and Casas et al. (2020) provide information about their sample collection procedures, which may be useful to practitioners interested in evaluating SSA. For details on sampling equipment and methods, please refer to the studies. Placement of the samplers depends on the goals of the evaluation. For example, if the study goal is to investigate concentrations in SSA in the breathing zone, then the intake for the sampler should be positioned to collect SSA from the approximate height of the breathing zone should be positioned to collect SSA from the approximate height of the breathing zone.

Ocean Foam

The previous paragraphs provided information regarding aerosolization and the release of SSA into the atmosphere. Not all the bubbles created by wave action immediately burst and release SSA. Instead, foam can form from the grouping of bubbles. The National Oceanic and Atmospheric Administration (NOAA) provided the following figure (**Figure 1-5**) on how foam is formed in the ocean (NOAA 2024).

If there are sufficient concentrations of surfactants available, they will group together around nonpolar substances forming spheres called micelles. In the case of sea foam, the micelles form around air bubbles, stabilizing them and keeping them from bursting right away. The stabilized bubbles combine and form foam (NOAA 2024).

Although the primary source of surfactants in the ocean is the decay of dead algae and phytoplankton (particularly from "blooms"), PFAS are surfactants that can enhance foam formation, but are not required to be present. When the algae/phytoplankton die off-shore, they release large amounts of decaying matter, which can wash toward the shore, providing the surfactants necessary to form micelles. Foam forms as this organic matter is churned up by the surf and air is entrained below the ocean surface as in the first phase of aerosolization (NOAA 2024). This foam can be quite stable, in contrast to foam formed in nonsaline rivers, which generally exists for minutes to hours before collapsing back into the water column (see **Section 16.5**). The stability and nuisance factor of the ocean foam can be seen in this video: https://www.youtube.com/watch?v=rZM6SrFlxn0.

As with aerosolization, the entrained air bubbles scavenge PFAS, organic matter, and salts. During the collection of the stabilized bubbles and micelles, these scavenged materials are included in the formed ocean foam. The PFAS will be similarly enriched in the foam as it is in the SSA during aerosolization. This foam can remain near the shore, move onto the shore (as seen in the referenced video), or move out to sea. Over time, the foam will collapse, releasing SSA and some of the content of the bubbles back into the ocean water as the bubbles burst or fall apart.

Like aerosolization, ocean foam can transport enriched concentrations of PFAS beyond the source area (ocean water) and provide another route of exposure from contact with the foam or release from the foam as bubbles release SSA into the atmosphere.

1.3.5.4 Bioaccumulation of PFAS in Marine Biota

Although there are many studies on the bioaccumulation of PFAS in fresh water (see **Section 5.5**), there are fewer studies on the bioaccumulation of PFAS in marine waters. Some recent studies have reported the bioaccumulation of PFAS in apex predators such as sharks off the coast of the New York Bight, as far afield as the Bahamas (Lee et al. 2024), and in the northwest Atlantic Ocean (Marciano et al. 2024). As with freshwater studies, these show that longer chain PFAS (> C10) were frequently detected above reporting limits and concentrations were higher in blood plasma than in muscle collected from the same organism. With PFAS precursors detected in sharks from New York Bight but not the Bahamas, Lee et al. (2024) speculated that this reflected the greater diversity of PFAS sources in a highly populated region.

Khan et al. (2023) provided a comprehensive review of the scientific literature for PFAS bioaccumulation in marine organisms, looking at data for PFAS in wild marine organisms (invertebrates, fish, reptiles, birds, and mammals) from research over the past two decades. The authors also evaluated PFAS data for plankton, surface water, and sediment. Their review found patterns of PFAS accumulation consistent with those of freshwater studies, such as preferential accumulation of shorter chain PFCAs in plankton and longer chain PFCAs in invertebrates, fish, birds, and mammals, and generally higher body burdens of PFCAs and PFSAs in higher trophic-level organisms, with the overall highest levels found in marine mammals.

Burkhard (2021) conducted an evaluation of PFAS bioconcentration factors (BCFs) and bioaccumulation factors (BAFs) reported in scientific literature. Although the data are fairly rich for carbonyl and sulfonyl PFAS, the data for phosphate, fluorotelomer, and ether classes are poor to nonexistent. As with other studies for PFAS, Burkhard (2021) found that PFAS concentrations were greatest in liver and lowest in muscle, with whole body concentrations in between. A comparison of freshwater to marine water BCFs and BAFs was limited by the lack of data for marine organisms.

In a later study, Burkhard and Votava (2023) assembled biota-sediment accumulation factors (BSAF) for PFAS in 17 different taxonomic classes, with one of the objectives being to find out whether there are differences between freshwater and brackish/marine species. These authors found that the highest BSAFs were for bony fish and annelid worms, whereas certain plants and bivalves had the lowest BSAFs. Although a larger dataset was available for BSAF (compared to BAFs), the results were variable, with few differences observed between freshwater and marine species. The authors highlighted the need for more paired sediment:biota data with which to derive BSAFs in the marine environment. SERDP is currently conducting research into the environmental factors that influence PFAS bioaccumulation in the marine food web, Project ER22-3359. More information can be found on the SERDP website **https://serdp-estcp.mil**.

Last, as discussed by Higgins et al. (2007), because PFAS have different affinities for organic carbon in sediment and tissue residues are controlled by active transport rather than lipid, the theory of equilibrium cannot be used to describe PFAS partitioning. Hence, where there are data available, it is recommended that PFAS BSAFs be expressed as kg-organic carbon/kg-ww rather than as kg-organic carbon/kg-lipid.

1.3.6 Effects of Suspended Sediment on Surface Water Sampling and Measurement of PFAS

This section provides information regarding the development of surface water sampling efforts for PFAS, including in water bodies with high suspended solids content. This information builds on various sections that should also be reviewed to properly use the information provided here:

- Surface Water Sampling and Analysis, **Section 16.4**
- Transfer of PFAS Between Groundwater, Surface Water, Pore Water and Sediment, **Section 5.3.4**
- Sampling and Analytical Methods, **Section 11.1**
- Surface Water Body Secondary Sources, **Section 10.3.1.2**

Several factors can affect the concentration of PFAS in surface water samples. This is due in large part to the fact that PFAS tend to sorb to suspended sediments. Concentrations of suspended sediments in surface water increase during stormwater runoff events due to higher sediment concentrations in runoff and mobilization of sediment from the river bottom due to increased flow velocity. As a result, the sample location, timing of collection, depth, sample type (for example, aqueous, bed sediment, and (or) suspended particulate matter), and sample analysis methods (dissolved, solid phase, or total) should be considered when designing a surface water sampling plan. Whether investigating impacts from an individual source area or impact(s) within a watershed, an investigator may need to sample during ambient (baseflow) *and* various storm conditions (before, during, or after peak flow) to properly understand the PFAS source(s), concentrations, mobility, and impact. **Section 5.3.4.2**, **Section 6.4**, **Section 11.1.7.3**, and **Section 11.2.1.2**, discuss the collection and analysis of stormwater runoff samples provides additional information not provided by sampling conducted during ambient conditions.

Because this section discusses considerations on the design of a sampling plan to measure PFAS in surface water, it is intended to augment other references that detail the collection of water quality data in general. For example, the US Geological Survey has produced a National Field Manual for the Collection of Water-Quality Data (USGS 2019). That reference, along with additional references found in **Section 1.3.6.1**, and **Section 16.4**, provide information and guidance to help in designing and conducting a

sampling and analysis plan for the collection of water quality samples from surface water, including some with PFAS-specific sampling techniques and some with an emphasis on stormwater.

1.3.6.1 Surface Water Sampling During/After Stormwater Runoff Events

Samples collected during ambient (baseflow) conditions reflect PFAS impacts from various non-stormwater-related discharges (groundwater discharging to a surface water body, wastewater, excess landscape irrigation, aerial or windblown deposition). However, various factors affect a surface water sample collected during rain events, making planning, collecting, and analyzing the results of the sampling more complex. For example, a dilution effect can occur if the waters that are flushed from upstream areas and subbasins during rainfall events contain lower PFAS concentrations compared to the areas of interest, thereby decreasing the measured PFAS concentrations downstream. Conversely, rainfall events can also *increase* PFAS and PFAS-sorbed particulates in surface water from PFAS source areas (such as biosolids application areas, AFFF sites, industrial areas) and the general urban environment. This occurs by mobilizing particles and bottom sediments on which PFAS are sorbed as well as solubilizing PFAS on surfaces (Borthakur, et al., 2021). Rainfall can also flush and deposit atmospheric PFAS on the ground, freeing it to be carried to storm drains and eventually surface water. Rainfall events can remove microplastics from the atmosphere and ground surfaces and deposit them into surface water where they act as suspended particulate matter (SPM) that provides additional surfaces for PFAS and other pollutant adsorption, see **Section 2.2.2** of the ITRC Microplastics (MP-1) Document (ITRC 2023). Thus, sampling only ambient conditions may not provide a complete understanding of PFAS impacts on surface water. Because rainfall often varies spatially and temporally (amount, intensity, and timing) across large watersheds, each storm may produce varying amounts of runoff from upstream subbasins, some of which may contain sources of PFAS and others not. The amount and source(s) of PFAS measured by the sample would depend in large part on storm dynamics in the watershed upstream of the sample location.

The degree of mixing within a stream may also influence how much of the dissolved and particulate-sorbed PFAS is measured at the sample location. That is, the PFAS may or may not be well mixed with depth or across the width of the stream, a condition that also holds for ambient flow conditions affected by wastewater and contaminated groundwater discharges (see **Section 1.3.6.3**).

In addition, stormwater events are associated with increased flow and turbulence in surface waters, along with additional mass of PFAS and other surfactant-type materials in the surface water. These conditions can lead to the formation of PFAS-containing foam. This foam removes a portion of PFAS from the water column, at least temporarily, and acts as a transport mechanism and new source of PFAS downstream or to another location when transported by wind away from the surface water. This complicates the assessment of PFAS in the water body. These concepts are discussed in more detail in **Section 16.5** and in **Section 1.3.5.3**.

To summarize, ambient (baseflow) sampling and stormflow sampling measure different aspects and components of PFAS in a watershed. Depending on the sampling objectives, any surface water sampling plan should consider whether to sample during ambient flow, during stormwater runoff conditions, or both, and should consider sample location, timing, depth, and type (aqueous, solid phase, or total).

1.3.6.2 PFAS Concentrations and Transport During Stormwater Runoff

Several studies, including those described in **Section 5.3.4.2**, have shown changes in surface water conditions during stormwater runoff events that influence dissolved and sorbed PFAS concentrations. Some of the results depend on site-specific conditions. The findings include the following:

- Short-chain PFAS (those with less than 7 carbon atoms) predominated in the aqueous-phase. Long-chain PFAS (those with 7 or more carbon atoms) predominated in the sorbed phase (Ahrens et al. 2010).
- During stormwater runoff events SPM contained significantly higher concentrations of PFAS than the sediments on the water body bed, showing that the increase was related to runoff from PFAS source areas more so than mobilization of sediment from the bed (Borthakur et al. 2021).
- SPM increased during stormwater runoff events (Borthakur, et al. 2021).
- SPM can be a sink, source, or transport vehicle of particle-bound substances such as PFAS, metals, and polychlorinated biphenyls (Gockener et al. 2022).
- Concentrations of PFAS on SPM originating from PFAS-impacted source areas can be much higher than found on SPM by equilibrium distribution (**Section 5.4.3.2**).
- Microplastics entering the water body increase during the stormwater runoff event and taper off as microplastics have been removed from paved and soil surfaces, as well as from the atmosphere (see ITRC 2023).
- "SPM-bound PFASs are positively correlated with transparent exopolymer particles (TEPs) content, providing evidence that TEPs may accumulate and concentrate more PFASs on the SPM" (Shiu et al. 2023).
- Surface waters where the predominant PFAS sources are from wastewater discharges and similar point sources tend to have highest PFAS concentrations during dry periods when stormwater runoff is low. Conversely, when the dominant PFAS sources are nonpoint sources (for example, biosolids application areas), the peak concentrations are during periods of stormwater runoff due to mobilization of PFAS from the source areas and conveyance to the surface water body by stormwater (Carneiro et al. 2025).

In addition to the studies above, SERDP-ESTCP has several projects to evaluate PFAS in stormwater, particularly at military facilities. These projects primarily look at treatment technologies for removing PFAS from stormwater runoff. More information can be found on their website **https://serdp-estcp.mil**.

1.3.6.3 Hypothetical Scenario to Illustrate Surface Water Sampling

The following discussion provides a hypothetical scenario to illustrate key considerations for sampling of surface water and is based on the information presented in the preceding sections. In addition, information is included for high-turbidity samples.

Figure 1-6 is a conceptualized representation of surface water conditions and PFAS distributions in surface water. The upper portion of **Figure 1-6** shows a cross-section in a water body during non-stormwater runoff events. PFAS are found throughout the water column with shorter chain PFAS more prevalent in the upper part of the water column and higher concentrations of longer chain PFAS sorbed to solids that are suspended in the water column and found in the river bottom sediments. River flows are not fluctuating significantly and PFAS molecules are in constant exchange, partitioning between the aqueous and solid states as mediated by the predominant sorption and desorption conditions. The riverbed is steadily being added to and moved slowly downstream.

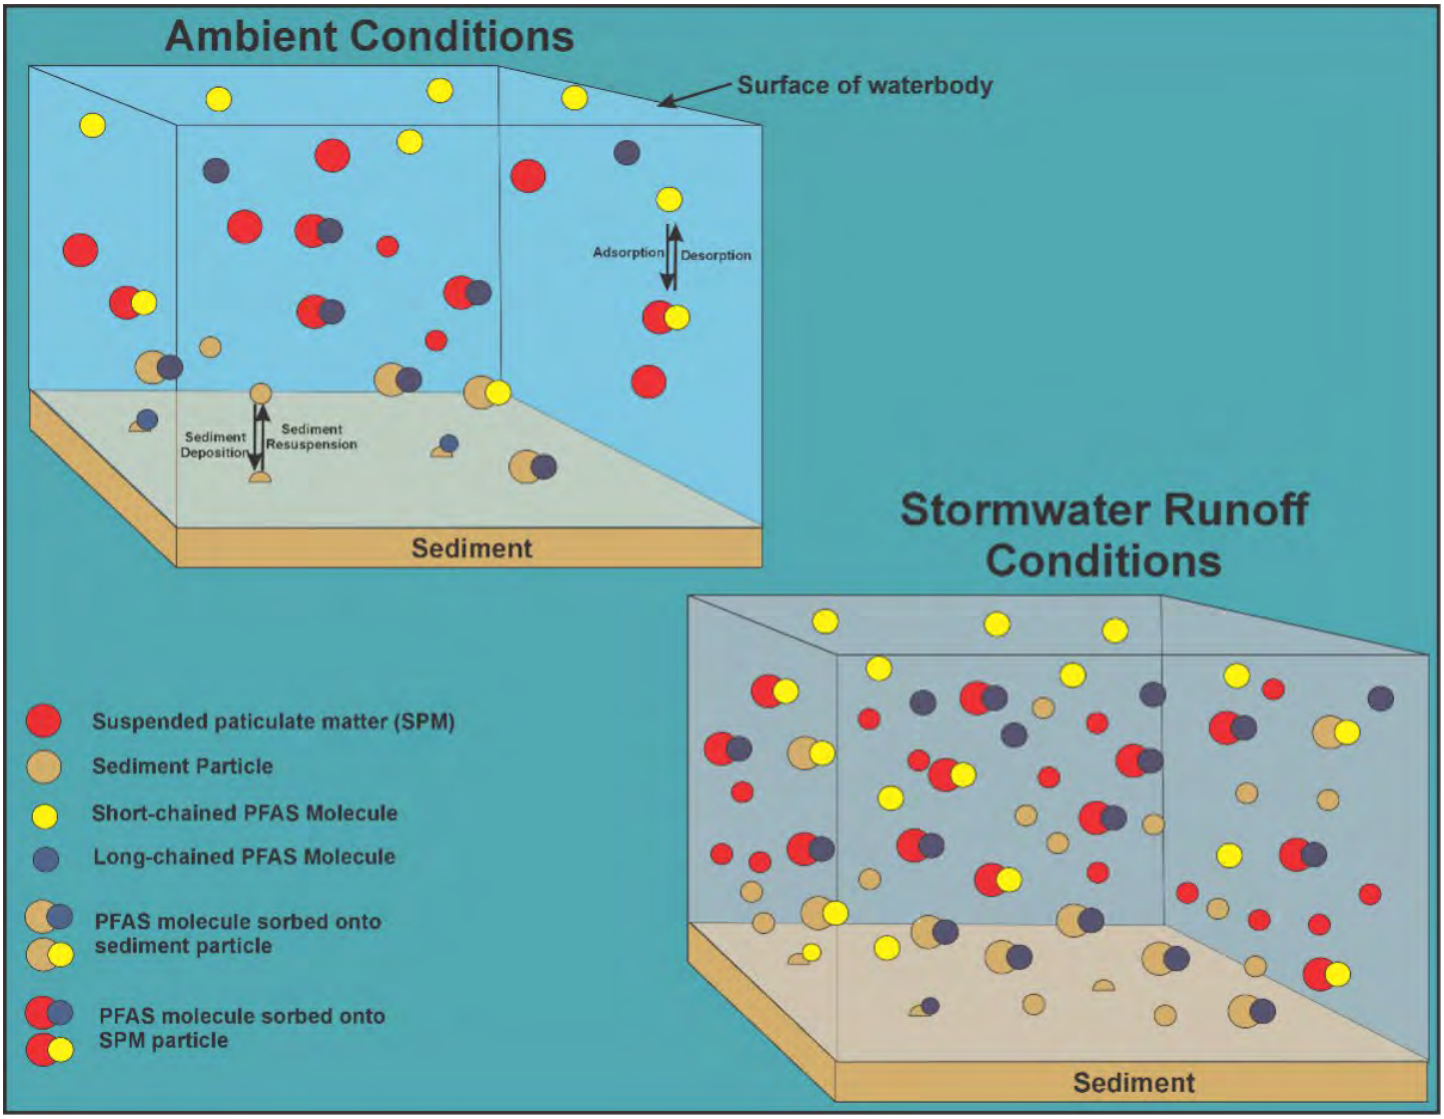

Figure 1-6. Water body conditions and conceptualized PFAS distributions.

Source: A. MacDonald, used with permission.

The bottom right portion of **Figure 1-6** shows the water column during a period of stormwater runoff. Total PFAS and SPM concentrations have increased. PFAS move between phases in response to differing mixtures and concentrations of PFAS, sorption to SPM and sediment, and concentration and makeup of SPM. Higher concentrations of SPM allow for additional sorption sites for PFAS and other pollutants. This sorption can potentially allow for increased PFAS transport downstream and deposit into the sediments of the riverbed. The system slowly reverts to ambient conditions as the storm subsides, and stormwater runoff ceases. Thus, depending on what questions are being addressed by collecting PFAS samples, the timing and location of sample collection must be carefully determined.

Factors Impacting When to Sample

PFAS concentrations and mass flux (concentration times the flow rate) in the aquatic system vary over time, during and following a storm. As discussed above, depending on the site and setting, storm flow that flushes otherwise PFAS-free subbasin(s) may dilute PFAS concentrations in downstream locations.

Often though, during a stormwater runoff event, PFAS will increase in the receiving water, and be expected to eventually diminish as runoff ebbs and first-flush effects have mobilized available PFAS, with lesser PFAS amounts available for flushing as the storm continues.

If the goal is to evaluate the PFAS impacts associated with runoff from a single facility, there are numerous stormwater sampling guides established under National Pollutant Discharge Elimination System (NPDES) permitting programs by states and the federal government. The guidance provided in those documents was not developed with PFAS in mind, but the guides are applicable to PFAS. As examples, Oregon, Washington, and California, as well as USEPA, have developed such guides (WA Dept. of Ecology 2015; CA Water Boards 2001; USEPA 2021). These guides provide information on selecting locations, storm events to be targeted, and timing to obtain samples during the first-flush of stormwater runoff.

Sample timing in a larger target area such as an entire watershed or urban area is more difficult to establish, as there may be several PFAS source areas at varying distances from the water body being evaluated. Peak runoff from these areas may arrive at different times depending on local rainfall intensity, slope, and land cover. Determining the appropriate timing of sample collection can be difficult, so high frequency sample collection, collection of time-weighted composite samples, or using integrated samplers may be preferred to single grab samples to reduce the potential of missing high or low concentrations (Beisner et al. 2024). Single grab samples can augment the data collected by these other compositing/integrating sample methods.

Factors Impacting Where to Sample

The choice of sample locations depends on the objectives of the sampling. Do the objectives include looking for peak concentrations, average concentrations at a point in time, average concentrations over an extended period of time, concentrations that may impact benthic organisms or organisms residing in the water column or both, impacts associated with a particular site, impacts associated with an entire watershed, a need to provide information for selection and monitoring of PFAS treatment/mitigation measures, or any combination of these and other potential objectives? The degree of mixing within a water body will also affect the selection of sample locations. Below is an ***example*** that highlights sample location considerations and the above components for consideration. It uses concepts, designs, and nonspecific results from a study conducted on surface water impacts as part of an NPDES permit. The example does not specifically represent the location and specifics of that project.

Example of Where to Sample

Figure 1-7 shows an urban area with two major rivers, one tributary to the other. The river coming from the right is the dominant of the two and has received discharges from a vast expanse of farmland upgradient of the urban area. The river coming in from the left originated in the mountains and has received drainage predominantly from the mountains and part of the surrounding urban area. A significant amount of rainfall has occurred providing sufficient runoff meeting the criteria for collection of samples for evaluating impacts from stormwater runoff. Note the darker color of the river receiving runoff from farmland compared to the river receiving only mountain and urban runoff. This indicates a greater turbidity (increased SPM) from the farmland river along with a greater potential for PFAS associated with biosolids application. There are no known significant industrial sources of PFAS in the surrounding urban area. he objective of a proposed study is to determine the impact on the dominant river from the urban area.

Where, and from what depth should the samples be collected?

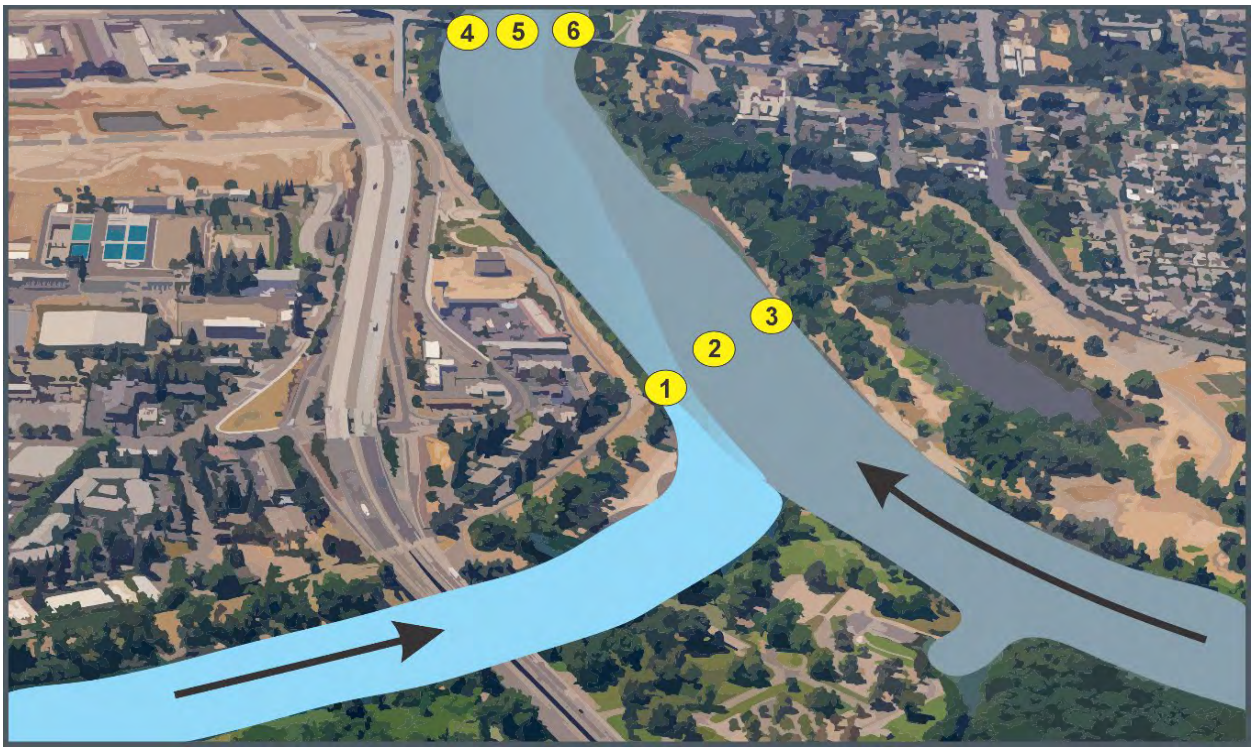

Figure 1-7. Example urban area with two major rivers.

Source: A. MacDonald, used with permission.

Discussion of sampling locations and depths

Because the goal is to determine impacts from the urban area, samples are needed just upstream of the first urban stormwater discharge points to the river to determine ambient concentrations. "Ambient" in this context means the river already impacted by the farmland, but not yet impacted by the study area. Those would be found upstream of points 1, 2, and 3, off the figure to the right. These samples would provide information for comparison to water quality standards and be used to determine the increase or decrease in PFAS concentration due to discharges from the urban area. Samples would also be needed at a downstream point in the river where there are no more urban stormwater runoff discharge points contributing to the river. This would be found some distance past the top of the figure. To determine which individual areas are contributing PFAS, point discharges of stormwater within the study area should be sampled. These sampling points would represent the discharge from the diffuse PFAS source areas in the watershed served by the discharge point.

If samples were to be collected at points labeled 1, 2, or 3 on the figure, the results could be misleading. Sampling at only location 1 would be representative mostly of the water entering from the river to the left. Sampling only location 2 would be representative of some sort of mixture of the two rivers. Sampling only location 3 would be representative only of the main river. The color of the receiving water provides a clue to the mixtures. One could sample all three locations and use the average of the three to represent the average concentrations across the cross-section of the river. However, this would likely not provide sufficient information for the study if there are additional urban inputs downstream. The same logic can be used for locations 4, 5, and 6. Ideally, the sampling is conducted even farther downstream, past all the urban discharge inputs and prior to other stormwater discharge inputs. If the downstream sample location occurs following a significant bend in the river that allows the river to mix across the entire cross-section, then representative samples can be gathered from several locations downstream of the bend. The concentrations could then be averaged if river velocity and depth of the river measurements are obtained at both the ambient and downstream locations. If that is not the case, then samples should be considered at several locations across the width of the river and at several depths at each location to account for some vertical stratification of SPM, resuspension of bed sediments, and potential reduced vertical mixing of urban runoff inputs.

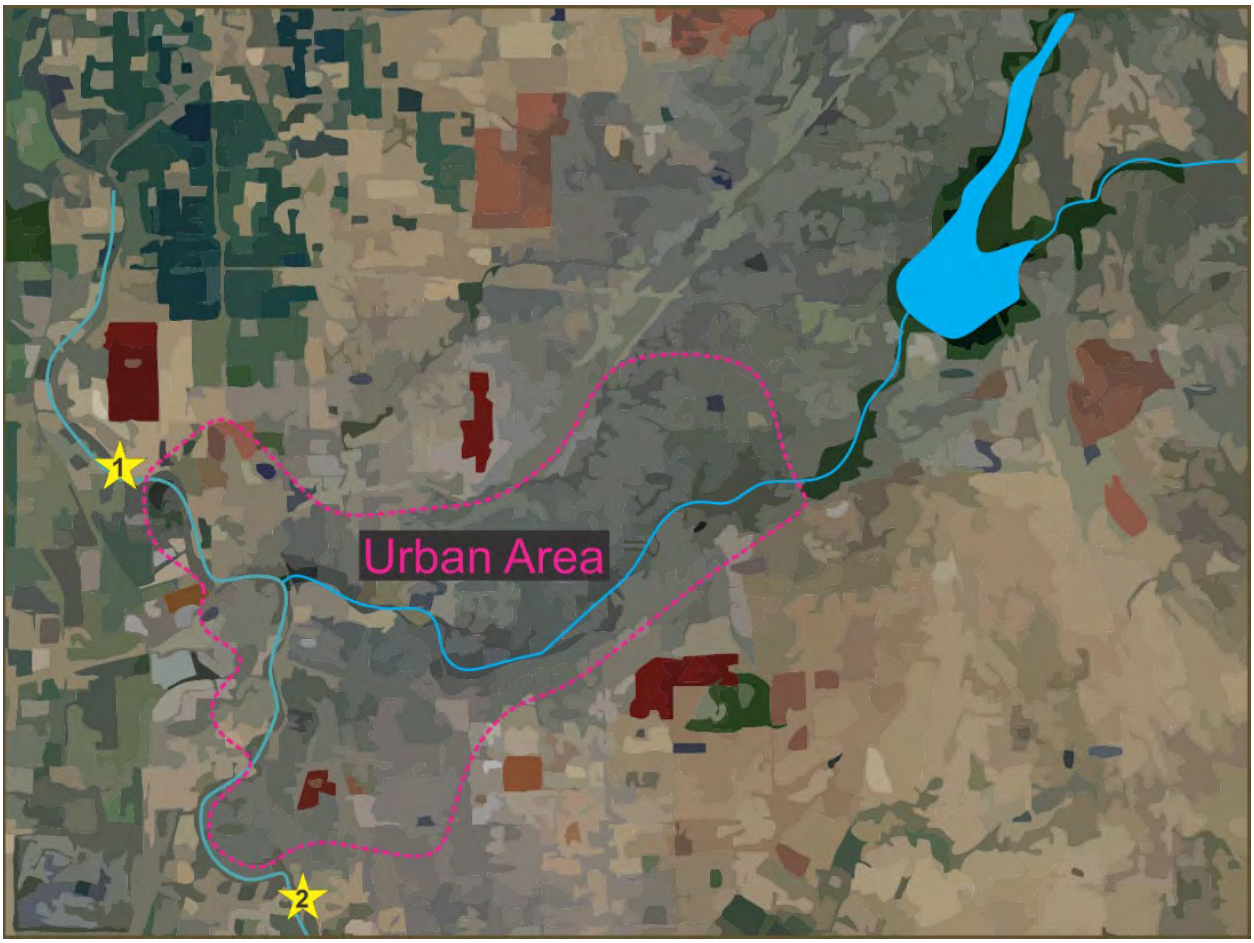

Figure 1-8. Example area with upstream and downstream locations identified.

Source: A. MacDonald, used with permission.

Figure 1-8 shows upstream sample location 1 and downstream location 2. Note location 2 is past the urban study area and downstream of a nearly 90-degree turn in the river, allowing for mixing across the river. Site-specific configuration of the river, and wastewater and stormwater discharge locations, will drive locations for sampling.

Because PFAS, if present, tends to be found throughout the water column, with a preference for some accumulation at the air-water interface (AWI), samples should be collected at several depths at a given location. The top sample would be at the AWI to include that accumulation site. The deepest sample would be near the river bottom to measure the higher turbidity that may be found there during higher river velocities mobilizing sediment. Additional samples between those two could be collected if needed, depending upon the depth of the receiving water and objectives of the sampling.

As mentioned above, there are many federal- and state-published guidelines on conducting sampling, including sampling to assess impacts of stormwater runoff. These should be consulted prior to developing a site-specific sampling and analysis plan.

Analytical Considerations with High Turbidity Samples

As described above, samples collected from stormwater and stormwater-impacted water bodies will have an increased solids content providing additional particles that can sorb PFAS and other pollutants. The analysis of high solids–containing samples (high turbidity samples) poses some additional complexity. This must be kept in mind and the objectives of the sampling must be discussed with the laboratory

analyzing the samples so the analysis can provide the information needed to address those objectives. **Section 11.2.1.2** includes information about preparing aqueous samples with particulates and suspended solids.

1.3.7 Source ID, Differentiation, and Forensics

This section supplements the material described in **Section 10.5** and highlights key forensic concepts tailored to PFAS site characterization. Environmental forensics is a multidisciplinary field that integrates chemistry, environmental science, historical research, and data analytics to identify contaminant sources. Although many techniques used for legacy contaminants (for example, polychlorinated biphenyls, polyaromatic hydrocarbons, and dioxins) are also applicable to PFAS (Plumb 2004; Johnson et al. 2015; Cejas and Barrick 2020; Bock et al. 2021), PFAS present distinct challenges that require tailored interpretation strategies (Dorrance, Kellogg, and Love 2017; Morrison 2000; Morrison and Murphy 2006; Mudge 2008; Murphy and Morrison 2015; Sullivan et al. 2001; Wang and Stout 2006).

1.3.7.1 Lines of evidence

Unlike many legacy contaminants, PFAS forensic evaluations must account for precursor transformation, differential partitioning, and complex transport behavior that can alter chemical fingerprints over time (see **Section 1.3.3**, **Section 1.3.4**, **Section 4**, and **Section 5**). These processes can mimic or obscure source contributions if not properly considered.

Despite these challenges, several lines of evidence can support reliable source identification, including:

- unique compound ratios and isomer distributions reflective of specific manufacturing processes
- indicator PFAS associated with particular industries or waste streams
- distinct spatial trends influenced by differential sorption and migration
- precursor transformation signatures detectable via advanced analyses
- use of non-targeted analysis and suspect screening techniques to expand the analytical window and reveal compound classes unique to specific sources

The accuracy of forensic interpretations depends on integrating analytical results with contextual data, including site history, use patterns, and fate-and-transport mechanisms. When interpreted holistically, forensic approaches can offer critical insights into source apportionment and plume evolution.

1.3.7.2 Historical Research

Several studies have shown that many sites are impacted by multiple PFAS sources (Anderson et al. 2016; Sun et al. 2016; Guelfo and Adamson 2018; Brusseau et al. 2020). This is particularly important in urban or industrialized areas. PFAS do not occur naturally but are found throughout the globe, including in remote areas (Herzke et al. 2023; Muir et al. 2019; Washington et al. 2019). Regional anthropogenic background levels reflecting nonpoint sources are present globally and can represent a significant fraction of the PFAS at a site. These ambient PFAS levels vary regionally and are often elevated in urban areas when compared to rural environments and remote locations (**Section 6**). In addition to identifying anthropogenic background, plausible PFAS-associated point sources in the vicinity of the investigation area should be identified and investigated.

Central to any source investigation is the evaluation of who or what may be wholly or partially responsible for site contamination based on when, how, and how much was contributed by each potentially responsible party (Sullivan et al. 2001). The answers to these questions almost always require an understanding of site history to develop information regarding:

- identification of possible local sources and site-specific anthropogenic background
- product usage history, accidental spills, or emergency response releases, environmental violations, waste handling, emission pathways and amounts
- plausible discharge pathways, such as aerial deposition, groundwater and surface water flow, soil disturbances and relocation

Numerous resources describe in more detail best practices for conducting historical research (Petrisor 2014; Sullivan et al. 2001; Murphy and Morrison 2015; Morrison 1999). The collected information should be interpreted in the context of the history of PFAS manufacture and use (**Section 2**). Note that historically, PFAS were often not included on material data sheets, therefore making it more challenging to determine whether historically used chemical formulations contain PFAS. As part of these investigations, surrogate non-PFAS markers of site wastes, discharge pathways, and transport pathways should be leveraged where appropriate.

1.3.7.3 Data Collection

Targeted sampling should follow historical research to test source hypotheses and characterize PFAS fingerprints (see **Section 10** for field investigation strategies). This section highlights how analytical method selection can support forensic differentiation (see **Section 11.2** for analytical methods for PFAS).

The diversity of PFAS formulations often necessitates looking beyond standard targeted methods. Although USEPA Method 1633A (2024) quantifies 40 PFAS, this may not fully capture site-specific profiles, especially when distinguishing between AFFF and non-AFFF sources.

To increase forensic resolution, high-resolution mass spectrometry techniques such as suspect screening and non-targeted analysis can detect a broader range of compounds and isomers, including precursors and source-specific chemistries (Glüge et al. 2020; Dasu et al. 2022). These approaches improve the statistical power and granularity of source attribution analyses (Strynar et al. 2023; Transport Research, Board NASEM 2023).

1.3.7.4 Preliminary Data Evaluation

Prior to applying advanced visualization techniques or multivariate data analytics methods, preliminary evaluation of the data quality is necessary. The integrity of forensic conclusions depends on understanding and addressing several common data issues:

- Censored values (below the detection limit): Nondetects should be reviewed in the context of detection and reporting limits, which may vary across samples or compounds. Decisions on data treatment (for example, substitution, statistical imputation) should align with data quality objectives (USEPA 2006; Helsel 2010).
- Approximate values (above but near the detection limit): Detected concentrations below the reporting limit may introduce uncertainty. Their influence on PFAS fingerprints should be evaluated, especially if they constitute a large portion of a profile.

- Extreme values (potential anomalies/outliers): Outliers may reflect analytical error or real, high-concentration releases. Graphical and statistical tools can help determine if such values distort the interpretation or reflect site-specific events (Helsel et al. 2020).

- Missing values (data gaps due to variable analytical methods): Variability in analytical methods over time (for example, USEPA Methods 537, 537.1, 1633A; see **Section 11.2.1** for more information about quantitative analytical techniques) can result in inconsistent compound lists. This may necessitate focusing multivariate analyses on a common subset of analyte, or the use of methods that accommodate missing data.

Early-stage data screening helps guide appropriate methods for fingerprinting, visualization, and multivariate evaluation. These steps support robust forensic interpretation by ensuring that statistical outputs reflect meaningful environmental trends rather than analytical artifacts.

1.3.7.5 Data Visualization

Typical site characterization visualization methods such as groundwater iso-concentration plume maps, hydrogeologic cross-sections or fence diagrams, and 3-D CSMs may be used to depict the horizontal and vertical extent of PFAS. Other visualization methods that depict the relative or absolute abundances of the various PFAS include:

- Bar charts: Side-by-side comparison of multiple PFAS (the bars), with bar height relating to relative or absolute abundance (**Figure 1-9**). Many constituents can be shown on a bar chart, with the overall pattern of the bars forming a sample's profile.

- Pie charts: Circular graphic (**Figure 1-10**) with compounds represented as adjacent quadrants and area proportional to relative abundance. Pie charts are readily displayed on maps.

- Radar plots: Circular graphic with concentrations displayed on individual axes, with increasing values away from the center (**Figure 1-11**). Unique fingerprints often form distinct shapes on a radar plot.

- Ternary plots: Triangular plots that depict the relative proportions of three PFAS in a mixture (**Figure 1-12**). These plots are commonly employed in soil science to differentiate soil types consisting of differing proportions of grain sizes, and in chemistry to differentiate chemical mixtures, among other applications.

- Scatter plots: Comparison of chemicals on rectangular (Cartesian) axes, to assess correlation, groups, or other trends.

- Family tree–style 3-D bar charts (Gamlin et al. 2024).

Bar, pie, and radar charts may be further enhanced by organizing PFAS by functional group, and sorting by physicochemical properties (chain length). Organizing the data in this way can assist with the interpretation of perfluoroalkyl carboxylic acid (PFCA) versus PFSA content and shed light on potential fate-and-transport signatures (that is, differential presence of shorter chain compounds). **Section 10.5.1.3** includes examples of visual representations of data. Additional figures are included here.

In some applications of PFAS forensics, it may be beneficial to show similarities or differences between samples using either the concentrations or relative abundances of one or more PFAS ratios. Double ratio plots (**Figure 1-13**) are a common tool in polycyclic aromatic hydrocarbon forensics (Sauer and Uhler 1994; Douglas et al. 1996; McCarthy et al. 2000), where ratios of one or more constituents are shown on the axes of a scatter plot. Double ratio plots greatly enhance the power to differentiate between samples and sources and have been applied to PFAS forensics.

Source: Provided by Michael Bock, PhD. Used with permission.

Raup et al. (2024) (see **Section 15.1.4**) used pie charts to depict fingerprint changes between surface water and overburden and bedrock groundwater, with potential contributions from septic systems. For this study, six PFAS were selected based on drinking water criteria, but a larger analyte list could potentially reveal more nuances in the chemical signatures. Tracers, such as artificial sweeteners and nitrogen species, were used alongside other lines of evidence (such as nearby wastewater treatment plant sample signatures) to support the notion of septic or other source contributions, or both. Ratios between PFAS concentrations and total PFAS clarified fingerprints within and between sampling areas, as well as potential source types. Low standard deviations calculated for many ratios indicated general geographic homogeneity of the signatures. Means and standard deviations served as statistical indicators for anomalous samples that could represent potential sources and further characterization targets. Additional case study examples are discussed in **Section 15.1**.

Gamlin et al. (2024) recently introduced a new method to visualize PFAS sample profiles (**Figure 1-14**). The method helps in identifying and interpreting patterns by organizing data by PFAS class, carbon number, and oxidation state. The concentrations or proportions are shown using 3-D bar plots. This framework can incorporate any analyte list, allowing it to evolve with advancements in analytical capabilities and scientific understanding. A 3-D modification of the Gamlin plot permits depiction of concentration levels as well.

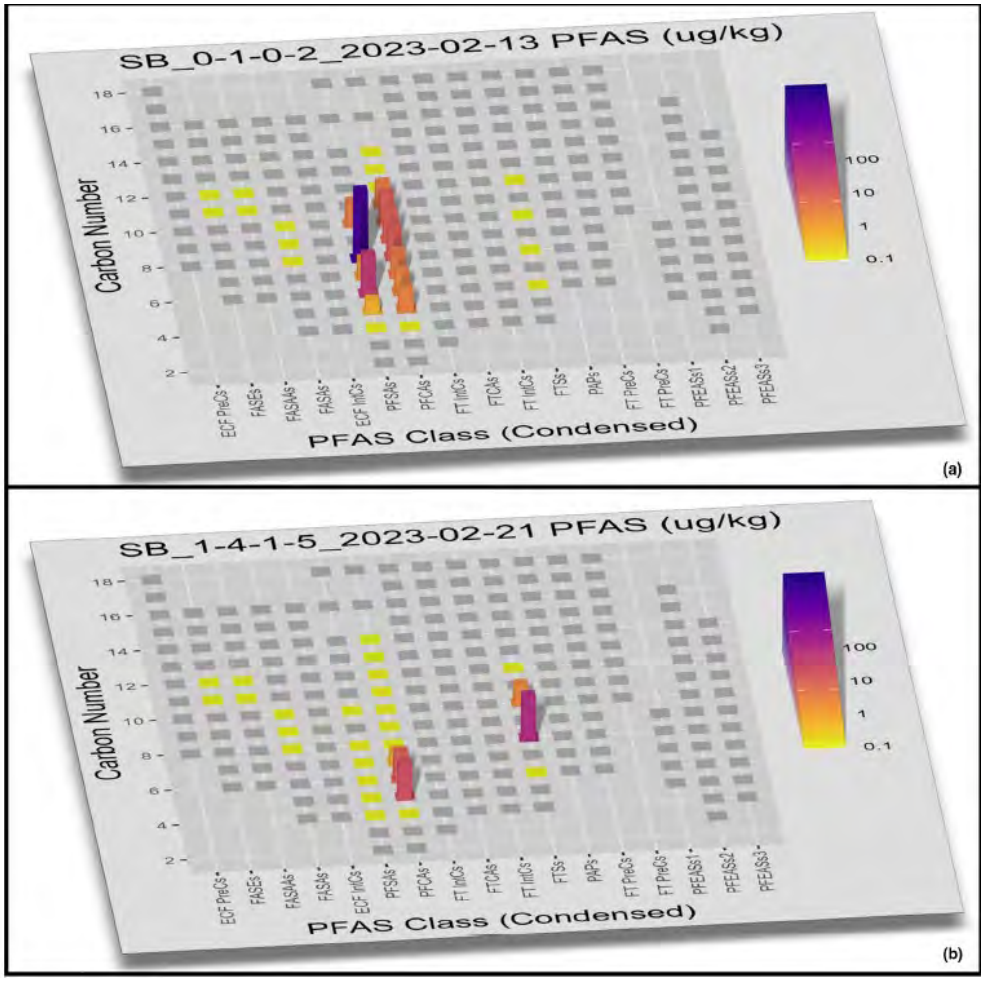

Figure 1-14. Comparison of PFAS signatures in two samples from Gamlin et al. (2024).

Source: Open Access. Gamlin et al. (2024). ***https://creativecommons.org/licenses/by/4.0/****.*

Most plots discussed here share a common disadvantage that only a few samples may be shown at a time, necessitating advanced (multivariate) methods that address the full chemical profile of many samples simultaneously.

1.3.7.6 Fingerprinting Calculations

Correlation coefficients and cosine-theta are two similarity indexes that are commonly used in a forensic evaluation to compare samples to each other and to sources (Davis 2002; Johnson et al. 2006). They have both been applied to PFAS forensics (Rose et al. 2024). These methods are adaptable to various PFAS sources and can be used to refine CSMs for better risk assessment and remediation. The correlation between two samples is calculated by ordering the PFAS in each sample before calculation. The resulting correlation coefficient provides an index of the similarity between these two samples. When calculated across many samples, the correlation matrix can be used to identify similarities. As with correlation metrics, cosine-theta provides a relative index of pattern or signature similarity of PFAS from samples, wells, or sources. It is also used to identify PFAS families in various cluster analysis approaches. No threshold value indicates a match (Johnson et al. 2006), but rather the determination of the strength of any match is based on the professional judgment of the statistician and the reader.

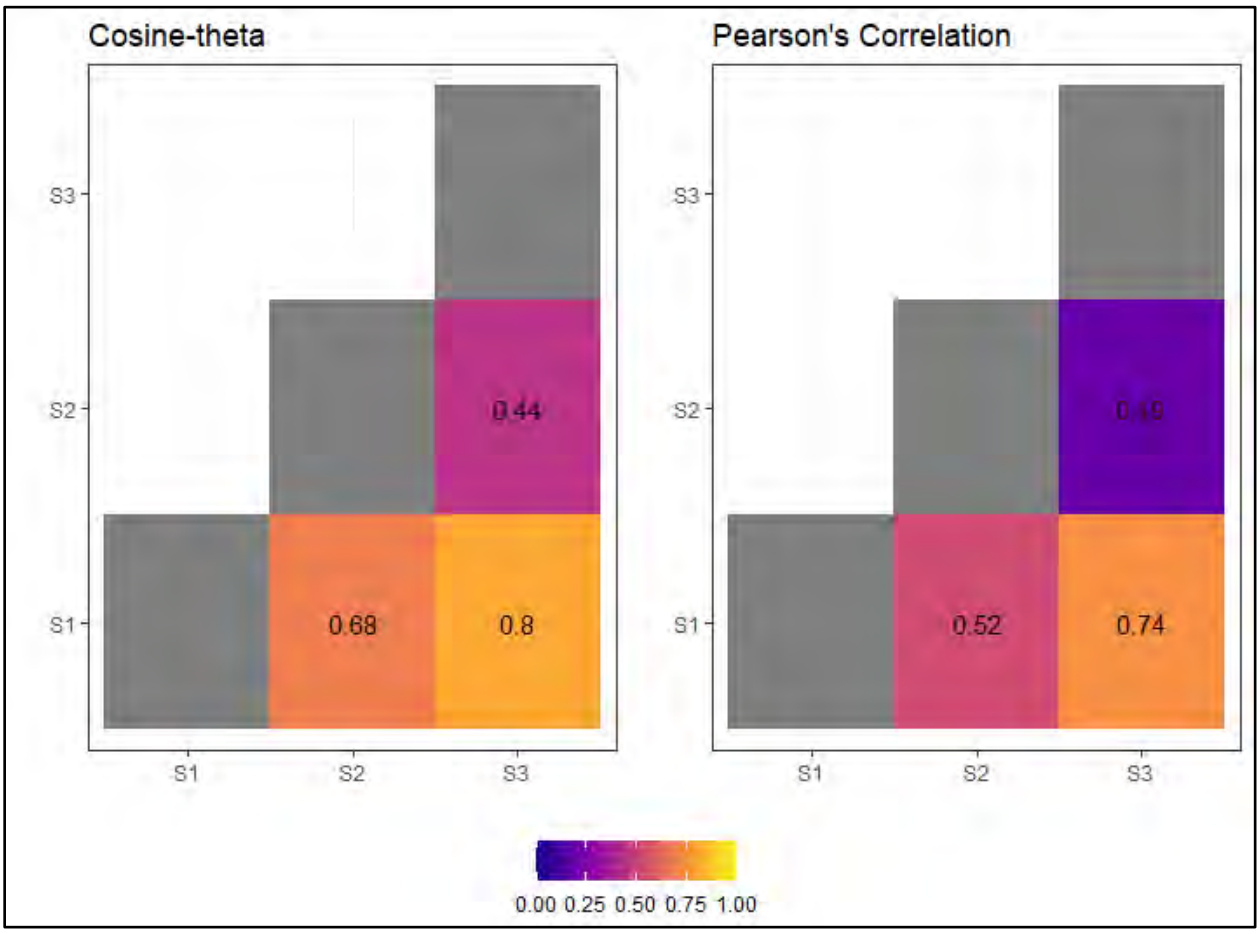

Figure 1-15. Comparison of PFAS profiles in three samples using cosine-theta and Pearson's correlation coefficients as a matrix. These are the same PFAS profiles depicted in Figures 1-9, 1-10, 1-11, 1-12 and 1-13.

Source: Provided by Michael Bock, PhD. Used with permission.

Figure 1-15 shows a Pearson's Correlation matrix and cosine-theta matrix for the sample profiles depicted in Figures 1-9 through 1-13. In the two matrix plots, higher values (illustrated with the color ramp from purple, low values, to yellow, high values) indicate a higher degree of similarity between the samples, with samples S1 and S3 being the most similar (lighter orange), S1 and S2 the next most similar (orange and pink), and S2 and S3 the least similar (darker pink and purple). The results demonstrate that these indexes provide a relative indication of similarity. It is up to the statistician to assess the importance of the specific values of these indexes. It is up to the statistician to assess the importance of the specific values of these indexes.

Correlation coefficients, such as Pearson, Spearman, or Kendall, can detect monotonic positive or negative relationships between columns of data, such as assessing the similarity of concentration trends between individual PFAS, between PFAS and other environmental chemicals (co-contaminants), or between PFAS and potential site-specific explanatory variables (distance to a source). For example, Pearson's correlation (r) compares observations, means, and standard deviations of two data columns, such that higher values near 1.0 indicate a strong, positive linear correlation, values near -1.0 indicate a strong, negative linear correlation, and values near 0.0 indicate no correlation (Helsel et al. 2020). Strong positive or negative correlations may indicate that spatially and temporally, individual PFAS align with specific spatial site features or other contaminants (or their absence). This type of assessment may be useful for assisting the interpretation of sources and subsurface processes.

Cosine-theta similarity is a traditional fingerprinting metric that geometrically represents the vector correlation between two data rows/samples (Nagai et al. 2019). The dot product produces a measure of alignment between chemical signatures, yielding a value of 1.0 for perfectly matching rows, and 0.0 for rows that do not match at all. This calculation is helpful for comparing a sample of unknown origin with a known or suspected chemistry source profile, to check for a positive match.

Together, these methods are adaptable to various PFAS sources and can be used to refine CSMs for better risk assessment and remediation. They support and are augmented by advanced analytics calculations that may more fully describe column-wise correlation (dimensionality reduction/regression) or row-wise similarity (clustering/classification).

1.3.7.7 PFAS Isomers

The PFAS analytical results described and visualized above combine the results for the various isomers into a single value (see **Section 11.3.5** and **Section 11.4.2** for more information about analyses of linear and branched isomers). As described in **Section 3.5**, PFAS such as PFOA can exist as a variety of isomers that have the same chemical formula, and the relative abundance of different isomers can be diagnostic of the original source. The ratio of branched to linear isomers is typically used to differentiate between PFAS produced using the electrochemical fluorination (ECF) process versus the telomerization process. For example, ammonium perfluorooctanoate (APFO)/PFOA was produced between 1947 and 2002 through ECF. Post-2002, virtually all PFOA was produced by telomerization. The ECF process would be expected to produce 70%–80% linear PFOA isomers and 20%–30% branched PFOA isomers while the telomerization process would produce 100% linear isomers (Buck et al. 2011). If investigators suspect multiple sources may be present in a PFAS plume, quantification of branched isomers may be an important line of evidence to show that an additional source exists or begin to identify its location. However, postrelease fate-and-transport processes may affect the distribution of the different isomers (see **Section 5**; Schulz, Silva, and Klaper 2020), potentially masking the isomeric composition of the original source material, so care must be taken when interpreting PFAS isomer data as a line of evidence in a forensic evaluation.

1.3.7.8 Data Gaps

Following the initial field investigation and data visualization, data gaps may become apparent that warrant additional sampling. For example, if sampled locations do not reflect known historical site processes or contaminant migration pathways, further sampling of source areas may be required. Inspection of concentration maps or time-series charts may also reveal potential but incomplete trends that would benefit from further characterization. Finally, additional quality assurance/quality control (QA/QC) samples may be needed to demonstrate exceptionally high or low levels of PFAS in a given area or vertical zone.

1.3.7.9 Advanced Data Analysis

At its core PFAS forensics is largely derived from, and benefits greatly from, the lessons that have been learned from the rich history of chemical forensic methods and applications. Multivariate methods have been applied to investigate sources of PFAS across the globe in a variety of matrixes, from serum in the Faroe Islands (Hu et al. 2018), to surface water in the United States (Zhang et al. 2016), and sediment in China (Pan et al. 2014). Multivariate methods are broadly categorized as self-training (unlabeled data) or predictive (labeled data). There is an acknowledgment in the forensics literature that many of these legacy methods generally fit under the umbrella of machine learning.

Self-training methods, which derive patterns without explicitly predefined labels, have been used for fingerprinting other chemical mixtures for decades. Recent years have seen an increased focus on predictive methods, where the data are linked to one or more columns of labels. Both approaches are described in more detail below in the Self-training Methods and Predictive methods sections.

Self-training Methods

Self-training methods are unique for forensics investigations, in that the algorithm is not provided a starting point with labels for the source profiles but rather uses the data itself to develop the model. PFAS signatures are inherently multivariate in that they comprise mixtures of multiple compounds. Often, site-specific chemistry data lack well-characterized source sampling records or clear, representative sampling locations for ambient levels. This makes it difficult to distinguish a range of different source profiles from each other or from fate-and-transport signatures, or to separate nonpoint ambient levels from nonpoint impacts. Certain algorithms, such as dimensionality reduction and clustering, are self-training in that they have been used to derive source (and other) signatures and latent (not explicitly measured) structure in the data.

Dimensionality Reduction

The objective of dimensionality reduction is to capture the essence of many data columns (that is, analytes) and express it with fewer columns (that is, relative source contributions). This operationally distills the data structure into a more focused format for an analyst to understand sources and their contributions. Dimensionality reduction can be performed in multiple ways, each with a different objective.

Principal Components Analysis

Principal components analysis (PCA) was first proposed by Karl Pearson in 1901 (Pearson 1901). It fits a series of orthogonal lines (the principal components) through a data cloud to preserve its variance. Often, PCA is performed using singular value decomposition (Joliffe and Cadima 2016), which resolves the data table into scores (representative of the data rows) and loadings (representative of the data columns). Visualized together on the same graphic, scores and loadings form a biplot, permitting the user to assess the relative effect of each analyte loading on each sample (score), as well as the overall configuration of

the data cloud (**Figure 1-16**). Figure 1-16, **Figure 1-17** and **Figure 1-18** use the same data. Fiedler et al. (2022) used PCA to identify correlations of three PFAS in multiple media and their trends in 266 samples from 26 developing countries, finding generally higher levels in biotic solid media from the Caribbean and Latin America. Li et al. (2022) likewise used PCA to differentiate trends in Florida surface water from four regional sampling locations, and in tap water from three regional locations. Antell et al. (2024) incorporated total oxidizable precursor (TOP) assay data into PCA to differentiate trends and patterns, separating multiple potential PFAS sources, including AFFF, wastewater treatment plants, and landfills. In each publication referenced above, biplots were used to draw visual conclusions regarding the separation or overlap of different groups, and assess trends in the data cloud pertaining to different PFAS chemicals, separating multiple potential PFAS sources, including AFFF, wastewater treatment plants, and landfills. In each publication referenced above, biplots were used to draw visual conclusions regarding the separation or overlap of different groups, and assess trends in the data cloud pertaining to different PFAS.

Receptor Models

Similar to PCA, receptor models use a variety of similar methods collectively called factor analysis to likewise resolve a chemistry data table into scores and loadings. However, forensic use of factor analysis typically does not require the loadings to be mathematically orthogonal, and instead are permitted to align obliquely with unique signatures in the data (that is, potential sources or fate-and-transport patterns; (**Figure 1-17**). Depending on the method of preprocessing used, patterns derived by receptor models may approximate sourcelike compositions. As part of the receptor modeling process, the user must specify the number of unique signatures to derive, requiring site-specific knowledge to make a reasonable estimate. Capozzi et al. (2023) used positive matrix factorization to assess PFAS signatures related to a nearby landfill, and make inferences about precursor depletion in the subsurface. Wang et al. (2022) used a similar method—nonnegative matrix factorization—to identify groundwater PFAS signatures, including a signature dominated by short-chain compounds interpreted to represent the phaseout of legacy PFOS and PFOA. Rose et al. (2024) used polytopic vector analysis to assess the effects of variable seeding methods, sample size, and noise on factor analysis of synthetic PFAS datasets with literature-based source profiles, with better results for datasets of 25 or more samples and specific automated seeding methods.

Manifold Learning

A newer class of dimensionality reduction methods, known as manifold learning, has emerged. Uniform Manifold Approximation and Projection (UMAP) is an example of manifold learning whereby the chemical similarity of samples (that is, the manifold) considering all data columns is preserved in fewer columns. Unlike PCA and receptor models, manifold learning methods are nonlinear and can fit to curved regions of the data cloud. Antell et al. (2024) used UMAP to strengthen differentiation of source signatures using TOP assay data, including different AFFF formulations.

Dimensionality Reduction Method Selection

Several concepts should be kept in mind when selecting a dimensionality reduction method. Because PCA identifies orthogonal directions in the data, it is good at summarizing the data cloud in a way that is visualized in 2-D or 3-D with Cartesian coordinates (that is, standard scatter plot axes). However, the principal components themselves do not describe source signatures unless the sources themselves align with the axes. Receptor models resolve oblique angles in the data that may more accurately represent source signatures. However, additional lines of evidence are necessary to determine the number of factors to use. Nonlinear methods such as t-distributed stochastic neighbor embedding (t-SNE) and UMAP identify potentially nonlinear structure in the data and warp the manifold to fewer dimensions for easy visualization. The principal advantage of these methods over PCA is that all the variability is expressed in two axes of one plot while with PCA only a fraction is expressed. The disadvantage is that the reduced dimensions are still subject to complex sample relationships (that is, are modeled with network graphs), and groups and trends must be interpreted carefully by an experienced analyst. Most manifold learning methods do not capture the relationship between columns (analytes) and rows (samples).

Clustering

Unlike dimensionality reduction methods that identify numeric trends in the data, clustering methods identify categorical groups. Some methods, such as K-means, identify optimal partitions between

discrete bins of similar data points. Others, such as Gaussian mixture modeling (GMM), rely on underlying statistical properties to resolve potentially overlapping groups. As with receptor models, clustering methods require the user to estimate the number of signals present in the data. If the user-specified number of clusters is more than the actual data structure accommodates, contiguous samples may be artificially separated into different signatures. Inspection of resolved clusters is needed to verify the outputs of partitioning methods.

Partitioning Methods

Partitioning-based cluster methods are helpful for quickly identifying groups that are clearly separated, by relating sample chemistries into similar groups (**Figure 1-18**). Zeng et al. (2024) used K-means to derive clearly distinct signatures differentiating various industrial, agricultural, and domestic sources of PFAS to the Pearl River Basin. Zhang et al. (2016) used hierarchical clustering to identify major sources of PFAS contamination in diverse watersheds in the northeastern United States. PCA and hierarchical clustering identified three distinct groupings of PFAS, showing different mixtures of compounds at various sites. Clustering-derived signatures were interpreted to relate to contemporary point sources such as airports and textile mills, waste-sector sources, and metal-plating operations. Ogunbiyi et al. (2024) studied the distribution of PFAS in surface and bottom water from the inshore and offshore areas in the Biscayne Bay area (Miami, FL) using the K-means clustering algorithm.

Results included three distinct clusters, each interpreted to represent different sources or levels of PFAS contamination associated with industrial discharge, urban runoff, or atmospheric deposition/agricultural runoff. The geographical mapping of these clusters revealed that industrial discharge was more prevalent in areas close to manufacturing sites, while urban runoff was dominant in densely populated regions, key supporting lines in a forensic evaluation.

Probability-based Methods

Probabilistic clustering methods, such as GMM, fit potentially overlapping statistical distributions to the data to resolve groups. Due to the additional information provided by using prespecified statistical

distributions, goodness-of-fit metrics such as Bayesian information criterion may be computed to assist with the selection of the number of clusters. GMM was proposed for use in characterizing site-specific metals background levels in soil (USEPA 2019). Anderson and Modiri (2024) later used a large dataset comprising thousands of surface soil samples from Air Force bases, representing both anthropogenic background and AFFF-impacted soils. GMMs were applied to log-transformed PFOS concentrations to model the distribution of PFOS in these samples. Various methods were employed to handle nondetects (approximately 8% of the data). Multiple GMMs were fitted, each with different numbers of components to capture the distribution of PFOS concentrations. Goodness-of-fit measures, such as the Bayesian information criterion and Akaike information criterion, were used to evaluate the models. These diagnostics were interpreted to support the existence of two clusters, establishing a general ambient range of potential nonpoint-source levels for PFAS, and distinguishing them from AFFF-impacted soils.

Clustering Method Selection

Several considerations may assist users in the selection of a clustering method. Theoretical support for the presence of underlying distributions would promote the use of statistical model-based methods such as GMM. These methods are also amenable to resolving overlapping clusters. Partitioning-based methods may be useful in situations where clusters are more clearly resolved or do not adhere to a set of theoretical probability distributions, or both.

Predictive Methods

Some statistical models are called predictive, in that they mathematically link user-specified input variables to one or more categorical or continuous output variables. Unlike self-training methods discussed in the Self-training Methods section above, the user must specify the continuous target (in the case of regression) or a categorical target (in the case of classification). Due to the requirement of prespecified labels, careful problem framing is required. It is important to keep in mind that statistical models do not typically incorporate physical or chemical heuristics (as a fate-and-transport model would), and must be interpreted as a line of evidence alongside physical and chemical site conceptualizations.

Regression

Regression methods relate one or more input data columns (X) to one or more numeric output columns (Y). Due to the requirement of the output column(s) to be of numeric form, regression-based approaches to PFAS forensics in the literature have mostly focused on relating PFAS concentrations to other variables, to add contextual links for source identification and environmental occurrence. An approach of this nature is a more advanced form of correlation analysis, relating potentially many drivers, co-contaminants, or other explanatory features to one or more outputs (PFAS levels). As with a correlation analysis, regression may be helpful as one line of evidence to support the overall conclusions of forensic investigation but should be accompanied by other lines of evidence.

Linear regression is a long-standing example of this effort, where the relationship(s) between inputs and outputs are linked by slopes and an intercept. Hu et al. (2016) used multiple linear regression to relate a large dataset of US drinking water samples from the US EPA UCMR3 program to the abundance of source types (major industrial sites, military fire training sites, AFFF-certified airports, and wastewater treatment plants) in eight-digit hydrologic-unit code watersheds. The results indicate that the source sites in a given watershed correlated with higher PFAS concentrations of PFBS, PFHxS, PFHpA, PFOA, PFOS, and PFNA, potentially linking impacts to their corresponding source types and providing diagnostic indicators for sites within a given watershed.

Other regression models used in the environmental sciences include nonlinear tree-based models. Breitmeyer et al. (2023) correlated the sum of 33 target PFAS from 161 sampled streams to land-use features and potential sources via a conditional inference tree. They found that upstream urban

developments were a primary driver of general increases in PFAS concentrations, with proximal water-pollution control and electronic-manufacturing facilities as key potential sources to surface water. As with Hu et al. (2016), regression formed the basis for linking specific source types to PFAS impacts in a forensic context.

DeLuca et al. (2023) used a random forest regression model to leverage geographic and industrial variables to predict the spatial distribution of summed PFAS in fish tissue due to a variety of sources in the Columbia River Basin of Washington State. Like other regression-based studies, the inclusion of a variety of potential sources in the analysis permitted forensic insight. Important drivers of PFAS in fish potentially included proximity to fire training facilities, metal coating facilities, paint facilities, and airports. The authors noted that cement manufacturing and glass production facilities were also scored as potentially significant drivers of PFAS contributions to surface water, although they were among the least represented industries in the dataset and should be interpreted carefully. The use of a "PFAS prospecting" regression model to support forensic inferences could hence support the identification of local sources or ambient levels of PFAS to environmental media and reveal potential data gaps in a source location analysis (undersampled/understudied pathways).

Classification

Classification methods relate one or more input variables to a categorical output. In environmental forensics, source types are a popular categorical association made during identification and allocation. Due to the relatively straightforward problem framing of relating source type labels to chemistry data, classification methods are more prolific in PFAS forensics literature. Prediction of source type based on chemistry data is useful as a screening tool to assist with characterizing impacts of unknown origin. As with other methods presented in this document, it is important to apply methods on a site-specific basis, or otherwise bring site-specific insight into a more generally trained model.

Kibbey et al. (2021) focused on distinguishing between AFFF and non-AFFF sources to groundwater PFAS impacts, using 12 different classification methods. Of the 12 methods, random forest and neural network classifiers were found to exhibit the highest accuracy (96.1% and 95.5%, respectively). The authors noted that PFAS with higher frequency of detection were generally more predictive features in the classifiers.

Kibbey et al. (2024) explored multiclass classification of PFAS sources, including AFFF, wastewater treatment plants, and landfills. The authors employed a tiered framework to identify chemical profiles from a variety of sources, and to recognize novel samples that differed from any sources in the training dataset. Blind prediction of site samples indicated reasonable predictive capability of the model. This study raises the important question of novel samples, which are different from all previously trained data classes, which must be considered when building a classification model.

Joseph et al. (2023) employed a supervised machine learning approach using support vector machines to classify PFAS sources. Support vector machines are particularly adept at handling high-dimensional data, which is common in PFAS analysis due to the large number of compounds and potential sources. The researchers used a kernel function to transform the data into a higher-dimensional space, making it easier to find a hyperplane that separates the classes. The study successfully identified distinct PFAS profiles for AFFF-impacted groundwater and landfill leachate, demonstrating the potential of support vector machines in environmental forensics.

Antell et al. (2024) created a predictive classifier that uses TOP assay data to predict source types. Sources included were AFFF sites, wastewater treatment plants, and landfills. A custom nearest-neighbor search algorithm was used to associate samples with source types. Preprocessing the data via principal components analysis improved the resolution of the classifier, with 88%–99% accuracy of the sources.

Predictive Method Selection

The choice between regression or classification methods varies depending on the study objective. When a numeric value is desired, regression methods may be used. Classification methods are suited for separating samples into different, user-specified groups.

To select a regression-based method, there are several considerations. Target (dependent) variables must be screened for extreme values, as these points may exert higher leverage during the fitting process and focus on less-representative structure in the data. Data transformations, such as logarithms or square roots, may assist in reducing the influence of extreme values deemed representative of site data. The relationships should also be assessed for nonlinearity. In the event of a nonlinear dataset, inclusion of feature interactions may make linear regression flexible enough to adequately fit the target, but must be assessed by an experienced practitioner. Nonlinear regression algorithms, like decision trees, may capture nonlinear structure. Care must be taken to not "overfit" the data (memorize the inputs without abstracting well), which may be alleviated by ensemble-based nonlinear regressors (for example, random forest or xgboost).

Classification methods likewise require a consideration of linearity. For classes that are visually separable by a straight line on a scatter plot, linear methods such as logistic regression or linear discriminant analysis may suffice. Nonlinear decision boundaries between classes may require a more flexible model, such as k-nearest neighbors or a decision tree. As with regression methods, ensemble models such as random forest or xgboost may achieve a balance of accuracy and generalizability (avoids overfitting), with sufficient tuning by an experienced user.

1.3.7.10 Model Validation

An often-overlooked aspect of many of the multivariate methods and models applied to PFAS forensics is validation. As with any statistical model, validation of the model should not be overlooked. Johnson et al. (2015), Gauthier and Hawley (2007), Ginevan (2007), and Bock et al. (2021) provided useful examples of model validation methods and examples of their use. Basic model validation techniques and tools include:

- comparison of the modeled versus the original chemical profiles, often in the form of bar plots
- plot of observed versus modeled, including the 1:1 best fit line
- goodness-of-fit statistics such as cosine-theta, r^2, and mean squared error
- evaluation of the data for trends unrelated to the CSM, such as systematic differences between analytical laboratories, analytical methods, or samples collection methods
- rigorous evaluation of the CSM, hypotheses, and alternative hypotheses. For example, is a change in profiles attributable to:
  - different sources.
  - differential fate and transport.
  - precursor transformation.
- comparison to source libraries
- comparison to potential anthropogenic background levels and profiles

PFAS mixtures are frequently impacted by nonpoint sources. These nonpoint sources are often classified as anthropogenic background, regional nonpoint sources, or baseline (see **Section 10.2**). The influence of potential anthropogenic background can be an important component of the results of a forensics evaluation. A discussion of methods to characterize anthropogenic background is beyond the scope of this section, but understanding how they can influence a forensic evaluation and how they are considered in the CSM should be determined prior to beginning the investigation.

1.3.8 Site Characterization Tools and Techniques

This section supplements the information in **Section 10** on unique considerations for PFAS site characterization and provides practical guidance for conducting PFAS site characterization, including strategy, approach, tools, and techniques. Because of the unique properties and environmental behavior of PFAS, site characterization efforts at PFAS sites may require collecting different types of information compared to investigations for other types of contaminants. Some tools provide one line of evidence, while others may have the ability and data to support more than one. This approach to assembling the key elements of site characterization is supported by **Section 11**, which provides greater detail on sampling and analysis tools and techniques for specific data acquisition.

1.3.8.1 Investigation Approaches

Investigation approaches are typically based on project goals and site characteristics, including but not limited to site history, setting, watershed characteristics, number and types of sources, and potential receptors. Two approaches are discussed below: "outside in" and "inside out." While each approach is described separately for simplicity, a combined or hybrid approach might be appropriate, depending on the characteristics of the site, regulatory program requirements, and other factors.

Outside-In Approach

The outside-in approach is generally based on a receptor-protection concept, whereby the extent of PFAS migration is identified first along with affected receptors, if any, distal to on-site PFAS sources. This would involve prioritizing the sampling of potential receptors (for example, supply wells, surface water bodies) and downgradient monitoring locations before source identification and pathway characterization. The investigation would then proceed back toward the site of interest and to on-site source locations. Though appropriate for proactive receptor protection, this approach may be confounded by commingled PFAS from other sources, especially in industrialized areas and where such facilities share a common surface water body to which PFAS discharge. An outside-in approach may be the only option when a PFAS plume has been identified without knowledge of the source.

Inside-Out Approach

This approach applies to the characterization of discrete sources of PFAS interior to a site and the investigation of potential migration pathways from those sources to delineation, receptors, or boundary conditions. Where such delineation is feasible, it will provide higher confidence in understanding overall impacts and long-term fate and transport concerns.

The inside-out approach is incremental and sequential, as follows:

- identify potential on-site sources of PFAS based on site history and use
- conduct targeted soil and groundwater sampling to confirm presence of PFAS associated with the release or application locations
- conduct broader lateral and vertical soil and groundwater sampling for PFAS to determine nature and extent from the source
- sample groundwater and surface water migration pathways until delineation, boundary condition, or receptor is encountered
- focus management measures on the source-pathway-receptor connection

This approach allows the investigator to isolate and proactively address PFAS occurrence emanating from a specific source and along migration pathways.

1.3.8.2 Surface Water Receptors

In many jurisdictions, surface water criteria are close to analytical detection limits due to concerns about bioaccumulation of PFAS and emerging human health criteria (for example, reference doses [RfDs]) related to surface water uses (see **Section 16** and the Environmental Media Values Table). Surface water receptors may be a sink for PFAS released from multiple commercial or industrial sources. Consequently, careful consideration should be exercised before sampling a surface water receptor (for example, river, estuary, lake, ocean) for PFAS, including its sediment or sediment porewater. **Section 16.4.1** includes information about surface water sampling for PFAS. An extension of the inside-out characterization approach is to conduct mass flux and dilution analysis where diffuse discharge of PFAS from groundwater to surface water is suspected (ITRC 2010). This again allows the investigator to isolate and proactively address PFAS occurrence emanating from a specific source and along particular migration pathways that are not confounded with multiple other PFAS discharges to surface water. In other instances, the site setting and promulgated or pending surface water criteria may warrant surface water sampling.

Mathematically, contaminant mass flux is the product of the contaminant concentration in groundwater and the groundwater flux. Evaluating mass flux will help determine the mass of PFAS discharging from groundwater to surface water, and the associated impacts to surface water or sediment. **Figure 1-19** illustrates the mass flux evaluation concept, which requires one or more vertical planes of discrete monitoring points. This represents a depth-discrete groundwater sampling approach, which is consistent with Kornuc et al. (2022). See the ITRC "Use and Measurement of Mass Flux and Mass Discharge" Technology Overview for more details on mass flux analysis (ITRC 2010).

Source: (Graphic courtesy HydroGeoLogic Inc.) Figure 2-4. in ITRC Use and Measurement of Mass Flux and Mass Discharge (ITRC 2010).

1.3.8.3 Selection of Analytical Methods

There has been rapid development of a variety of methods for analyzing environmental media for PFAS and other fluorinated compounds. When selecting methods, their utility and limitations should be understood to avoid employing unnecessary methods or inaccurate interpretation of results. See **Section 11.2** for more information about analytical methods.

The following list provides suggestions and caveats for strategic use of these methods:

- Target analyses—Target analytical methods (for example, USEPA Method 1633A, USEPA 2024) are most commonly used and appropriate for PFAS site investigations. They use certified calibration standards to detect and quantify a list of specific PFAS in a variety of environmental media. Often, the full method analyte list is run, particularly for initial site investigation. Multiple analytes allow for: 1) forensic assessment, 2) determination of firefighting foam composition, 3) identification of precursors and associated transformation, 4) PFAS fractionation evaluation, and 5) accounting for type and mass of multiple PFAS affecting treatment and remediation. Reducing the reporting list may be warranted after collection of a robust data set and thorough investigation of potential PFAS sources.

- Non-targeted analyses — Combined with a suspect screening search, non-targeted analyses can identify the presence of a broad range of PFAS not typically reported with target analytical methods. Non-targeted analyses, such as quadrupole time-of-flight (qTOF), are useful for forensic purposes and to validate the detection of individual PFAS by target analyses but are not quantitative. Non-targeted analysis may also identify unexpected PFAS that may warrant additional inquiry or explanation. See **Section 11.4.3**.

- Total organic fluorine analyses—Analytical methods for the detection of total organic fluorine, such as adsorbable organic fluorine or extractable organic fluorine, have been in recent development. Results may include PFAS and non-PFAS and do not identify individual PFAS or other compounds. These methods typically have higher method detection limits than target analyses. Of these methods, USEPA Method 1621, Determination of Adsorbable Organic Fluorine in Aqueous Matrices by Combustion Ion Chromatography, is multilab-evaluated and accredited for compliance monitoring (USEPA 2024; see **Section 11.2.2.4)**. This type of analysis may be useful for applications such as treatment system design or performance monitoring by mass removal, where the system is affected by all organofluorine molecules. This type of analysis should not be used as a site investigation "dragnet" for the broad detection and identification of PFAS. Such an approach would result in nonspecific results that could be affected by non-PFAS or unregulated PFAS with no criteria for evaluation, potentially creating an unfounded inference that the site is adversely affected by regulated PFAS.

- TOP assay—This method has been in existence for several years and is generally well established. The method subjects a sample to aggressive oxidation conditions, which forcibly transforms precursor PFAS to fully fluorinated terminal PFAS. It is useful to evaluate the potential for precursor transformation in the environment or within certain treatment systems (for example, emerging destructive technologies such as supercritical water oxidation [SCWO]). It can also be used to normalize concentrations of samples in various stages of precursor degradation for forensic comparison. Ateia et al. (2023) provided additional insight for the applications and challenges of TOP assay. The oxidation step in TOP assay transforms precursor PFAS to terminal PFAAs, but the terminal products in this reaction are not necessarily the same as the ones that would be produced in nature. For example, TOP assay transforms PFSA precursors into PFCAs. Also, the strongly oxidizing conditions can result in chain-cutting reactions, such that the mixture of PFAA compounds produced may be smaller on average than would be found under normal environmental conditions. TOP assay results should not be construed to indicate that precursors

will necessarily degrade to terminal degradation products in the environment because TOP assay laboratory conditions do not represent field conditions (see **Section 11.2.2.2** for more information about the TOP assay).

1.3.8.4 Appropriate Application of Criteria

Regulatory criteria have been (and are being) developed for PFAS in a variety of environmental media with certain ecological and human exposure scenarios in multiple jurisdictions (see the **Environmental Media Values Table**). Sometimes these criteria are misapplied out of a sense of caution/conservatism, convenience, or due to misunderstanding of the CSM. Certain comparisons may be protective as a screening-level evaluation but may warrant additional site-specific assessment before they drive remedial action. Examples include comparing leachate concentrations to groundwater criteria or comparing groundwater results to surface water criteria. Investigation data should be collected in a manner that supports comparison to applicable regulatory criteria.

- ***Drinking water criteria are not necessarily applicable to groundwater concentrations.*** Drinking water criteria are commonly the basis for groundwater remediation standards. In some instances, groundwater may be nonpotable, restricted, or of insufficient yield. Turbid groundwater samples can reflect an elevated PFAS concentration in water that would not be consumed by humans due to the turbidity. Well development/rehabilitation and proper well construction should be implemented to reduce turbidity for groundwater samples that are more representative of potential drinking water. In some instances, groundwater criteria are based on various aquifer classifications or use scenarios. Criteria should be selected according to site conditions and setting. Exceeding a generic drinking water criterion may warrant further evaluation.

- ***Soil leachate sample results do not represent groundwater concentrations.*** PFAS in soil leachate samples (for example, synthetic precipitation leaching procedure [SPLP]) are measured under laboratory conditions and differ from field leachate concentrations (see **Section 1.3.8.6** for additional information about leaching). Leachate may undergo additional processes before encountering groundwater (for example, resorption as leachate migrates through the vadose zone, precursor transformation, and dilution in groundwater). Leachate sample results should be compared to leachate-specific regulatory criteria where these criteria exist. Otherwise, a site-specific evaluation relative to potential groundwater impacts may be warranted (see **Section 1.5.1**).

- ***Groundwater results do not represent surface water concentrations.*** Groundwater discharge to surface water often involves additional sorption to organic sediments, enhanced sequestration to sediments due to brackish or saline porewater, and dilution in the surface water body. If groundwater concentrations exceed surface water criteria, additional evaluation is warranted. Refer to **Section 1.3.4** on PFAS Groundwater-Surface Water Interactions and **Section 1.3.8.2** on Surface Water Receptors for a mass-flux approach to evaluate the potential impact to surface water.

- ***There are multiple factors for surface water criteria.*** Surface water criteria are commonly very stringent (close to analytical detection limits) due to the potential for bioaccumulation of PFAS to higher trophic levels, other ecological effects, and for protection as drinking water. Ecological criteria for surface water may be less stringent when they reflect the effect of PFAS on certain organisms without bioaccumulation. In some instances, there are surface water criteria for human recreation, based on dermal exposure and limited/incidental ingestion; these tend to be less stringent. Surface water criteria may also be differentiated based on fresh versus brackish versus seawater; these should not be used interchangeably. Emerging human health concerns, unrelated to drinking water, are also driving stringent criteria (for example, full-body-contact recreation sites, aquatic life harvesting, and subsistence fishing).

1.3.8.5 Repurposing and Refining the Conceptual Site Model

PFAS may occur at a site for which a CSM has already been developed for other contaminants. In this case, it can be efficient and cost-effective to use findings and elements from the existing CSM for purposes of the PFAS investigation. Such elements include hydrostratigraphic framework, groundwater flow direction, seepage velocity, aquifer structural/matrix properties, pathways, and receptors. In some instances, PFAS may interact with other known contaminants (for example, NAPL) that should be accounted for in the CSM. In most cases, the CSM will likely require additional PFAS-specific spatial, physical, and chemical information to be useful and reliable.

Characterization of PFAS vertically through the soil profile is an important aspect of the PFAS CSM, due to unique retention properties (for example, air-water interfacial sorption) and accumulation at discrete horizons (for example, clay– or organic carbon–enriched layers). Pre-existing, detailed soil characterization can be repurposed in the PFAS CSM or profiled in detail for the first time to support the PFAS CSM. Continuous and discrete vertical characterization of PFAS in the soil profile should be considered (at least at targeted locations) and can be augmented with potentially unconventional tools such as lysimeters to characterize PFAS concentration in porewater/retained at the AWI.

A strategic consideration for the PFAS CSM is the effect of the capillary fringe (tension-saturated zone above the water table and below the unsaturated zone). Fluctuations in the capillary fringe may mobilize PFAS (Das et al. 2024), especially where they are otherwise retained by air-water interfacial sorption. Porewater characterization (for example, sampled with lysimeters) of the capillary fringe is a means to quantify aqueous concentrations of PFAS in this zone of saturation above the water table, which could not otherwise be sampled via a monitoring well.

PFAS CSMs should also account for migration, attenuation, and transformational processes affecting PFAS: precursor degradation, sorption, dispersion, and matrix diffusion (Kornuc et al. 2022; Newell et al. 2021; Newell et al. 2021). Adamson et al. (2022) noted the marked concentration reduction of PFAS measured in groundwater along the migration pathway from the source areas, attributing this to nondestructive retardation/retention processes of hydrophobic, air-water interfacial sorption, and electrostatic partitioning. **Section 5** includes information about PFAS fate and transport process.

1.3.8.6 PFAS Characterization by Media and Pathway

This section describes the approach, tools, and techniques for sampling and investigation design. **Figure 1-20** presents a conceptual graphic for the characterization of PFAS, using an AFFF site as an example. Sites with other PFAS sources may require different conceptualization for investigation design.

Beyond sampling for PFAS specifically, several site-specific parameters related to soil and aquifer matrix properties and solutions chemistry affect the partitioning, mobility, and distribution of PFAS. These include soil type (mineralogy and grain size), pH, and organic matter/total organic carbon (TOC) (Hubert et al. 2023; Feng et al. 2024, Wanzek et al. 2023). Refer to **Section 5.2** for information about phase partitioning. For information about collecting samples for PFAS, refer to **Section 11.1**.

Soil

Many PFAS (for example, PFOS) are sorptive, recalcitrant, and nonvolatile. When released to the surface of soil, they may be retained for relatively long durations (depending on soil characteristics), preserving the pattern of the original surface release. High-density, shallow soil sampling of suspected source areas and drainage ways for PFAS analysis is often appropriate. This can be conducted by manual methods (for example, hand-auger, shovel, or trowel) or direct-push sampling apparatus. Designating a percentage of these samples (spatially distributed) for PFAS leachate analysis (for example, SPLP) will provide an indication of PFAS leaching potential. As noted above, laboratory leachate results are not a direct indicator of expected groundwater PFAS concentrations. Consider also sampling soil downwind (which may be hydraulically upgradient) where PFAS may have migrated by aerial dispersion and deposition or deposition by mist drift, as with firefighting foam.

Though retained in shallow soil, PFAS are commonly distributed vertically through the vadose zone, partitioning to organic carbon and charged mineral surfaces (**Figure 1-21**). PFAAs and other amphiphilic PFAS are also retained by air-water interfacial adsorption, which is unique to this class of contaminants (Brusseau et al. 2019; Brusseau and Van Glubt 2019). See **Section 1.3.1** for more information about vadose zone characterization and transport and **Section 1.5.1** for information about leaching methods. Retention by air-water interfacial sorption is transient and cyclic, as PFAS may be leached and mobilized to groundwater by infiltration and subsequently resorbed, as air and water phases return in the pore space. Inversely, PFAS may also be mobilized vertically upward in the soil profile because of evapotranspiration or fluctuation of the capillary fringe (Wallis et al. 2022). **Figure 1-21** illustrates a hypothetical **example** vertical PFAS concentration profile relative to soil type and TOC concentration. The

figure shows the discrete vertical distribution of PFAS both by concentration and proportion of individual PFAS and how they are affected by discrete soil characteristics.

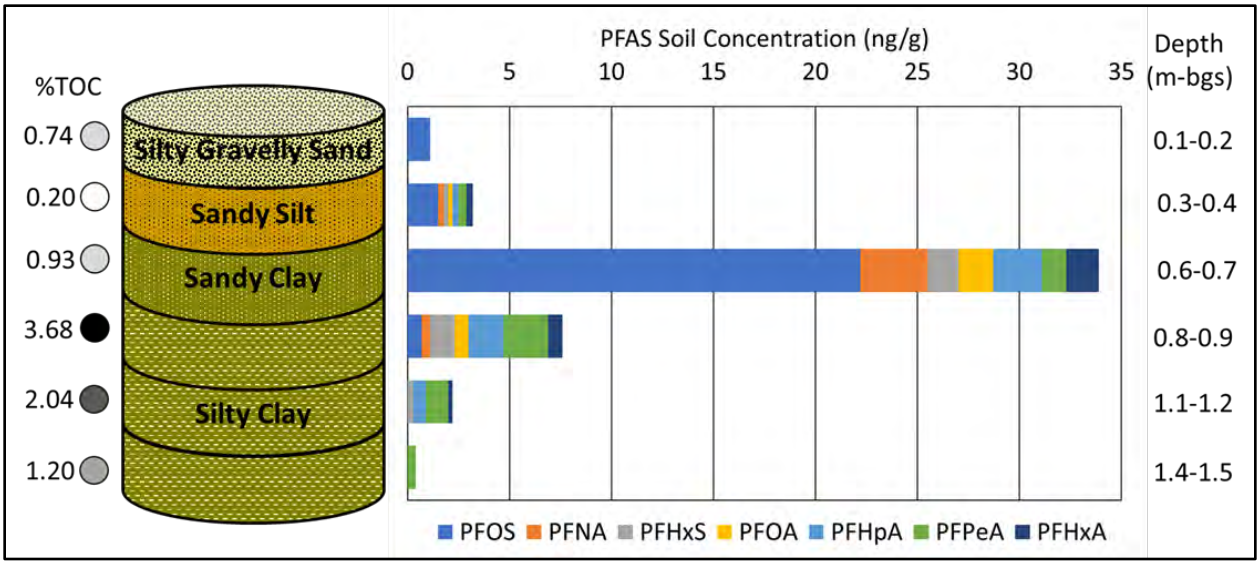

Figure 1-21. Hypothetical example of PFAS vadose zone distribution and matrix. Depth given in meters below ground surface (m-bgs).

Source: J. Hale, Kleinfelder. Used with permission.

Table 1-7 provides a summary of the types of soil characteristics that can be collected to produce a vertical profile of the vadose zone, including the purpose or utility and suggested sampling frequency for each category of soil characteristics. Campos-Pereira et al. (2023) described the effects of pH, surface charge, and soil properties on PFAS partitioning to solids in a variety of soils. A proportion of surface soil sample locations should be designated for vertical profiling, selected to provide spatial coverage, and biased toward areas of natural runoff. High-resolution and depth-discrete soil sampling is consistent with the approach taken by Kornuc et al. (2022).

Table 4-1 shows that laboratory and field studies have resulted in a wide range of sorption values (K_d or K_{oc}) for individual PFAS, indicating the degree of sorption or leaching for various PFAS species is highly dependent on the setting due to parameters noted above. Because of this variation, some regulatory agencies, including the USEPA, advise the derivation and use of site-specific sorption coefficients to inform potential risk of PFAS leaching to groundwater. Two common methods are discussed in USEPA (2025) and are summarized below. Navarro et al. (2024) provided a comprehensive summary of additional methods for evaluating PFAS leaching from soil and other solid materials.

SW-846 Test Method 1312: Synthetic Precipitation Leaching Procedure is a relatively common method for assessing PFAS leachability from soil (USEPA 1994). The procedure involves mixing an extraction fluid composed of reagent water adjusted to a pH of 4.2 or 5.0 (depending on the sample's geographical origin) with a mix of nitric and sulfuric acids and shaking the mixture for 18 hours with the intent to simulate natural leaching in the environment. The USEPA (2025) guidance described a modified SPLP procedure that is specific to PFAS. Modifications include differences in materials as well as a reduction of sample volume and the use of a methanol solution for total extraction in parallel with the standard extraction fluid.

Lysimeters can be used to extract and analyze porewater from the vadose zone and capillary fringe, where PFAS may be sequestered via air-water interfacial sorption. Lysimeters are purged by applying

vacuum to the system, which moves porewater through the apparatus into a secondary containment vessel. The sample volume from each purge event of the lysimeter may be less than the required volume for analysis. In this case, samples from multiple events may need to be composited or arrangements made with the laboratory to analyze a lesser sample volume. Ideally, samples will be acquired during discrete events that reflect the then-current porewater saturation and infiltration conditions. USEPA (2025) noted that while lysimeters have the advantage of measuring actual pore water conditions at a site, there are uncertainties regarding whether commonly used materials in lysimeters adsorb PFAS and the implementation and interpretation of results is complex compared to SPLP. Results of studies using lysimeters to derive site-specific values to protect groundwater should be interpreted with caution.

Testing/Analysis	Purpose	Sample Selection
Field Description		
Texture, Grain Size, Moisture	Understanding of soil type; cofactors in PFAS sorption & leachability	Continuous vertical description
Soil Mineralogy		
Color		
Organic Matter, Staining, NAPL		
PFAS		
Soil PFAS	PFAS distribution in soil profile	One sample per discrete interval (0.5 ft or 0.1 m)
SPLP PFAS	Leachability of PFAS and correlation to soil concentration	
Porewater PFAS	PFAS porewater concentrations and migration to groundwater potential	Collected via dedicated lysimeters over time to capture range of infiltration and soil moisture conditions
Geotechnical, General Chemistry, & Matrix Parameters		
Grain Size (sieve and hydrometer)	Understanding of soil type; cofactors in PFAS sorption & leachability	One sample per soil type per boring
Unified Soil Classification System (USCS) Soil Classification; Engineering		
Soil Mineralogy		
Soil pH		
Soil Salinity/Conductivity		
Anions (sulfate, fluoride, chloride)		One sample per soil type (minimum one sample from each material type comprising the soil; samples from multiple locations preferred)
Cations (Ca^{2+}, Mn^{2+}, Mg^{2+}, Fe^{3+})		
Cation/Anion Exchange Capacity		
Moisture Content		One sample per discrete interval (0.5 ft or 0.1 m)
Total Organic Carbon (TOC)		

Groundwater

Table 1-8. Aquifer matrix and groundwater chemistry sampling.

Testing/Analysis	Purpose	Sample Selection
Field Parameter Measurements		
pH	Lower pH (elevated hydrogen ion activity [H^+]) enhances anionic PFAS sorption (reduced aqueous concentration)	Measure with field meter at every monitoring well sampled
Salinity/Specific Conductivity	Positively correlated to PFAS sorption (reduced aqueous concentration)	
Oxidation-Reduction Potential (ORP)	Oxidizing conditions conducive to aerobic precursor transformation; reducing conditions limit aerobic transformation	
Turbidity	PFAS adhere to solid particles and colloids. Turbidity can affect and skew PFAS concentration results	
Aqueous Laboratory Analyses		
Calcium Ion (Ca^{2+}) Concentration	Positively correlated to PFAS sorption (reduced aqueous concentration)	Discretionary analysis for more robust characterization of sorption influences
Aquifer Matrix Parameters		
Grain Size (sieve and hydrometer)	Understanding of aquifer matrix and permeability	Laboratory analysis. Obtain from prior investigation or collect from saturated zone when installing monitoring wells for PFAS sampling (minimum one sample from each material type composing the aquifer matrix; samples from multiple locations preferred)
USCS Soil Classification; Engineering		
Total Organic Carbon (TOC)	Positively correlated to PFAS sorption (reduced aqueous concentration)	
Cation/Anion Exchange Capacity	Cofactors in PFAS sorption & leachability	
Bulk Density	Fate & transport retardation parameter	
Effective Porosity	Key parameter for seepage velocity of dissolved PFAS	Select samples of aquifer matrix (in saturated zone) acquired via borings or in conjunction with monitoring well installation
Aquifer Hydraulic Characteristics		
Hydraulic Conductivity	Key parameter for seepage velocity of dissolved PFAS	Slug testing of select monitoring wells or aquifer testing. Data may exist from prior site characterization

In some circumstances, existing monitoring wells are useful for initial groundwater characterization of PFAS. The following considerations should be evaluated when using an existing monitoring well network for initial PFAS investigation:

- location of monitoring wells relative to the suspected source and in the downgradient direction, informed by PFAS soil characterization results
- depth and screened interval of monitoring wells
- status of monitoring well construction, development, and rehabilitation
- potential for prior use of PFAS-containing materials in the construction of the monitoring wells
- presence of NAPL

Notably, turbidity in monitoring wells is problematic due to the sorptive nature of certain PFAS and the low detection/regulatory criteria (ng/L) for PFAS. Consequently, redevelopment of existing monitoring wells, and proper design (screen slot size and filter pack) and development (bidirectional surging, purging, and field parameter monitoring) of new monitoring wells, are important to reduce turbidity. The analytical laboratory should be consulted if the groundwater samples remain visually turbid.

In the absence of suitable existing monitoring wells, new monitoring wells should be installed based on knowledge of PFAS sources and groundwater flow directions, informed by the desktop review and surficial soil sampling. Monitoring wells should be constructed with and installed using PFAS-free equipment and materials. As an example, the US Navy conducted a study on coated bentonite pellets used in monitoring wells and found PFAS in the leachate from several different brands of pellets (Radford et al. 2023). Drill cuttings and purge water may have special handling and disposal requirements based on the potential presence of PFAS.

PFAS are soluble, so screen interval and placement should not be based on expectations of a "floating" or "sinking" separate phase, but rather potential for vertical hydraulic gradients. The occurrence of PFAS in groundwater will be determined during the initial phase of PFAS characterization sampling of groundwater monitoring wells. Similar to other solutes, PFAS in groundwater migrate by advection and dispersion and, depending on the specific PFAS, may be subject to varying degrees of retardation (though generally expected to be less than in the vadose zone). Investigators should obtain hydraulic conductivity from existing site characterization information or conduct aquifer testing (for example, slug or pumping tests) by conventional means for the calculation of seepage velocity, if needed. Aquifer matrix characteristics and aquifer chemistry influence the sorption of and potential precursor transformation of PFAS. Refer to **Table 1-8** for aquifer matrix and groundwater chemistry parameters for measurement and analysis.

Retention of PFAS in Concrete

PFAS are known to partition into and leach from concrete. Consequently, concrete surfaces (for example, fire training pads, storm sewers) represent sinks and sources of PFAS. PFAS in concrete can be characterized by coring, cutting into discrete disks, and laboratory analysis of PFAS and PFAS in leachate (for example, SPLP). Alternatively, PFAS-free water can be rinsed over or maintained in contact with concrete surfaces and subsequently analyzed for the accumulation of PFAS in the water. The phenomena of PFAS sorption and release from concrete, along with methods for analysis, are addressed by Thai et al. (2025, 2025). See **Section 1.5.6** for more information about concrete and asphalt sampling and analysis.

Surface Water Runoff and Storm Sewer Flow

Informed by the desktop analysis, investigators should sample soil and sediment from stormwater conveyances and accumulation features (swales, drainage channels, and stormwater sewer pipes) that may convey PFAS from the source or release locations.

Even after PFAS have partitioned into environmental media following release or application, conveyance by stormwater flow may occur. PFAS can be desorbed from soil, sediment, and concrete during transient precipitation events, or soil and sediment with sorbed PFAS may be mobilized by stormwater flow. Collect aqueous samples of stormwater runoff and storm sewer flow based on prior soil/sediment sampling and desktop review. It may be necessary to coordinate this sampling with forecasted precipitation or simulate the flow, as with concrete washing.

1.4 Priority Topics for Human and Ecological Health Effects

Section Number	Topic
1.4.1	**Potential Human Health Effects of PFAS Exposure Arising from AFFF in Drinking Water**
1.4.2	**Potential PFAS Exposures from Consumer Products**
1.4.3	**Dermal Uptake of PFAS in the Environment**
1.4.4	**Health Effects of Ultra-short-chain PFAS**
1.4.5	**New Information on Considerations for Addressing PFAS as a Class**
1.4.6	**Potential PFAS Exposures in Occupational Setting**
1.4.7	**Evaluating Risk to Livestock from PFAS Exposure**
1.4.8	**Reptiles Toxicity Data**

1.4.1 Potential Human Health Effects of PFAS Exposure Arising from AFFF in Drinking Water

Releases of AFFF (aqueous film-forming foam) to the environment have contaminated drinking water with PFAS worldwide, including in the United States and Scandinavia, with emerging threats to human health still being studied (Hu et al. 2016; Reinikainen et al. 2022; and additional references discussed in this section). Detailed information on AFFF is found in **Section 3**. Health effects studies of populations who ingest AFFF-contaminated drinking water are of interest because AFFF contains a mixture of PFAS, and these populations therefore typically receive higher exposures to multiple PFAS than the general population. The most extensive and complete investigations to date of the potential health effects of exposure to PFAS in AFFF-contaminated drinking water are from a population in Ronneby, Sweden. However, the design of the studies of the Ronneby population was ecologic (as opposed to, for example, cross-sectional or case control) in that PFAS exposure was based on groups categorized by timeframe for use of residential drinking water with high or low PFAS concentrations, not on individual serum levels of PFAS or other measures of individual exposure. The uncertainty associated with the results of this type of study may be addressed in the future as federal Agency for Toxic Substances and Disease Registry (ATSDR)-sponsored studies of the health effects based on individual serum PFAS levels in several US communities with AFFF-contaminated drinking water are published (ATSDR 2025; Pavuk et al. 2025). The potential human health effects of PFAS are discussed in detail in **Section 7.1** and **Section 17.2**.

In the municipality of Ronneby, Sweden, approximately one-third of the households received drinking water described by the investigators as being "highly contaminated" with PFAS arising from AFFF during the mid-1980s to 2013 (Xu et al. 2021). The highly contaminated water supply (one of two water supplies that served Ronneby) was closed shortly after PFAS detection in 2013. The AFFF originated at a nearby military base; however, there are no detailed records of the composition of the AFFF that was used (Xu et al. 2021). A 2013 analysis of perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkane sulfonic acids (PFSAs) in drinking water from the most contaminated water supply showed that the PFAS present at the highest concentration were perfluorooctane sulfonic acid (PFOS) (8,000 ng/L) and perfluorohexane sulfonic acid (PFHxS) (1,700 ng/L), followed by perfluorohexanoic acid (PFHxA) (320 ng/L), perfluorobutane sulfonic acid (PFBS) (130 ng/L) and perfluorooctanoic acid (PFOA) (100 ng/L), among other lesser occurring PFAS (Xu et al. 2021). Although the proportions of specific PFAS found in AFFF-contaminated water differed among locations, the PFAS reported in Ronneby are also frequently prominent in AFFF-contaminated water elsewhere, including in the United States (see **Section 3.1**, **Section 3.5.1**, and **Section 3.5.3**). Biomonitoring of ~3,300 Ronneby residents in 2014 revealed geometric mean serum levels of PFHxS, PFOS, and PFOA of 114, 135, and 6.8 ng/mL, respectively. These serum levels were approximately 135, 35, and 5 times higher, respectively, than PFAS levels in a reference

population in which concentrations of measured PFAS in drinking water were below detection limits (Xu et al. 2021).

Several studies have been reported from the population that lived in Ronneby at any time during the period of PFAS contamination (1985–2013). These studies examined associations between exposure to PFAS from the contaminated drinking water and health conditions, including cancer (Li et al. 2022); thyroid disease (Andersson et al. 2019); thyroid hormone levels (Li et al. 2021); birthweight (Engström et al. 2022); type 2 diabetes (Xu et al. 2023); breastfeeding (Nielsen et al. 2022); COVID (Nielsen and Joud 2021); inflammatory bowel disease (Xu et al. 2020); and bone fractures (Xu et al. 2023), and are further discussed below.

To characterize exposure, the study authors relied on residency records that linked individual residence addresses to drinking water delivered by the contaminated water supply and another nearby water supply that was minimally contaminated. Another unexposed municipality served as a reference population. Several categories were used by these authors (Li et al. 2020, 2022; Andersson et al. 2019; Li et al. 2021; Engström et al. 2022; Xu et al 2021; 2023; 2023; Hammarstrand et al. 2021; Nielsen et al. 2022; Nielsen and Joud 2021) to categorize PFAS exposure groups relevant for their analysis. Most authors categorized residents who had received the most highly contaminated water as “ever high,” while “never high” was defined as Ronneby residents supplied by the minimally contaminated water source (PFOS = 27 ng/L, all other measured PFAS individually <=10 ng/L) and who never received highly contaminated water during the entire study period of 1985–2013 (Li et al. 2020; Hammarstrand et al. 2021 ; Xu et al. 2021; Li et al. 2022; Xu et al. 2023; 2023). Additional exposure subcategories of “early high” (residential time: 1985–2004) and “late high” (residential time: 2005–2013 and may include 1985–2004) were used to evaluate the impact of the time period when residents had received highly contaminated water. Residents in the “late high” group had higher serum levels of PFOS (geometric mean: 239 ng/mL), PFHxS (geometric mean: 210 ng/mL), and PFOA (geometric mean: 13 ng/mL) when compared to the “early high” (geometric mean: PFOS: 48 ng/mL, PFHxS: 43 ng/mL, and PFOA 3.6 ng/mL) or the “never high” (geometric mean: PFOS: 40 ng/mL, PFHxS: 30 ng/mL, and PFOA 3.5 ng/mL) exposure groups. Geometric mean serum levels of the “never high” exposure group were similar to the “early high” exposure group (Li et al. 2022; Xu et al. 2023; 2023). The mean geometric serum associated with the “ever high” category was reported as PFOS: 199 ng/mL, PFHxS: 179 ng/mL, and PFOA: 11 ng/mL (Li et al. 2022).

Using these exposure groupings, Li et al. (2022) evaluated PFAS exposure and cancer in Ronneby residents across each exposure group and in comparison, to an external reference group consisting of residents from a neighboring municipality whose drinking water was not contaminated with PFAS during the exposure period. The overall risk of cancer was not elevated in the exposed populations, and there was no excess prostate or breast cancer risk. Statistically insignificant increases in hazard ratios (HRs) were observed for several cancers (such as kidney, bladder, brain, bone and cartilage, thyroid, and testicle) in the “ever high” group. The authors concluded that there was some evidence for an elevated risk of kidney cancer. This conclusion was based on an increased (non-statistically significant; HR: 1.27; 95% CI: 0.85, 1.91) standardized cancer incidence ratio for kidney cancer in the “ever high” versus “never high” groups, with a non-statistically significant increase in the HR of kidney cancer in the “late high” (HR: 1.85; 95%CI: 1.00, 3.40) versus “early high” (HR: 1.05; 95%CI: 0.64, 2.84) group.

Xu et al. (2023) used the same exposure categories to examine the risk of bone fractures and PFAS exposures in the Ronneby population. There were significantly increased HRs of major osteoporotic fractures (HR 1.11, 95% CI 1.03–1.19) and a non-statistically significant increase in hip fractures (HR: 1.12; 95% CI: 1.00–1.24) between the “ever high” and “never high” exposure groups. Significantly increased HRs for major osteoporotic fractures (HR 1.29, 95% CI 1.16–1.44) and for hip fractures (HR 1.22, 95% CI 1.01–1.47) were also documented in individuals in the “late high” group when compared to the “early high” group.

Andersson et al. (2019) found no increased risk of hyperthyroidism among those residents who received PFAS-contaminated drinking water; an increased risk in a surrogate measure of hypothyroidism was attributed to chance given that the response was not dose-related. Similarly, no consistent evidence was reported by Li et al. (2021) to link ingestion of PFAS-contaminated drinking water to alterations in the levels of hormones (free T3 and free T4 or thyroid-stimulating hormone) affecting thyroid function.

Hammarstrand et al. (2021) reported that exposure to higher levels of PFAS were associated with significantly higher HR for polycystic ovarian syndrome (HR: 2.18; CI: 1.43, 3.34) and non-statistically significant elevated HR for uterine leiomyoma (HR: 1.28; CI: 0.95, 1.74), but not for endometriosis in premenopausal women.

HRs for diagnosed inflammatory bowel disease (IBD), such as Crohn's disease, ulcerative colitis, and "other IBD," were not increased in "mid" (a group who received highly contaminated drinking water during 1995–2004) and "late" (2005–2013) period exposure groups, while individuals in the "early" period exposures (1985–1994) had increased HRs for Crohn's disease and nonspecified IBD (Xu et al. 2020). Xu et al. (2020) concluded that there was no consistent evidence for PFAS increasing the occurrence of IBD given that individuals exposed in the "late" period had higher PFAS serum levels than those from the "early" period and that IBD cases in the "early" and "late" exposure groups had 2.5 versus 4.8 years of early exposure prior to diagnosis, respectively. Thus, the higher HRs in the "early" period were not explained by either higher PFAS exposure or a longer exposure time.

Consistent with the studies included in the recent reviews by the European Food Safety Authority (EFSA) (2018) and others (see **Section 17.2.4**), Li et al. (2020) reported statistically significant increases in mean total cholesterol and low-density lipoprotein in the "total exposed" population (recently exposed + nonrecent/uncertain exposure). Li et al. (2020) also found positive associations between serum levels of PFOS, PFHxS, and PFOA and serum levels of total cholesterol, LDL, and high-density lipoprotein (HDL) in the "recently exposed" group (that is, those who were provided contaminated drinking water in 2005–2013).

Long-term exposure to PFAS in drinking water was also associated with increased risk for type 2 diabetes in the Ronneby population (Xu et al. 2023). Xu et al. (2023) found elevated HRs for type 2 diabetes in the "ever high" (HR: 1.18, CI: 1.03–1.35) exposure group, including the subgroups of "early high" (HR: 1.12, CI: 0.98–1.50) and "late high" (HR: 1.17, CI: 1.00–1.37) when compared to the "never high" exposure group after adjustments for age and sex. A higher HR was associated with younger age group (18–45 years old) when compared to the older age group (>45 yrs old), indicating the potential for early onset diabetes. This HR estimate was attenuated when the study sample was adjusted for educational level as a socioeconomic factor but still indicated the direction of association toward higher HRs (Xu et al. 2023).

Standardized incidence ratios (SIR) for occurrence of COVID-19 were significantly higher in both the overall Ronneby population (SIR: 1.19; 95% CI: 1.12, 1.27) and in the contaminated area (SIR: 1.16; 95% CI: 1.01, 1.30) (Nielsen and Joud 2021). The total Ronneby population has greater concentrations of PFAS in the serum than the general population, and this may reflect an association between COVID-19 and PFAS exposure, but this needs to be explored further. This study was based on aggregate data collected over the first year of the pandemic and thus, the individual data that would have been preferable to explore effect relationships at the lower exposure levels are lacking.

Pregnant women in the Ronneby municipality were recruited between 2015 and 2020 to study PFAS in serum, breast milk, and colostrum of mothers exposed to PFAS in drinking water (Blomberg et al. 2023; Blomberg et al. 2023). Seven PFAS—PFOS, PFOA, PFHxS, perfluorononane sulfonic acid (PFNA), perfluorodecanoic acid (PFDA), perfluoroundecanoic acid (PFUnDA), and PFHpS—were found in samples of serum, colostrum, and breast milk, with higher concentrations strongly correlating to highly exposed mothers. On average, PFHxS and PFOS were the largest contributors to total PFAS in colostrum and breast milk (Blomberg et al., 2023; Blomberg et al. 2023). PFAS concentration also varied over the course

of lactation, with PFOS increasing by 21% while PFOA and PFHxS decreased by 17% and 12%, respectively, from colostrum to mature breast milk (Blomberg et al. 2023). Over an 8-month lactation period, the general trend was a greater monthly decrease in PFOA concentrations, while PFHxS and PFOS exhibited small and nonsignificant decreases (Blomberg et al. 2023). The transfer efficiencies of PFAS from serum to colostrum and breast milk were similar across exposure groups (categorized by the PFHxS concentration) with greater transfer efficiencies for PFCAs (such as PFOA) than PFSAs (such as PFHxS and PFOS) (Blomberg et al. 2023). The higher transfer efficiency may contribute to the faster decline in PFOA observed over the course of lactation (Blomberg et al. 2023). The transplacental transfer efficiency reported in a similar study found that overall transfer efficiencies were higher for PFHxS, PFOA, and branched PFOS, and lowest for the n-PFOS isomer (Norèn et al. 2025). These studies have indicated that high exposure to PFAS leading to high maternal serum concentrations may result in higher absolute prenatal exposure (Norèn et al. 2025), as well as newborn exposure throughout the lactating period (Blomberg et al. 2023; Blomberg et al. 2023).

Additionally, Nielsen et al. (2022) studied breastfeeding initiation and duration in Ronneby mothers. A non-statistically significant increase in not initiating breastfeeding at birth (relative risk: 1.2; 95% CI: 0.9, 1.6) was observed in mothers who lived at an address served by the highly contaminated water supply for one year or longer. Regarding duration of breastfeeding, there was a statistically significant 1.6-fold increased risk (95% CI: 1.2, 2.1) of not breastfeeding at 6 months and a non-statistically significant 1.2-fold increased risk (95% CI: 0.9, 1.6) of not exclusively breastfeeding at 3 months in highly exposed (i.e., living at an address served by the highly contaminated water supply for one year or longer) mothers.

PFAS contamination was associated also with birth weight variations, which differed in direction in males versus females, in the Ronneby population. Engström et al. (2022) found statistically significant differences in birth weight for “high exposure” infants born after 2005 but not before. “High exposure” was defined as an infant whose mother was exposed to highly contaminated water for at least one year of the 5 years before the birth of the infant, whereas “low exposure” referred to infants whose mothers had lived in an area of Ronneby without highly contaminated drinking water. For male infants, these differences were exhibited as lower mean birthweights, whereas female infants had higher mean birthweights. These birthweight differences were approximately 50 g in both sexes, a change that the authors considered to be small and indicative of a “minor influence” on birth weight. The findings in this study add to the discussion in **Section 17.2.4**, where it was noted that long-chain PFAS, particularly PFOA and PFOS, were associated with changes in infant birthweight.

This review focused on the PFAS exposure from AFFF contamination in drinking water in the Ronneby population during the mid-1980s to 2013. These studies indicated high exposure to PFAS may be associated with an observed increased risk for several health outcomes, such as osteoporotic fractures, female reproductive diseases (polycystic ovarian syndrome and uterine leiomyoma), higher cholesterol levels, type 2 diabetes, and COVID-19 in the exposed Ronneby community. Prenatal exposure to PFAS was also of concern because high transplacental transfer efficiencies were demonstrated for several PFAS in pregnant women (Norén et a. 2025). Evidence was also presented for PFAS in the serum, colostrum, and breast milk of exposed mothers, indicating exposure to PFAS through breastfeeding (Blomberg et al. 2023; Blomberg et al. 2023). Furthermore, the presence of PFAS in mothers was associated with changes in breastfeeding patterns (Nielsen et al. 2022) and small variations in birthweight (Engström et al. 2022). However, these studies were not without limitations, as most of them were based on ecological study of exposure groups that were location- and time period–specific rather than on serum concentration or other more specific attributes of exposure (Nielsen and Jöud 2021; Hammarstrand et al. 2021; Nielsen et al. 2022; Xu et al. 2023; Xu et al. 2023). Most of the health effects data came from census and other health registers with limited individual information on relevant potential confounding variables (Hammarstrand et al. 2021; Li et al. 2020; Li et al. 2022; Nielsen et al. 2022; Xu et al. 2023; Xu et al., 2023). Nevertheless, similar associations were found in several epidemiological studies, as presented in **Section 17.2.4**, noting PFAS exposure, particularly to PFOA and PFOS and changes in serum cholesterol, birthweight, immunity, and carcinogenicity.

1.4.2 Potential PFAS Exposures from Consumer Products

Section 2.5 presents information about PFAS that may be found in products. In this section, potential direct exposures to PFAS from consumer products are discussed. Direct exposure refers to the human intake of PFAS that may occur during the intended use of a consumer product, such as dermal absorption from treated textiles, ingestion from food contact materials, or inhalation of volatilized substances, and excludes exposure due to environmental dispersion, legacy contamination, or degradation of PFAS-containing waste materials. This section summarizes information on major categories of consumer products that may contain PFAS and may contribute to human exposure, but this should not be viewed as a definitive and exhaustive review given the evolving understanding about the uses of PFAS in consumer products, the state of analytical methods (see **Section 1.5.4**), and regulatory definitions that may include or exclude certain PFAS from existing reporting requirements. The **Regulatory Programs Table** includes information about regulations related to the ban of PFAS in certain categories of consumer products.

Existing literature has sought to identify and categorize PFAS use across applications, including consumer products. One of the earliest comprehensive efforts was Glüge et al. (2020), who published an overview of PFAS uses in distinct product categories, including consumer and industrial applications using information from databases, patents, PFAS manufacturers, and primary literature. The overview further differentiated industrial categories (for example, building and construction materials) and other use categories, including certain consumer products (Glüge et al. 2020). More recent efforts have focused on similar categories of consumer products for comparing PFAS concentrations as reported by manufacturers or identified through independent analyses. Dewapriya et al. (2023) reviewed available data and publications for 1,040 consumer products from 15 countries to compare total PFAS concentrations that ranged from parts per thousand (ppt) to parts per million (ppm). Textile products (381 products) had the highest mean concentration of total PFAS (303 ppm), followed by household cleaning products such as fabric treatments and detergents (122 products) estimated to have a mean concentration of 208 ppm, and then lower mean concentrations in lubricants and oils (121 ppm across 5 products), building materials (79 ppm across 62 products), and cosmetics (58 ppm across 75 products) (Dewapriya et al. 2023). However, the maximum concentrations reported within each of these consumer product categories demonstrate significant variability of total PFAS concentrations that range by a factor of 2–10. As noted in the Dewapriya et al. (2023) review article, there are inherent uncertainties about the reported concentrations in various products due to a lack of standardized analytical methods, quality assurance/quality control (QA/QC) practices for different matrixes, and changes in target analytes. Such reviews highlight the likely occurrence of PFAS in consumer products with considerable variability in total concentrations and provide a framework of subcategories to further evaluate and prioritize for human exposure potential.

Outside of primary literature, the US Consumer Product Safety Commission (CPSC) commissioned a report to summarize available information on the potential for human exposures to PFAS in consumer products (RTI 2023), including releases to the environment from initial production to disposal. RTI (2023) reviewed 28,299 patents across consumer product categories including “childcare products; clothing, apparel, jewelry, and accessories; containers and packaging; electronics; food products; household products; infant formula; outdoor recreation, sports, and fitness.” The report identified PFAS based on available peer-reviewed literature, patent reporting, and multiple US Environmental Protection Agency (USEPA) databases, with limited examples of specific PFAS, but it is not an exhaustive listing of the amounts and types of each individual PFAS in consumer products. With respect to human exposure, the report concluded that several processes, including abrasion, transfer to indoor surfaces, transfer to skin, transfer to saliva, absorption into food, and the volatilization of PFAS in various consumer products, likely contribute to multiple exposure pathways (RTI 2023). However, quantifying the risk is complicated due to the diversity of products and limited quantitative information on these processes.

A significant challenge for characterizing the occurrence of PFAS in consumer products by the studies of Dewapriya et al. (2023) and RTI (2023) and other reports or studies has been the historical lack of PFAS

labeling requirements in products. There have generally been no labeling requirements specific to PFAS based on the intentional use of PFAS in final consumer products or for the unintentional addition of PFAS through manufacturing processes, or the presence of PFAS in ingredients or components in the final product. Although not specific to PFAS, other consumer product labeling requirements such as ecolabels (for example, Cradle to Cradle Certified, Green Seal, Declare 2.0) include certain definitions of PFAS or reporting requirements for very specific groups of consumer products (USEPA 2023; 2025). Much of the available primary literature on the presence of PFAS in products is the result of product-specific testing rather than broader sampling of products across larger categories of consumer products. **Section 8.2.3.1** and the **PFAS Regulatory Programs Summary** Excel File provide more specific information about state-level regulations that may require labeling for products containing PFAS; however, the adoption and implementation deadlines for these requirements are frequently changing and readers are advised to confirm current labeling requirements with state regulatory agencies.

The following sections provide summaries of available information on exposure to PFAS in subgroups of consumer products. These subcategories include the products and related products through common applications (for example, upholstery/carpets and carpet cleaning agents). Given the potential variety of consumer product categorization schemes, combined with the limited literature for each of these highly specified groupings, the following sections reflect groupings that are based on broader categories of related products or similar intended function of PFAS in consumer products. The groupings in the following sections also considered similarity of potential exposure pathways from products. The aforementioned reports (Dewapriya et al. 2023; RTI 2023) provide detailed information about specific consumer products. Other sections of this ITRC document provide more details about PFAS in product categories that apply to both personal consumer goods and commercial or industrial applications (**Sections 2.5** and **2.6.1**). This includes a summary in **Table 2-6**.

1.4.2.1 Textiles, Including Furniture, Furnishings, and Apparel

PFAS are applied to fabrics and textiles used in furniture, upholstery, carpets, and other products to impart water-, oil-, and stain-repellant properties. During production, treatment, use, or disposal of these materials, workers and consumers may potentially be exposed to PFAS (European Environment Agency 2024). Potential consumer exposure could occur through direct skin contact and absorption, hand-to-mouth transfer after handling these textiles, direct contact with the mouth (for example, mouthing behaviors of infants and small children) or the generation of dusts, volatiles, or other airborne forms of PFAS that might be inhaled.

Nationally, regulatory oversight of textiles and fabric products in apparel, furniture, carpeting, and similar materials generally falls to either the CPSC or Federal Trade Commission (RTI 2023). Regarding home application of fabric treatments, a case study found elevated levels of PFHxS in the blood of household members, when compared to contemporary community averages, that was traced to frequent application of stain-resistant carpet treatment and indoor upholstery (Beesoon et al. 2012). Beesoon et al. (2012) found PFHxS in dusts (2,780 ng/g) and sampled carpeting (2,880 ng/g) and inferred that these contributed to exposure via indirect ingestion or inhalation of dusts. Some recent studies also rely on estimates of exposure from survey data matched with serum PFAS concentrations (Zhu et al. 2021) or inferring carpet-related exposures from associated dusts (Wu et al. 2020). However, direct measurement of exposure from treated carpet and flooring is challenging due to varied behaviors that influence direct and indirect contact with these surfaces, their potential for absorption by compound, and PFAS exposure from other sources.

The historical phaseout of certain PFAS (for example, PFOS) as textile and fabric treatment is summarized in **Section 2.4**. Recent state-level bans on PFAS in textile products have set requirements for reporting and phasing out PFAS in certain textile products (see **PFAS Regulatory Programs Summary** for state-specific information). One example is California's Assembly Bill (AB) 1817 (CA Assembly 2022), which prohibits PFAS in textiles beginning January 1, 2025, with exemptions for outerwear for extreme

conditions that are not marketed to the public. New York's Senate Bill 56291A prohibits PFAS in apparel beginning January 1, 2025, although "professional uniforms" and "outerwear intended for extreme conditions" are excluded (NY DEC 2025). **Section 2.5.3** includes information about efforts to reduce or eliminate PFAS in products.

1.4.2.2 Children's Products

The CPSC defines children's products as consumer products designed for use by infants and children under 12 years old (CPSC 2025). Examples of such products include, but are not limited to, toys, bedding and mattresses, school uniforms, certain games, and crafts materials. Further guidance on the determinants of children's products is available (CPSC 2020). A major determinant of whether a product is a children's product is whether it is intended for use by or is marketed to children less than 12 years old (CPSC 2020; 2025), which is notably different from the USEPA's definition of children (conception to ≤21 years of age) used for typical human health risk assessments of environmental media (USEPA 2021). Beyond such regulatory definitions, similar terminology is used throughout the primary literature to characterize consumer products for children, as well as adolescents less than 18 years old, which creates challenges for aligning regulatory reporting requirements with primary literature studies.

Children's products have elevated concern for exposure due to the behaviors of infants and small children. Normal development behaviors such as teething or mouthing present an obvious exposure via the oral route, where toys, fabrics, food packaging, and crafting supplies, despite labeling, may end up in a child's mouth. Skin contact with clothing, bedding, and other items for children has been routinely identified as a concern with any chemical exposure due to the relatively thin skin of infants and children in comparison to adults. As with other consumer products, the primary challenges are identifying products that likely have PFAS present (labeling), quantifying the total amount of PFAS present in these items, and then accurately estimating potential for exposure (for example, transfer efficiency) in a variety of exposure scenarios.

An example of the analytical challenges is Rodgers et al. (2022), who tested for the presence of PFAS in children and adolescent products that were labeled as "green" or with other terms used for advertising safer product chemistry. This study used a combination of a total fluorine assay, targeted analysis of solvent extractions (11 analytes), and the total oxidizable precursor (TOP) assay (see **Section 11.2.2.2**) to evaluate for PFAS in 93 products. This included apparel (for example, clothing, face masks, and underwear), bedding (sheets, mattress protectors, and pillow protectors), and furnishings such as area rugs and upholstered chairs. They found that "green" labeling for children's products was not predictive of the presence/absence or concentration of total fluorine or specific PFAS in any tested materials, despite the presumption of green labeling being indicative that a children's product is PFAS-free (see **Section 2.5.3**). Rodgers et al. (2022) observed a correlation between total fluorine and the presence of several PFAS analytes, which is consistent with PFAS results reported in children's products from other studies (Liu et al. 2014; Lassen et al. 2015; Robel et al. 2017; Xia et al. 2022).

1.4.2.3 Cosmetics and Personal Care Products

Cosmetics and personal care products are consumer products regulated by the U.S. Food and Drug Administration (USFDA). Cosmetics are used internally or externally to alter any aspect of appearance (USFDA 2013). Personal care products do not possess a specific regulatory definition and are evaluated on a case-by-case basis as related to their usage and may include certain cosmetics, drugs, soaps, and devices. The report by RTI (2023) identified 15,409 patents for cosmetics and personal care products that potentially contain PFAS based on product information or functional characteristics.

PFAS may be intentionally added to cosmetics or personal care products to function as surfactants, emulsifiers, solvents, and conditioning and viscosity agents (Ragnarsdottir et al. 2022; Schultes et al. 2018; Whitehead et al. 2021; Namazkar et al. 2024). Additionally, some PFAS may be unintentionally

added to cosmetic or personal care products due to impurities in the raw materials or due to breakdown of unidentified precursor PFAS that are intentionally added (USFDA 2024), as well as their presence in the production of certain plastic containers (Whitehead and Peaslee 2023). As related to direct exposures, dermal contact is the primary route of concern given the intended application of cosmetic and personal care products, although incidental ingestion also requires consideration, depending on the article. **Section 1.4.3** provides a detailed discussion about the nuance of dermal absorption, factors that require consideration for exposure estimation and sources of uncertainty, especially as they pertain to differences in physicochemical characteristics of individual PFAS. Products that are designed to remain in the skin, form films or barriers, or otherwise produce prolonged contact (for example, lotions, creams, makeup) create exposure scenarios in which there is more time for potential absorption across the skin. Abraham and Monien (2022) highlighted the significance of dermal absorption with a study that monitored uptake of radiolabeled PFOA (110 µg) into a volunteer who applied the full dose via sunscreen application (30 g) across their entire body. Interpretation of the findings merit caution, as the study relied on only a single participant, but the worst-case scenario of PFOA bioavailability from the sunblock application was estimated to be approximately 1.6% using certain assumptions about toxicokinetics (for example, a volume of distribution of 0.17 L/kg). The contribution to the volunteer's background PFOA serum concentration was estimated to be nearly 9.4% (Abraham and Monien 2022). More recently, Chen et al. (2024) used simulated sunblock mixtures with in vitro and in vivo (mouse) models to estimate dermal uptake rates and other kinetic parameters for several PFSAs and PFCAs. That study is further described in **Section 1.4.3**. Keawmanee et al. (2024) provided an example of a quantitative approach to estimating PFAS exposure doses from cosmetic products and found relatively low risk based on their assumptions about the rates of product use and existing toxicity factors for select PFAS (PFOA, PFOS, PFBS). When considering other cosmetic or personal care products, a diversity of applications and products creates vastly different exposure scenarios for evaluating potential risks (for example, makeup versus dental floss), which is furthermore complicated by potential off-label applications by consumers.

PFAS have been detected using total organic fluorine (TOF) analysis and some targeted analyses in several cosmetic and personal care products, including anti-aging cream, eyeliner, antiperspirants, body creams and lotions, shampoo, soaps, sunscreens, and period products (tampons and menstrual pads) (Rodgers et al. 2022; Zhou et al. 2023). As with other media, discussed in **Section 11.2**, methods for these products may be challenged by the sample matrix and other chemicals present in these products.

The FDA acknowledges the presence of certain PFAS in cosmetics products (USFDA 2024). Based on past reporting requirements and the Organisation for Economic Co-operation and Development (OECD) definition of PFAS (OECD 2021), the FDA identified 35 specific PFAS likely used across 578 cosmetic products. The FDA is tentatively expected to release a risk assessment of PFAS in cosmetics in late 2025 that would provide more updated information specific to the United States (USFDA 2024). Internationally, a risk assessment of PFAS in cosmetic products conducted by the Danish Ministry of Environment and Food determined that the presence of various PFAS in a sample of 18 cosmetic products from the Danish market presents risks to consumers based on several exposure and toxicity assumptions used at that time (Ministry of Environment and Food of Denmark EPA 2018). Products included blemish balms, body lotions, color-correcting creams, concealer, cream/lotion, eyeliner, eye shadow, facial scrubs, foundation, hair spray, highlighter, and powder.

1.4.2.4 Food Packaging and Cookware

PFAS are used in food packaging, cookware, and other products that may result in contamination of food. This is a concern for human exposure to PFAS by ingestion of food or liquids containing PFAS. Food contact materials (FCMs) are materials that come in contact with food and beverages during storage, packaging, or consumption (USFDA 2025), and PFAS may be added to these FCMs to impart grease- and water-resistant functionality. Cookware, such as nonstick frying pans, have been identified as consumer products that may contain PFAS (Glüge et al. 2020). Last, PFAS may be used as a processing aid in food preparation equipment that has the potential to contaminate food. In all these cases, the migration of

PFAS from the product into food or beverages is the primary concern for direct exposure (Ramírez Carnero 2021; Begley et al. 2005; Choi et al. 2018; Curtzwiler et al. 2021). Populations with higher reliance on packaged foods, such as children, students, and individuals in institutional settings, may experience disproportionate dietary PFAS exposure due to higher consumption of processed foods and associated FCMs (Susmann et al. 2019; Susmann et al. 2023; Hampson et al. 2024; Hampson et al. 2025; Pacyga et al. 2025). Due to the varied migration rates of PFAS from food packaging into dietary items, consumer risk assessments are scarce, as there is inherently high uncertainty from the limited data on PFAS concentrations in these materials and variability in related food consumption patterns.

Several studies have examined the presence of PFAS in FCMs via TOF, extractable organic fluorine (EOF), and targeted analytical methods (for example, Vázquez Loureiro et al. 2024; Hu et al. 2025). Whitehead and Peaslee (2023) identified fluorinated plastic containers as a potential source of PFAS exposure because short-chain PFCA migrate into the food. **Section 11.2** includes references and explanations of existing methods that have been used for food packaging, including targeted analysis and particle-induced gamma-ray emission (PIGE).

Similar to other categories of consumer products, multiple state-level bans have been either proposed or passed that target PFAS in food packaging and cookware. Nationally, the USFDA (2025) announced the market phaseout and revocation of use for PFAS in grease-proofing of food packaging sold in the United States.

1.4.3 Dermal Uptake of PFAS in the Environment

Since dermal uptake of PFAS was initially addressed in **Section 17.2.3**, information on dermal uptake of PFAS has continued to evolve. There is now recognition of the fact that perfluoroalkyl acids (PFAAs) are largely ionized in aqueous solution at environmental pH (~pH 6–8) and that dermal uptake of these charged forms of PFAS is limited due to their ionic character (ATSDR 2024; USEPA 2025; Mellard, 2024; Franko et al. 2012). The dermal uptake of other PFAS from both aqueous and nonaqueous media remains largely uncharacterized. This section provides information on our current understanding of dermal uptake of PFAS in aqueous solutions and briefly describes the results of one study of dermal uptake of neutral PFAS from the gas phase (Kissel et al. 2023, 2023). There are currently no data on the extent of dermal uptake of PFAS from soil or dust; however, the USEPA Regional Screening Levels (RSLs) for PFCAs and PFSAs incorporate an assumption that 10% of these PFAS are dermally absorbed from soil (USEPA 2025). Note that two of the studies discussed in this section were previously mentioned in **Section 17.2.3** (Fasano et al. 2005; Franko et al. 2012) but are described in more detail here to provide a more complete picture of our current understanding of dermal uptake of PFAS.

How, and to what extent, dermal uptake of PFAAs or other PFAS occurs from cosmetics, sunscreen, or other consumer products is likely more variable than uptake from aqueous solutions and is also harder to predict given the complex mixtures that comprise many consumer products. Other than the studies of Abraham and Monien (2022) and Chen et al. (2024), who examined the dermal absorption of PFOA from sunscreen (see **Section 17.2.3** and **Section 1.4.2**), no publications have quantified the dermal uptake of PFAS from consumer products.

1.4.3.1 The Process of Dermal Absorption

Human skin consists of three different layers (epidermis, dermis, hypodermis), with the outer layer of the epidermis—the stratum corneum—providing an important barrier function (National Center for Biotechnology Information [NCBI], 2024). The main pathway for chemicals to move through the stratum corneum is by passive diffusion; chemicals can also cross human skin via sweat glands and hair follicles. For a chemical to be available for absorption through the skin and to become “bioaccessible,” it must be in solution (in sweat or sebum) and be in contact with the skin. Some or all of the bioaccessible chemical can then be absorbed and is potentially able to reach the systemic circulation (Ragnarsdottir et al. 2022).

Chemicals retained in the epidermis may or may not reach the circulatory system in that they may be removed by desquamation (the normal sloughing of dead epidermal cells) if they persist in human skin—without absorption—for extended periods (USEPA 2004).

A recent review by Yeh et al. (2024), as well as studies by Fasano et al. (2005); Franko et al. (2012), and Ragnarsdottir et al. (2024), have recognized several kinetic parameters used to characterize dermal absorption of PFAS:

- the fraction absorbed (expressed as a percentage of applied dose)
- steady-state flux J_{ss}, μg/cm^2-h—that is, the rate at which a chemical is absorbed through the skin once constant (steady state) absorption has been reached
- dermal permeability K_p, cm/h—that is, the rate at which a chemical is able to penetrate the stratum corneum

Two different types of experimental approach—finite and infinite dose protocols—are used in the assessment of dermal uptake (Yeh et al. 2024).

An "infinite dose" experimental protocol uses concentrations of a chemical selected to ensure a continuous excess of test compound in order to achieve maximal amounts of dermal absorption; depletion of the chemical does not occur (Frasch et al. 2014). Infinite dose protocols are considered appropriate to determine J_{ss} and K_p, as they can approximate steady-state conditions. Although an infinite dose testing protocol is consistent with OECD guidance (OECD 2004), it is not directly relevant to real-life conditions where much lower and noncontinuous doses are expected. Instead, "finite" dose protocols are used to mimic environmentally realistic exposure amounts, with limited amounts of chemical applied. Finite dose protocols are considered appropriate to determine the fraction of chemical that is dermally absorbed (Frasch et al. 2014).

Several studies have reported the fraction (percentage) of one or more PFAS that was absorbed following dermal exposure (Fasano et al. 2005—ammonium perfluorooctanoate in water; Franko et al. 2012—PFOA in acetone [primary experiment]; Ragnarsdottir et al. 2024—17 individual PFAAs and PFSAs in methanol; Espartero et al. 2025—mixture of 30 PFAS in methanol, and perfluorobutanoic acid (PFBA), perfluorobutane sulfonamide (FBSA), perfluoropentanoic acid (PFPeA), and perfluoropropanesulfonic acid (PFPrS) individually in water). However, the fraction of PFAS (or other chemical) that is absorbed depends on the applied dose (Kissel 2011), as well as on the vehicle. Because organic solvents such as acetone and methanol likely increase the dermal absorption of PFAS by potentially increasing solubility or enhancing both diffusion and uptake (Chiang et al. 2012; ATSDR 2024; Ragnarsdottir et al. 2024), the absorption estimates of Franko et al. (2012) and Ragnarsdottir et al. (2024) and the mixtures experiments of Espartero et al. (2025) likely reflect greater dermal absorption than would occur in experiments that used water as the vehicle. Buist et al. (2009) and Kissell (2011) have also pointed out that an inverse relationship may exist between dermal loading and fractional absorption. Because of the dependence of absorption on dose, the USEPA (2004) recommended that dermally absorbed dose calculations use K_p, the skin permeability coefficient (cm/h) (see discussion below).

1.4.3.2 Relative Permeability of Animal and Human Skin

Studies in animals have demonstrated that dermal absorption of PFAS does occur, as evidenced by rodent toxicity studies that have shown systemic adverse effects after dermal dosing (for example, Kennedy 1985; Shane et al. 2020; Weatherly et al., 2023; Weatherly et al. 2024). In a study designed to evaluate the photocarcinogenic potential of PFAS, Donslund et al. (2025) detected PFOA in the serum (57–160 ng/mL) and liver (90–2,614 ng/g) of hairless mice treated topically with 10 μg/g (that is, 10 mg/kg) three times over the course of a week following exposure to ultraviolet radiation. PFOA was

detected at substantially higher concentrations (40,059–316,309 ng/g) in the livers of hairless mice (not previously exposed to ultraviolet) measured 1, 4, or 24 hours after a single topical application of 10 mg/g PFOA. Rodent skin has been estimated to be several-fold to approximately 34 times more permeable than excised human skin (from surgeries or cadavers) (Fasano et al. 2005; Jung and Maibach 2015). These species-dependent differences in absorption mean that direct extrapolation from rodent dermal uptake data to humans will likely overestimate human dermal uptake.

Hall et al. (2023) showed that PFCAs were absorbed across freshly collected porcine skin in an in vitro flow-through model system at pH 7.3–7.5. Over the 8-hour exposure period, the relative rates of absorption were PFBA > PFHxA > PFOA for both artificial perspirant (that is, artificial sweat) and acetone vehicles. The PFOA K_p's measured (8.28×10^{-5} cm/h and 5.73×10^{-5} cm/h for artificial perspirant and acetone, respectively) were comparable to those measured by Franko et al. (2012) with human skin at pH 5.5. These results indicated that porcine skin may be more appropriate than rodent skin for assessing dermal uptake in humans (Franko et al. 2012).

Human skin equivalent models, which were used in a recent study of PFAA dermal uptake (Ragnarsdottir et al. 2024), may also be more permeable than intact human skin used by Franko et al. (2012), Fasano et al. (2005), and Espartero et al. (2025). These human skin equivalents consist of reconstructed human skin that is grown from keratinocyte stem cells. Although they reportedly possess many characteristics of intact human skin, the extent of the difference between dermal absorption of PFAS in human skin equivalents and intact human skin has not been characterized; thus, results should be interpreted or extrapolated with caution (see discussion of Ragnarsdottir et al. (2024) in **Section 1.4.3.5**).

1.4.3.3 Toxicokinetics of Dermal Exposure

Several recent publications have reported on the use of rodent models to evaluate the toxicokinetics of dermal uptake of PFAS. As discussed in **Section 1.4.3.2**, there are differences in the permeability of rodent and human skin that preclude direct extrapolation between species. Nonetheless, these rodent studies provide information regarding the potential for extended uptake due to the potential retention of PFAS in skin postexposure. For example, Chen et al. (2022) used rats to estimate the dermal penetration efficiency of 15 PFAS applied as a mixture to shaved skin in "low" and "high" exposure groups (1.25 µg/cm^2 and 6.25 µg/cm^2, respectively). Exposure was maintained for 6 hours by occluding the area of application then removing any residue. At 144 hours after the end of exposure, between 4.1% and 18.0% and 5.3% and 15.1% of the applied PFAS in the low and high groups, respectively, were absorbed, with peak concentrations of PFAS in plasma attained at 8–72 h. This indicates that concentrations of PFAS in the blood continued to increase following the end of exposure and that PFAS retained in one or more skin layers likely served as a reservoir for the continued movement of PFAS into the circulation.

To support development of a physiologically based pharmacokinetic (PBPK) model of PFAS uptake, Zhu et al. (2023) studied differences in the toxicokinetics of PFAS in mice administered a mixture of PFHxS, PFOS, and PFOA by oral, nasal instillation, or dermal exposure. For the dermal portion of this study, equal amounts of the three PFAS in an aqueous solution of 0.5% TWEEN (1 mg/kg of each PFAS [low dose] or 5 mg/kg of each PFAS [high dose]) were administered in a single 50 µL intradermal injection—a procedure that introduces the chemicals directly into the dermis, bypassing the epidermis. The results of this study were described in terms of whether the PBPK model provided reasonable estimates of observed PFAS uptake—raw data on uptake were not included. Despite this limitation, the results of Zhu et al. (2023) appear to indicate that the time to reach peak plasma concentrations was estimated to be much longer (34.1–83.0 h) after dermal exposure than after nasal instillation (0.960 h) or oral exposure (time not specified). The data of Zhu et al. (2023) also indicate that the exposure route affects the rate and extent of PFAS uptake in mice, with dermal exposure resulting in the lowest uptake and bioavailability of the three exposure routes considered.

Using mixtures of 13 different PFAAs, PFCAs (10, with carbon chain lengths of 4 to 12 and 14) and PFSAs (3, with carbon chain lengths of 4, 6, and 8), Chen et al. (2024) investigated the dermal absorption and accumulation of PFAS in mice following exposure to PFAS in laboratory-formulated sunscreens and commercial sunscreens. Although these exposures are not truly environmental in character, this study is included here as it provides some insight on the relative dermal uptake of PFCAs and PFSAs following an ex vivo 36-h exposure or a 30-day exposure period in whole animals. In the ex vivo exposures, there was significantly higher bioaccessibility of all of the PFAS in the control water-in-oil (W/O) than in the control oil-in-water (O/W) formulations (31.7%–54.2% and 15.2%–39.6%, respectively), potentially due to enhancement of partitioning into the lipid-rich stratum corneum by the oil dispersion system in the W/O sunscreen. For animals exposed to PFAS for 30 days, the absorption fraction of PFAS was similar between sunscreens and varied from 10.9% to 45%, depending on the PFAS (not on the formulation). In general, shorter chain PFAS were more highly absorbed than longer chain PFAS, and PFSAs were more highly absorbed than PFCAs with the same number of fluorinated carbons. The results of the ex vivo study were used to select the O/W and W/O formulations most favorable to dermal penetration of PFAS ("worst-case" formulations) for the subsequent in vivo study.

In the in vivo study, dermal penetration and absorption of the 13 PFAS were evaluated in male mice at time points up to 30 days using the laboratory formulations identified as "worst case" in the ex vivo study (O/W with high concentrations of chemical sunscreen, TiO2, and moisturizer, and W/O with high concentrations of chemical sunscreen and moisturizer) and two commercial sunscreens, one O/W and one W/O. After 30 days of exposure, the absorption fraction of the 13 PFAS ranged from 15.8% to 45.0% in the "worst case" O/W laboratory formulation, 14.9% to 29.4% in the commercial O/W sunscreen, 10.9% to 42.6% in the "worst case" W/O laboratory formulation, and 10.8% to 33.4% in the commercial W/O sunscreen. In contrast to the ex vivo results, the absorption fraction of short-chain PFAS in the laboratory-formulated sunscreens was 1.4%–8.6% higher in the W/O formulations, while long-chain PFAS were 0.8%–7.3% higher in the O/W group. These findings notwithstanding, in both the mice exposed to the "worst case" O/W and W/O laboratory formulations, short-chain PFAS were absorbed to a greater extent than long-chain PFAS (0.6–31% higher), and there was greater absorption of PFSAs than PFCAs with the same number of fluorinated carbons. PFAS levels in the dermis continued to increase throughout the 30-day exposure period, with the dermis identified as the likely main reservoir of PFAS in skin. This finding is consistent with Chen et al. (2022), who concluded that one or more layers of the skin may store PFAS after dermal exposure, with potential for its release over time into the bloodstream.

1.4.3.4 Effect of Ionization on Dermal Uptake

Franko et al. (2012) provided the clearest example of the effect of ionization on the dermal absorption of PFAAs from aqueous solution. Using PFOA and an in vitro protocol with human skin, they showed an approximately 1,000-fold difference between dermal uptake of the acidic (protonated) form and the ionized form of PFOA. In 24-h exposures to aqueous solutions of PFOA, experiments at pH 2.25, where PFOA would have existed as the protonated acid, the K_p was 5.5 x 10^{-2} cm/h. In solutions of aqueous buffer at pH 5.5, where PFOA would have existed as the anion, the K_p was 4.4 x 10^{-5} cm/h.

1.4.3.5 Estimates of K_p (cm/h)

The USEPA has recently identified or estimated certain chemical property parameters in support of calculating tap water Regional Screening Levels (RSLs) for select PFAS (USEPA 2025). RSLs are medium-specific and risk-based concentrations back-calculated from a target noncancer hazard quotient or a target cancer risk level, and they are intended to account for multiple routes of exposure specific to the medium. The tap water RSL includes exposure via the dermal pathway (for example, bathing). USEPA calculated K_p values for select PFAS using chemical-specific log octanol water partition coefficients (log Kow) and methodology presented in USEPA (2004) or USEPA (2017). K_p values are provided for a number of PFCAs and PFSAs and their salts, Gen X, and lithium bis [(trifluoromethyl)sulfonyl]azanide) (see **Table 1-9**). The USEPA (2025) also provided other parameters needed to estimate the dermally absorbed dose;

these include the lag time per dermal exposure event (t_{event}) and the time to reach steady state (t*). The tap water dermal parameters were used in combination with cancer slope factors (PFOA and salts) or noncancer reference doses (all other PFAS evaluated) to derive tap water dermal RSLs.

Table 1-9. K_p values for select PFAS (USEPA 2025).[1]

PFAS	K_p (cm/h)
Hexafluoropropylene oxide dimer acid (HFPO-DA—Gen X)	8.7 E-02
Lithium bis[(trifluoromethyl)sulfonyl]azanide	4.1 E-06
PFBS	1.9 E-05
PFBA	4.1 E-03
PFDA	6.0 E-01
PFDoDA	3.2 E+00
PFHxS	2.6 E-04
PFHxA	2.7 E-04
PFNA	2.0 E-04
PFODA	4.7 E+02
PFOS	4.7 E-07
PFOA	2.2 E-05
PFPrA	1.8 E-03
PFTetDA/PFTA	1.7 E+01
PFUDA	1.4 E+00

[1] All K_p values calculated by the USEPA (2025) were based on parameters in EPISuite (USEPA 2017) or on methods in "Risk Assessment Guidance for Superfund"(RAGs), Volume I, Human Health Evaluation Manual, Part E (USEPA 2004). Additional details of how the K_p values were derived are not provided in the RSL tables.

The ATSDR used their SHOWER model to estimate K_p values for 13 different PFAS (ATSDR 2024; Mellard 2024) (**Table 1-10**). For those PFAS evaluated by both the USEPA and the ATSDR, the majority of the USEPA's K_p values are greater than those of ATSDR, with some greater by 1 to 4 orders of magnitude. For PFOA, the K_p values are similar between the two agencies (2.2×10^{-5} and 8.74×10^{-5} cm/h, for the USEPA and ATSDR, respectively).

These PFOA K_p values are also similar to the experimentally determined PFOA (ionic form) K_p's of 5.8×10^{-5} and 4.4×10^{-5} cm/h determined by Franko et al. (2012). ATSDR's K_p values for PFAAs other than PFOA and for Gen X compounds are also generally similar in magnitude to the K_p determined experimentally by Franko et al. (2012) for ionized PFOA and indicate that dermal absorption of these PFAAs from aqueous solutions is not expected to be extensive given the low K_p values. Fasano et al. (2005) determined a K_p for PFOA of 9.5×10^{-7} cm/h. It is not clear why this K_p is lower than the results of Franko et al. (2012), as both were measured at similar pH.

The recently published experimental results of Ragnarsdottir et al. (2024) are not consistent with the experimental results of Fasano et al. (2005) or Franko et al. (2012), or the estimates of the USEPA (2025) or ATSDR (2024). For example, Ragnarsdottir et al. (2024) determined a PFOA K_p (cm/h) of 3.83×10^{-3}, which is approximately 100 times greater than these other sources. K_p values were also determined for seven other PFAAs; where K_p values were available for comparison, those determined by Ragnarsdottir et al. (2024) are also higher than those estimated by the USEPA or ATSDR. The reason(s) for the higher estimated dermal uptakes of Ragnarsdottir et al. (2024) is not known with certainty but may be attributable to the use of human skin equivalent as opposed to human skin; to the possibility that the

PFAAs were protonated (the pH was not reported), or to the use of methanol as a solvent for the PFAS. Although the effects of using methanol as a solvent are not known with certainty, it is possible that it solubilized skin lipids and allowed greater dermal penetration of PFAAs (Ragnarsdottir et al. 2024).

1.4.3.6 Dermal Uptake of Neutral PFAS

As discussed, anionic PFAS molecules appear to have a low potential for dermal permeation. However, dermal uptake may be more extensive for neutral PFAS. Kissel et al. (2023, 2023) estimated the potential for dermal uptake of neutral PFAS based on partitioning from the gas phase to the skin. For 11 PFAS, this model-based exercise yielded dermal-to-inhalation ratios of sufficient magnitude to indicate that direct dermal absorption of neutral PFAS may contribute a greater proportion of exposure than for ionic PFAS. These PFAS include:

- N-Methylperfluorooctanesulfonamidoethanol (N-MeFOSE)
- N-Ethylperfluorohexanesulfonamidethanol (N-EtFOSE)
- N-Methylperfluorobutanesulfonamidoethanol (N-MeFBSE),
- N-Methylperfluorohexanesulfonamidoethanol (N-MeFHxSE)
- N-Ethylperfluorohexanesulfonamidoethanol (N-EtFHxSE)
- N-Ethylperfluorobutanesulfonamidoethanol (N-EtFBSE)
- PFAS with -diol and -amide functional groups

1.4.4 Health Effects of Ultra-short-chain PFAS

1.4.4.1 Introduction

Although definition(s) of ultra-short-chain (ultrashort) PFAS from government agencies or other authoritative organizations were not identified, ultrashort PFAS are generally considered to be PFAS with three or fewer carbon atoms (Ateia et al. 2019; CFPUA, undated; Neuwald et al. 2022; Liang, Steimling, and Chang 2023; Zheng et al. 2023). In general, shorter chain PFAS are equally persistent as their longer chain homologues, but they are more mobile in the environment and more difficult to remove from water (Ateia et al. 2019; Neuwald et al. 2022).

Examples of ultrashort PFAS include:

- perfluorocarboxylic acids (PFCAs): trifluoroacetic acid (TFA), and perfluoropropanoic acid (PFPrA), with two and three carbons, respectively
- perfluorosulfonic acids (PFSAs): trifluoromethanesulfonic acid (TFMS), perfluoroethane sulfonic acid (PFEtS), and perfluoropropane sulfonic acid (PFPrS), with one, two, and three carbons, respectively
- perfluoroether carboxylate: perfluoro-2-methoxyacetic acid (PFMOAA)
- 1,1,1-trifluoro-N-(trifluoromethyl)sulfonylmethanesulfonamide (TFSI) and its salt, lithium bis[(trifluoromethyl)sulfonyl]azanide (HQ-115), which have two carbons.

It should be noted that TFA is not considered to be a PFAS under some existing definitions of PFAS (for example, definitions that exclude compounds with only one fully fluorinated carbon) (see **Section 2.2**). For more examples and additional detail, see **Section 1.1.3.1**.

Of the ultrashort PFAS listed in **Table 1-2**, in **Section 1.1.3.1**, health effects information was identified for TFA (CASRN 76-05-1), PFPrA (CASRN 422-64-0), PFMOAA (CASRN 674-13-5), TFMS (CASRN 1493-13-6), and TFSI (CASRN 82113-65-3) and its lithium salt, HQ-115 (CASRN 90076-65-6), and this information is reviewed below. When information is available, a summary of the environmental occurrence of these PFAS is also provided; these occurrence summaries are not intended to be comprehensive.

Although ultrashort PFAS are highly persistent in the environment, as longer chain PFAS are, they are expected to be less bioaccumulative than longer chain PFAS, although this may not necessarily always be the case. Because the same dose of a less bioaccumulative PFAS results in a lower body burden (for example, blood serum level) than would a more bioaccumulative PFAS, doses that cause toxicity are expected to be higher for ultrashort PFAS than for longer chain PFAS, all other things being equal. Again, this cannot be assumed to be the case for all ultrashort PFAS. This is because the dose that causes toxicity depends on both a compound's toxicity when it is present at a certain concentration within the body, which may vary among PFAS independent of their chain length, and the concentration within the body after a certain external dose, which is expected to be lower for ultrashort PFAS than longer chain PFAS.

1.4.4.2 Trifluoroacetic Acid (TFA)

This section discusses relevant studies that were identified in the scientific literature or in publicly available secondary sources (for example, European Chemicals Agency (ECHA) and EFSA documents) as of October 2024. Information on the toxicokinetics and toxicity of TFA was reviewed by EFSA (2014), Umweltbundesamt (UBA) (2020), ECHA (2022), the National Institute for Public Health and the Environment in The Netherlands (RIVM) (2023), and Dekant and Dekant (2023). More recent ECHA documents (ECHA 2025; ECHA 2025) review additional biomonitoring, toxicokinetic, and toxicology studies that are not discussed below.

Occurrence

TFA has been detected in numerous environmental media, including surface water, groundwater, drinking water, wastewater, precipitation, the ocean, the atmosphere, sediments, vegetation, and aquatic biota, and concentrations in the environment appear to be increasing (reviewed by Garavagno et al. 2024; Arp et al. 2024; Albers and Sültenfuss 2024). In some studies, TFA was present in surface water or drinking water at higher concentrations than other PFAS. For example, in a study of Indiana residences, TFA was found in house dust in 84% of residences at ≥ 73 ng/g (median—220 ng/g; maximum—1,400 ng/g) and in tap water in 95% of residences at ≥ 27 ng/L (median—79 ng/L; maximum—210 ng/L) (Zheng et al. 2023). In this study, median TFA concentrations in drinking water were >1 to several orders of magnitude higher than any of the other ultra-short-, short-, and long-chain PFAS analyzed.

Biomonitoring

Kim et al. (2022) first reported detection of TFA in human urine samples. In a study of Indiana residents, TFA was found in the blood serum of 74% of the participants at ≥ 4.4 ng/L (median—6.0 ng/L; maximum—77 ng/mL) and in the urine of 31% of the participants at ≥ 3.5 ng/L (maximum—290 ng/mL) (Zheng et al. 2023). It was detected in the blood serum of 97% of subjects, at a median concentration of 8.46 ng/L, in a study of adults from a highly industrialized Chinese city (Duan et al. 2020).

Toxicokinetics

Information on the toxicokinetics of TFA is summarized in ECHA (2022). TFA is rapidly absorbed orally. It is also absorbed via inhalation, and it is predicted to be absorbed through the skin at noncorrosive/irritant concentrations based on its physical/chemical properties. It is not metabolized, and it is distributed throughout the body in the anionic form. Laboratory animal studies summarized by ECHA (2022) indicate that TFA crosses the placenta and is found in amniotic fluid. It is released into the small intestine in bile, after which it can be reabsorbed from the gastrointestinal tract and undergo enterohepatic circulation, and it is also excreted in urine. The half-life in rabbits after intravenous administration was 34.4 hours and was reduced to 15.6 hours when enterohepatic circulation was eliminated via a bile fistula (EFSA 2014).

Zheng et al. (2023) estimated the human half-life of TFA as 12 days based on urinary clearance determined from paired urine-serum measurements and the assumptions that urine is the only route of excretion and that the volume of distribution of TFA is the same as for PFBA. TFA is a metabolite of the anesthetic halothane, and the half-life of TFA in children after administration of halothane was estimated as 42 hours (approximately 2 days; Wark et al. 1990) from the change in daily urinary TFA excretion over time after halothane was administered. It is not known whether the difference in these two half-life estimates is age-related or due to differences in the way each half-life was determined.

Human Epidemiology Studies

No human epidemiology studies specific to TFA were identified by ECHA (2022) or in a PubMed literature review.

Laboratory Animal Toxicology Studies

The toxicological information for TFA and its salt, sodium trifluoroacetate, reviewed below, includes acute oral and inhalation studies in rats, a subchronic dietary (oral) study in rats, a subchronic inhalation study in rats and guinea pigs, a chronic (one year) drinking water study (oral) in rats, a one-generation dietary (oral) reproductive/developmental study in rats, oral (gavage) developmental toxicity studies in rats and rabbits, and several in vitro genotoxicity assays. Additional studies are reviewed in ECHA (2025a,b). No studies of the potential carcinogenic effects of TFA are available. TFA dissociates to its anionic form in

the body, and the salt form, sodium trifluoroacetate, was tested instead of TFA in some studies in order to avoid potential irritating/corrosive effects resulting from the very low pH of TFA.

Oral Toxicity

ECHA (2022) reported that the oral acute median lethal dose (LD_{50}) of TFA in rats is between 500 and 1,000 mg/kg and that acute effects of oral exposure included hemorrhage and necrosis of the mucous membranes of the stomach. In contrast, oral administration of a dose of 7,000 mg/kg of the neutralized acid (the salt form) did not cause mortality or tissue damage, indicating that the toxicity of the acid form results from its corrosive properties.

In a subchronic (90-day) rat study described by ECHA (2022), identified as Bayer CropScience (2007) in ECHA (2025), sodium trifluoroacetate was administered in the diet at 0, 160, 1,600 and 16,000 ppm (0, 8.4, 82.3, 876 mg/kg/day in males; 10.1, 103.3, 1,021 mg/kg/day in females). Absolute and relative liver weight were increased in both sexes at the mid- and high doses. Histopathological changes in the liver at the mid-dose, or high-dose group, or both groups, included hepatocellular hypertrophy and loss of periportal hepatocellular vacuolation in both sexes, and an increased incidence of hepatocellular necrotic foci in high-dose males. Other effects included decreased body weight at the highest dose in both sexes, hematologic changes (decreased hemoglobin, mean corpuscular volume, and hematocrit) in mid-dose or high-dose females, or both groups of females, increased serum levels of liver enzymes in mid- and high-dose males, and decreased serum levels of total bilirubin and glucose and increased urinary ketones in both sexes at the mid- and high doses. The low dose (160 ppm, corresponding to 8.4 mg/kg/day in males and 10.1 mg/kg/day in females) was identified as the no observed adverse effect level (NOAEL). Based on results of this study and other toxicological data, RIVM (2023) concluded that TFA is 2,000-fold less potent than PFOA in male rats in regard to increased relative liver weight after subchronic exposure.

UBA (2020) and RIVM (2023) provided information on a study, identified as WuXi AppTech (2019) in ECHA (2025), in which TFA was administered to rats in drinking water at concentrations of 0, 30, 120, and 600 ppm (corresponding to 0, 1.8, 7.6, and 37.8 mg/kg/day) for up to one year; the full study report does not appear to be available online. The histopathological changes in the liver (hepatocellular hypertrophy and necrotic foci) reported at doses of approximately 100 and 1,000 mg/kg/day in the 90-day dietary rat study described above were not observed at the lower doses (up to 37.8 mg/kg/day) administered in the one-year drinking water study. In the one-year study, serum alanine aminotransferase (ALT), an enzyme that is an indicator of liver damage, was not increased at an interim timepoint of 90 days of exposure to TFA, but it was significantly increased by severalfold after one year of exposure to drinking water containing 120 and 600 ppm (7.6 and 37.8 mg/kg/day), with a greater increase at 120 ppm than 600 ppm. ALT returned to control levels 6 weeks after the one-year exposure period ended, indicating that liver damage caused by TFA in this study may be reversible (UBA 2020). UBA (2020) also presented data from other shorter duration studies of TFA in drinking water in which ALT levels were elevated after exposure to concentrations greater than 600 ppm. UBA (2020) reported that Solvay Hannover, the sponsor of the one-year drinking water study, concluded that the NOAEL in this study was 600 ppm (corresponding to 37.8 mg/kg body weight in males), which was the highest dose in the study. However, UBA (2020) concluded that the NOAEL in this study was 30 ppm in drinking water, corresponding to 1.8 mg/kg/day, based on increased ALT at the higher doses.

ECHA (2022) reported on a one-generation reproductive/developmental study in rats, identified as Labcorp Laboratories (2021) in ECHA (2025), in which sodium trifluoroacetate was administered in the diet at concentrations of 0, 120, 600 or 3,000 ppm, corresponding to 0, 10, 50, and 250 mg/kg/day, for 10 weeks during premating (males and females), gestation, and lactation. Because food consumption is higher during lactation, dietary concentrations were decreased to 0, 60, 300 and 1,500 ppm in lactating females. These lower concentrations were also administered to offspring from weaning at postnatal day 21 until postnatal day 35, and offspring were then dosed with the original concentrations (0, 120, 600, and 3,000 ppm) until sacrifice at age 13 or 14 weeks.

In addition to reproductive and developmental parameters, systemic effects (for example, organ weights, histopathology, clinical chemistry, urinalysis) were evaluated in the parental (F0) and offspring (F1) generations, and several statistically significant effects, primarily at the higher dose levels, that are not directly related to reproduction or development, were reported in the F0, F1, or both F0 and F1 animals. Increased relative liver weight, an effect common to many PFAS (see **Section 17.2**), occurred at the two highest doses in both sexes of the parental (F0) and offspring (F1) generations but was not considered adverse because no histopathological changes in the liver were observed. Kidney weights were increased in both sexes in the parental generation, and plasma sodium and potassium levels were increased in males and females, respectively, in both the parental generation and the offspring. These renal effects were considered "non-adverse within the context of this [developmental] study," because there were no effects on kidney weight in the offspring, urinary parameters in the parental generation, or renal histopathological changes in either generation. Testes weight was decreased in male offspring, but changes in sperm parameters were not consistently observed. TFA also caused histopathological changes, described as minimal to slight, in the glandular stomachs of parental (F0) and offspring (F1) females, but the study authors did not consider these effects adverse because food consumption and body weight were unaffected. Clinical chemistry changes, primarily at the two higher doses, in one or both sexes in the F0 and F1 generations included decreased levels of glucose, free fatty acids, triglycerides, and bilirubin in the plasma. Hematologic changes, although not noted in the study summary, were reported in both the parental and offspring generations. Decreased levels of serum thyroxine (T4) occurred in both sexes in both the parental generation and offspring, but this change was not considered adverse because it was not associated with effects on reproductive and developmental parameters that depend on normal thyroid function.

The study authors stated that no adverse effects were observed on "general condition, body weight or food consumption, reproductive performance, fertility or offspring development/sexual maturation." It was concluded that the NOAEL for reproductive, developmental, and general systemic toxicity in this study was 3,000/1,500 ppm (dose decreased during lactation), corresponding to approximately 203–222 mg/kg/day, which was the highest dose used.

ECHA (2022) also reported on a developmental toxicology study, identified as Huntingdon Life Sciences (2010) in ECHA (2025), in which pregnant rats were dosed by oral gavage with 0, 37.5, 75, or 150 mg/kg/day on gestation days 6–19 and sacrificed on gestation day 20. Soft tissue abnormalities were evaluated in half of the fetuses, and skeletal abnormalities and ossification state were evaluated in the other half. There were no effects at any dose on maternal mortality, body weight/body weight gain, food consumption, reproductive parameters (pregnancy rate, number of aborted fetuses, pre- and postimplantation loss, number of resorptions, number of dead fetuses, pregnancy duration, number of live offspring, fetal weight, sex ratio, litter size or weight, weight of the placenta and uterus) or fetal abnormalities, variations, or ossification parameters. TFA caused increased maternal liver and kidney weight, but the study authors did not consider these effects adverse. The NOAEL was identified as 150 mg/kg/day, the highest dose used.

An additional rat study, Saillenfait et al. (1997), evaluated hepatic and renal effects of TFA in dams and offspring after maternal exposure to 75 or 150 mg/kg/day via oral gavage on gestation days 10–20. There were no effects on duration of gestation, litter size, or offspring survival to postnatal day 3. Maternal absolute and relative liver weights were increased at both doses at the end of gestation, while there were no effects on liver weight in the offspring at age 7 weeks. Serum levels of glutamate dehydrogenase (GDH) and aspartate aminotransferase (AST), enzymes indicative of liver damage, and urea were elevated at postnatal day 3, but not at postnatal days 12 or 49 (age 7 weeks). Kidney weight was not affected in dams or offspring, but urinary levels of beta-2-microglobulin, an indicator of damage to the renal tubules, were elevated in offspring at 150 mg/kg/day on postnatal day 3 and 75 mg/kg/day at age 7 weeks.

In addition to the rat studies discussed above, ECHA (2022) reported on a developmental toxicity study, identified as Covance Laboratories (2021) in ECHA (2025), in which pregnant rabbits were dosed by oral gavage with 0, 180, 375, or 750 mg/kg/day sodium trifluoroacetate from gestation days 6–28 and sacrificed on gestation day 29. Maternal effects included decreased body weight gain, adjusted for the weight of the gravid uterus, by 20, 48 and 56% compared to control at 180, 375, and 750 mg/kg/day, respectively; the decreases at the two higher doses were statistically significant. Food consumption was decreased until the middle of the study (gestation days 14, 15, or 16) and increased at the end of the study (gestation days 26–28) in the dosed groups. Hepatic effects (increased relative liver weight, hepatocellular hypertrophy, and bile duct hyperplasia/fibrosis) occurred in a dose-related manner in all treated groups.

Mean weights of the fetus and total litters were significantly reduced at 375 and 750 mg/kg/day in a dose-related manner. In contrast to the developmental studies in rats described above, there was an increased incidence of major abnormalities in the fetuses, predominantly in the eyes, including multiple folded retinas and absent aqueous/vitreous humor, at the two higher doses compared to both concurrent and historical controls. At the low dose, microphthalmia with multiple folded retinas and absent aqueous/vitreous humor occurred in one fetus. ECHA (2022) stated that although this occurrence was within the historical control range, "a relationship to treatment could not be completely ruled out." Based on these data, the NOAEL for maternal toxicity was identified as 180 mg/kg/day, and the NOAEL for developmental toxicity was identified as <180 mg/kg/day (that is, below the lowest dose tested), indicating that developmental toxicity occurs at doses below those that cause maternal toxicity.

Inhalation Toxicity

Studies of acute inhalation toxicity of TFA in rats are reviewed in ECHA (2022). In a preliminary study in which rats were exposed to TFA concentrations of 0, 30, or 300 mg/m^3 for 4 hours, indicators of inflammation (alkaline phosphatase levels and the number of neutrophils) were increased in bronchioalveolar lavage fluid at 300 mg/m^3, and males were more sensitive than females. In the main study, male rats were exposed to 0, 30, 100, and 300 mg/m^3 for 4 hours. The only effect observed was very slight focal degeneration of the epithelium of the dorsal part of the nasal septum, indicative of local irritation, in high-dose rats sacrificed one day after exposure ended. This effect did not occur in animals sacrificed 14 days after exposure ended, indicating that it was reversible. There were no effects on body weight, bronchioalveolar lavage parameters, or histopathology of other parts of the respiratory tract or other organs in the main study.

ECHA (2022) described a subchronic inhalation study in which rats and guinea pigs "were exposed to a mixture of vapors and aerosols" of TFA at concentrations "between 0.025 and 0.05 mg/L or 0.4 and 0.7 mg/L." The animals were exposed for 4 hours per day, 6 days per week for four (guinea pigs) or five (rats) months. ECHA (2022) stated that detailed information on the study design was not available, and that TFA caused severe respiratory and ocular irritation, effects in the liver and kidney, and decreased body weight; a NOAEL was not identified. While ECHA (2022) did not provide a citation for the study, it was later described and identified as Institute of Work Health and Safety of the USSR (1964) in ECHA (2025).

In Vitro Genotoxicity

In vitro genotoxicity assays of sodium trifluoroacetate were negative, and no in vivo genotoxicity data are available (ECHA 2022). Specifically, sodium trifluoroacetate was negative in the bacterial reverse mutation assay in five strains of *Salmonella typhimurium* both with and without metabolic activation; the chromosome aberration assay in human primary lymphocyte cultures; and the mammalian cell gene mutation assay in mouse lymphoma L5178Y cells.

1.4.4.3 Perfluoropropanoic Acid (PFPrA)

Occurrence

PFPrA has been detected in surface water and groundwater. For example, it was detected in surface and ground water used as drinking water sources in Germany (median—12.6 ng/L, maximum 180 ng/L; Neuwald et al. 2022), and is stated to have been found in surface and groundwater in the vicinity of manufacturing facilities by USEPA (2023). It has been reported in drinking water in several studies. For example, it was the most frequently detected PFAS among the 70 PFAS analyzed in a study by Pelch, McKnoght, and Reade (2023) of 44 tap water samples from locations known or suspected to be contaminated with PFAS in 16 U.S. states. In this study, PFPrA was detected at concentrations of 2.5–140 ng/L in 24 of the 30 samples in which any PFAS was detected (Pelch, McKnoght, and Reade (2023)). PFPrA was also found in house dust (median—26 ng/g; maximum—200 ng/g) and tap water (median—6.9 ng/L; maximum—19 ng/L) in Indiana residences (Zheng et al. 2023).

Biomonitoring

PFPrA has been detected in blood serum, urine, and semen in individuals from the general population. It was found in the blood serum (median—1.0 ng/mL; maximum—2.9 ng/mL) and urine (median—0.051 ng/mL, maximum—6.8 ng/mL) in a study of residents of Indiana (Zheng et al. 2023), as well as in blood serum in three studies of Chinese populations (median values: 0.48 ng/mL, Duan et al. 2020; 0.16 ng/mL, Li et al. 2017; 0.62 ng/mL, Song et al. 2018). Song et al. (2018) also detected it in semen (median value—0.95 ng/mL).

Toxicokinetics

The human half-life of PFPrA was estimated as 88 days, based on urinary clearance determined from paired urine-serum measurements. These estimates were based on the assumptions that urine is the only route of excretion and that the volume of distribution of PFPrA is the same as for PFBA (Zheng et al. 2023). No other toxicokinetic data were identified.

Human Epidemiology Studies

USEPA (2023) identified three studies (Duan et al., 2020; Song et al. 2018; Li et al. 2017) that examined associations of health effects with PFPrA blood concentrations in humans. Each of these was a cross-sectional study from the general population in China. As reviewed by USEPA (2023), these studies did not demonstrate statistically significant associations with the health endpoints evaluated (glycemic indicators, thyroid hormones, semen parameters) after adjustment for potential confounding factors and or had limitations in their design or reporting.

Laboratory Animal Toxicology Studies

USEPA (2023) summarized information on laboratory animal toxicology studies of PFPrA. USEPA (2023) discussed two oral studies of PFPrA in rats—a 14-day range-finding study and a 28-day study.

No acute, chronic, or reproductive/developmental studies by any exposure route or repeated dose inhalation studies were discussed by USEPA (2023) or identified in a PubMed literature search.

In the oral 14-day range-finding study, rats were dosed with 0, 50, 250, or 1,000 mg/kg-day PFPrA. USEPA (2023) stated that information provided about this study is limited (for example, no information on number and sex of the animals, methods of endpoint evaluation, or quantitative dose-response data). USEPA (2023) reported that effects included changes in hematologic parameters and organ weights in all dose groups. Clinical chemistry abnormalities and necropsy findings were in the mid- and high-dose

groups, and clinical signs of toxicity, changes in body weights, and histopathology were observed in the high-dose group.

In the 28-day study, male and female rats (6 per dose level per sex) were dosed by oral gavage with 0, 5, 20, 80, or 320 mg/kg-day PFPrA. The study included control and high-dose animals recovery groups that were sacrificed 14 days after dosing ended. Body weight and food intake were not affected by exposure to PFPrA. Like other PFAS (**Section 17.2**), PFPrA caused hepatic toxicity. Male rats were more sensitive to these effects than females. However, because no toxicokinetic data are available, it is unknown whether this sex difference is due to more rapid excretion in male rats than female rats such as occurs for several other perfluoroalkyl acids (**Section 17.2**). Absolute and relative liver weight were increased in a dose-related manner at 20, 80, and 320 mg/kg/day in males, with statistically significant increases in relative liver weight at the two highest doses; this effect persisted in high-dose animals throughout the recovery period. Smaller increases in relative liver weight that were not statistically significant occurred in females. Histopathological changes in the livers of males included a dose-related increase in the incidence of hepatocellular hypertrophy, as well as slight focal necrosis in 1 of 6 animals in each of the two highest dose groups (80 and 320 mg/kg/day). These effects were not observed in the high-dose group after the recovery period. Serum levels of alanine aminotransferase (ALT) and alkaline phosphatase (ALP), markers of liver damage, were increased in a dose-related manner in males, with statistically significant increases in the higher dose groups (80 ng/kg/day and 320 ng/kg/day). Other effects, some of which did not occur in a dose-related manner, included decreased total bilirubin in males at all doses and in females at the two highest doses, increased relative kidney weight in both sexes, and decreased total cholesterol in males.

Genotoxicity Studies

In vitro genotoxicity assays of PFPrA were negative, and no in vivo genotoxicity studies were reported (USEPA 2023). Specifically, PFPrA was negative for mutagenicity in the bacterial reverse mutation assay (Ames test) in four strains of *Salmonella typhimurium* and in *E. coli,* both with and without metabolic activation. It was also negative in the chromosomal aberration assay in Chinese hamster lung fibroblasts, both with and without metabolic activation.

1.4.4.4 Perfluoro-2-methoxyacetic Acid (PFMOAA)

Occurrence

PFMOAA has been detected at high concentrations (~10,000 ng/L) in the United States in finished drinking water whose source is a river impacted by discharge from an industrial facility (McCord et al. 2018) and in private wells near this industrial facility at up to >200 ng/L (Kotlarz et al. 2024). It has also been found in coastal waters and aquatic species downstream of a Chinese industrial source (Li et al. 2023).

Biomonitoring

In a study of individuals living near a Chinese fluorochemical plant, PFMOAA was detected in the blood serum of all 977 subjects with a median concentration of 12.9 ng/mL and a maximum concentration of 158.2 ng/mL (Yao et al. 2023). PFMOAA was also detected in the blood serum of all subjects in a study of 294 children, age 7–10, from Yiwu, China. The median concentration was 0.29 ng/mL and the range was 0.01–53.6 ng/mL (Xu et al. 2025),

PFMOAA was also detected in the breast milk in 95.5% of 1,099 women from locations throughout China at a median concentration of 3.4 ng/L and a maximum of 1,086 ng/L (Yao et al. 2023). PFMOAA was measured in cord blood and neonatal (first postnatal week) urine in a subset of 80 mother-child pairs in this study. It was detected in 98.8% of cord blood samples with a median of 122.5 ng/L (0.12 ng/mL) and

a maximum of 4,628 ng/L (4.6 ng/mL) and in 100% of neonatal urine samples with a median of 35.3 ng/L and a maximum of 2,784 ng/L.

Toxicokinetics

Yao et al. (2023) estimated the half-life of PFMOAA in infants to be 0.221 years (80.7 days) based on urinary clearance determined from the paired urine-cord blood measurements mentioned above. This half-life estimate assumed that urine is the only route of excretion and that the volume of distribution of PFMOAA in human infants is the same as for perfluoro(3,5,7-trioxaoctanoic) acid PFO3OA in mice, based on its structural similarity to PFMOAA.

In a developmental toxicity study in rats in which PFMOAA (10–450 mg/kg/day) was administered to dams from gestation day 8 to postnatal day 2, PFMOAA concentrations in serum and liver increased linearly with dose, with concentrations in serum approximately 3 times higher than in liver (Conley et al. 2024).

Human Epidemiology Studies

In a study of 977 individuals residing near a Chinese fluorochemical facility, all of whom had measurable concentrations of serum PFMOAA, serum PFMOAA was significantly associated with decreased serum glucose but not with other biochemical parameters, including serum lipids and liver enzymes (Yao et al. 2020).

In a study (Xu et al. 2025) of 294 Chinese children 7–10 years of age, all with measurable concentrations of serum PFMOAA, serum PFMOAA was significantly associated with serum levels of high-density lipoprotein but not with serum levels of other lipid parameters, including total cholesterol, triglycerides, low-density lipoprotein, and apolipoproteins A1 and B. In statistical analysis of the association of exposure to mixtures of serum PFAS and serum lipid parameters using Weighted Quantile Sum regression, PFMOAA had the most influence on serum levels of high-density lipoprotein of the 14 PFAS evaluated in the study (Xu et al. 2025).

Laboratory Animal Toxicology Studies

No acute, subchronic, or chronic oral or inhalation studies of PFMOAA in laboratory animals were identified.

Developmental effects of PFMOAA in rats were evaluated in a study in which dams were administered 0, 10, 30, 62.5, 125, or 450 mg/kg/day by oral gavage from gestational day 8 to postnatal day 2. Birth weight was decreased at doses $\geq$30 mg/kg/day (Conley et al. 2024). In pups sacrificed at birth, liver glycogen was depleted at all doses, hypoglycemia occurred at the two highest doses, and there were changes in expression of genes involved with fatty acid and glucose metabolism. On postnatal day 2, pup survival was decreased at the two highest doses. At this timepoint, effects observed at all doses in both dams and pups included increased liver weight, increased serum levels of the liver enzyme AST, and decreased levels of thyroid hormones. Additionally, serum cholesterol was markedly elevated in the pups.

The potential for PFMOAA (0, 0.00025, 0.025, and 2.5 mg/kg/day) to cause toxicity to the immune system was evaluated in a 30-day oral gavage study in male and female mice (Woodlief et al. 2021); these doses are much lower than those in the rat developmental toxicity study (Conley et al. 2024) discussed above. In this study, PFMOAA did not affect body weight; absolute liver, spleen, or thymus weight; thymus or splenic cellularity; subpopulations of thymus T cells or spleen cells; or hepatic activity of a marker for peroxisome proliferation. Relative liver weight was increased by 7% in high-dose females, but this change was not statistically significant.

PFMOAA, at concentrations up to 80 micromolar (approximately 16 mg/L) did not cause developmental toxicity or suppress the respiratory burst (a component of immune function in which neutrophils and macrophages rapidly produce reactive oxygen species) in larval zebrafish (Phelps et al. 2023).

Other Studies

PFMOAA, at concentrations up to 80 micromolar, did not suppress the respiratory burst in cultured human nHL-60 neutrophil-like cells (Phelps et al. 2023).

1.4.4.5 1,1,1-Trifluoro-N- (trifluoromethanesulfonyl)methanesulfonamide (TFSI) and Lithium bis[(trifluoromethyl)sulfonyl]azanide (HQ-115)

The information below comes from the USEPA (2023) Office of Research and Development (ORD) Human Health Toxicity Value for lithium bis[(trifluoromethyl)sulfonyl]azanide (HQ-115) and the ECHA (2020) Registration Dossier for Lithium bis(trifluoromethylsulfonyl)imide (90076-65-6) (Note: The latter is another synonym for HQ-115). Health effects information on HQ-115 (the lithium salt of TFSI) is also applicable to TFSI, since HQ-115 completely dissociates to TFSI in the human body (USEPA 2023).

Occurrence

USEPA (2023) stated that TFSI or HQ-115 has been detected in surface water and wastewater near manufacturing facilities.

Biomonitoring

No information on biomonitoring is reported in USEPA (2023) or ECHA (2020).

Toxicokinetics

No information on toxicokinetics (absorption, distribution, metabolism, excretion) is reported in USEPA (2023) or ECHA (2020).

Human Epidemiology Studies

No information on human epidemiology studies is reported in USEPA (2023) or ECHA (2020).

Laboratory Animal Toxicology Studies

No inhalation toxicology studies of TFSI or HQ-115 were identified. Dermal and oral toxicity studies are reviewed below.

Dermal Toxicity

In a study using male and female rabbits and doses of 200, 350, 500, or 2,000 mg/kg and an observation period of 2 weeks, the dermal LD_{50} of HQ-115 in rabbits was estimated as 371 mg/kg in males and 418 mg/kg in females, suggesting that dermal absorption occurred. In contrast, in a rat study using a dose of 2,000 mg/kg and an observation period of 2 weeks, the dermal LD_{50} of HQ-115 was estimated as >2,000 mg/kg (USEPA 2023; ECHA 2020).

Oral Toxicity

Three acute oral rat studies of HQ-115 are summarized in USEPA (2023). In a study using doses of 50, 500, or 5,000 mg/kg and an observation period of 2 weeks, the LD_{50} was estimated as 160 mg/kg in

males and 210 mg/kg in females. In a study of male and female rats using doses of 25 or 200 mg/kg HQ-115 and an observation period of 2 weeks, mortality occurred at 200 mg/kg and the oral LD_{50} was estimated at >200 mg/kg. In a third study of female rats using a dose of 200 mg/kg of HQ-115, the LD_{50} was estimated as >200 mg/kg (USEPA, 2023; ECHA 2020).

A 7-day oral gavage study of HQ-115 in male and female rats (Huntingdon Research Center, 1992; summarized by USEPA 2023) used doses of 0, 10, 20, 50, or 100 mg/kg/day. Rats dosed with 100 mg/kg/day were sacrificed after the second dose due to severe clinical signs of toxicity, including piloerection, hunched posture, abnormal gait, pallor in the extremities, tremors, lethargy, and loose feces. Less severe clinical signs were also reported at 50 mg/kg/day. Other reported effects included reduced food consumption in females at ≥ 50 and males at 100 mg/kg/day, reduced body weight gain in both sexes at 100 mg/kg/day, and increased absolute liver weight (14%–16% in males; 8%–19% in females) at ≥ 30 mg/kg/day.

Two studies in which HQ-115 was administered to male and female rats by oral gavage for 4 weeks (28 or 29 days) are discussed by USEPA (2023) and summarized below.

In a study conducted by Huntingdon Research Center (1993), male and female rats were dosed with 0, 1.67, 10, or 60 mg/kg/day HQ-115 by oral gavage for 28 days, and with additional control and high-dose (60 mg/kg/day) recovery groups maintained for 14 days after the dosing period ended. Reported effects included decreased body weight gain in females dosed with 60 mg/kg/day and clinical signs of toxicity at 10 and 60 mg/kg/day in both sexes. Increased relative liver weight and hepatocellular hypertrophy occurred in both sexes at the high dose (60 mg/kg/day), and the liver was enlarged in one high-dose male at the end of the recovery period. Hepatic extramedullary hematopoiesis, which may indicate hepatic toxicity, occurred at lower doses in both sexes and in high-dose females at the end of the recovery period. Serum alkaline phosphatase (ALP), stated by USEPA (2023) to be a marker of hepatobiliary damage, was significantly elevated at the high dose (60 mg/kg/day) in males and at all doses, although not significantly, in females. Additionally, a dose-dependent increase in the serum albumin/globulin ratio, which may result from liver or kidney toxicity, occurred at all doses in both sexes. Serum cholesterol was decreased at the highest dose in males and at all doses in females, and serum triglycerides were also decreased in high-dose males. Absolute or relative kidney weight, or both were increased at the high dose in both sexes; other effects related to renal function included increased blood urea nitrogen and increased urine volume in high-dose males and decreased urinary pH at mid- and high doses in both sexes. Several other effects in dosed groups, not detailed herein, were considered sporadic or of unclear biological significance (USEPA 2023).

In a study conducted by a chemical registrant and reported in ECHA (2020), male and female rats were dosed with 0, 15, 45, or 90 mg/kg/day HQ-115 by oral gavage for 29 days. The study included control and high-dose recovery groups maintained for 14 days after dosing ended. In this study, body weight gain was decreased in mid-dose males and females and high-dose males, while body weight gain and food consumption were increased in high-dose females. Clinical signs of toxicity were reported in both sexes at the mid- and high doses. Increased absolute and relative liver weight, as well as hepatocellular hypertrophy, occurred in mid- and high-dose males and high-dose females. Increased liver weight did not persist in the high-dose recovery groups, and hepatocellular hypertrophy data were not reported. In the high-dose groups, serum alanine aminotransferase, albumin, and albumin/globulin ratio were increased in both sexes, and alkaline phosphatase was increased in males. There was a dose-related decrease in serum cholesterol and triglycerides at all doses in both sexes. Other effects included increased white blood cells at the mid- and high doses and relatively small decreases in red blood cell parameters in both sexes at all doses, changes in the thyroid in high-dose females, and the presence of foamy alveolar macrophages at the high dose in both sexes (USEPA 2023).

Finally, ECHA (2020) described a one-generation rat reproduction/developmental toxicity study of HQ-115 conducted by a chemical registrant. Males were dosed with 0, 15, 30, or 60 mg/kg/day for 2 weeks prior

to mating and up to 2 weeks during mating; females were dosed at the same levels for 2 weeks prior to mating, during mating, and during and after gestation through lactational day 4. Mortality occurred in parental males and females at both 30 and 60 mg/kg/day, and no females in the high (60 mg/kg/day) dose survived until the end of the study. Body weight or body weight gain was decreased in parental males at some time points at 60 mg/kg/day and at 15 and 30 mg/kg/day during lactation in parental females. Clinical signs of toxicity occurred at 60 mg/kg/day in both sexes and in one male at 30 mg/kg/day. Reproductive effects were reported in females at doses at which systemic toxicity occurred, including a lower number of pregnancies at 30 and 60 mg/kg/day and increased postimplantation loss and, changes in indicators of estrus cyclicity at 60 mg/kg/day. Only a few females in the high-dose (60 mg/kg/day) group delivered. There was a dose-dependent increase in the percent of offspring that died by postnatal day 4 in all dose groups, with no pups in the 60 mg/kg/day group surviving. There were also dose-dependent decreases in offspring body weight/body weight gain on postnatal days 1 and 5 and increases in the number of litters with pups with no milk in the stomach in all dose groups.

In Vitro Genotoxicity Studies

Eight reports on genotoxicity studies of HQ-115 are reviewed in USEPA (2023). Four reports included results of mutagenicity assays in *Salmonella typhimurium* and *E. coli* with and without metabolic activation, all of which were negative. A mutagenicity study in mouse lymphoma L5178Y cells and two chromosomal aberration studies in human lymphocytes, with and without metabolic activation, were also negative. In a chromosomal aberration study in Chinese hamster lung fibroblasts, the proportion of cells with chromosome aberrations was increased both with and without metabolic activation, with the doses causing this effect varying with the time period of exposure. Additionally, in cells exposed for 48 hours (the longest exposure duration in the study) without metabolic activation, the proportion of polyploidy cells was increased at the highest concentration tested.

1.4.4.6 Trifluoromethanesulfonic Acid (TFMS)

Unless otherwise noted, the information below comes from ECHA (2021).

Occurrence

In aqueous samples from several European nations, TFMS was detected in urban effluent at approximately 10–100 ng/L, surface water at approximately 1 to > 1,000 ng/L, groundwater at approximately 1–100 ng/L, and drinking water at <1 to approximately 1,000 ng/L (Zahn et al. 2016).

Biomonitoring

No biomonitoring data for TFMS were identified.

Toxicokinetics

No studies of the toxicokinetics of TFMS were identified. Systemic toxicological effects (for example, in the liver, kidney, and spleen) after oral exposure to TFMS indicate that oral absorption occurs (ECHA 2021). Based on its perfluorinated chemical structure, it is not expected to be metabolized (ECHA 2021). ECHA 2021 also concludes that TFMS is expected to be excreted in the urine and that it has no bioaccumulation potential.

Human Epidemiology Studies

No epidemiology studies of TFMS were identified.

Laboratory Animal Toxicology Studies

Dermal and oral toxicity studies are reviewed below.

Dermal Toxicity

In an acute dermal toxicity study in rats, application of 50 mg/kg TFMS to shaved skin did not cause mortality, but 2,000 mg/kg caused severe local effects (for example, ulceration) necessitating humane sacrifice of the test animals. The dermal LD50 was not determined (ECHA 2021).

In a dermal irritation study, TFMS (0.5 ml undiluted compound) was applied to the shaved skin of a rabbit at three sites with exposure times of 3 minutes, 1 hour, or 4 hours, and skin irritation was assessed at time points up to 7 days after exposure ended. TFMS caused irritation (erythema and edema), and necrosis was present 7 days after exposure ended for all three exposure periods (ECHA 2021).

TFMS was negative for skin sensitization in a study performed in guinea pigs (ECHA 2021).

Oral Toxicity

As noted above, the information in this section comes from ECHA (2021), unless otherwise noted. The acute toxicity of TFMS was evaluated in male rats (10 per dose group) dosed with 0, 539, 700, 910, 1,183, 1,538, and 2,000 mg/kg via oral gavage and observed for 14 days; these doses were selected based on a preliminary study in which mortality occurred at 2,000 mg/kg but not at 500 mg/kg. There was no mortality at $\leq$ 910 mg/kg, and mortality occurred in 1/10, 6/10, and 7/10 animals at 1,183, 1,538, and 2,000 mg/kg, respectively. The LD_{50} was determined to be 1,605 mg/kg. Clinical signs such as decreased spontaneous movement and sedation were observed, with more effects at higher doses, and weight gain was decreased at $\geq$ 1,183 mg/kg. Gross and microscopic pathology examination revealed damage to the stomach and small intestine, as well as other organs, including liver, spleen, and thymus.

The repeated dose toxicity of TFMS was evaluated in male and female rats (6 per dose group) dosed via oral gavage with 0, 8, 40, 200, and 1,000 mg/kg/day for 28 days, and additional control (0 mg/kg/day) and high dose (1,000 mg/kg/day) were evaluated at the end of a 14-day recovery period. TFMS did not cause mortality or affect body weight or food consumption. TFMS at 1,000 mg/kg/day caused slight, non-statistically significant decreases in hematologic parameters related to red blood cells (decreased hemoglobin, hematocrit, mean corpuscular volume, and mean corpuscular hemoglobin) in males; only the decrease in mean corpuscular hemoglobin persisted through the recovery period. In females dosed with 1,000 mg/kg/day, platelet count was increased, and this effect did not persist through the recovery period. In females dosed with 1,000 mg/kg/day, serum levels of protein were reduced and urea nitrogen and creatinine were increased, and these changes did not persist through recovery. In males dosed with 200 mg/kg/day, serum cholinesterase was increased, and there were several clinical chemistry changes, including increased total cholesterol and triglycerides in the high-dose (1,000 mg/kg/day) group at the end of the recovery period. In females dosed with 1,000 mg/kg/day, urinary ketone bodies and glucose levels were increased, and these effects did not persist through recovery. No effects on organ weight were observed in males or females.

Effects in the forestomach (boundary ridge protrusion) and glandular stomach mucosa (reddening in males; roughening and blackening in females) were observed at necropsy at 1,000 mg/kg/day. Histopathological changes included squamous epithelium hyperplasia in the forestomach in males at 200 mg/kg/day and both sexes at 1,000 mg/kg/day. Reduction in glandular stomach parietal cells, surface epithelial cell hyperplasia, submucosal bleeding, and loss of villi in the duodenum were observed in both sexes at 1,000 mg/kg/day; and necrosis of the duodenal mucosa, renal tubular necrosis, and urinary casts were observed in females at 1,000 mg/kg/day. Some of these effects were observed in males dosed with 1,000 mg/kg/day at the end of the 14-day recovery period.

Reproductive and developmental effects of TFMS were evaluated in a study in which 0, 100, 300, or 1,000 mg/kg/day were administered via oral gavage to male and female rats (10 per sex per dose level) starting 2 weeks prior to mating and during the mating period, and, in females, throughout gestation until postnatal day 4. In parental males and females, there was no mortality, and body weight and food consumption were not affected. There were no effects on pairing, mating, or fertility, and effects on mean delivery date were not considered to be toxicologically significant. At sacrifice, no effects on reproductive organ weight or macroscopic or microscopic pathological changes of the reproductive organs were noted. Offspring were sacrificed on postnatal day 5. There were no effects on pup viability, no changes in body weight that were considered toxicologically significant, or and no effects on the percentage of males versus females at birth. Organ weight and gross and microscopic pathological changes were not evaluated in the offspring. ECHA (2021) concluded that the NOAELs for parental toxicity, parental reproductive performance, and toxicity to offspring were 1,000 mg/kg/day, the highest dose used in the study.

Zhou et al. (2020) evaluated effects on the liver and intestine in male mice dosed with 0, 0.001, 0.01, or 0.1 mg/kg/day TFMS via oral gavage for 12 weeks. This study used lower doses and a longer exposure duration than the studies reported in ECHA (2021). Body weight and liver:body weight ratios were not significantly affected by TFMS, while epididymal fat and the ratio of epididymal fat:body weight were decreased in a dose-related manner. Changes in levels of serum lipids and glucose occurred at one or more doses, but they did not exhibit a consistent dose-response relationship. Hepatic triglyceride levels were significantly reduced at all doses, while hepatic total cholesterol was not significantly changed at any dose. Histopathological examination revealed inflammatory cell infiltration in the liver at the two higher dose levels. Changes in intestinal microbiota were also observed in mice treated with TFMS.

In Vitro Genotoxicity Studies

In vitro genotoxicity studies of TFMS include two bacterial reverse mutation studies, a mammalian chromosome aberration study, and a mammalian cell gene mutation test (ECHA 2021).

TFMS was negative in bacterial reverse mutation assays, with and without metabolic activation. One study included four strains of *S. typhimurium* and one strain of *E. coli,* while another included two of the four *S. typhimurium* strains used in the first study.

TFMS was also negative in mammalian gene mutation assays using L5178Y mouse lymphoma cells, with and without metabolic activation, and in a mammalian chromosome aberration test using Chinese hamster lung fibroblasts, both with and without metabolic activation.

Based on results of these studies, ECHA (2021) concluded that TFMS is not genotoxic.

1.4.5 New Information on Considerations for Addressing PFAS as a Class

Considerations for regulation of PFAS as an entire class were previously reviewed in Section **7.1.7**. As reviewed in **Section 7.1.7**, toxicity has been evaluated for only a small number of the thousands of PFAS used commercially. Of those PFAS that have been studied (all of which are nonpolymeric PFAS), all were capable of causing adverse effects in animals and or humans (see **Section 7.1** and **Section 17.2**). Because substantial time and resources are required to characterize the chemical and physical properties and potential health effects of each individual chemical (for example, **NTP 2022**), the conclusion that it is not feasible and is not necessarily health-protective to follow the “chemical-by-chemical” regulatory paradigm for PFAS has gained increasing attention. For example, ECHA proposed to restrict all PFAS with a single regulation (**ECHA 2023**) based on concerns about their common property of persistence, since virtually all PFAS persist indefinitely or can transform to terminal PFAS that persist indefinitely. It is important to note the distinction between approaches for addressing the entire class of PFAS, which are

generally not based on risk assessment considerations, and approaches for human health risk assessment of PFAS mixtures (discussed in **Section 7.1.5** and **Section 17.2.7**), which require health effects information for each of the specific PFAS that are included in such an approach. Although efforts to address PFAS as a class do not assume that all PFAS are equally toxic and are generally not based on risk assessment considerations, the underlying rationale for addressing PFAS as a class is, as stated by Cousins et al. (2020), "The continuous release of persistent chemicals will lead to widespread, long-lasting, and increasing contamination, which will inevitably result in increasing probabilities of known and unknown adverse effects on human health and the environment."

Section 7.1.7 reviewed proposed strategies for grouping PFAS as of 2023. This section reviews more recent considerations related to addressing PFAS as a class, including examples of actions taken by regulatory agencies to address PFAS as a broad class and analytical techniques used to estimate total PFAS. As discussed below, such considerations are different for PFAS intentionally added to products than for PFAS present in environmental media (for example, drinking water). As discussed in **Section 2.2**, the suite of compounds defined as PFAS varies among authoritative organizations, notably differing as to whether compounds with one fully fluorinated carbon (for example, trifluoroacetic acid) are included.

Until recently, most actions to address PFAS as an entire class focused on products that contain PFAS rather than PFAS that are present in environmental media (for example, drinking water). Approaches that address PFAS as a class in products based on intentional use, including use in processing aids in manufacturing, are typically based on knowledge of the components used to make the products and do not require that the products be analyzed to determine whether any PFAS are present. In addition to the ECHA and California Department of Toxic Substances Control (DTSC) efforts to regulate PFAS as a class in certain consumer products (reviewed in **Section 7.1.7**), several state agencies, including Maine DEP (2025), Minnesota Pollution Control Agency (undated), and Washington state described by Smith et al. (2024), have enacted legislation to address PFAS as a class in products or certain categories of products. An additional example of a regulation that addresses PFAS as a class is the USEPA Toxic Substances Control Act (TSCA) rule scheduled to go into effect in 2026 (USEPA 2025). This rule requires that "any person that manufactures (including import) or has manufactured (including imported) PFAS [as defined by TSCA] or PFAS-containing articles in any year since January 1, 2011, to electronically report information regarding PFAS uses, production volumes, disposal, exposures, and hazards (USEPA 2024)."

Considerations for addressing PFAS as an entire class in drinking water or other environmental media differ from those for addressing PFAS that are intentionally present in products because the identities of all PFAS that are present are not known. Specifically, current targeted analytical techniques detect only a subset of the individual PFAS that may be present, and current methods that estimate the concentration of aggregate ("total") PFAS (reviewed below) may not be inclusive of all PFAS that may be present. Additionally, such methods may not be approved for regulatory use for the medium of concern. Additionally, because all PFAS that are present may not be effectively removed by the same treatment removal technologies (for example, granular activated carbon), multiple treatment removal approaches may be required to remove PFAS as a class from environmental media, such as drinking water or wastewater (see **Section 12**).

As reviewed below, several states have evaluated addressing PFAS as the entire class in environmental media, most commonly drinking water, or plan to do so. In response to a legislative requirement, the Vermont Agency for Natural Resources (VT ANR 2020) evaluated regulation of PFAS in drinking water as a class or subclass. VT ANR (2020) concluded that it was "technically infeasible" to establish a maximum contaminant level (MCL) for PFAS as a class because the necessary toxicological information and analytical methods were not available. They also concluded that a treatment technique–based standard was not appropriate.

The Hawaii Department of Health Interim PFAS Guidance (HI DOH 2024) and supporting files (HI DOH 2024), include a screening approach for estimation of the potential human health risk of total PFAS in soil

and water samples. This approach is based on assumed additive toxicity for mixtures of PFAS, specifically the sum of the hazard quotients for 1) PFAS included in target analysis for which toxicity factors are available; 2) PFAS precursors that are converted in the total oxidizable precursor (TOP) assay to terminal PFAS that are target analytes with available toxicity factors; and 3) additional PFAS whose concentration is estimated with a total organic fluorine (TOF) method. The toxicity of these additional unidentified PFAS, which is stated to be typically composed of ultrashort PFAS, is assumed to be the same as the ultrashort PFAS perfluoropropionic acid (PFPrA). HI DOH explained that this approach is intended for use as an initial screening tool to guide further evaluation.

California Assembly Bill 178 (CA Assembly 2022) included requirements to "develop standard operating procedures for and validate a broad-spectrum test for the class of PFAS" in drinking water and "develop a treatment-based regulation for the entire class of PFAS" in drinking water.

In response to these requirements, the CA Water Board conducted a method comparison study to determine the "most appropriate broad-spectrum analytical method for characterizing the occurrence of 'total PFAS' in drinking water" (CA Water Board 2024). The study tested samples from nine public water system wells and evaluated the recovery of several categories of PFAS over a wide concentration range in the analytical methods that were evaluated. Methods evaluated (reviewed below) included an adsorbable organic fluorine-combustion ion chromatography (AOF-CIC) method using an extraction procedure modeled after USEPA Method 1621; an extractable organic fluorine-combustion ion chromatography (EOF-CIC) method using an extraction procedure modeled after USEPA Method 533; and non-targeted and target analysis using several different sample preparation approaches.

AOF-CIC with Method 1621 extraction procedures was identified as the "the most appropriate and commercially available broad-spectrum analytical method available" (CA Water Board 2024). Compared to EOF-CIC with Method 533 extraction, it was concluded that the AOF-CIC method with Method 1621 extraction was superior in both capturing organic fluorine and minimizing interference from inorganic fluorine compounds. Results presented in CA Water Board (2024) appear to indicate that a considerable portion of organic fluorine captured by the AOF-CIC method was not captured by a targeted analytical method. Currently, a larger study of almost 4,000 public wells serving disadvantaged communities in rural and urban areas throughout California is ongoing and is expected to be completed in 2026. In this study, samples are being analyzed with both AOF-CIC (broad-spectrum PFAS) and ion chromatography-mass spectrometry-mass spectrometry (IC-MS/MS, for ultrashort PFAS, which are missed by AOF-CIC), and with the targeted USEPA Method 533 for comparison. About 700 of the 4,000 samples will also undergo "full non-target analysis" with the assistance of USEPA. Results of this study will inform California's regulatory process for a treatment-based approach for PFAS as a class (CA Water Board 2024).

The New Jersey legislature (2024) enacted S3176/A4760, a law that requires the New Jersey Department of Environmental Protection to conduct "an assessment of the feasibility of establishing an MCL or other standard for the entire class, or for certain subclasses or mixtures, of PFAS in drinking water, rather than for each individual substance."

The USEPA Drinking Water Contaminant Candidate List 5 (CCL5) (USEPA 2022) includes PFAS as a group. However, USEPA (2022) explained that listing PFAS as a group instead of as individual contaminants "does not necessarily mean that EPA will make subsequent regulatory decisions for the entire group." USEPA (2022) stated that the intent of listing PFAS as a group is to "limit duplication of … efforts, such as data gathering, analyses and evaluations" and that USEPA "will evaluate scientific data on the listed groups, subgroups, and individual contaminants included in the group to inform any regulatory determinations." USEPA (2024) requested public input on drinking water analytical methods for contaminants listed in CCL5, including PFAS as a group, and asked for "comments to support development and consideration of aggregate PFAS measurement."

USEPA (2025) and Idowu et al. (2025) reviewed methods that can be used to estimate total PFAS concentrations in environmental samples, and they are illustrated in **Figure 1-22**. Methods that measure organic fluorine include TOF, extractable organic fluorine (EOF), and adsorbable organic fluorine (AOF).

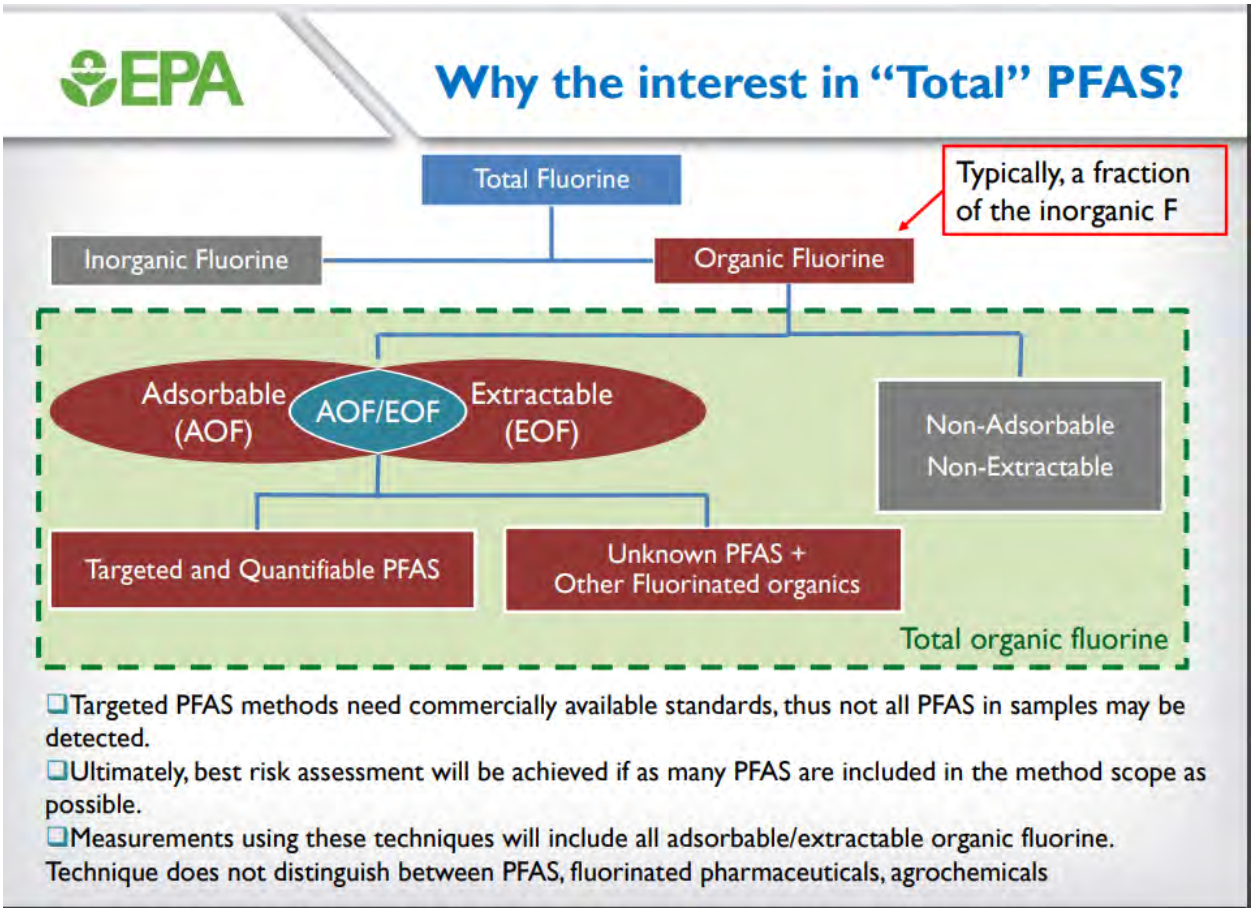

Figure 1-22. Why the interest in "Total" PFAS?

Source: Slide from Small Drinking Water Systems Webinar, PFAS Drinking Water Methods: Past, Present, and Future, USEPA (2023).

USEPA 2025 includes information about PFAS analytical techniques that can potentially be used for analyzing wastewater discharge samples for NPDES monitoring. The analytical techniques discussed include TOF, AOF, EOF, TOP Assay, PIGE, and ^{19}F-NMR. Each technique results in concentration measurements that may include PFAS, organofluorine compounds that are not PFAS, and inorganic fluorine. TOF, AOF, and EOF use CIC to completely decompose fluorinated organic compounds present in the sample, and the concentration of organic fluorine is estimated from concentration of inorganic fluoride produced during CIC. Inorganic fluoride present in the sample is also measured and must either be accounted for or removed from the sample. Available data indicate that targeted analytical methods may not account for a considerable portion of the organic fluorine present in drinking water. However, fluorinated organic compounds that are not PFAS (for example, some fluorinated pharmaceuticals and pesticides) contribute to the organic fluorine measured in drinking water with AOF and EOF (Spaan et al. 2023). Additionally, the adsorption or extraction steps in these methods may not capture all the organic fluorine that is present.

Factors affecting the differences in the results of the methods include the sample preparation steps and detection limits that can be achieved. Strengths and weaknesses of each technique and the expected

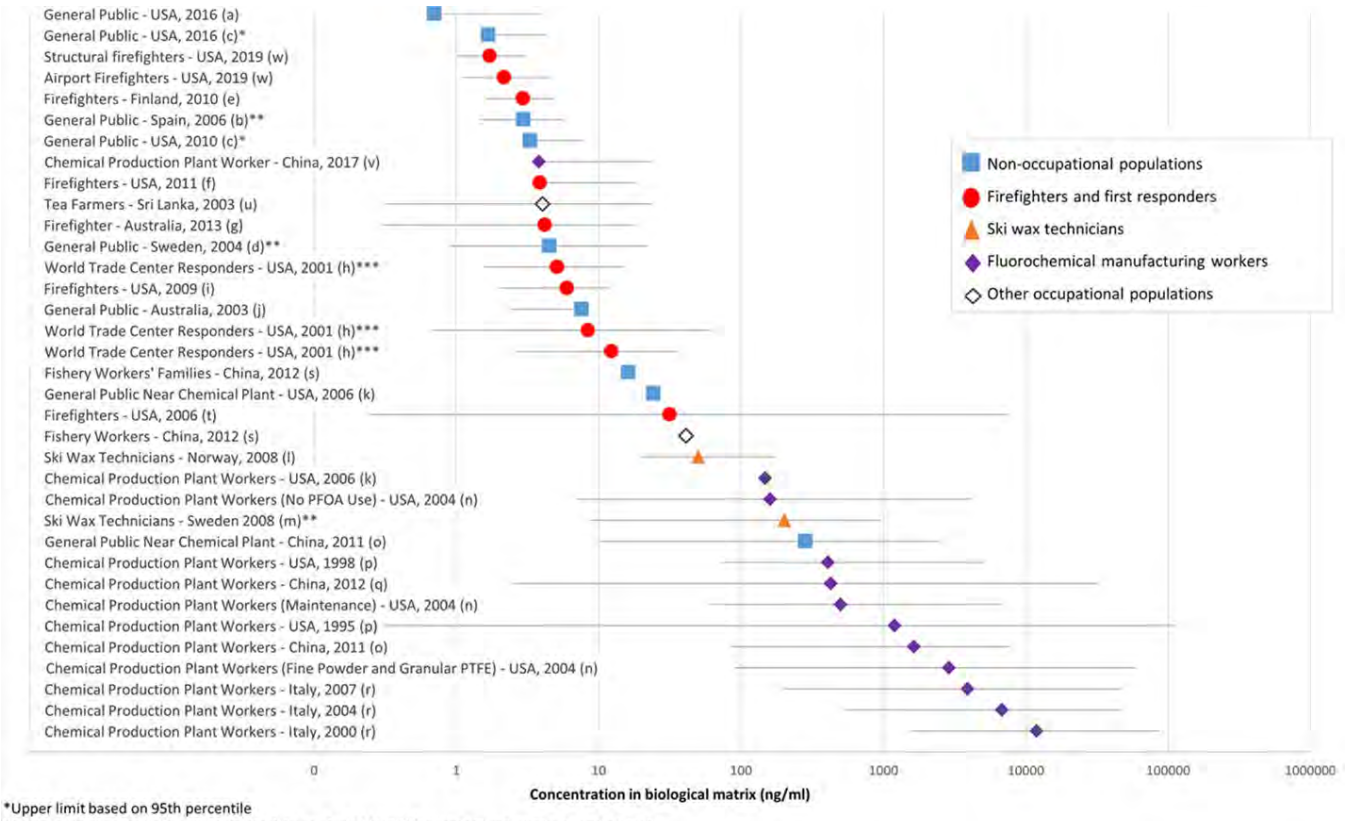
results are summarized in USEPA (2025). Additional information about TOP assay, USEPA Method 1621, including AOF and EOF, and PIGE are included in **Section 11.2.2**.

USEPA Method 1621 is detailed in (USEPA 2024). Additional information is given in USEPA (2024) about the use of Method 1621. The detection limit for Method 1621, is much higher than the detection limits for individual PFAS in USEPA Method 533 (USEPA 2019), Method 537.1 (USEPA 2020), and Method 1633A (USEPA 2024). Additional information about quantitative techniques is in **Section 11.2.1**. Ultrashort PFAS such as trifluoroacetic acid (TFA) and perfluoropropionic acid (PFPrA), which may contribute a considerable percentage of the total PFAS in a water sample, are not accurately measured by AOF (Neuwald et al. 2022).

USEPA 2024 is a federal register notice that includes information about a draft USEPA method EOF (extractable organic fluorine) for screening of drinking water samples.

These methods provide estimates of total PFAS concentration without identification of the specific PFAS present, see **Section 11.2.2** and **Section 1.5.4**. Therefore, the data obtained with these methods cannot be used in estimating the health risks of the PFAS mixture using the mixtures risk assessment approaches discussed in **Section 7.1.5** and **Section 17.2.7**.

Because specific treatment removal technologies remove different PFAS from environmental media (for example, drinking water) with higher or lower efficiencies, multiple technologies used sequentially would likely be necessary to effectively remove the entire class of PFAS from drinking water or wastewater (see **Section 12**). Additionally, a treatment-based standard for the entire class of PFAS would require the use of analytical methods that can determine whether all PFAS have been removed.



1.4.6 Potential PFAS Exposures in Occupational Settings

Section 2.3.1 indicates that workers in some occupations may be more highly exposed, and more at risk, than other populations. The text in this section provides more detailed information about specific occupations where workers may have elevated PFAS exposures based on the existing literature.

As indicated in **Section 2.1** and **Figure 2-2**, human exposure to PFAS may occur as a result of (1) direct interaction with PFAS in the workplace during manufacturing, (2) professional use of PFAS-containing materials, (3) use of or contact with commercial and consumer products containing PFAS, or (4) exposure to environmental media impacted by PFAS. Occupational exposures include both workplace exposure and professional use/application of PFAS-containing materials. This is an important category of exposure to discuss because there is the potential for much higher exposures than those in the general population. In addition, occupational exposures can be regulated by different laws and rules than environmental exposures, which may be incurred by the general population. The **Regulatory Programs Table** and **Section 2.5** include information about regulations related to the ban of PFAS in certain categories of consumer products.

Christensen and Calkins (2023) conducted an extensive literature search on PFAS exposure in occupational settings using four literature databases and searching for peer-reviewed articles published between 1980 and 2021. They found that most early research focused on fluorochemical workers, but additional workers in other occupations were studied after 2010. These additional occupations include firefighters and ski wax technicians, with fewer studies on other occupational settings including (but not limited to) textile mill workers, metal plating workers, clothing retail workers, office workers, fishermen, and barbers. It should be noted that PFAS exposures of fishermen/fishery workers were driven by consumption of fish from contaminated water bodies rather than by other exposure pathways and media. Therefore, worker exposure comparisons to fishermen/fishery workers were not included in the discussions in the following sections. Christensen and Calkins (2023) provided figures presenting a comparison of the levels of PFOA and PFOS in serum, plasma, or whole blood in workers of various

occupations based on results of their literature search, which are reproduced as **Figure 1-23** and **Figure 1-24**, respectively, here. Additional information for the studies included in the literature review is available in the Christensen and Calkins (2023) paper.

This section discusses currently available information regarding potential occupational exposures to PFAS by workers in a few of these occupational settings. This section should not be viewed as a definitive and exhaustive discussion of all potential occupational exposures, given the ongoing studies in various occupational settings.

The Department of Defense developed an occupational medicine fact sheet that includes a brief discussion of the different exposure pathways for PFAS (USDOD 2024). These include occupational exposures through inhalation of aerosols and particulates containing PFAS. The fact sheet indicates that more research is needed to evaluate how inhalation exposures compare to other potential exposure routes. The Agency for Toxic Substances and Disease Registry does not consider skin absorption as a significant exposure route for PFAS (ATSDR 2021). A detailed discussion with additional information on dermal absorption of PFAS is provided in **Section 17.2.3** and in **Section 1.4.3**.

1.4.6.1 Fluorochemical Workers

Fluorochemical workers may be exposed to PFAS by touching surface dust and breathing in PFAS-contaminated air. Among fluorochemical workers, the extent of exposure is dependent on specific job tasks (for example, cell and chemical operator, waste operator, maintenance worker), with cell and chemical operators having the highest reported serum levels of PFOA, PFOS and PFHxS. Table 5-27 of ATSDR (2021) presents the range of concentrations of PFOA, PFOS, and PFHxS measured in the serum of fluorochemical workers at several facilities in the United States, Belgium, and Italy and indicates that the levels in workers were frequently 100 to 1,000 times higher than in the general population. PFOA mean concentrations in serum ranged from 262 to 19,700 ng/mL, PFOS mean concentrations in serum ranged from 403 to 2,440 ng/mL, and PFHxS mean concentrations in serum ranged from 170 to 290 ng/mL. Based on their literature review, Christensen and Calkins (2023) reported that fluorochemical workers had the highest blood concentrations of PFOA and PFOS compared to other workers in other occupations. Table 1a of Christensen and Calkins (2023) presented the median serum PFAS levels in fluorochemical workers and indicated PFOA median serum levels ranging from 11 to >10,000 ng/mL, PFOS median serum levels ranging from 11 to 10,000 ng/mL, and PFHxS median serum levels ranging from <1 to 1,000 ng/mL. Figures 3 and 4 of Christensen and Calkins (2023) (reproduced as **Figure 1-23** and **Figure 1-24**

here) provided a comparison of PFOA and PFOS levels in blood of workers by industry (and in the general population), indicating that fluorochemical workers had the highest PFOA and PFOS levels measured in blood.

1.4.6.2 Firefighters

Potential occupational exposures of firefighters to PFAS include inhalation of aerosolized aqueous film-forming foam (AFFF); skin contact with AFFF, contaminated fire equipment and personal protective equipment ("turnout gear"), and PFAS-contaminated dust; and inhalation of PFAS in smoke, air, and dust while firefighting and at fire stations (for example, Nilsson et al. 2022; Rosenfeld et al. 2023). Christensen and Calkins (2023) reported firefighter blood concentrations of PFOA and PFOS in comparison to the general population and other occupational workers. Table 1a of Christensen and Calkins (2023) presented the median serum PFAS levels in firefighters and indicated PFOA and PFOS median serum levels ranging from 1 to 100 ng/mL. Figures 3 and 4 of Christensen and Calkins (2023) (reproduced as **Figure 1-23** and **Figure 1-24** here) provided a comparison of PFOA and PFOS levels in blood by industry (and in the general population), indicating that both PFOA and PFOS levels in firefighters' blood were lower than those reported in fluorochemical workers, and PFOA levels in firefighters' blood were lower than those reported in ski wax technicians.

Nilsson et al. (2022) examined the serum concentrations of 40 different PFAS in 799 Australian firefighters. The results showed that the arithmetic mean serum concentrations of PFHxS, PFHpS, and PFOS in firefighters with historical exposure to AFFF were higher than the corresponding mean serum concentrations among the general Australian population of similar age (PFHxS: 14 versus 2.1 ng/mL; PFHpS: 1.7 vs. 0.24 ng/mL; PFOS: 27 versus 5.7 ng/mL). However, the mean PFOA levels in firefighters were similar to the general Australian population. Rosenfeld et al. (2023) reviewed 10 published studies and found that firefighters were reported to have elevated serum levels of various PFAS, including PFOA, PFOS, PFNA, PFHxS, PFHpS, PFDeA, PFDoA, PFDA, and PFUnDA. However, not all studies found elevated serum levels of PFAS; there were many instances among the studies reviewed in which the geometric mean serum levels for specific PFAS were not statistically significantly higher than control populations, and most studies analyzed only a few PFAS.

PFAS are used in firefighter turnout gear due to their water- and oil-repellent properties. Several studies (Peaslee et al. 2020; Maizel et al. 2023) have shown that the textiles used in turnout gear are a potential source of PFAS exposure to firefighters. Mazumder et al. (2023) provided a summary of the findings from available studies of the presence of PFAS in textiles used in various components (moisture barriers, outer shells, and thermal liners) of turnout gear. PFAS-treated textiles in turnout gear can degrade during washing and high temperature situations, resulting in release of volatile PFAS and fabric dust/lint, which may lead to exposure through inhalation, ingestion, or dermal contact.

Maizel et al. (2023) evaluated the presence of PFAS in the manufacturing of new firefighter turnout gear. PFAS were detected in all 20 textiles that were analyzed, with the number of detected PFAS ranging from 1 to 17 out of 53 PFAS analyzed. A higher number of PFAS detected and higher concentrations were found in textiles used for moisture barriers and outer shells. The total PFAS concentrations varied among textile types, with the largest differences observed among moisture barrier textiles, suggesting that the amount of PFAS depends on the specific textiles used in manufacturing the turnout gear. The highest concentrations detected were of three fluorotelomers: 2-(Perfluorohexyl)ethyl methacrylate(6:2 FTMAC), 6:2 fluorotelomer alcohol (FTOH), and 6:2 fluorotelomer sulfonic acid (FTS).

The Department of Defense (2024) developed an occupational medicine fact sheet that includes a brief discussion of the various PFAS exposure pathways for firefighters. These include exposures through contact with AFFF, turnout gear, and inhalation of aerosols and particulates containing PFAS. The fact sheet notes that dermal absorption of PFAS is not thought to be a significant exposure route (ATSDR

2021). A detailed discussion with additional information on dermal absorption of PFAS is provided in **Section 17.2.3** and in **Section 1.4.3**.

1.4.6.3 Professional Ski Waxers

Ski waxers apply glider waxes onto the bottom of skis and snowboards to enhance glide across the snow. The waxes are available in powder, solid block, or liquid form, and often contain PFAS. The powder and solid waxes are melted onto the ski by a heated iron, while the liquid waxes are dripped or sprayed onto the ski. In addition to applying glider waxes, ski waxers manually remove excess glide wax using plastic scrapers and rotating brushes (Freberg et al. 2013; Fang, Plassmann, and Cousins 2020). The waxing process can release PFAS into volatile, aerosol, or particulate fractions, which can be inhaled or settle in the vicinity of the worker (Nilsson et al. 2013; Freberg et al. 2010; 2013; 2014; Hämeri et al. 1996). Exacerbating the situation, ski waxers often work in poorly ventilated areas (Freberg et al. 2013; 2014; Hämeri et al. 1996).

Freberg et al. (2010) presented the results of PFAS analyses on 11 solid glide wax blocks and 11 glide wax powders from six different manufacturers. Twelve PFAS were detected in the samples, with higher maximum detected concentrations in glide wax powders than in solid blocks for all PFAS analyzed except perfluorotridecanoic acid (PFTrDA). The highest detected concentrations were of perfluorotetradecanoic acid (PFTeDA), followed by PFDoDA, PFOA, and PFHxA.

Christensen and Calkins (2023) reported ski wax technician blood concentrations of PFOA and PFOS in comparison to the general population and other occupational workers. Table 1a of Christensen and Calkins (2023) presented the median serum PFAS levels in ski wax technicians and indicated PFOA median serum levels ranging from 11 to 1,000 ng/mL and PFOS median serum levels ranging from 11 to 100 ng/mL. Figures 3 and 4 of Christensen and Calkins (2023) (reproduced as **Figure 1-23** and **Figure 1-24** here) provided a comparison of PFOA and PFOS levels in blood by industry (and in the general population), indicating that ski wax technicians had PFOA levels measured in blood that were lower than fluorochemical workers. Christensen and Calkins (2023) also found that ski wax technicians had PFOS levels measured in blood that were lower than fluorochemical workers and firefighters.

Paris-Davila et al. (2023) conducted a literature search for peer-reviewed articles published through December 2022 addressing occupational exposures to PFAS via inhalation. Results indicated that ski waxers were exposed to the highest total PFAS air concentrations compared to other reported occupations, including textile manufacturing, firefighting, and floor waxing. For ski waxing, the maximum reported total PFAS air concentration was 10 µg/m^3. For ski waxers, PFOA, PFHxA, PFDoDA, and PFDA were detected at a maximum concentration of 1 µg/m^3 (per PFAS) in personal sampling, a concentration approximately two to four orders of magnitude (depending on the specific PFAS) higher than those reported for other occupations. In ski waxing facilities, FTOH 8:2 air concentrations were reported as high as 1,000 µg/m^3, approximately two orders of magnitude higher than in other occupations. Freberg et al. (2010) measured 14 PFAS in the serum of professional ski waxers and observed that the highest median serum levels were for PFOA, followed by PFOS, PFNA, and PFDA.

Nilsson et al. (2013) also reported that blood levels of PFOA are elevated among professional ski waxers due to high PFAS concentrations in workplace air during ski waxing. Nilsson et al. (2013) reported that ski waxers are exposed to high levels of volatile FTOHs in air, with 8:2 FTOH detected in 100% of personal measurements (cartridge samples – samplers worn during work) and 6:2 FTOH and 10:2 FTOH detected in 96% of the personal measurements (n=84). The highest PFAS concentration in the personal measurements was 8:2 FTOH at 997 µg/m^3 (average = 113 µg/m^3), while the average 6:2 FTOH and 10:2 FTOH concentrations were 2.22 µg/m^3 and 0.32 µg/m^3, respectively. The average PFHxA, PFOA, PFTrDA, and PFTDA levels in personal measurements were 3.89 µg/m^3, 0.526 µg/m^3, 0.043 µg/m^3, and 1.27 µg/m^3, respectively. As indicated in Nilsson et al. (2010), FTOHs can be metabolized to PFCAs (for example, 8:2 FTOH metabolized to PFOA) in the body.

1.4.6.4 Textile Manufacturing Workers

Textile manufacturing facilities can be a source of PFAS exposures for workers where water-, oil-, or stain-resistant textiles are produced. Exposure pathways can include both dust ingestion and air inhalation.

PFAS are used in manufacturing some high-performance fabrics to protect against water, stain, and oil penetration. Heydebreck et al. (2016) evaluated the presence of PFAS in air, airborne particles, and settled dust in a textile manufacturing plant in China. The plant produces both heavyweight and lightweight garments such as uniforms, fashion clothes, sportswear, and outdoor clothes. Thirty-two PFAS were analyzed in the samples; 27 PFAS (12 neutral PFAS and 15 ionic PFAS) were detected in air samples, 27 PFAS (12 neutral PFAS and 15 ionic PFAS) were detected in airborne particle samples, and 16 PFAS were detected in settled dust samples. Worker exposures in the textile manufacturing plant via inhalation were estimated using PFAS concentrations detected in air, airborne particles, and dust samples. PFOA (ionic), PFDA (ionic), 8:2 FTOH (neutral), and 10:2 FTOH (neutral) were the dominant PFAS detected in air and airborne particle samples, while PFOA, PFDA, and PFNA (ionic) were the dominant PFAS detected in settled dust. Results indicated that inhalation exposures to neutral PFAS were three orders of magnitude higher than to ionic PFAS. Worker exposures (in China) to FTOH in air were estimated to be up to five orders of magnitude higher than background exposure of the general population in Western countries.

Results from Heydebreck et al. (2016) also indicated that estimated exposures to PFAS via dust ingestion were much lower than estimated exposures via air inhalation, with air inhalation exposures estimated to be orders of magnitude higher primarily due to inhalation of neutral PFAS.

Christensen and Calkins (2023) reported textile worker blood concentrations of PFOA, PFOS, and PFNA in comparison to other occupational workers. Table 1a of Christensen and Calkins (2023) presented the median serum PFAS levels in textile workers and indicated median serum levels ranging from 1 to 10 ng/mL for PFOA, PFOS, and PFNA. Table 1a of Christensen and Calkins (2023) also provided a comparison of PFOA, PFOS, and PFNA levels in blood by industry, indicating that textile workers had PFOA and PFOS levels measured in blood that were lower than fluorochemical workers, ski wax technicians, and firefighters, and PFNA levels measured in blood that were lower than ski wax technicians.

1.4.6.5 Summary

Most early research (1980–2010) on PFAS exposure in occupational settings focused on fluorochemical workers. After 2010, additional occupations were studied, but most were related to firefighters and ski wax technicians. However, some post-2010 studies evaluated occupational settings, including textile mill workers, metal plating workers, clothing retail workers, office workers, and barbers (Christensen and Calkins 2023).

There are inherent uncertainties in making direct comparisons between occupational settings and drawing conclusions about potential exposure. Some sources of uncertainty may include the specific PFAS analyzed (which vary between studies), the lack of standardized analytical methods, and differences in QA/QC practices incorporated into the study. The types of environmental matrixes sampled (for example, surfaces, dusts, particulate fraction in air, aerosol fraction in air, volatile fraction in air) also vary between studies. In addition, the location where air samples were collected (personal monitoring versus area monitoring) varies. Other factors that contribute to uncertainties in comparisons include the sampling time/duration, the number of samples collected (number of observations), and the time of sampling in relation to the time of exposure. A significant source of uncertainty is introduced when attempting to correlate environmental matrix data (for example, air data) to blood serum data and make comparisons between exposure levels.

1.4.7 Evaluating Risk to Livestock from PFAS Exposure

1.4.7.1 Introduction

The subject of PFAS contamination in agricultural settings has received considerable attention over the past decade; for example, USEPA recently released its draft document "Sewage Sludge Risk Assessment for Perfluorooctanoic Acid (PFOA) and Perfluorooctane Sulfonic Acid (PFOS)" (USEPA 2025). The US Department of Agriculture's Agricultural Research Service (USDA ARS) recently developed a research roadmap for PFAS in U.S. agriculture to address challenges and identify solutions for PFAS in the agricultural industry (USDA ARS 2024). AFFF releases, either directly or indirectly, have contaminated soil, groundwater, and surface water bodies, and atmospheric deposition from facility emissions can have long-range impacts to land and water across broad areas (see **Section 5** and **Section 6**). Biosolids have been used for decades as a low-cost fertilizer for adding nutrients and organic matter to farmland, including use on food crops, pasturage, forested land, and reclamation sites (Marchuk et al. 2023), often resulting in PFAS contamination of farmland. For this section the term "biosolids" will be used to refer to treated sewage sludge (see **Section 1.7**). The biosolids may be generated from residential sources or from utilities that receive a mixture of residential and commercial and industrial wastewater inputs (see **Section 1.7** for discussion of PFAS sources, migration pathways, and bioaccumulation for biosolids).

Certain PFAS have been shown to accumulate in pasturage and crops grown on contaminated farmland, resulting in accumulation of PFAS in livestock that graze or consume feedstock from that land. For example, biosolids from a wastewater treatment plant contaminated with PFOS had been historically applied to fields at a farm in Michigan, resulting in PFOS in beef samples taken from this farm at levels warranting a human consumption advisory (MI DHHS 2023). Similarly, the State of Maine discovered PFAS contamination in cows' milk at a small dairy farm that had its well water, soil, and hay contaminated with PFAS, with PFOS being the primary PFAS detected in all media. The Maine Department of Environmental Protection has been investigating PFAS in other farmlands in the state where sludge and septage have been applied and have detected PFAS in water, soil, hay, and milk (ME DEP 2023). In 2022, Maine banned the land application and distribution of sludge and sludge-derived compost without first testing and screening for PFAS, and later amended legislation to encompass a larger ban of wastewater biosolids for use as soil amendments or fertilizers (Maine Legislature 2022).

An abundance of information indicates that certain PFAS readily bioaccumulate in animals, with most data limited to PFAAs (for example, Houde et al. 2011; Giesy and Kannan 2001). Many studies have focused on understanding the direct effects of PFAAs on plants, laboratory animals, some aquatic organisms, and wildlife, as well as on evaluating potential health risks associated with PFAS exposure to humans through diet (see **Section 1.7.3**). Studies have shown that some PFAS accumulate in chickens, eggs, and other protein sources at levels that, in some instances, could potentially be significant with respect to human exposure and health risk (for example, Arcadis 2024; USEPA, 2025; also see **Section 9.1.2** and **Section 1.7**). To date, however, there has been little focus on the direct toxic effects of PFAS on livestock. Note that the term "livestock" is herein defined to include cattle, sheep, goats, and other ungulates, and, for convenience, poultry, rabbits, and other terrestrial animals typically farmed for human consumption.

This section presents an overview of the available scientific information on PFAS exposure and health effects in livestock. This topic discusses the exposure routes through which livestock may be exposed to PFAS in agricultural environments, summarizes available information on PFAS bioaccumulation in various livestock species, describes potential health effects to livestock associated with PFAS exposures, discusses methodologies of evaluating the risk of harm to livestock, and concludes with a discussion of data gaps and uncertainties associated with the current state of toxicology and risk characterization of these receptors.

1.4.7.2 Exposure Pathways

Relevant exposure pathways for livestock may include direct soil and water contamination from spills, atmospheric deposition, or land application of biosolids. PFAS may also be transported through the environment via runoff of PFAS in soils into nearby surface water bodies, leaching of PFAS into underlying groundwater (and subsequent migration in groundwater), generation of dust that can become airborne, and volatilization of certain volatile PFAS. PFAS can also accumulate in pasture vegetation and crops used for feedstock. See **Section 1.7** for more information and **Figure 1-28** for a conceptual site model of PFAS transport and migration pathways.

Based on these transport mechanisms, livestock could be exposed to PFAS through contact with contaminated soils, dust, surface water, or groundwater that is used for pasturing, grazing, and watering. Livestock may be exposed by consuming plants grown as forage and feedstock. Livestock exposure to PFAS is not only limited to exposures incurred on a farm. Off-farm sources, such as PFAS-contaminated commercial feed and bedding materials may also be important sources of PFAS exposure.

The primary exposure pathways for livestock to be exposed to PFAS include diet, drinking water ingestion, and incidental ingestion of soil. As discussed below, while absorption of PFAS through the skin and inhalation of PFAS (either through dust entrainment or volatilization) may also be viable pathways, it is expected that exposure via these routes is less significant than exposure via ingestion, based on currently available information. PFAS can also be transferred from mother to offspring during fetal development and nursing. These exposure pathways are discussed in more detail below, although the discussion does not include quantitative estimates of exposure, which can be found elsewhere in the scientific literature (for example, USEPA 2025). **Figure 1-25** illustrates the main exposure pathways for livestock, as discussed in the following sections.

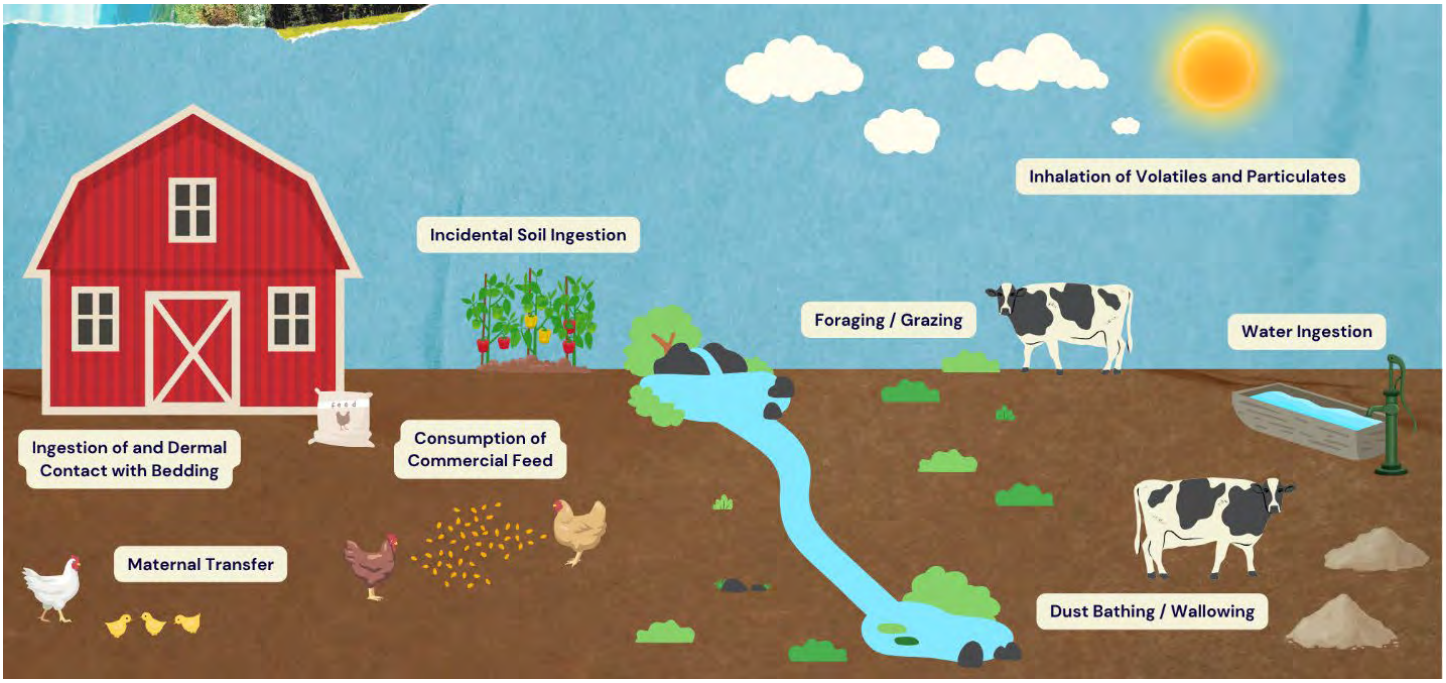

Figure 1-25. Conceptual site model for main exposure pathways for livestock.

1.4.7.2.1 Drinking Water Ingestion

All livestock consume water. Dairy cows can consume up to 50 gallons of water per day while lactating, and up to 80% of their daily water intake can come from their drinking water supplies, with the remainder

from moisture in food items (Becker 2024). Groundwater or surface water contaminated by PFAS sources can thus be a major source of PFAS exposure to livestock.

Drew, Hagen, and Champness (2021) described a case study where beef cattle and sheep were exposed to PFAS in stock water over several years. The stock water was obtained from an impoundment at a farm that had been contaminated from a nearby AFFF release and had PFOS initially detected at concentrations up to 6,690 nanograms per liter (ng/L). The study authors collected stock water, soil, and blood serum samples over multiple sampling rounds spanning several years. PFOS and other PFAS (primarily 6:2 FTS, PFHxA, PFPeA, PFHxS, perfluoroheptanoic acid (PFHpA), PFBS, and PFBA) were consistently detected in stock water samples. In soil, PFOS, PFHxS, PFNA, PFPeA, PFHxA, and PFHpA were detected at "very low" concentrations; the authors estimated PFAS intake (for cattle) from soil to represent only 1% of the calculated PFAS intake from water. No PFAS were detected in pasture grass samples. However, PFOS and PFHxS were detected in serum from both sheep and cattle; PFOS concentrations ranged up to 1,944 nanograms per milliliter (ng/mL) and 248 ng/mL for cattle and sheep, respectively, whereas PFHxS was detected at levels up to 840 ng/mL and 170 ng/mL, respectively. PFAS serum levels decreased concomitantly with decreases in stock water PFAS levels over time.

Wilson et al. (2021) conducted a study where laying hens were exposed to drinking water containing PFOS, PFOA, PFHxS, and PFHxA over a 61-day period, at concentrations up to 300,000 ng/L. PFOS and PFHxS were detected in eggs at the overall highest (and similar) concentrations, followed by PFOA and PFHxA. The study determined that >99.7% of total PFAS accumulated in the yolk relative to the albumen. Egg residues remained relatively stable for 20–30 days postexposure. The authors found a strong, positive linear correlation between PFOS, PFHxS, and PFOA levels in drinking water and eggs; this association was observed for PFHxA only at the highest administered dose. From this study, the authors calculated average half-lives of 3.5 days, 7 days, and 5.4 days for PFOS, PFHxS, and PFOA in eggs, respectively, and 2 days for PFHxA (only at the highest administered dose).

1.4.7.2.2 Food Ingestion

Livestock may ingest PFAS through grazing on pasture or through silage and other feedstock. The uptake of PFAS into plants has been well documented (for example, Adu, Ma, and Sharma 2023; Wang et al. 2020) (see **Section 1.7**, **Section 5.6** and **Section 6.5.1**). Hay, silage, and other feed crops grown on contaminated agricultural land can accumulate PFAS, potentially resulting in exposure for livestock that rely on those food items.

Omnivorous free-range poultry such as chickens and turkeys may also ingest PFAS by consuming insects, worms, and other small animals upon which they prey, where those prey items accumulate PFAS from their environment. PFAS (primarily PFOS followed by PFOA) levels in eggs from free-range chickens in a Dutch study were attributed to PFAS in earthworms, even though PFAS soil concentrations were relatively low and did not correlate with the concentrations found in chicken eggs; PFOS and other long-chain PFAS were present in soil at concentrations considered representative of background levels (Arcadis 2024).

Animal byproduct feeds (for example, animal fats, fish oils, fish meal, hydrolyzed proteins, collagens, milk, eggs) may also be a PFAS source because long-chain PFAS have been found to bioconcentrate in animal products and particularly in those that are fish-based. For example, Choi et al. (2023) detected PFAS in multiple types of animal feed used for laboratory animals, finding that plant-based feeds contained mainly short-chain PFCAs and feeds that contained animal ingredients (such as insects, fish, and shrimp) contained longer chain PFSAs, with total PFAS levels as high as 215.6 micrograms per kilogram (µg/kg) (dry weight). Fishmeal is often fed to swine, poultry, cattle, and sheep for its high protein content, and this product could be an important source of PFAS to livestock's diet even in uncontaminated settings. In a study by Granby et al. (2024), nine PFAAs were detected in eggs from organic farms in Denmark (primarily PFOS), whereas eggs from larger commercial farms had either low or no PFAS detected. The

elevated PFAS concentrations in the organic eggs were believed to be related to the fishmeal used in feedstock. PFAS levels in eggs decreased following elimination of fishmeal from the diet.

1.4.7.2.3 Soil Ingestion

Soil ingestion by livestock can constitute a considerable part of the livestock diet (Fries, Marrow, and Snow 1982; Healy, 1968; Beyer et al. 1994). Soil may be ingested either indirectly via foraging/grazing or preening, or intentionally via geophagy for minerals, and chickens and other poultry may ingest soil by obtaining grit to aid digestion. However, few experimental data are available to accurately quantify livestock soil ingestion rates, which are also dependent on the density of livestock and the amount of bare soil within a foraging area. For example, pastured dairy cows may consume soil at an average of 4%–8% of total dry matter (that is, food and soil) intake, although intake can vary considerably depending on plant availability and growing season, with soil representing up to 14% of the dry matter intake in seasons with poor plant growth; and similar soil ingestion patterns exist for beef cattle and sheep (Fries, Marrow, and Snow 1982; Healy 1968). Beyer et al. (1994) estimated that soil composed approximately 9% of a wild turkey's diet, and similar amounts may occur for free-range domestic turkeys. Jurjanz et al. (2015) found that the soil percentage in the diet of free-range hens (allowed to forage but also provided with chicken feed) was approximately 4% or less of total dry matter, and the percentage varied with the age of the chicken and whether the yard was tree- or grass-covered. For free-range poultry that have regular access to soil in which they can scratch, forage, and bathe, soil intake may be a significant source of environmental contaminants. As discussed earlier, earthworms may contain contaminated soil and accumulate PFAS. Additionally, livestock may consume plants may have soil deposited on leaves and stems.

1.4.7.2.4 Dermal Contact

Dermal exposure is typically considered a less-significant exposure pathway for wildlife relative to soil and food/water ingestion (for example, Sample and Suter, 1994). However, many livestock species frequently engage in dust bathing and wallowing behaviors, suggesting that PFAS in soil or water could be deposited on the skin and then potentially absorbed. Additionally, animal bedding generated from recycled paper, wood materials, and crop byproducts could potentially contain PFAS. Fernandes et al. (2023) detected PFAS in various bedding materials, with median total PFAS (sum of PFOS, PFOA, PFNA, and PFHxS) concentrations ranging from 6 µg/kg wet weight (ww) in unused wood shavings (control material) to 16 µg/kg ww in bedding made with dried paper sludge. The authors also found that these four PFAS accumulated in muscle, skin, and liver, as well as eggs from hens raised on bedding material that contained PFAS. Livestock, particularly poultry, may also inadvertently ingest bedding material and inhale dust while foraging.

Dermal absorption studies in laboratory rodents have shown that some PFAS can be absorbed through the skin, particularly for personal care products (see **Section 1.4.3** and **Section 17.2.3**). However, livestock studies on the absorption of PFAS through the skin because of contact with soil or water are not yet available.

1.4.7.2.5 Inhalation

PFAS can be transported through the air in volatile form or entrained on soil or dust particles and subsequently inhaled by livestock. Poultry can generate a substantial amount of dust through litter, feces, dander, and feathers while foraging and preening. As with the dermal route, little information is available for livestock on inhalation exposure of PFAS. Conceptually, livestock at farms located closer to industrial emissions may have higher exposure potential via inhalation of aerosols and particulates, whereas livestock kept largely indoors (without the benefit of outdoor dilution) may potentially have higher exposure potential to dust inhalation from soil and bedding material. However, the implications of this potential exposure pathway with regard to livestock health are currently unclear.

1.4.7.2.6 Maternal Transfer

Studies show that, in mammals, PFAS can cross the placenta and be transferred to the developing fetus (for example, Guruge et al. 2008; **Gronnestad et al. 2017**; **Houde et al. 2006**; see **Section 7.1.2**). PFAS also can be transferred in milk, which has been shown to be a major excretion route, as it is rich in proteins (Kowalcyzk et al., 2013; Milolajczyk et al. 2023). This transfer has been demonstrated by studies in Michigan, Maine, New Mexico, and other states showing detectable concentrations of PFAS in dairy products (in addition to meat and eggs) resulting from exposure to PFAS in biosolids/residuals on agricultural lands (ME DEP 2023). Thus, both fetal and nursing mammalian livestock can be exposed to PFAS via both transplacental and lactational transfer pathways up through weaning. Conversely, increased milk yield can result in overall decreased PFAS levels for the lactating animal (van Asselt et al. 2013). Also, hens may transfer PFAS to their eggs following a hen's exposure to PFAS-contaminated soil, food, or water (for example, Wilson et al. 2021).

1.4.7.3 Bioaccumulation in Livestock

Oral absorption has been studied for several PFAS, and it has been demonstrated that PFAS are readily absorbed through the gastrointestinal tract and that protein-rich tissues (for example, blood serum, liver, kidneys) are the primary PFAS accumulation sites (see **Section 17.2.3**). Although accumulation of PFAS can be highly variable depending on the organism, route of ingestion, and types and concentrations of PFAS to which the organism is exposed, *in general*, the long-chain PFAS (such as PFOS) tend to accumulate at a greater rate in animals relative to the short-chain PFAS (Houde et al. 2011). Functional group (for example, sulfonic vs. carboxylic acid) also appears to have a larger role in bioaccumulation potential relative to chain length, consistent with general findings from a wide range of tissue residue studies in wildlife (for example, Rupp et al. 2023; Draghi et al. 2024) and laboratory animals, as discussed in **Section 17.2.3**. Perfluoroalkyl sulfonic acids tend to accumulate at a higher rate relative to perfluoroalkyl carboxylic acids due to the higher binding capacity of sulfonates within the body (for example, Ng and Hungerbühler 2014).

With respect to livestock, much of the available information on PFAS accumulation is associated with food studies of animal products (milk and other dairy products, meat, eggs) intended for human consumption. Consequently, while there is ample information on PFAS residuals in various types of livestock tissues, there is not always corresponding information on the animal's exposure to PFAS prior to processing. Given their utility for both meat and dairy products, there are currently more studies on bioaccumulation of PFAS in cattle relative to other livestock (Death et al. 2021).

Animal product studies that focused on human health risks from food exposure also highlight bioaccumulation potential in livestock. Guruge et al. (2008) analyzed PFOS and other PFAS in blood and liver samples from a variety of farm animals across multiple farms and regions of Japan and found that PFOS was detected at the highest concentrations and frequency relative to other PFAS. In general, chicken had the highest blood serum PFOS concentrations, followed in decreasing order by cattle, goat, horse, and pig. Liver PFOS concentrations were again highest in chicken, followed by pigs and cattle. However, no information on PFAS levels in farm soil, water, or fodder was provided in this study. Death et al. (2021) provided a review of bioaccumulation studies (both dosed and ambient studies) in cattle, sheep, poultry, and pigs (as well as wild game species). Collectively, the authors indicated similarities in PFAS tissue distribution among the different animals. PFOS was typically the most prevalent of the PFAS, and concentrations were generally highest in blood, liver, and kidney relative to muscle. Notable differences in PFAS concentrations were also observed among species, dose, and sex.

The disposition of PFAS in livestock mirrors the findings from studies of laboratory animals (see **Section 17.2.3**). For example, Kowalczyk et al. (2012) found that urinary excretion was the primary PFOA clearance route for dairy sheep exposed via corn silage with PFOA over a 21-day period, accounting for 51%–55% of clearance compared to 1%–2% for feces and less than 1% for milk. This same study found

that PFOA levels in plasma, liver, kidney, and muscle tissue were reduced to nondetectable levels after a PFAA-free feeding period of 21 days. The excretion of PFOS was less clear; the authors estimated that approximately 5% and 2% of PFOS was excreted in feces and milk, respectively. This study did not report PFOS concentrations in urine.

Numata et al. (2014) found that of the PFAS they studied (seven PFCAs and five PFSAs), most accumulated in the blood plasma (up to 51%) and the muscle and fat tissues, collectively (up to 49%), with relatively low accumulation observed in the liver (<7%) and kidney (<2%). The exception to these general findings was PFOS, which preferentially accumulated in liver (35%) relative to other tissues. The authors also indicated that in pigs, PFAAs had a higher affinity for plasma (relative to other tissues) than that observed for sheep and cattle.

Studies also demonstrate interspecies variability. In a study by Numata et al. (2014), PFAAs (mainly PFOS, PFHxS, and PFBS) were found to have longer elimination half-life in pigs than has been observed in other types of livestock. For example, PFOS had a serum half-life of 634 days in pigs versus 74 days in cattle (Drew, Hagen, and Champness 2021).

1.4.7.4 Toxicology

Toxicological effects data for PFAS remain under development, and data suitable for determining risk to livestock are lacking for the majority of individual PFAS and receptor groups. Overall, there are relatively few toxicity studies specifically on livestock species. Toxicological data from avian and mammalian studies that potentially may be applied to livestock are available only for a few relatively well-understood PFAS (for example, PFOS and PFOA). The following sections summarize toxicity data for birds and mammals that are representative of typical livestock species. A more comprehensive discussion of PFAS effects data is presented in **Section 7.2** and in review documents such as Ankley et al. (2021) and Johnson et al. (2021).

Birds

PFAS uptake and effects have been studied in various avian species, and these results may potentially be applied to evaluating risk in poultry based on the relevance of the toxicological endpoints (survival, growth, reproduction). See **Section 7.2.3.3** for a discussion of wild bird studies. However, many of these studies were egg injection studies, with fewer studies conducted on dietary intake, which is a more relevant route of exposure for livestock. Overall, toxicity studies in birds have demonstrated effects on developing bird embryos and hatchlings, endocrine pathways and neurodevelopment, with adult mortality typically occurring only at the highest dose levels (see **Section 7.2.3.3**).

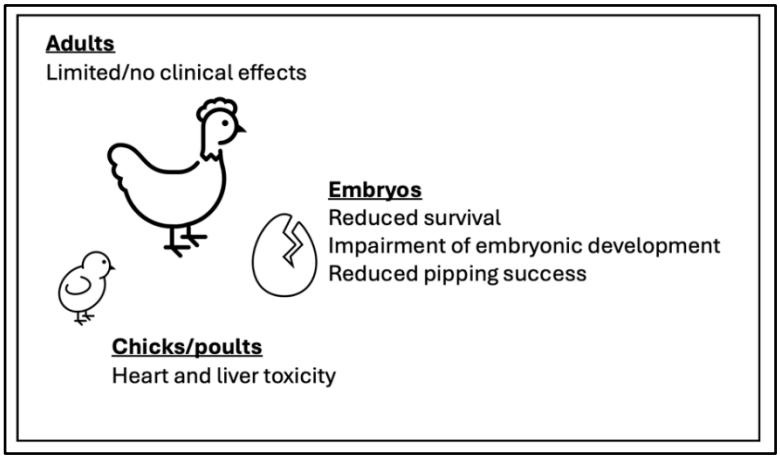

Figure 1-2. PFAS Effects noted in poultry studies.

Egg injection and embryonic studies on domestic chickens show that certain PFAS at high doses may result in effects on chick pipping success, embryo development and chick behavior, on the liver and heart, and on the endocrine system, especially thyroid hormone–responsive genes (**Figure 1-26**).

For example, Cassone et al. (2012) conducted an egg injection study of PFHxS and PFHxA in chicken embryos and demonstrated that PFHxS exposure resulted in a reduction in pipping success and embryonic development. The study also found that PFHxS exposure caused upregulation of hepatic and neuronal mRNA expression of thyroid hormone–responsive genes, and a reduction of free T4 concentrations in plasma. These effects were not observed in PFHxA-exposed eggs. Vongphachan et al. (2011) conducted an in vitro study on domestic chickens and herring gulls, and found that several PFAS (PFHxA, PFHpA, and PFNA) altered changes in mRNA expression of thyroid hormone–responsive genes, noting that PFAS with fewer than eight carbons (PFBS, PFHxA, PFHxS, and PFHpA) altered mRNA expression to the greatest extent compared to longer chain PFAS. Pinkas et al. (2010) found that in ovo exposure to PFOA and PFOS was associated with reduced survival and hatching, and elicited behavioral changes (reduced imprinting ability) in chicks after hatching. Ni et al. (2023) reported that in ovo exposure to PFOA resulted in cardiotoxicity and hepatotoxicity in hatchlings, and that cardiotoxicity persisted for several months following exposure.

Limited studies exist related to toxicological effects from dietary exposure of PFAS on domestic poultry (for example, chickens, turkeys), and those studies suggest limited or even no clinical significance of PFAS exposure via ingestion on posthatch birds. The Wilson et al. (2021) study described in **Section 1.7.3** (in which adult laying hens were administered PFAS in drinking water) noted no negative health outcomes (hen weight, egg production, or other observable adverse effects) at any of the administered PFAS doses. Yeung et al. (2009) exposed 1-day-old male chicks to PFOA by oral gavage at doses up to 1.0 mg/kg body weight with no dose-dependent statistically significant differences in body/organ weights. Yoo et al. (2009) similarly did not observe clinical effects (body weight, growth rate, histological changes, blood biochemistry) other than a reduction in cholesterol and phospholipids associated with PFOS in male leghorn chickens exposed to PFOS and PFOA via subcutaneous implants for 4 weeks.

Mammals

Although there are a growing number of studies on bioaccumulation of PFAS in ungulate livestock (for example, horses, cattle, pigs, sheep; see **Section 1.4.3**), of the few toxicological studies identified for this group of animals, most were biomarker studies, and none reported clinical effects. Death et al. (2021) described several short-term studies in cattle, sheep, and pigs. However, these studies did not evaluate direct adverse effects of PFAS exposure to livestock. Numata et al. (2014) conducted a study on a mixture of PFAAs in feed into edible tissues of 24 fattening pigs. The study focused on bioaccumulation and elimination, and although the study did not directly evaluate adverse effects on the pigs, the authors assessed the general health of the test subjects and did not report any observed adverse effects. Watanabe et al. (2010) investigated effects of PFAS and other contaminants in wild pigs. Although positive correlations were observed between other pollutants (PCBs, pesticides) and various blood, hepatic, and immunological endpoints, the investigators did not find any significant correlation between PFAS concentrations and these effects. Several in vitro studies on swine ovaries evaluated reproductive effects of PFOA or PFOS, showing inhibition of granulosa cell proliferation and steroidogenesis (Basini et al. 2023; Chaparro-Ortega et al. 2018). Rock et al. (2023) found significant associations between the levels of multiple PFAS in horse serum and biomarkers of liver and kidney function.

As mentioned, most laboratory toxicity studies for PFAS have been conducted in rodents. General effects from exposure to PFAS in laboratory animal studies have included reduced body weight gain, liver damage, developmental effects, immunotoxicity, and mortality (see **Section 7.1**). Although these studies have demonstrated the acute and chronic toxicological effects of PFAS in mammals (see **Section 7.1**), their utility in evaluating risks to mammalian livestock is unknown, given ungulates' differences in size, dietary requirements, uptake and elimination kinetics, gestational period length, and unique digestive system.

1.4.7.5 Risk Characterization

Although little work has been done on PFAS risk assessment of livestock, work has been conducted to evaluate effects from other types of contaminants. For example, Stickney et al. (2001) and API (2004) derived health-based concentrations of petroleum compounds in cattle's drinking water. The methods used to calculate health-based concentrations were similar to methods described by USEPA (1997) in the "Ecological Risk Assessment Guidance for Superfund" for evaluating risks to wildlife and included derivation of toxicological benchmarks and estimation of daily dose of chemicals from drinking water ingestion and soil ingestion.

The basic hazard quotient (HQ) equation is:

HQ=Exposure Dose/Toxicity Reference Value

Where the HQ is unitless, the exposure dose is in milligrams of constituent per kilogram body weight per day (mg/kg-d) and the toxicity reference value (TRV) is in units of mg/kg-d (USEPA, 1993).

The exposure dose represents the cumulative intake of a contaminant through multiple exposure pathways. For livestock, this equation might be represented as follows:

Exposure dose = Food intake + Water intake + Soil intake

The ecological risk assessment approach for wildlife (see **Section 9.2**) includes a standard hazard quotient (HQ), which can also be used to assess the risk from PFAS intake for various livestock species (see sidebar.) The USEPA (1993) Wildlife Exposure Factors Handbook provides equations to model intake of contaminants in wildlife (see sidebar). These same equations may be applied to livestock when used in conjunction with receptor-specific life history and physiological attributes such as grazing area, dietary composition, food and water ingestion rates, and body weights. The USEPA exposure model is based heavily on dietary concentrations, which for livestock could include measured PFAS concentrations in livestock food items or be based on bioaccumulation or transfer factors (for example, soil to forage plant; see **Section 1.7**). Transfer factors representing the ratio of the concentration of PFAS in livestock to the concentration of PFAS in abiotic media (for example, bioconcentration factors/bioaccumulation factors/soil-plant-livestock transfer factors) can be used to estimate animal-specific tissue concentrations. For example, Drew, Hagen, and Champness (2021) derived transfer factors from water to cattle serum, and Wilson et al. (2021) developed transfer factors from water to hens.

The modeled intake dose is compared to a toxicity reference value (TRV) to calculate an HQ. HQs equal to or greater than 1 may suggest a potential health risk to the livestock. Similar to the methodology used by USEPA (2005) in developing Ecological Soil Screening Levels, TRVs for evaluating risks to livestock could be developed based on the existing body of avian and mammalian toxicity data described previously, with the caveat that livestock-specific toxicological studies on PFAS are not available for most species. Adjustment factors (such as body scaling or use of uncertainty factors) could potentially be required. Dennis et al. (2021), Newsted et al. (2005), and others have already developed avian TRVs for use in risk assessment. Others have derived PFAS risk-based screening levels for avian and mammalian wildlife species (Divine et al. 2020; Grippo et al. 2024). To date, few studies (Newsted et al. 2005; Dennis et al. 2021) have developed tissue-based (versus dose-based) TRVs that could be compared with estimated or measured livestock tissue concentrations.

1.4.7.6 Uncertainties and Data Gaps

Many of the uncertainties related to characterization of risk to livestock from PFAS exposure are the same as those identified for human health and ecological risk (see **Section 7** and **Section 9**). These uncertainties center around the general lack of information on the numerous PFAS to which livestock may be exposed (and the mixtures of these PFAS), and variability among species in both PFAS accumulation and sensitivity. Existing livestock bioaccumulation studies have focused on a relatively limited number of PFAS analytes, whereas thousands of individual PFAS exist and most of these have not been routinely or ever analyzed in the environment.

In terms of dietary intake, uptake of PFAS in plants depends on several factors (type of plant, type of PFAS, soil characteristics). Likewise, uptake into animals can vary considerably depending on the species, age, sex, gestation/lactation status, feed supply, and other behavioral and physiological factors. The contribution of both direct and indirect PFAS exposure pathways can also vary according to environmental contamination and feed and bedding sources, as discussed previously. Another key uncertainty in the exposure assessment is the proportion of livestock diet that consists of grazed/foraged dietary items versus supplemental commercial feed and drinking water. For example, even if site-specific risk assessments incorporate measured concentrations of diet, feed, and water, the relative intake rates of each are expected to vary substantially, depending on livestock management practices.

Existing studies indicate that toxic effects to livestock from PFAS exposures have generally not been observed unless exposure occurs at levels higher than those generally expected from land application of biosolids (Death et al. 2021) or resulting from background sources such as precipitation. However, there is a paucity of toxicological studies focused on livestock species. Most studies have centered on poultry, and even within those studies, many focused on in ovo exposures. It is unclear how the results from egg or subcutaneous injection studies relate to real-life exposures from feed and the environment.

Some livestock species are also entirely unrepresented in the existing literature. For example, camels are replacing cattle in areas subject to extended drought in areas such as Kenya (Hochet-Bodin 2024), but there is no PFAS information on uptake or toxicity of PFAS in camelids.

Given these uncertainties, although there are standard risk assessment tools available to use for evaluating livestock risk, it is unclear if the risk to livestock from PFAS contamination in the agricultural setting can be meaningfully quantified at this time (Sharp et al. 2021). Studies show that livestock exposures to PFAS are routinely occurring, and additional toxicological studies specific to livestock species are needed to fill in data gaps and provide a more accurate representation of health risk to these species. Various agencies are recognizing the need to address these data gaps; for example, the University of Maine recently expanded their partnership with the USDA ARS to explore the effects of PFAS on US agriculture (**USDA** 2024).

1.4.8 Reptiles Toxicity Data

Section 7.2 includes information about available toxicity information for invertebrates, vertebrates, and mammals. **Section 7.2.3.2** includes information primarily for amphibians, and as noted, previously no studies for reptiles were found in the literature. This section provides a brief review of the currently available research for reptiles.

Although PFAS exhibit high environmental persistence and growing ecological concern, relatively few toxicological studies have been conducted on reptiles exposed to PFAS, and toxicity to reptiles remains a significant data gap for ecological risk assessment. The following is a summary of currently available toxicological data for reptiles, noting that additional data regarding bioaccumulation of PFAS and effects on non-apical endpoints (for example, metabolic responses) are also available, but not covered herein.

Bangma et al. (2019) conducted a study in diamondback terrapins (*Malaclemys terrapin*). A total of 75 terrapin plasma samples were collected from five creeks in Charleston County, South Carolina, and investigated for 15 legacy PFAS. Three PFAS (PFOS, PFNA, and PFHxS) were observed to have negative correlations between plasma and body mass (Bangma et al. 2019).

Furst et al. (2019) presented results from a pseudo-gavage study of PFOS and PFHxS exposure on the brown anole (*Anolis sagrei*). The study indicated that 90-day PFOS exposure to adult males at doses up to 1.35 mg/kg/day (the highest exposure level) elicited no strong effects on either body or organ mass, although significant effects on growth of young lizards after 35 days was observed at a dose rate of 2 mg

PFOS/kg/day. Exposure to PFHxS for 63 days was not found to have a significant effect on body or organ size of either males or females, but did result in decreased egg viability in females.

Salice et al. (2025) conducted two studies on brown anole to develop toxicity testing protocols for the species and to generate toxicity data to support ecological risk assessment. During the two studies, subadult males and then mature males were dosed with PFOS via pseudo-gavage with maximum doses in the range of 2 mg/kg/day. Subadults were exposed for 35 days and adult males were exposed for 90 days. Although no significant mortality was observed, PFOS significantly reduced subadult male size and growth rate at a dose rate of 2.98 mg/kg/day, with a corresponding no-effect level of 0.20 mg/kg/day. There were no significant effects on size metrics of mature male anoles from the 90-day study, although several metrics showed dose-dependent decreases (Salice et al. 2025).

Zhang et al. (2020) conducted a study on Mongolia racerunner lizards (*Eremia argus*). Organisms were exposed to PFOA in soil at 0.05 mg/kg, 0.5 mg/kg, and 5 mg/kg for 60 days, and were evaluated for various physiological and biological effects. By day 60, a significant reduction in growth was observed in males at all three test levels, and in percent survival in the highest test level; these reductions were not observed, however, in females (Zhang et al. 2020). Australia and New Zealand used the Zhang et al. (2020) study as the basis for deriving their interim Ecological Guideline Value for PFOA in soil of 0.005 mg/kg for reptiles (HEPA 2025).

Lettoof et al. (2023) conducted a study on wild-caught tiger snakes (*Notechis scutatus occidentalis*) in which liver tissues were analyzed for 28 PFAS. The investigators found that a higher liver concentration of PFAS (largely consisting of PFOS) was associated with a lower body condition, although noted that results could have been explained in part by other contaminants such as metals. The study also found that PFAS exposure resulted in the significant enrichment of 11 different groups of metabolites, suggesting perturbation of metabolic pathways. The authors postulated that the observed lower body condition may be a result of PFAS-induced perturbation of energy production pathways (Lettoof et al. 2023).

1.5 Priority Topics for Sampling and Analysis

Section Number	Topic
1.5.1	**Leaching Methods**
1.5.2	**Fish Sampling and Laboratory Homogenization**
1.5.3	**Ultrashort-chain PFAS Analysis**
1.5.4	**Consumer Product Testing**
1.5.5	**ISM for PFAS Sampling**
1.5.6	**Concrete and Asphalt Sampling and Analysis**
1.5.7	**Field Screening Tools**

Information in these Priority Topics was prepared to supplement the information published in **Section 11** and the **PFAS Analytical Methods** Excel file. Information about Strategic Environmental Research and Development Program (SERDP) and Environmental Security Technology Certification Program (ESTCP) projects for Sampling and Analysis can be found at **https://serdp-estcp.mil/**.

1.5.1 Leaching Methods

Approaches, methods, and tools available to evaluate PFAS leachability were previously discussed in **Section 10.4.1**. Information presented here provides an update on the current state of methods and studies since the last update of the Guidance Document in 2023.

The US Environmental Protection Agency (USEPA) has published two hazardous waste methods (SW-846) relating to leaching. One, SW-846 Method 1311 (USEPA 1992), the Toxicity Characteristic Leaching Procedure (TCLP), simulates landfill leachate conditions to evaluate the mobility of organic and inorganic analytes present in liquid, solid, and multiphase wastes. The other, SW-846 Method 1312 (USEPA 1994), the Synthetic Precipitation Leaching Procedure (SPLP), simulates weathering in situ by acid rain to model the leaching of organic and inorganic analytes present in liquids, solids, and multiphase wastes under normal weather conditions.

In addition to these two methods, the Leaching Environmental Assessment Framework (LEAF) is the result of long-standing collaboration between experts and scientists in association with the Vanderbilt University School of Engineering, the Energy Centre of the Netherlands, Arcadis-US Inc., and the USEPA Offices of Research and Development and Solid Waste and Emergency Response. In 2011, USEPA released a report providing detailed background information for the LEAF Methods (USEPA 2011). The LEAF documentation provides for standardizations of multiple leach testing methods and pairs premade laboratory data collection templates with both laboratory data management and data analysis tools.

LEAF testing is currently represented by four defined methods:

- Method 1313—Liquid-Solid Partitioning as a Function of Extract pH Using a Parallel Batch Extraction Procedure (USEPA 2017)
- Method 1314—Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio for Constituents in Solid Materials Using an Up-Flow Percolation Column Procedure (USEPA 2017)
- Method 1315—Mass Transfer Rates of Constituents in Monolithic or Compacted Granular Materials Using a Semi-Dynamic Tank Leaching Procedure (USEPA 2017)
- Method 1316—Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using a Parallel Batch Extraction Procedure (USEPA 2017)

These four leaching test procedures follow a tiered approach presented by Kosson et al. (2002) (Vanderbilt University 2025) and can provide insights into the rate and extent of leaching processes through evaluation of pH, liquid-to-solid ratio, and leaching time representing the tested conditions.

Use of such innovative testing, data management, modeling, and presentation tools is of immense benefit to environmental practitioners related to data evaluation and sharing and reflects the increasing availability of powerful data processing technologies.

The framework is supported by the following downloadable tools (Vanderbilt University 2025)

- Preliminary versions of USEPA leaching test methods
- Data templates for collecting, archiving, and uploading laboratory leaching test data
- Latest “for distribution” version of LeachXS Lite
- Various publications (or links to sources) that support and demonstrate LEAF for several materials

The downloads are free but require application submission to obtain a free user license. The USEPA has developed a LEAF How-To Guide and currently maintains a website regarding LEAF Methods and Guidance (USEPA 2019). The relevant LEAF supporting downloads are only available through Vanderbilt University. These links are provided above.

Both the LEAF methods and guidance and the two SW-846 methods have not, however, been validated specifically for use in evaluating per- and polyfluoroalkyl substances (PFAS) mobility (Strock 2024). SERDP has funded one project (ER23-3761) focused on the optimization of LEAF for the evaluation of PFAS mobility. Vanderbilt University and the USEPA are evaluating these optimized protocols through a multilaboratory validation study. Release of these optimized protocols is pending the outcome of this validation effort. Release of these optimized protocols is pending the outcome of this validation effort.

Outside of the US, entities have published their own leaching procedures. For example, Australia published the Australian Standard Leaching Procedures tests, AS4439.2:2019: *Wastes, sediments, and contaminated soils. Part 2: Preparation of leachates—Zero headspace procedure* and AS4439.3:2019: *Wastes, sediments, and contaminated soils, Part 3: Preparation of leachates—Bottle leaching procedure*. However, these tests have also not been optimized for the evaluation of PFAS leachability. See Appendix H of HEPA (Heads of EPA Australia and New Zealand) (2025) for more information. Kleja et al. (2025) evaluated the ISO leaching tests and Kalbe, Pieochotta, and Bandow (2024) evaluated European leaching tests for use on soils containing PFAS.

New Jersey Department of Environmental Protection (NJDEP) has a developed guidance and a spreadsheet calculator for site-specific soil-to-groundwater screening levels and soil-water partition coefficients (Kd) for specific PFAS using Synthetic Precipitation Leaching Procedure (SPLP) results. Within the "Soil and Soil Leachate Migration to Ground Water Exposure Pathway Calculator," SPLP analytical results are adjusted to field conditions through NJDEP's calculator and are intended to be compared to existing soil leachate remediation standards (NJDEP 2025).

A number of publications have evaluated the application of existing leaching methods to PFAS (for example, Navarro et al. 2024; Kalbe et al. 2024; Rayner et al. 2022), all of which support the conclusion that optimization for the evaluation of PFAS is needed. Others evaluated PFAS leaching in situ using high-resolution characterization techniques (for example, Bigler et al. 2024). PFAS sorption and desorption processes with a focus on understanding leaching is another active research area. For example, Bierbaum et al. (2023) examined rate-limited leaching in column and lysimeter experiments, the relevance of sorption to the air-water interface, and colloid-facilitated transport. USEPA (2025) provides information about using SPLP with modifications for PFAS.

1.5.2 Fish Sampling and Laboratory Homogenization

The goal of this section is to summarize current knowledge on fish sample collection and preparation. The sample collection discussion presents information about containers, shipping, and general best practices, as available in the literature. Seasonal variability is discussed. Avoiding cross contamination with processing steps such as homogenization is discussed, including parameters to be considered (for example, whole body fish, fillets, skin on/skin off). Sampling procedures for fish are discussed in **Section 11.1.7.11**. Information presented here provides an update on the current state of methods and studies since the last update of the Guidance Document in 2023.

1.5.2.1 Sampling Design Considerations

Multiple studies in the literature have measured PFAS in fish, but few standardized approaches inform field collection and laboratory preparation of fish. Most recently, USEPA released Method 1633A, a standardized method including general guidance for sample collection, preparation, and analysis of 40 PFAS in biological tissues (USEPA 2024). FDA C-010.03 provides laboratory preparation and analysis guidance for 30 analytes in food matrixes, including fish and shellfish, with validation in salmon and clams (USFDA 2024). USDA CLG-PFAS 2.04 provides laboratory preparation and analysis of 16 PFAS in catfish muscle, as well as some mammalian and poultry tissues (USDA 2023) .

Beyond USEPA Method 1633A, more detailed protocols for fish sampling activities remain limited. However, some existing guidance designed for other contaminants may provide general guidance for fish sampling efforts for PFAS (USEPA2000). Additionally, general techniques and best practices that delineate sampling in other matrixes may be applicable to fish and other biota. For example, field and laboratory activities should avoid PFAS-containing equipment and supplies to minimize the risk of cross-contamination, as recommended for collection of water, sediment, and other ecological matrixes (MI DEQ 2019; USEPA 2024).

PFAS levels in fish vary based on organism phenology or seasonal environmental fluctuations impacting ambient PFAS levels (Petali et al. 2024; Taylor 2019). For example, fish have been demonstrated to transfer PFAS to their eggs depurate PFAS during egg-laying (Conard et al. 2022). Seasonal migration, dietary changes, or behavioral changes can also impact organismal interactions with the environment and resulting PFAS accumulation (Petali et al. 2024). Seasonal hydrodynamics may cause changes to ambient PFAS levels in water and may impact observed body burdens in resident fish, though some data suggest migratory patterns may primarily drive PFAS body burdens as compared to ambient water levels (Pignotti et al. 2017; Tokranov et al. 2021; Taylor 2020). Stocked fish may rapidly accumulate PFAS in situ depending on ambient water concentrations, therefore stocking date should be considered if sampling stocked fish (Danielson 2023). Additionally, operational and safety constraints may limit site accessibility to certain seasons or periods. The timing of collection activities should consider relevant seasonality or periodicity impacting target species; those studies seeking interannual comparisons should collect fish within a similar time frame each year.

Varied diet, habitat, and migratory choices result in inherent variability in PFAS concentrations found in fish, with implications for sample size goals (Petali et al. 2024). Guidance offered by a state fish collection standard operating procedure suggests at least ten fish should be collected, including both sexes (MI DEQ 2019). A modeling effort examining the impact of sample size on derived mean and median concentrations suggested collection of at least 20 individuals per location, with a suggested sample size of 30–50 individuals, to derive robust concentration medians for use in human health risk assessment (Taylor 2019). In practice, budget constraints and laboratory bandwidth are also key factors dictating sample size.

The size of fish included in PFAS sampling may vary, as the relationship between fish length and PFAS body burden is unclear. This uncertainty has notable implications for study design. Some studies suggest PFAS levels correlate to animal size—for example, mass or length—while others find no such relationship or nuanced size–PFAS relationships in different species or habitats (Taylor 2019; Hedgespeth et al. 2023; Fair et al. 2019). In practice, a range of fish lengths may be sampled to achieve population summary data, while only fish of a specific size class, as an indicator of age class, may be targeted for derivation of more accurate bioaccumulation or biomagnification characteristics.

Given the unique factors influencing PFAS body burdens in fish, a work plan delineating study design, field sampling plans, and associated quality assurance measures should be constructed prior to initiating field efforts, specifically considering how sampling elements facilitate PFAS study goals. For example, if spatial comparison is an objective, wide-ranging, common species that occur across the region of interest should be targeted. If human health risk assessment is a project goal, fish species and sizes typically consumed by anglers should be sampled. If ecological risk assessment is the primary goal, fish species and sizes regularly consumed by birds, mammals, or other focal predatory species should be collected.

1.5.2.2 Sampling, Equipment, and Supplies

Multiple mechanisms exist to collect fish, including seine trawls, electrofishing, rod and line, or fish traps; shellfish may be collected by hand or bottom trawl. Each approach is inherently opportunistic, as sampling efforts are constrained to those individuals randomly inhabiting a given location and capable of

interacting with the collection gear. No data exist documenting the impact of collection mechanism on PFAS body burdens in fish, though some guidance suggests the risk of contamination during collection is minimal given the presence of PFAS within internal tissue reservoirs and the order of magnitude difference of biota concentrations (typically ppb) compared to water (typically ppt).

Sample container material recommendations depend on the size and number of fish or shellfish to be collected. USEPA Method 1633A recommends wrapping collected fish in aluminum foil or storing in polyethylene tubing, whereas MI DEQ (2019) guidance suggests rinsing fish with ambient water before storing individually in polyethylene bags. Literature studies used polyethylene bags, high-density polyethylene (HDPE) or polypropylene vessels, or glass vessels to store fish samples (Blazer et al. 2024; Fair et al. 2019; Soudani et al. 2024). USEPA Method 1633A recommends storing collected fish or fish tissues at or below 6°C from the time of collection until receipt by the processing laboratory for a maximum of 24 hours. If a longer transport time is necessary, 1633A recommends freezing the sample upon collection before storage and shipment on dry ice or otherwise chilling to maintain sample temperature below 6°C.

Once received by the laboratory, USEPA Method 1633A recommends sample storage in a manner protected from light at or below -20°C until prepared for laboratory activities. USEPA Method 1633A also recommends that sample storage should be no more than 90 days from collection to sample extraction. Preliminary data from a 2023 USEPA retrospective study of archived tissues suggest fish fillet tissue samples may be frozen for up to 5 years without significant impacts on PFAS measurements, but further study may be required to validate holding times for specific species and tissue types to be used for regulatory purposes (McCarty et al. 2024).

1.5.2.3 Sample Dissection, Homogenization, and Lyophilization

Materials that directly contact fish tissue during dissection and sample processing should be PFAS-free. Recommended decontamination approaches include rinsing equipment and consumables with water and available/appropriate solvents prior to use and between samples (MI DEQ 2019; USEPA 2024). Existing guidance suggests general dissection procedures used to obtain tissue samples for other contaminant monitoring efforts may be used to obtain fish tissue samples for PFAS analysis, accounting for PFAS-specific contamination risk (MI DEQ 2019; NY DEC 2023; USEPA 2000). Fish plasma, muscle fillets with and without skin, muscle plugs, liver, and internal organs have been used for PFAS measurements in addition to whole fish carcass (whole body) samples (Nilsen et al. 2024; Blazer et al. 2024; Levanduski et al. 2024; Miranda et al. 2023). Although skin-off fillets have been found to contain lower PFAS concentrations compared to skin-on fillets, the decision to retain skin should consider routine consumption trends and prior sampling practices to ensure data comparability to any archived samples (Figueroa-Munoz et al. 2025). Muscle plugs have been used for PFAS analysis, though no published information currently compares concentrations derived via plugs to whole muscle samples, as has been demonstrated for heavy metals (Miranda et al. 2023; Stahl et al. 2021). Additionally, no published information documents the impacts of homogenization on subsequent PFAS measurement in tissue, though a limited comparative effort suggests variable homogenization efficiency between different tools (Shaw et al. 2024). Lyophilization may be used during tissue preparation to address variable water content in different tissue matrixes and increase extraction efficacy of organic solvents. Literature suggests partial loss of some volatile compounds during lyophilization of tissue with good retention of long-chain PFAAs (Balgooyen et al. 2025; Carrizo et al. 2023). USEPA Method 1633A does not include lyophilization, and multiple datasets have derived PFAS measurements directly from wet tissue (Blazer et al. 2024; USEPA 2022).

1.5.2.4 Analysis

Analytical strategies validated for analysis of fish tissue are detailed by recently published methods such as USEPA Method1633A (USEPA 2024), FDA C-010.03 (USFDA 2024), and USDA CLG-PFAS 2.04 (USDA

2023) , as well as a substantial body of peer-reviewed literature (Valsecchi et al. 2013; Nakayama et al. 2019). These methods provide separation and detection conditions for specific anionic analytes in fish tissue and other complex matrixes. Regardless of applied method, the complexity of endogenous chemicals (for example, lipids, fatty acids, and proteins) inherently present in fish tissues varies by species and life stage, which may present unique analytical challenges. Some endogenous chemicals may interfere with analytical measurements of PFAS conducted using tandem mass spectrometry platforms. Variable preparation strategies, separation techniques, or high-resolution mass spectrometry (HRMS) can be leveraged to confirm or refute potential interferences (Bangma et al. 2024;, MI EGLE 2024). Endogenous molecules may also impact ionization efficiency; some peer-reviewed studies include the use of matrix-matched curves to better account for matrix effects during analysis and quantification (Carrizo et al. 2023; Malinsky et al. 2011). Continued efforts seek to refine analytical strategies for fish tissues and other complex matrixes, leveraging techniques such as HRMS and non-targeted analysis, ion mobility, total oxidizable precursor (TOP) assay, and extractable organofluorine analysis to expand analytical coverage of PFAS in fish tissues (Boatman et al. 2024; Pickard et al. 2022; Pickard et al. 2024). These methods have not been validated or standardized across the range of fish species and tissue types; therefore, data derived using these methods should be used with caution.

1.5.3 Ultrashort-chain PFAS Analysis

This section provides information regarding the analysis of ultrashort-chain PFAS (ultrashort PFAS), including the feasibility and challenges of using existing PFAS analytical methods. This topic supplements **Section 11.2**, which addresses analytical methods and techniques. For additional information about ultrashort PFAS, see **Section 1.1.3.1**. For additional examples and occurrences and health effects associated with ultrashort PFAS, see **Section 1.4.4**. In addition, see the updated **Table 4-1** for physical and chemical properties of some ultrashort PFAS.

1.5.3.1 Overview

The measurement of ultrashort PFAS was not seen to be as important as the measurement of short-chain and long-chain PFAS in the early days of PFAS testing. However, the implementation of "replacement" PFAS, the higher concentrations of ultrashort PFAS in the environment, and the presence of ultrashort PFAS almost everywhere increased the importance of ultrashort PFAS measurement over time. Much of the development for the measurement of ultrashort PFAS has occurred in recent years as the need to evaluate them has increased (Ateia et al. 2019). USEPA added two ultrashort PFAS to the Regional Screening Levels table: perfluoropropanoic acid (PFPrA) and 1,1,1-trifluoro-N-[(trifluoromethyl)sulfonyl]methanesulfonamide (TFSi).

1.5.3.2 Ultrashort-chain PFAS

Table 1-11 lists ultrashort PFAS that currently have commercially available analytical reference materials. As of September 2025, no consensus methods have been published for this class of compounds. Most ultrashort PFAS analyses will not include all these compounds, but any of them may be expected to be reported from an ultrashort PFAS analysis. Note that the salt forms associated with these acids will have different CAS Registry numbers. See "Anions Versus Acids" in **Section 2.2.3.1** for an explanation.

Numerous methods have been developed and published for the analysis of ultrashort PFAS (for example, Wang et al.2024; Zou et al. 2024; Liang, Steimling, and Chang 2023; Jacob and Helbling 2022). A significant challenge in measuring ultrashort PFAS is their incompatibility with reversed-phase liquid chromatography, which is the preferred technique for analysis of PFAS having four or more carbon atoms.

This challenge is commonly overcome using a different stationary phase. Various choices are available, including hydrophobic-interaction liquid chromatography (HILIC), ion exchange chromatography, and

various hybrids of those reversed-phase, HILIC, and ion exchange stationary phases (Bjornsdotter et al. 2020). The ideal column, mobile phases, and gradient will depend on the ultrashort PFAS being analyzed.

Aside from issues with retention on the cartridge or column, another major challenge with measuring ultrashort PFAS is blank contamination, particularly from TFA. This can impact the interpretation and quantitation of analytical results. Prior work has shown that laboratory consumables, particularly those containing fluoropolymers, can leach ultrashort-chain PFAS such as TFA (Joudan et al. 2024).

Table 1-11. Commonly reported ultrashort-chain PFAS.

Analyte Name	Acronym	CAS Number
2,2,3,3-Tetrafluoropropanoic acid	2,2,3,3-TFPA	756-09-2
2,3,3,3-Tetrafluoropropanoic acid	2,3,3,3-TFPA	359-49-9
Perfluoropropanoic acid	PFPrA	422-64-0
1,1,1-Trifluoro-N-[(trifluoromethyl)sulfonyl]methanesulfonamide	TFSi	82213-65-3
Trifluoroacetic acid	TFA	76-05-1
Trifluoromethanesulfonic acid	TFMS	1493-13-6
Perfluoropropane-sulfonic acid	PFPrS	423-41-6
Perfluoroethanesulfonic acid	PFEtS	354-88-1
Difluoroacetic acid	DFA	381-73-7
Perfluoro-2-methoxyacetic acid	PFMOAA	674-13-5

1.5.3.3 Simultaneous Analysis of Ultrashort-chain and Other PFAS

For the most part, the use of these alternative liquid chromatography (LC) stationary phases prevents the inclusion of larger PFAS in the same analysis, although 4-, 5-, and even 6-carbon PFAS may be analyzed along with the ultrashort PFAS. Larger PFAS typically have less retention on these columns as the number of carbons increases, although exceptions may exist. More complicated chromatographic systems involving combinations of columns can be attempted to address this issue, but the desire to have a single analysis must be balanced against the increased complexity and vulnerability to problems that increase with such an approach.

Recently, LC stationary phases that mix either HILIC or ion exchange or both with reversed-phase LC stationary phases provide some hope that ultrashort PFAS may be analyzed in the same analysis as larger PFAS (Waters Corporation 2023; Restek Corporation 2024). This aspect of ultrashort PFAS analysis is very much in its early phase, and one can reasonably expect that things will change. Until new approaches to simultaneously analyze a wide range of PFAS with varying carbon chain lengths emerge, analysis of ultrashort PFAS will often be a separate analysis from the short- and long-chain PFAS.

1.5.3.4 Sample Preparation

Sample preparation before analysis is another area of active development. Water samples of various sorts are typically handled by weak-anion exchange (WAX)/reverse-phase hybrid SPE sorbents. Solid samples likewise follow other methods in that an initial extraction of the solid in basic methanol is followed by dilution in water and SPE in the same manner as water samples. The QuECHeRs (Quick, Easy, Cheap, Rugged, and Safe) method has been explored for food samples, but it is not clear whether stable-isotope-labeled extraction standard recoveries were comparable to those obtained with WAX SPE (Santa-Mayor et al. 2023).

Other options for sample preparation for the analysis of ultrashort PFAS include preparation for direct injection analysis and on-line SPE (Jacob and Helbling. 2022). Direct injection analysis is particularly appropriate for many ultrashort PFAS due to the near-ubiquitous presence of ultrashort PFAS in all parts of the environment and the relatively high concentrations in the environment of many of them. One study from the State of California Division of Drinking Water showed elevated detection limits when performing direct injection analysis compared to WAX SPE (CA Water Boards 2024).

On-line SPE combines the process of extraction and analysis of a sample into a single process by placing SPE columns in-line with the analytical LC column. This technique simplifies and reduces the cost of SPE when it works well, but the relatively small bed volume of SPE columns and reusable nature of them can lead to degradation in SPE performance, contamination, and building of back-pressure that can cause analysis to halt.

1.5.3.5 TOP Assay

Many implementations of the TOP assay have not included any measurement of ultrashort PFAS (Neuwald et al. 2022). Conversion of precursors containing four or more carbons to end products having three or fewer carbons is therefore not assessed. Likewise, conversion of molecules with two or three carbons is not assessed when ultrashort PFAS are not measured.

TOP assay typically produces a higher concentration of perfluorocarboxylic acids (PFCAs) with decreasing chain length thereof. Thus, in a typical measurement of PFCAs having between 4 and 14 carbons, perfluorobutanoic acid (PFBA) is the most increased in abundance, followed by perfluoropentanoic acid (PFPeA), then perfluorohexanoic acid (PFHxA). That pattern suggests that one should reasonably expect that PFPrA would be more abundant than PFBA, and TFA more abundant than PFPrA. Although the precise proportion of conversion products is not known, it is a reasonable assumption that a significant proportion of conversion products is not captured when ultrashort PFAS are not measured. Note that other possible distributions of products could occur, depending on the precursors present. More information about TOP assay is included in **Section 11.2.2.2**.

One example of a study in which ultrashort PFAS were analyzed after oxidation can be found in Tsou et al. (2023). This study showed, as expected, that both PFPrA and TFA were found in samples that had been oxidized. The relative proportions of the ultrashort PFAS to one another and short- and long-chain PFAS varies from sample to sample, but the ultrashort PFAS content is, as one would anticipate, significant relative to the other PFAS. Another example can be found in Janda et al. (2019), which provides information on an improved protocol for the TOP assay when targeting 2- to 14-carbon chains.

1.5.3.6 High-Resolution Mass Spectrometry of Ultrashort-chain PFAS

Studies of ultrashort PFAS using HRMS for non-targeted analysis (NTA) are relatively few, but ultrashort PFAS should be detectable in NTA, provided they are high enough in concentration to be detected. Those ultrashort PFAS with reference standards can be unambiguously identified. Other compounds may be more difficult to identify.

As with any HRMS NTA, the precise concentration of a compound cannot be known without a quantitative standard. Both ionization and fragmentation can be (and usually are) affected by changes in molecular composition or structure. Therefore, one cannot determine a detection limit without a quantitative standard. These factors result in some uncertainty in the ability to detect compounds in an NTA.

As with targeted analysis, high polarity of ultrashort PFAS introduces another difficulty in that a column other than the usual reversed-phase column must be used to separate the ultrashort PFAS from other components to avoid distortion of the mass spectrum from interfering compounds.

1.5.4 Consumer Product Testing

This section describes the current testing methods, types of analyses, data uses, and regulations related to the testing of PFAS in consumer products such as textiles, food packaging, cosmetics, nonstick cookware, and juvenile products. This topic supplements **Section 11.1.7**, which discusses PFAS sampling in various media but does not discuss consumer products.

1.5.4.1 Current Testing Methods

A variety of analytical methods is available for PFAS testing; however, only a few of them have been validated for consumer products and other chemical products with complicated matrixes. Testing of PFAS in consumer products can be addressed through multiple analyses and may use a workflow combining fluorine content analysis, target analysis, and non-targeted or suspect screening analysis methods. See ASTM F3700-25 Standard Guide for Selecting and Applying Analytical Methods to Evaluate PFAS in Consumer and Related Products (ASTM 2025).

Consumer products testing presents unique challenges due to the sample matrix, differentiating them from environmental media testing. The sample matrix for products is typically a complex composition from diverse materials (paper, fabric, natural materials, plastics). PFAS could be included in consumer products at percent levels to provide a certain function or could be residues or impurities from the manufacturing process. Other chemicals in the matrix can interfere with PFAS analytical processes from sample preparation to instrument analysis. Extra techniques are required to reduce matrix effects but issues such as co-elution in chromatography, ion suppression in mass spectrometry, or signal masking, may still be present. Sample preparation can be difficult for consumer products made with polymeric PFAS.

1.5.4.2 Targeted Analysis

In targeted analysis, testing methods generally involve LC or gas chromatography (GC), and mass spectrometry (MS). LC/MS is capable of monitoring short-chain PFAS and ionic PFAS, while GC/MS will measure the more neutral and volatile PFAS (TemaNord 2024). In commercial labs, LC/MS is more available for PFAS analyses.

Validated methods for PFAS testing in consumer products are very limited. USEPA has a single laboratory validated method from 2024 for testing 31 PFAS in plastic container walls such as HDPE by LC/MS/MS, and it may be used with modifications for solid samples such as fabric or packaging paper (USEPA, 2024). ISO published an LC/MS/MS method to determine extractable nonvolatile PFAS in leather and coated leather (ISO 23702-1:2023 | IULTCS/IUC 39-1) (ISO 2023). This method is specifically designed for long-chain PFAS (C7-C14). Europe combined LC and GC in method EN 17681-1:2025 (European Committee for Standardization (CEN) 2025) and EN 17681-2: 2022 (European Committee for Standardization (CEN) 2022) to test textiles and textile products for selected extractable PFAS (PFOA, PFOS).

In instances when a validated method does not exist for a specific consumer product, methods validated for soil, sludge, and solids, such as USEPA Method 1633A (USEPA 2024), DIN 38414-14 (DIN 2014), ASTM D7979 (ASTM 2020), and ISO 25101(ISO 2009), are often modified or used as the basis for testing. All targeted methods have a list of predefined PFAS. A primary limitation of these methods comes from the availability of analytical reference standards for individual PFAS.

Other targeted analytical techniques are still in the research phase and lack established or standard methods. For example, pyrolysis-gas chromatography-mass spectrometry (pyr/GC/MS) can be used for the bulk characterization of fluorinated polymers (polymeric PFAS) in consumer products. Pyr/GC/MS methods involve pyrolyzing a sample directly (without extraction) at temperatures between 250°C and

1,000°C, followed by online analysis of the degradation products. Skedung et al. (2024) used a pyrolysis method, applying a maximum pyrolysis temperature of 700°C to 45 consumer products and identified polytetrafluoroethylene (PTFE, most used fluorinated polymer) in cookware, dental products, and electronics at concentrations as low as 0.1–0.2 wt%. It was also possible to use pyr/GC/MS to distinguish between three different side-chain fluorinated polymers in textiles (Skedung et al. 2024). Recent work has established solid-phase microextraction protocols for both aqueous- and gas-phase PFAS analysis (Martínez-Pérez-Cejuela et al. 2025). Such work may allow for outgassing or emissions testing of consumer products; ASTM (2025) acknowledges the application of "off-gassing techniques to determine the potential release of PFAS from products over the product life cycle" (F3700-25, 1.4). Earlier emissions work employed thermal desorption focusing on fluorotelomer alcohols (FTOHs) (Robbins et al. 2023).

In addition to these targeted methods, some laboratories have applied TOP assay to measure PFAAs derived from precursors that undergo oxidation by hydroxyl radicals. To measure precursor concentrations, the most common target PFAS are measured before and after the oxidation using conventional targeted PFAS analysis such as LC/MS (Ateia et al. 2023). However, some PFAS precursors may not be extracted, and incomplete oxidation can occur (for example, PFAS with ether functional groups that are resistant to oxidation), or oxidation products could be missed (for example, ultrashort PFAS) in traditional target analysis. The limitation of TOP assay on ultrashort PFAS is not limited to consumer product testing and is also discussed in **Section 1.5.3.5**.

Targeted analysis is the most sensitive and confirmative method to measure PFAS in consumer products. But major challenges still exist, including the lack of standard methods, the limited number of individual PFAS that can be measured, and the need for optimalization of extraction procedures (TemaNord 2022).

1.5.4.3 Fluorine Screening

Although they are not yet validated, this section discusses several useful methods for detecting fluorine instead of individual PFAS. For fluorine screening, it is important to note that while all PFAS contain fluorine, not all fluorine-containing compounds are considered PFAS. NTAs discussed in this section include methods that look for totals, such as extractable organic fluorine or total fluorine, and do not reference the NTA looking at suspect screening or unknown targets present in a sample.

Polymeric vs. Nonpolymeric PFAS

Many state-level legislative actions for consumer product bans use total organic fluorine (TOF) as the determining factor for presence or absence of PFAS. If a legislative action does not specifically exclude polymeric PFAS in the TOF content, then it should be assumed that polymeric PFAS is included as part of the TOF. For example, New Mexico's legislation on PFAS (HB 212), signed on April 8, 2025, specifically excludes fluoropolymers from the legislative action. Inclusion or exclusion of polymeric PFAS is an important factor in determining which analytical tests are the best fit for determining organic fluorine content. For more information about analytical tests for determining organic fluorine, see **Section 1.4.5**.

Types of Analysis

TOF refers to *all* organic fluorine present in a given sample. Although there is currently no test to directly measure TOF, there are methods to approximate a TOF concentration. The current conventional tests for fluorine include:

- Total fluorine (TF), which includes all fluorine present in a sample, inorganic and organic, including polymeric and nonpolymeric forms if present. This can be used for both aqueous and solid samples.

- Inorganic fluoride (IF), which includes soluble inorganic fluoride. This can be used for both aqueous and solid samples.

- Extractable organic fluorine (EOF), which includes organofluorine compounds, encompassing both PFAS and non-PFAS. This can be used for aqueous and solid samples.

- Adsorbable organic fluorine (AOF), which includes organofluorine compounds that will adsorb to carbon, encompassing both PFAS and non-PFAS. This applies only to aqueous samples.

Each of these have some limitations. Where TF includes all fluorine present in a sample, this could overestimate the concentration of organofluorine compounds in the sample. EOF will include only the organofluorine compounds amenable to the extraction process. For example, aqueous samples will depend on the type of solid-phase extraction (SPE) cartridge used. Weak-anion exchange (WAX) cartridges will target anionic PFAS and mostly exclude cationic and zwitterionic PFAS. A hydrophilic-lipophilic balance cartridge may include a larger range of PFAS (Idowu et al. 2025). For solid samples, EOF efficiency will be based on the extraction solvent used and the affinity for each class of PFAS to that extraction solvent (example methodology can be found in Spaan et al. 2020; Spaan et al. 2021). EOF may contain some polymeric PFAS but will not include all polymeric PFAS present in a sample. AOF is limited to aqueous samples. The affinity for shorter chain PFAS (< C4 chain length) to carbon may present a negative bias for shorter chain PFAS. AOF may include some but will not include all polymeric PFAS if present.

To put this in perspective, the potential concentrations for each group would be TF > TOF > EOF > AOF (Ateia et al. 2023). As there is currently no method to directly measure TOF, it is typically reported mathematically by subtracting the IF concentration from the TF concentration, but this method has limitations. These limitations include differences in reporting limits, with limits for inorganic fluoride in the mg/kg (ppm) range and limits for TF and EOF in the ng/g (ppb) range. Use of this calculation may also be confounded by insoluble inorganic fluoride, including naturally occurring minerals such as fluorite, also known as fluorspar (CaF_2). There are currently no published methods for the quantification of insoluble inorganic fluoride. Both EOF and AOF may be reported as TOF, however, the limitations discussed above should be considered when using this convention. It is important to consider the type of consumer product being tested and the potential types of IF, as well as polymeric PFAS, that could be present in a sample. For example, testing TF may be sufficient for determining presence or absence of PFAS in a sample when IF is not present. Conversely, a consumer product high in insoluble inorganic fluoride may need a different approach. It is equally important to consider the end use of the data because TOF may detect organofluorine chemicals that are not PFAS.

These analyses are not specific to consumer product testing but are very relevant tools when TOF or TF are part of a regulation for PFAS in consumer products.

Combustion Ion Chromatography

Combustion ion chromatography (CIC) is used to measure TF, IF, AOF, and EOF, see **Section 11.2.2.4**. If a sample is combusted by CIC prior to adsorption or extraction, then the resulting fluoride concentration corresponds to TF, which refers to both the organically and inorganically bound fluoride present in the sample. TF may not be as reliable of a proxy for PFAS if, for example, fluorine-containing minerals or IF are present at high concentrations in the sample.. USEPA Method 1621 quantifies the concentration of AOF in aqueous samples by adsorbing the organofluorine compounds to a granular activated carbon cartridge that then is combusted (USEPA 2024). EOF can measure organic fluorine in both aqueous and solid samples by extracting the organofluorine compounds from the sample prior to combustion. The methods used for EOF extraction are similar to those used for targeted PFAS extraction with the addition of a step that removes the inorganic fluorine from the sample (Ruyle et al. 2023). There is no standardized EOF method, but it has been validated through interlaboratory comparisons (Kärrman et al.

2021). Ruyle et al. (2023) provides a table of recommended best practices for EOF analysis that can be referenced because there is no standardized method yet.

Other Total Fluorine and Organofluorine Methods

- Particle-induced gamma-ray emission (PIGE), see **Section 11.2.2.3**. This is a nondestructive rapid screening tool that measures TF. Like TF above, PIGE does not distinguish between types of fluorine and would include inorganic fluorine, polymeric PFAS, nonpolymeric PFAS, and other organic fluorine.

- X-ray photoelectron spectroscopy (XPS). This analytical technique is used to measure fluorine on the surface of a product, looking at the top few nanometers of a sample (Tokranov et al., 2018). This process is highly sensitive to fluorine. XPS can distinguish between different types of chemical bonds, differentiating classes of PFAS (but not identifying individual compounds). There are sample preparation challenges, because XPS requires samples to be analyzed under high vacuum, which can cause issues for certain matrixes.

- Soluble inorganic fluoride in consumer products can be measured by extracting with water or weak acid followed by analysis by a published method. Methods that include soluble inorganic fluoride include USEPA Method 300.1 (USEPA 1997); ASTM D1179 (ASTM 2021); and ASTM D4327 (ASTM 2025).

- TOP assay, see **Section 11.2.2.2**. The TOP assay is a proxy method to determine additional PFAS present in a sample that cannot be measured by current targeted methods. This method uses the current targeted analytical methods, with a pre- and post-oxidation sample analysis. The difference in PFCAs between these two samples is attributed to the conversion of oxidizable precursors to PFCAs.

Fluorine Screening Methods

There are currently no validated methods that are specific to TOF in consumer products. In European standards, there is no method specified for the determination of organic fluorine in consumer products, only a reference to EN 14582:2016 Characterization of Waste (European Committee for Standardization 2016), which specifies a combustion method for the determination of halogen and sulfur contents. Oxygen combustion in closed systems and determination methods is frequently referenced for consumer product testing. A few research papers compared the target analysis with TF or TOF analysis and revealed the huge discrepancy between fluorine and speciated PFAS. It was consistently found in consumer product testing that the total amount of fluorine cannot be correlated with the sum of speciated PFAS. For example, Rodgers et al. (2002) tested 54 samples with total fluorine over 10 ppm for 36 targeted PFAS via a methanol extraction followed by LC/MS/MS and found that the total amount of fluorine attributable to methanol-extractable target PFAS analytes and to PFAAs generated from oxidizable precursors in samples never exceeded 0.1% of the total F measured in these products.

1.5.4.4 Non-targeted Analysis

Suspect screening and NTA are designed to detect and identify a wide array of known and unknown PFAS without prior knowledge of the chemicals' exact structures or identities, see **Section 11.4**. Though NTA, such as HRMS, has been successfully applied to a wider range of PFAS in contaminated matrixes, these analytical approaches are not yet common in consumer product analysis (Bugsel, Zweigle, and Zwiener 2023). Most method developments are in the research phase.

A notable study by Stroski et al. (2024) developed NTA workflows to investigate unknown PFAS in various food packaging materials, including paper-based and foil wrappers. The research identified both legacy

and emerging PFAS, such as 6:2 fluorotelomer phosphate diester (6:2 diPAP) and its transformation product 2H-perfluoro-2-octenoic acid, also known as 6:2 fluorotelomer unsaturated carboxylic acid (6:2 FTUCA), in these materials. Beyond food packaging, NTA has revealed the presence of PFAS in several other consumer products, including textiles, cosmetics, and household items. A recent study by the National Institute of Standards and Technology (NIST) employed liquid chromatography-HRMS combined with suspect screening to analyze over 4,000 PFAS in firefighter turnout gear textiles (NIST 2025). One major challenge of using HRMS for PFAS detection in consumer products is the lack of analytical standards and reference spectra for the thousands of known and emerging PFAS. In addition, complex product matrixes (for example, cosmetics, textiles) can interfere with PFAS signal detection and introduce false positives or reduce confidence in compound annotations (Bugsel, Zweigle, and Zwiener 2023). Recent work has applied machine learning and two-dimensional GC analysis for consumer product emissions testing, which may establish a new workflow for PFAS emissions testing (Watson et al. 2025).

1.5.4.5 Regulations

The **Regulatory Programs Table** includes information about regulations related to the ban of PFAS in certain categories of consumer products.

Manufacturers can use PFAS testing data to show compliance with regulations, ensure consumer safety, maintain brand reputation, or identify potential contamination sources and take appropriate measures to ensure the integrity of their products. On the other hand, regulatory agencies use PFAS testing data to bring the regulated industries into compliance, guide remediation or prevention efforts, and inform rule-making decisions.

Compliance and enforcement usually require testing to follow strict quality assurance/quality control (QA/QC) procedures, use accredited laboratories, and use standardized analytical methods that are rigorously validated for various PFAS and matrixes.

1.5.5 ISM for PFAS Sampling

Incremental sampling methodology (ISM) is a method for collecting and compositing soil samples to achieve a result that is more representative of a given decision unit. Practitioners have found that the sampling density afforded by collecting many increments, together with the disciplined processing and subsampling of the combined increments, in most cases yields more consistent and reproducible results than those obtained by discrete sampling approaches (ITRC 2020). Given the unique properties and potentially low action levels associated with PFAS, there is substantial interest in determining whether ISM is an effective approach for these compounds and whether there are concerns or limitations to its use. This topic supplements **Section 11.1**, which discusses sampling equipment and procedures for PFAS in soil but does not address ISM. **Section 1.7.2.4** discusses the application of ISM-type sampling for biosolids land application sites.

Although peer-reviewed research on ISM for PFAS sampling is, to date, very limited, the Department of Defense (DoD) Environmental Data Quality Workgroup (EDQW) has evaluated the use of ISM for PFAS and identified several factors to consider that were enumerated in a white paper released on 31 January 2025 (DOD EDQW 2025). In short, the current DoD position is that ISM sampling and analysis protocols should not be adopted for PFAS without first performing a validation study of the protocol to determine and remedy sources of positive and negative bias inputs followed by publication of the validated method by the USEPA. The issues identified by the EDQW include some field sampling but are mainly laboratory processes.

Following is a general outline of the concerns highlighted in the DoD report (DOD EDQW, 2025): The grinding step cannot be performed on the ISM soils due to the decontamination procedure that would be required after each sample would cause increased surface rusting of the equipment. Another potential

concern related to grinding is the level of volatilization of the more volatile PFAS chemicals that may result from the heat generated during the grinding process. The drying and grinding steps could also potentially promote volatilization and loss of the ultrashort- and short-chain PFAS analytes. Extracted internal standard (EIS), ongoing precision and recovery (OPR), and low-level ongoing precision and recovery (LLOPR) spikes require reference materials that are not commercially available, and even if they were, would likely be cost-prohibitive and taxing on manufacturers of such standards. Finally, when collecting soil samples in the field, typical ISM sampling is performed within the top 18 inches of the soil surface. However, the report cited concerns that PFAS would likely be deeper in the soil column.

Although DoD has published their reservations with several aspects of ISM, at least three states (Hawai'i, Maine, and Michigan) are actively using modified versions of ISM for investigations involving PFAS impacts (HI DOH 2025; ME DEP 2023; ME DEP 2023; MI EGLE 2024). Specific Maine Department of Environmental Protection (DEP) methods are not outlined in reports but are referred to in their published homeowner guidance and legislative report. Hawai'i employs the Decision Unit and Multi Increment methodologies, which are similar to the ISM-type investigation methods (HI DOH, 2025). Michigan has used the full ISM to investigate areas that land-applied biosolids (MI EGLE 2024). Generally, states seem to use the planning and data quality objectives from ISM and find them applicable to sampling for PFAS in some scenarios, but there are still some debates on the 8330b laboratory processing methods. For example, Maine DEP has used a modified ISM procedure that excludes drying and sieving in the laboratory as an effort to alleviate the issues outlined by the DoD (see **Section 1.7.2.4**).

1.5.6 Concrete and Asphalt Sampling and Analysis

Frequent, historical use of aqueous film-forming foam (AFFF) at various firefighting training grounds (for example, military bases, airports, and oil refineries) has led to significant contamination of PFAS in many industrial areas to the infrastructure materials present. Two such materials of concern are the contamination present in concrete and asphalt, which are common matrixes at industrial sites. There are currently no standardized methods for sampling and analysis of PFAS in these matrixes, although many principles applied to sampling and analysis of other solid matrixes may apply.

For the purpose of this section, concrete matrixes are inorganic matrixes formed from aggregate, sand, and a complex cement (for example, Portland cement), which can vary significantly regarding ratios and input materials. Other materials, such as reinforcing steel bars and plastic fibers, have also commonly been used to enhance the engineered functions. Concrete properties can vary over time as minerals age and fracture, with rehealing also possible. Douglas et al. (2023) reviewed literature on PFAS in concrete and asphalt and found relatively little information available at present, though information on the distribution and leaching of PFAS is emerging. Although essentially a monolithic material, porosity is important for concrete sorption properties, including anticipated transport, ingress, and egress of water and PFAS (Douglas et al. 2023). Asphalt is a mixture dominated by aggregate in an organic bitumen matrix. Partitioning of PFAS in asphalt may therefore be more influenced by hydrophobic interactions than electrostatic interactions that may play a more prominent role for concrete (Douglas et al. 2023). Asphalt may also change significantly in properties over time as lower molecular weight organic solvents are lost to volatilization and other components are subject to oxidative change. Douglas et al. (2023) also concluded that use and contamination with other products, such as hydraulic fluids, oils, and degreasing solvents, can also change PFAS interactions with both concrete and asphalt.

PFAS sampling in concrete and asphalt is an important tool in managing these materials post-PFAS contamination (for example, reuse, remediate, or dispose), understanding if the contaminated matrix could pose as a secondary source of PFAS runoff during precipitation events, and determining the fate and transport of PFAS through the matrix. To date, most studies have focused on concrete with regards to understanding PFAS impacts. Best practices regarding sample collection, extraction, and analysis of concrete matrixes are discussed in the following sections. Additionally, the fate and transport of PFAS

within the matrix is also discussed to highlight considerations when trying to collect a representative sample.

Although there is currently no federal or state guidance available, the purpose of this section is to promote consistency of approaches for sampling and analysis of concrete and asphalt until more formal guidance is available. This topic supplements **Section 11.1.7**, which discusses PFAS sampling procedures for various media but does not cover concrete or asphalt.

1.5.6.1 Sample Collection and Extraction

Due to the complexities of concrete and asphalt matrixes, and the potential for changes over time, sampling is not straightforward. Work at a concrete firefighting training pad from Baduel et al. (2015) showed that PFAS concentrated in the top few centimeters, with penetration to depth largely correlating with chain length or molecular weight. In contrast, Williams et al. (2023) showed that for a different firefighting training pad, there was considerably more variability in concentrations and relationships between different PFAS with depth, with chain length a poor predictor of penetration distance. These differences could be due to the chemistry of the AFFF released, environmental conditions (for example, precipitation), or the exact composition of the concrete, as this is not uniform. Any sampling plan for PFAS analysis in these matrixes must consider potential for spatial heterogeneity and site-specific conditions.

Asphalt and concrete samples are collected as cores for transport to the laboratory. Standard coring techniques can be used. Air- and water-cooled corers are available. If water-cooled corers are used, the water used for lubrication/cooling should be verified as PFAS-free to an appropriate limit of reporting prior to use. Cores can be subsampled by dry cutting with a diamond saw into segments for monolith leach testing and for subsampling monoliths (Vo et al. 2023; Williams et al. 2023; Srivastava et al. 2024). Potential for PFAS transformation due to heat when cutting or coring does not appear to have been studied.

Cores can be collected using drilling or coring techniques that use PFAS-compatible materials (for example, stainless steel). Reused parts contacting the core should be decontaminated between each core collected. Once cores have been collected, they should be transported to the laboratory in a PFAS-compatible container (for example, an HDPE bag) at 4°C.

Although cores are valuable, obtaining sufficient cores to understand horizontal spatial variability will rarely be practical. Researchers to date have reported collecting surface samples by creating dust with a handheld electric drill (Williams et al. 2023; Vo et al. 2023; Thai et al. 2025; Thai et al. 2025). This method has also been used for sample preparation for laboratory analysis (see **Section 1.5.6.2**).

Shipping, storage, and holding times should follow guidance for other solid matrixes, for example, USEPA Method 1633A, in the absence of guidance specific to concrete and asphalt.

Samples need to undergo a methanol solvent extraction for analysis, which requires the asphalt/concrete to be finely ground to ensure sufficient extraction from the solid phase. Methods such as drilling or crushing can be used to create asphalt/concrete powder that is then subjected to the methanol extraction process. To date there has not been a standardization on the drilling/crushing of asphalt/concrete. Variables such as particle size, drill hole depth, drill bit diameter, and drill speed could alter concentrations of PFAS that are obtained in the dust sample. Though no standardized method has been developed for sample collection, any drill bit or saw blade, for example, used to process the sample for extraction should be cleaned with methanol prior to sample collection.

Methanol extraction can be enhanced by the addition of an acid or base to improve extraction efficiencies of charged PFAS. Enhanced methanol extraction in addition to sequential extraction could benefit the analysis of more complex matrixes, such as asphalt.

Information about SERDP and ESTCP projects designed to establish standardized methods for sampling asphalt and concrete contaminated with PFAS can be found on their website (**https://serdp-estcp.mil**).

1.5.6.2 Sample Analysis

LC/MS/MS is the most common analytical technique used for the measurement of PFAS in environmental samples. Paired with solid-phase extraction (to remove matrix bias and improve detection limits) or centrifugation, this method has been used for analyzing PFAS in both asphalt and concrete samples (Baduel et al. 2015; Li et al. 2024; Liu et al. 2024; Srivastava et al. 2022). There are no specific instrumental analytical considerations for concrete and asphalt extracts, but proper sample preparation is crucial to obtain more accurate results.

1.5.6.3 Fate and Transport of PFAS in Concrete

The fate and transport of PFAS within concrete is important in understanding the extent of contamination that occurs within the matrix. Horizontal transport of PFAS from a source typically behaves similarly to the natural flow path of the concrete pad. Williams et al. (2023) studied a concrete pad from a fire training area where AFFF has been used. They found that concentrations of PFAS varied considerably within relatively short distances. Understanding the contaminant flow path may help in collecting spatially representative samples. Additionally, Williams et al. (2023) identified that PFAS was found to migrate within the vertical length of the core. Depth of PFAS impacts varied depending on the concrete material (which may affect diffusion/back diffusion), age of the material, bulk flow over the material (for example, stormwater), and the material's adsorption/desorption capacity. Additionally, transport of PFAS tended to be species dependent, for both horizontal and vertical movement (Williams et al. 2023).

The transport of PFAS from a concrete slab during precipitation events can indicate whether the matrixes serve as a secondary source of contamination. Thai et al. (2022) conducted a study of concrete from a fire training area where AFFF has been used to understand the effect of rainfall to release PFAS from the concrete. During successive rainfall simulations the similar concentrations of PFAS in the simulated runoff suggested the water evaporation between simulations may generate a potential wicking effect in the concrete bringing PFAS back to the surface (Thai et al. 2022). The PFAS can be released with the next stormwater runoff event, supporting the theory that concrete could serve as a secondary source of PFAS contamination. Ponding was another scenario that Thai et al. (2022) investigated, with regards to surface water impacts from PFAS-impacted concrete. Results indicated that an initial rapid release of PFAS concentrations occurred, while subsequent ponding events noted decreased concentrations (though similar concentrations between subsequent events). This would also support the potential for concrete to serve as a secondary source of contamination (Thai et al. 2022).

1.5.6.4 Leaching Testing of Concrete

To date, information regarding leachability of PFAS from concrete is limited, one study (Srivastava et al. 2024) is discussed below, and further research is required to develop and validate leaching tests under field conditions to fully assess leaching behavior in concrete. However, it is a topic of interest because understanding leaching behavior can determine disposal needs, potential remediation methods, and reuse options.

Based on a 2024 study (Srivastava et al. 2024) some leaching characteristics and considerations were preliminarily determined. Using a modified LEAF 1315 method (USEPA 2017), three long-chain (PFOS, PFOA, and PFHxS) and one short-chain (PFHxA) compound were analyzed for their leaching behaviors.

The study determined that, of the four constituents, PFOA was retained in the concrete, with relatively low leachability, while PFHxS readily leached out of the material. This highlights the variability in behavior based on species present.

Unlike samples analyzed in a powder form, leaching tests in this study (Srivastava et al. 2024) were conducted with quartered pucks extracted from a core collected in the field, resulting in a more complex surface (rather than a homogenized mixture). As such, leaching behavior was assumed to be driven by characteristics of the concrete being tested. For example, the age of the concrete was an important factor. As concrete ages, it experiences a net loss of alkalinity and cations via surface wicking (rainfall or other fluid distribution over the surface). This can influence adsorption and desorption within concrete pores. Development of secondary minerals over time may also decrease accessibility to pore space and adsorption/desorption potential of PFAS.

Similarly, van der Waals interactions may influence sorption/desorption of charged species to the surface of the concrete. Hydrophobic properties can also develop within the matrix and influence the ability for PFAS to bind to the matrix (Srivastava et al. 2024). The formation of micelles (colloidal particles with a hydrophobic core and a hydrophilic exterior), which has previously been observed in sediment matrixes, may also be a factor in leaching behavior for concrete given its porous nature (Srivastava et al. 2024). Further research is needed to fully understand and define these interactions, and resulting concentrations of PFAS in leachate produced from concrete. Better understanding of matrix interactions and characteristics that affect observed PFAS concentrations can help determine best practices for representative sample collection for this analysis method in the future.

1.5.7 Field Screening Tools

The goal of this section is to briefly summarize the development and availability of options for field screening for PFAS. Field screening tools are of interest because of the potential for portability (on-site use), ease of use, rapid results, and cost-effectiveness, all of which can improve the effectiveness and efficiency of PFAS analysis, and, ultimately, site characterization and remediation. However, there are currently no validated analytical methods that apply to field screening tools. This topic supplements **Section 11.2**, which addresses laboratory analytical methods/techniques.

Although not yet widely accepted by regulators, several PFAS screening approaches and tools are in various stages of development and validation (Erickson 2023; Menger et al. 2021), and some have recently been commercialized. SERDP released a Statement of Need in November 2024 titled *Real-Time Sensors for Detection and Quantitation of PFAS in Soil and Groundwater at AFFF-Impacted Sites* (SERDP 2024). More information about SERDP projects can be found on their website (**https://serdp-estcp.mil**).

Sensing technologies that have been evaluated in academic laboratories include those based on electrochemistry, optics, and nonconventional approaches, such as hydrogel swelling and thermal detection (Thompson, et al. 2024). Nanoparticle-based sensors, which may be made of metal-based nanoparticles, quantum dots, or carbon dots, can measure PFAS by detecting the optical or electrochemical changes that occur because of interaction with PFAS (Sendão et al. 2023). Different technology approaches provide different results, with some tools yielding total PFAS or TOF results and others reporting individual compounds, such as PFOS or PFOA, down to single-digit nanogram per liter levels for comparison to drinking water standards. As an alternative approach, fixed commercial laboratories are offering modified HPLC-MS/MS analyses, generally based upon ASTM D8241-25 (ASTM 2025), USEPA Method 537 (USEPA 2020), or USEPA Method 8327 (USEPA 2021), but perhaps omitting some sample preparation or quality assurance/quality control steps to achieve faster turnaround times, on the order of 1–10 days. Additionally, these streamlined analyses can be performed for a lower cost, as much as 50% reduced from full, National Environmental Laboratory Accreditation Program (NELAP)-certified analyses. It should be noted that screening tools, even when fully developed, properly validated, and commercialized, may not be approved by regulatory agencies for decision-making regarding site

risks, comparison to standards, or assessment of remedial actions. It is likely that results will have to be confirmed with an accredited laboratory using a validated and published analytical method.

1.6 Priority Topics for Treatment Technologies

Section Number	Topic
1.6.1	**Thermal Treatment Update**
1.6.2	**Supercritical Water Oxidation**
1.6.3	**Investigation-derived Waste**
1.6.4	**Treatment of Sediment**
1.6.5	**Treatment of Biosolids**
1.6.6	**Updated and Recent and Relevant Technology Review Papers**

Information in these Priority Topics was prepared to supplement the information published in **Section 12** and **Table 12-1 Treatment Methods Table** Excel file. The new Sorption-based Treatment Technologies Guidance is included in **Section 18**. ECOS (2025) compiled information from state environmental agencies about their policies and actions to address PFAS, including topics around remediation, destruction, and disposal. Information about Strategic Environmental Research and Development Program (SERDP) and Environmental Security Technology Certification Program (ESTCP) projects for Treatment Technologies can be found at **https://serdp-estcp.mil/**.

1.6.1 Thermal Treatment Update

Thermal methods have been used to treat a variety of contaminants in both solids and liquids for decades. The impacts of thermal methods on many hazardous compounds are well known, particularly when executed within hazardous incinerators, which have been regulated since the 1970s. The ability of individual methods to destroy or recover PFAS specifically is less well documented, though efforts to do so have increased in the last several years.

1.6.1.1 Thermal Methods

Three thermal technologies are considered and discussed below for PFAS treatment: incineration, pyrolysis/gasification, and thermal desorption. The general operating conditions and equipment for each thermal technology are also described below. The conditions under which each technology is applicable are discussed. Incineration, pyrolysis/gasification, and thermal desorption generally rely on thermal energy to drive their respective treatment mechanisms; however, there are some key differences. Incineration relies on combustion processes in the presence of excess oxygen; pyrolysis and gasification are thermal processes that operate in the absence of oxygen or at levels below what is required for complete combustion (sub-stoichiometric). Thermal desorption uses heat to volatilize PFAS from impacted media followed by subsequent gas phase destruction.

Other thermal technologies, such as supercritical water oxidation (SCWO) (see **Section 12.6.3.12** and **Section 1.6.2**), hydrothermal alkaline treatment, carbon reactivation (see **Section 12.6.5**), and smoldering technology (see **Section 12.7.2**), are not included in this section. Incineration and pyrolysis/gasification may be applied to solids or liquids containing PFAS with mechanisms of PFAS desorption and destruction, whereas thermal desorption is applicable for the treatment of PFAS-impacted solids (case studies limited to soils). The destruction of PFAS through pyrolysis may also occur during thermal desorption, though the PFAS affected and their permanence will be less inclusive and complete.

Incineration

Information on incineration is included in **Section 12.4**. In the United States, hazardous waste incinerators (HWIs) are regulated primarily by the Resource Conservation and Recovery Act (1976) and the Clean Air Act of 1963 and its subsequent amendments (1977, 1979, and 1990). HWIs destroy contaminants in the presence of oxygen at temperatures ranging from 1,600°F to 2,500°F (870°C–1,370°C) (Winchell et al. 2024; USEPA 2025). Gases produced during the process are treated further in an afterburner heated to high temperatures prior to atmospheric discharge (Weitz et al. 2024). Solids are retained as ash and recovered as particles in several stages of air treatment equipment. These include virtually all solid capture methods available, including centrifugal and wet and dry methods, due to the importance of achieving success. Solid treatment residuals (ash) are characterized and disposed at a hazardous waste landfill, with or without solidification, as allowed in the facilities permits.

Pyrolysis and Gasification

Pyrolysis and gasification are similar processes to convert or destroy organic matter. They differ by the temperature of the process and the amount of oxygen present. Pyrolysis produces biochar and hydrocarbon gases in the absence of oxygen. Gasification produces chemical feedstocks for industry and either liquid or gaseous fuel by further refining the biochar in the presence of oxygen, air, or steam (Winchell et al. 2023). The fuel, or synthetic fuel (synfuel), is often used to power electrical generation plants. Pyrolysis and gasification are discussed individually below.

Pyrolysis—Organic waste is heated to 570°F–1,650°F (300°C –900°C) in the absence of oxygen. Organic materials are converted to smaller organic molecules in the form of solids, liquids, and gases. This process is primarily used to produce biofuels and char/biochar and has been evaluated for the treatment of PFAS-impacted materials as discussed further in **Section 1.6.1.2**. Due to the strong carbon-fluorine bonds in PFAS molecules, high temperatures are required for complete decomposition. These elevated temperatures may not be achievable through pyrolysis alone.

Gasification—This process is conducted at temperatures from 1,470°F to 2,190°F (800°C–1,200°C). Organic material is heated in an atmosphere with a specific oxygen concentration. The most common product is synthetic gas (syngas), which can be burned to produce heat or electricity. Syngas can be used to produce synfuels. Gasification for PFAS destruction is an area of active research (Kumar et al. 2023; Abu-Orf 2025; USEPA 2021).

Thermal Desorption

Thermal desorption is a low-temperature physical separation process in which heat is applied to waste material (for example, soil, sediment, sludge) for the purpose of volatilizing water and organic contaminants. As relevant for PFAS, thermal desorption has been demonstrated for ex situ application as discussed in **Section 12.7.2**. Ex situ soil treatment through thermal desorption can be considered using various technologies such as thermal conductive heating technology. Thermal desorption generally entails a temperature range from 350°C to 400°C (662°F to 752°F) (Crownover et al. 2019; Stallings et al. 2023; NAVFAC 2024).

1.6.1.2 Performance

The performance of thermal technologies with respect to PFAS and PFAS-impacted materials is not well documented in peer-reviewed literature. Incineration is a PFAS destruction technology included in the US Environmental Protection Agency (USEPA) interim guidance and 2024 updated interim guidance on the destruction and disposal of PFAS and materials containing PFAS (USEPA 2020 and 2024).

For the non-incineration technologies, most thermal treatment data are collected from pilot and small-scale projects conducted without clear guidance on performance criteria (such as generation of products of incomplete combustion or destruction [PICs/PIDs]). This challenge has been slowly addressed as more providers increase their testing and inform or involve regulators and as analytical and testing methods become available through research, testing, and technology demonstrations.

The crux of the comparison challenge is the PFAS concentration in the tested material. If the concentrations of one or more PFAS are not sufficiently high in the original material and the treated material concentrations are not sufficiently low, calculation of destruction and removal efficiency (DRE) of PFAS of at least six orders of magnitude (99.9999%; historic performance required for hazardous incinerators for chemicals such as dioxin, polychlorinated biphenyls) is not mathematically achievable due to the available detection limits. This situation can be addressed by adding a larger mass of one or more PFAS to the original material (spiking) to raise PFAS concentrations in both the raw and treated material above nondetection levels and enable calculation of DRE values.

Before selecting a non-incineration thermal treatment technology, it is important to know if the technology can meet a DRE of 99.9999% preferably, or if it can achieve ~100% PFAS reduction regardless of feedstock concentrations. In cases where PFAS concentration in the original material is too low to support calculation of a DRE of 99.9999, some providers of thermal destruction or separation technologies present nondetection treated sample analytical results as proof of performance equal to hazardous incinerators that can prove 99.9999 DRE. Note that uncertainties are associated with this approach. Nondetection results arise from the capabilities and limitations of the analytical method and equipment. A DRE of 99.9999 means 999,999 of 1,000,000 PFAS molecules have been destroyed. Detection or nondetection at 1 microgram per gram requires a starting PFAS concentration of 1,000,000 micrograms per gram to demonstrate comparable control. These concentrations are rarely present in waste materials treated via incineration except for some PFAS-containing water or soil or in concentrated volumes of unused liquids—for example, aqueous film-forming foam (AFFF). Therefore, generally it is impossible for any thermal destruction technology to demonstrate a 99.9999 DRE without using spiked materials.

Incineration

The performance of incineration in the destruction of PFAS wastes, PFAS-based materials, such as firefighting foams, and waste containing PFAS, such as textiles, is the subject of continued uncertainty and research. Uncertainties exist around the degree to which PFAS mineralization occurs (breaking of all C-F bonds in a PFAS molecule and conversion to CO_2 and water). Additional uncertainties exist regarding the concentration and composition of PICs. Further uncertainties of the incineration process include factors such as, but not limited to, temperature and residence time. Research to resolve these uncertainties includes the development of emission sampling methods to detect and capture PFAS and analyze their thermal decomposition byproducts (Meegoda et al. 2022; USEPA 2020; Ryan and Gullett 2020).

Most HWIs operate from 980°C to 1200°C. The thermal destruction of most organics in the waste, including PFAS, will be achieved at HWIs, whose operating temperature range is roughly twice as high as the temperature required for thermal destruction of most organic compounds (Meegoda et al. 2022). Notably, in one full-scale study by Solo-Gabriele et al. (2020), increasing incinerator temperatures decreased total treated PFAS concentrations. Importantly, not all PFAS species decreased with increasing temperature. Shields et al. (2023) found that for a legacy AFFF (containing primarily PFOS and PFHxS) combusted at temperatures above 1090°C, destruction efficiencies were greater than 99.99% for ten PFAS, with relatively few volatile PFAS PIDs observed. However, while temperatures below 1000°C often resulted in destruction efficiencies greater than 99.99%, at these lower temperatures there were higher concentrations of volatile PFAS PIDs. **Section 3.1** includes information about AFFF formulations.

USEPA (2024) noted that some uncertainties remain about the effectiveness of hazardous waste incinerators but also concluded that research suggests that the use of higher temperatures, well mixed combustion environments, and longer residence times may be more conducive to destroying PFAS and controlling related products of incomplete combustion.

As part of permit compliance, permitted HWIs are required to document strict adherence to discharge limitations. A study at the Aragonite facility in Utah on stack samples was done in conjunction with the DoD using USEPA OTM-45, OTM-50, and 0010 (which will become OTM-55) methods (USEPA 2025). The results showed the following:

- DRE values for all spiked PFAS, except hexafluoropropylene oxide dimer acid (HFPO-DA), were 99.999% to greater than 99.9999%. DRE values for HFPO-DA were 99.95% to 99.998%.
- OTM-45: 69% of stack gas emission results were nondetects.
- OTM-50: In USEPA's analyses, six potential PIDs in the stack gas were identified above the method detection limit, but below the reporting limit; two compounds were detected in the blanks.
- 0010: No fluorinated compounds were identified.
- DRE values for hexafluoroethane (C_2F_6) were greater than 99.99% to greater than 99.9999%.
- Air emission modeling results were 2–8 orders of magnitude lower than identified regulatory standards or guidelines from five state regulatory agencies (Michigan, Minnesota, New Jersey, New York, and Texas), see Appendix M, Table M-1 in USEPA (2025).

USEPA (2025) presented information about the evaluation of the HWI stack emissions.

Pyrolysis/Gasification

One difference between pyrolysis and gasification is that gasification produces synthetic fuel. One potential concern with synthetic fuel is that it will be distributed to multiple outlets, industrial and residential, where it may be combusted at temperatures below those adequate to destroy PFAS in their very short residence in the combustion chamber then released to the atmosphere through a stack without an afterburner or emissions controls.

Facilities using pyrolysis or gasification are regulated under the Clean Air Act and must meet strict emissions monitoring and reporting requirements, as do HWIs. As for the performance of these processes for the destruction of PFAS-impacted material, the high temperatures and residence times coupled with thermal oxidation could potentially destroy PFAS by breaking carbon-fluorine bonds; however, generation of PIDs is also possible (USEPA 2021).

PFAS desorption and destruction mechanisms and completeness through pyrolysis/gasification have not been well studied (Wallace et al. 2023). In one study, pyrolysis bench testing was performed on PFAS-impacted biosolids (Williams et al. 2021). In this study biosolids were treated in the absence of oxygen at temperatures of 500°C and 700°C. Pyrolysis resulted in the formation of biochar, bio-oil, and pyrogas. The feedstock for testing included 500 grams of 95% dry biosolids in which 20.09 µg of total PFAS were identified with perfluorooctane sulfonic acid (PFOS) and N-ethyl perfluorooctane sulfonamido acetic acid (EtFOSAA) as the dominant PFAS. After pyrolysis at 500°C, PFAS were still detected in the biochar and pyrogas. PFHxS, perfluorooctanoic acid (PFOA), PFHxA, and perfluoropentanoic acid (PFPeA) were found to dominate. However, after pyrolysis at 700°C, PFAS was detected only in the pyrogas, with PFNA, PFHxA, PFPeA, and PFOA predominating the weight percentage. Results from this bench test (Williams et

al. 2021) highlighted the potential for PFAS to concentrate or biotransform into the pyrogas after pyrolysis. Further, these results suggest that to achieve complete destruction of PFAS through pyrolysis, a temperature exceeding 700°C would be required. Additional factors such as residence time and the presence of catalyst, which could help lower the required temperature for PFAS destruction, can be additional factors in the performance of this technology. Additional testing is needed to evaluate the potential for short-chain PFAS byproducts in the resulting pyrogas.

Another project, conducted as a pilot study, by Thoma et al. (2022), used a commercial pyrolysis system to process biosolids to investigate the reduction of PFAS concentrations in the biochar that was produced. Samples from the biosolids were analyzed for 41 PFAS, resulting in 21 being detected (reported range of approximately 2 µg/kg–85 µg/kg). The samples from the biochar were below the detection limits. Air emissions were analyzed for some PFAS. Additional research is needed to understand the PICs and potential concentrations of PFAS that were not in the 41 analyzed.

In contrast to pyrolysis, gasification uses higher temperatures as discussed in **Section 1.6.1.1** and requires that some oxygen be present, though less as compared with incineration. Given the inherent higher temperatures, gasification is a promising technology for treating PFAS-contaminated material (for example, biosolids, wastewater sludge). Potentially, gasification could break down PFAS in waste but publications are extremely limited. Similar to pyrolysis, byproducts (for example, biochar and syngas) would need to be evaluated for PFAS composition as compared with the original material. Gases could require further treatment in a thermal oxidizer potentially outfitted with a scrubber to address potential hydrofluoric acid (HF) production. A benefit of gasification is the reduction of overall waste volume as the waste is converted to gas, leaving smaller volume residuals that could require landfill disposal. More research is needed to fully understand the potential PIDs with gasification.

Thermal Desorption

Thermal desorption is the removal of compounds from solids via the addition of heat followed by treatment of the gases and vapors and the reuse of the resulting solid material for construction and other purposes. This can be done in two modes, either at a permanent facility or more recently, via mobile equipment to treat impacted soil on site, either in situ or ex situ. Both have been effective for removal of many common contaminants, with a history of documented success treating petroleum hydrocarbons and chlorinated solvents. SERDP and ESTCP are funding a number of thermal desorption projects (for example, ER20-5198, ER20-5250, ER23-8369, and ER23-8378).

Thermal desorption has been demonstrated to address excavated PFAS-impacted soils. Results from a laboratory treatability study show that at temperatures of 350°C and 400°C, PFAS soil concentrations were reduced by 99.91% and 99.998%, respectively (Crownover et al. 2019; Heron et al 2021; Stallings et al. 2023). In situ application is also possible. A study from Beale Air Force Base, California, focused on an in situ thermal desorption approach for removing PFAS from vadose zone soil (NAVFAC 2024). Impacted soils with high PFAS concentrations and located in remote areas distant from fixed facilities for incineration or landfills would make this treatment approach attractive. This technology will require PFAS off-gas management. It can be combined with a scrubber to transfer the desorbed PFAS in vapors to the liquid condensate, which is a concentrated, low-volume solution. GAC can also be used as an off-gas management technique. Desorption providers continue to improve their designs and equipment to improve performance and control costs. See also **Section 12.7.2**.

1.6.1.3 Applicability

Based on thermal technologies described above, three areas are considered critical when evaluating thermal technologies for PFAS treatment. Considerations of these areas during treatment system design would reduce risks and result in the preferred outcome.

- Critical temperature—Individual PFAS are stable until exposed to a critical temperature unique to each. Above that temperature the effects are unique to each compound or group of compounds. Effects include PFAS desorption into vapors, pyrolysis/gasification (incomplete combustion to one or more fragments of the original compound), and complete destruction of all carbon-fluorine bonds.

- Treatment duration—While temperature is the primary treatment metric the duration of suitable and maintained temperatures determines how long the PFAS-containing materials are exposed to the temperature. The duration is critical to the completeness of destruction. Incomplete destruction can form unwanted PFAS intermediates or byproducts (PIDs).

- Confirmation of the treatment process—Elevated temperatures have differing effects on PFAS-impacted solids and liquids. Such effects can include, but are not limited to, evaporation of water, combustion of organic matter in solids, desorption of PFAS, transformation and incomplete destruction of PFAS, and possibly complete destruction of all individual PFAS. All solid, liquid, and gas residuals and emissions must be carefully monitored, contained, destroyed, and managed to eliminate impacts to the environment.

1.6.2 Supercritical Water Oxidation

This section focuses on supercritical water oxidation, including a description of the process, state of development, effectiveness, and sustainability considerations. Information in this section was prepared to supplement the information published in **Section 12** and **Table 12-1 Treatment Methods Table**.

1.6.2.1 Treatment Description

Supercritical water oxidation (SCWO) is a technology designed to destroy organic contaminants, including PFAS. SCWO operates above water's critical point (374°C, 22.1 MPa). SCWO systems typically function at 400°C—650°C and 22–28 MPa, achieving high destruction efficiencies for organic compounds. SCWO operates by using the unique properties of water at conditions above water's critical point, where phase boundaries are absent—neither fully liquid nor gas. This state exhibits enhanced solubility for organic compounds and oxygen, promoting rapid oxidation reactions and thus enhancing mass transfer. Water itself actively participates in hydrolysis reactions, further facilitating contaminant breakdown.

SCWO allows for the destruction of hazardous organic materials, including PFAS in both liquid and solid waste streams. SCWO is suitable for treating solids that can be effectively slurried or suspended in an aqueous solution. Solids such as soils, sediments, or other materials that are challenging to slurry or maintain in suspension are generally not appropriate feedstocks for SCWO systems. Oxygen, air, or hydrogen peroxide is introduced as the oxidizing agent, breaking down the carbon-fluorine bonds found in PFAS. SCWO enables the mineralization of PFAS into end products such as water, carbon dioxide, and salts. SCWO is not a new technology and has been evaluated and applied to various organic compounds in liquid streams for decades (Tester et al. 1993). With the appropriate reaction temperatures, pressures, and residence times, almost any organic pollutant can be destroyed by SCWO. More recently, with a focus on PFAS, bench- and pilot-scale systems have been evaluated (Jama et al. 2020; Hori et al. 2008; USEPA 2021; McDonough et al. 2022; Krause et al. 2022; Li et al. 2023).

When the supercritical point is reached, the rapid reaction time (2–10 seconds) allows for continuous processing and scalability while minimizing equipment footprint requirements (Krause et al. 2022). Typical residence times in SCWO reactors depend on reactor design, feed characteristics, and target contaminants. Monitoring of PFAS and non-PFAS parameters for reaction byproducts (for example, incompletely oxidized contaminants, HF, greenhouse gas or unreacted harmful oxidants) may be detected depending on the SCWO feedstock and operation processes.

1.6.2.2 Treatment Mechanism

Treatment of PFAS by SCWO is a destructive process that leverages the supercritical phase of water achieved by increasing temperature and pressure of a solution to a minimum of 374°C and 22 MPa, respectively, as shown in the conceptual diagram in **Figure 1-27**. In this phase, oxygen is fully soluble, resulting in rapid and complete oxidation of organics, transforming the feedstock into carbon dioxide (CO_2), water, and inorganic salts (Krause et al. 2022). In terms of PFAS treatment, SCWO results in the mineralization of both long- and short-chain PFAS, producing CO_2, water, and HF. HF production is typically mitigated using a neutralization dosing agent such as sodium hydroxide (NaOH) at the system effluent or elsewhere in the treatment system. Because this is an oxidative process, an oxidant source must be present in sufficient quantity to account for the total organic carbon content of the waste being processed. Typical oxidant sources for SCWO applications include air, pure oxygen, or hydrogen peroxide (H_2O_2). An advantage to PFAS treatment by SCWO is that any organic co-contaminants will also be destroyed during waste processing. Another distinguishing feature of the supercritical phase is that salts precipitate out of solution. Depending on the treatment technology, waste streams with high salt content may pose an issue for treatment by SCWO and require a salt separation pretreatment step.

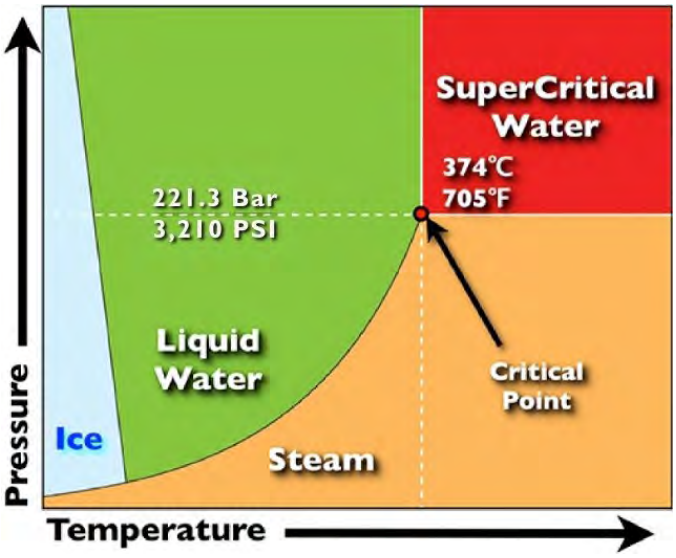

Figure 1-3. Conceptual water temperature-pressure phase diagram highlighting the supercritical region. Value for the pressure (in bar) was corrected to 221.3.

1.6.2.3 State of Development

SCWO technology has been developed and commercialized since the 1990s and thus has not been considered a new technology. However, its application for PFAS destruction is considered more recent and has shown promising results. For example, Sahle-Demessie et al. (2022) tested SCWO through partnership agreement with technical providers to verify PFAS destruction within AFFF. The same study showed that in all USEPA-Office of Research and Development tests, PFAS and total organic carbon destruction efficiencies were greater than 99.99%. PFAS target compounds were not detected above the background level in the gas analyses.

McDonough et al. (2022) adopted OTM 45 for stack sampling in a field trial to destroy PFAS in diluted AFFF. The study suggests greater than 99.999% destruction and removal efficiency of 12 perfluoroalkyl acids (PFAAs) after two ~120-min continuous flow trials with overall defluorination of ~62.6%. Various

bench-scale SCWO studies for PFAS destruction in aqueous matrixes were also documented (Scheitlin et al. 2023) with 5-log (99.999%) reduction in concentrations.

Chiang et al. (2023) tested the PFAS destruction in one spent granular activated carbon (GAC) sample and two spent anion exchange resin (AER) samples. AERs are a specific type of resins used for ion exchange (IX). See **Section 12.2.1.1** for more information about GAC and **Section 12.2.1.2** for more information about IX. The study revealed effective PFAS destruction and the decomposition of GAC and AER in a field-scale SCWO treatment system, leaving no solid wastes requiring further management. This study suggests the potential of SCWO to treat solid wastes, although more studies on feedstock characterizations and PFAS mass balance are needed. The readiness of SCWO systems for full-scale PFAS destruction can vary by technology provider but are generally more mature for destruction of liquid concentrates, particularly diluted AFFF. The scale-up SCWO system has been chosen by state agencies as part of their AFFF take-back programs to destroy AFFF. Several states are actively addressing AFFF, and specifically the transition of AFFF to F3. Many more states have initiated take-back programs or intend to initiate take-back programs.

In 2023, ESTCP partnered with the Defense Innovation Unit to demonstrate SCWO technology, among other treatment methods, for destruction of PFAS in multiple media. Cost and performance results of these demonstrations are forthcoming (USDOD 2023). More information about analytical methods is included in **Section 11.2** and **Section 1.5**.

1.6.2.4 Effectiveness

The broad effectiveness of variations of SCWO to destroy various groups of PFAS is well established in the literature (Hori et al. 2008; Hori et al. 2012; Hori et al. 2015; Jama et al. 2020; Pinkard et al. 2021; USEPA 2021; Krause et al. 2022; Li et al. 2022; McDonough et al. 2022; Sahle-Demessie et al. 2022; Austin et al. 2023; Chiang et al. 2023; Li et al. 2023; Scheitlin et al., 2023). The completeness of this defluorination (mineralization) has been verified to the extent practicable using commercially available analytical and sampling tools. The liquid effluent from SCWO demonstration studies in the literature and industry consistently achieves decreases to near or below relevant detection limits for those PFAAs typically reported (Li et al. 2022; McDonough et al. 2022; Sahle-Demessie et al. 2022; Austin et al., 2023; Chiang et al. 2023; Li et al. 2023; Scheitlin et al. 2023). Numerous gaseous sampling and analytical technologies have been used to verify the completeness of PFAS mineralization using SCWO, with satisfactory results (Hori et al. 2008; Li et al. 2022; McDonough et al. 2022; Sahle-Demessie et al. 2022; Chiang et al. 2023; Li et al. 2023; Scheitlin et al. 2023), however PFAS analysis in air samples continues to evolve. More data would be needed to confirm no breakthrough of PFAS in the air effluent stream. Extremely low detections of PFAAs reported based on gaseous sampling techniques are likely related to ambient PFAS within cooling/neutralization water (McDonough et al. 2022; Sahle-Demessie et al. 2022) or associated with the sampling apparatus itself. Four to six orders of magnitude reduction in less than 30 seconds for liquid, gaseous, or both effluent streams is a consistent result when using SCWO to destroy PFAS (Krause et al. 2022; Li et al. 2022; McDonough et al. 2022; Sahle-Demessie et al. 2022; Austin et al. 2023; Li et al. 2023; Scheitlin et al. 2023).

Many effectiveness demonstrations of SCWO include most of the typical list of PFAAs (that is, C4 to C14 PFCAs and C4 to C10 PFSAs). The application of SCWO to mineralize trifluoroacetate (TFA) has also been recently observed (Li et al. 2023), suggesting that SCWO (when operated ~650°C) is likely applicable to ultrashort PFAS (<C4) as well. More studies investigating the fate of ultrashorts in gaseous and liquid effluents from SCWO reactors are needed. In keeping with various PFAS destruction technology verification studies, fluorine mass balances have been attempted with confirmed defluorination ratios of ~36% to 100% (Hori et al. 2008; Hori et al. 2012; Hori et al. 2015; Pinkard et al. 2021; Krause et al. 2022; Li et al. 2022; McDonough et al. 2022; Sahle-Demessie et al. 2022; Austin et al. 2023; Li et al. 2023; Scheitlin et al. 2023). The range of defluorination percentages versus consistent complete fluorine mass balances has been hypothesized to include partially defluorinated volatile

species (Hori et al. 2008; Austin et al. 2023; Li et al. 2023), variable operating conditions, and unquantified inorganic fluoride within the steam effluent (McDonough et al. 2022).

The complexity of a waste stream has less influence on the effectiveness of SCWO to destroy PFAS than some other PFAS-relevant destruction technologies. As SCWO has been historically validated for the destruction of organic constituents, optimized concentrations of organic constituents may enable autogenic operation where the influent organics can sustain the necessary reaction temperature. This can offset energy demands in achieving supercritical conditions (Tester et al. 1993; Hong and Spritzer 2002; Yesodharan 2002; General Atomics 2005; Marrone 2013; Adar et al. 2019; Wang et al. 2019; USEPA 2021; Wei et al. 2021; Krause et al. 2022). The presence of inorganic constituents in high concentrations may necessitate the management of precipitated solids, corrosion, and scaling, though innovations in the technology over time have found relevant management solutions (Tester et al. 1993; Kritzer and Dinjus 2001; Yesodharan 2002; Marrone et al. 2004; Marrone 2013; Adar et al. 2019). Because inorganic constituents are not applicable to SCWO and separate from the fluid prior to discharge, common deleterious air emissions (for example, nitrogen and sulfur oxides) are not concerns with SCWO (Tester et al. 1993; Pinkard et al. 2021).

Although the effectiveness of SCWO to achieve mineralization of a broad range of PFAS is established, its current applicability is best suited to smaller volumes of high PFAS concentrations. The comparatively rapid residence time for SCWO is attractive for a continuous flow application (Tester et al. 1993; Krause et al. 2022; Austin et al. 2023; Li et al. 2023); however, the capital cost and equipment footprint to construct SCWO reactors capable of achieving 10s of gallons per minute may be infeasible in many scenarios (Tester et al. 1993; Kritzer and Dinjus 2001; Marrone 2013; Adar et al. 2019). The SCWO technology is insensitive to the initial PFAS concentration; however, there is a considerable energy demand to initiate supercritical conditions and pretreatment strategies to concentrate PFAS will improve the energy per mass effectiveness (Jama et al. 2020; Li et al. 2022; McDonough et al. 2024). Importantly, pretreatment of a waste stream to increase the PFAS concentration factor will also concentrate inorganic constituents that may challenge the efficiency/effectiveness of SCWO and require corrosion and scaling management (Tester et al. 1993; Kritzer and Dinjus 2001; Marrone et al. 2004; Li et al. 2022; Chiang et al. 2023).

1.6.2.5 Design/Operating Considerations

SCWO presents a viable solution for treating many PFAS-contaminated waste streams. Operating above water's critical point (374°C, 22.1 MPa), SCWO systems typically function at 400°C–650°C and 22–28 MPa, achieving high destruction efficiencies for organic compounds. Prior to treatment, a comprehensive waste stream assessment is crucial. Key parameters to evaluate typically include PFAS concentration, total organic carbon, chemical oxygen demand, TOF, organohalide content, pH, conductivity, total dissolved and suspended solids, and metals. PFAS speciation may be useful for regulatory or reporting purposes but is not typically necessary for SCWO system operation. Operational considerations include feed and oxidant flow rates, reactor temperature, system pressure, residence time, and post-SCWO effluent stream management (air, condensate, effluent and mineral residuals). Safety assessments should address corrosivity, material compatibility, and potential for fouling or hazardous gas formation. SCWO facilities require significant electrical power, water supply, and oxidant sources (typically pure oxygen, air, or hydrogen peroxide). Ambient temperature should be noted as a key operating consideration for SCWO, as systems installed outdoors in cold climates may require supplemental heating to maintain operational stability (similar to other systems installed outdoors); additionally, SCWO relies on highly specialized equipment and skilled personnel, which can impact site readiness and deployment planning. Permitting for SCWO operations involves navigating complex environmental, local, state, and federal regulations, including specific PFAS-related requirements, safety protocols, and waste management standards. SCWO may be viewed favorably in the permitting process, as verified analytical results from both liquid and vapor effluent streams provide greater transparency to regulatory permitting

agencies. Early engagement with regulatory agencies is essential to ensure compliance with all applicable permits and operational guidelines.

1.6.2.6 Sustainability Considerations for Supercritical Water Oxidation

Considerations for SCWO technology sustainability metrics may be aligned with the fundamental principles of environmental, societal, and economic interrelated factors. As noted in **Section 12.9**, Sustainability of PFAS Treatment, best management practices for SCWO may incorporate life cycle analysis (LCA) for materials destruction. A key consideration is the need for a pre-SCWO volume reduction step, such as concentration (for example, foam fractionation, reverse osmosis, evaporation), because SCWO systems are best suited for treating lower volumes of high-concentration PFAS waste streams rather than large volumes of dilute PFAS waste. Few SCWO units are available on the commercial market at this time, and therefore, materials may need to be transported significant distances to be managed with SCWO.

Examples of SCWO LCA facets may include:

- whether SCWO is performed on-site or waste is transported off-site for treatment or concentration affects environmental impacts such as carbon and greenhouse gas emissions
- whether the number of required samples before, during, and after treatment, and carbon footprint for the sample analysis at a remote laboratory, affect environmental impacts such as carbon and greenhouse gas emissions
- whether the permitted SCWO facility is located in a disproportionately disadvantaged community and is treated as a societal impact
- whether the cost per unit volume in energy consumption, sample analysis, and the going market rates are project- and community-viable

SCWO unit permitting requirements may vary by state. Those located in states where complete or nearly complete destruction is required prior to any residuals disposal may be weighted preferentially over those SCWO units located in states with less rigorous permitting standards. This consideration may allow for greater confidence in ending the PFAS waste cycle.

Sustainability balancing factors may include how complete or full destruction is defined by the regulating authority for a given material type and composition. This may dictate the degree to which these sustainability factors, including environmental compliance with liquid and vapor effluent regulatory requirements, are valued and weighted by project stakeholders.

1.6.3 Investigation-derived Waste

This section describes some of the key factors affecting the management of PFAS-impacted investigation-derived waste (IDW), with an emphasis on portable and field-adaptable technologies suitable for handling heterogeneous waste streams generated during site investigations. It includes the current state of practice regarding this topic and recent research efforts. Information in this section was prepared to supplement the information published in **Section 12** and **Table 12-1 Treatment Methods Table**. This section focuses on field-relevant strategies, that are modular, portable, or scalable that address the logistic constraints and episodic nature of PFAS-impacted IDW. Given the accelerating pace of PFAS site investigations and the associated accumulation of IDW, the development of sustainable on-site PFAS management strategies has become a priority.

Prior to any remediation activities, to identify PFAS-impacted source zones and optimize management strategies, comprehensive site investigations need to be conducted. These investigations, however, have introduced a secondary challenge: the management of IDW (Yanagida et al. 2022).

The majority of IDW generated during well development, installation, and sampling at PFAS-impacted sites comprises purged groundwater, equipment decontamination residues, soil, drill cuttings, and debris from the removal of asphalt and concrete (Vatankhah et al. 2023). This generated waste frequently contains varying concentrations of PFAS alongside other co-occurring organic and inorganic contaminants. Current IDW management practices primarily involve transportation to waste landfills or incineration facilities. However, these methods are both costly and too limited to fully address the long-term environmental liabilities posed by PFAS-contaminated waste (Singh et al. 2019).

Additionally, at many large PFAS-impacted sites, ex situ remediation of impacted water matrixes, through sequestration techniques such as sorption-based processes and high-pressure membrane systems, often begins concurrently with ongoing site investigations (Murray et al. 2023). This introduces an additional challenge, as the accumulation of exhausted media and membrane reject streams exacerbate the existing difficulties associated with IDW generation.

With respect to remediation efforts, numerous advanced sequestration technologies have been implemented for capture and removal of PFAS from IDW streams and impacted soil. Although soil washing is common in large-scale remediation, it is generally not practical for IDW due to the limited and variable waste volumes. For solid IDW, thermal desorption using roll-off boxes or covered soil piles may offer a more feasible alternative (Lei et al. 2023). Some of the most established sequestration technologies include GAC (Murray et al. 2021; Appleman et al. 2014; Yu et al. 2009; Carter et al. 2010), IX (Franke et al. 2019; Franke et al. 2021; Boyer et al. 2021; Tajdini et al. 2023), high-pressure membranes (that is, nanofiltration), (NF), and reverse osmosis (RO)) (Liu and Sun 2021; Liu, Strathmann, and Bellona 2021). See **Section 12.2.2.1** for more information about NF and **Section 12.2.2.2** for more information about RO. Despite the effectiveness of these technologies for separation and removal of PFAS, they serve only as interim treatment actions involving physical mass transfer. For aqueous IDW, integration into existing on-site PFAS treatment systems such as modular GAC or IX units can provide an efficient management route. Alternatively, discharge to municipal facilities with PFAS treatment capabilities may be appropriate where allowed.

To effectively mitigate the long-term risk of recontamination from IDW, PFAS-laden sorbents, and membrane reject streams, it is imperative to evaluate both on-site and off-site end-of-life disposal technologies that achieve complete mineralization of PFAS. Depending on the quantity of the IDW, while on-site approaches reduce transportation and handling, off-site options may be more cost-effective depending on local infrastructure and waste volume. Eliminating the long-term risks associated with impacted IDW requires technologies that ensure complete defluorination, as degradation or partial defluorination may result in formation of more recalcitrant byproducts, also known as PIDs (for example, volatile PFAS, unsaturated PFAS, PFCAs, -F/+X-substituted PFAS) with elevated risks of bioaccumulation (Evich et al. 2022).

In recent years, a series of focused research efforts has been initiated and led by SERDP to develop and investigate a series of innovative end-of-life disposal technologies capable of complete mineralization of all PFAS in IDW (Vatankhah et al. 2023). SERDP and ESTCP projects for field-scale evaluations of PFAS-impacted IDW include ESTCP project ER19-1403, which examined UV/TiO_2-activated alkaline treatment for concentrated liquid residuals, and ER21-7591, which tested hydrothermal alkaline treatment (HALT) technology in a field deployment.

To better understand the end-of-life technologies during the management of IDW, it is important to assess PFAS destruction by evaluating the extent of PFAS degradation and defluorination as represented in Equations 1 and 2, where $[F^-]$ corresponds to fluoride ions, N_F is the quantity of fluorine atoms, $[PFAS]_0$

is the initial concentration of PFAS, and $[PFAS]_{degraded}$ is the concentration of degraded PFAS (Banayan Esfahani et al. 2022).

Defluorination efficiency (%) = $F^{-}/([PFAS]_0 \times N_F) \times 100$	(1)
Degradation efficiency (%) = $[PFAS]_{degraded}/[PFAS]_0 \times 100$	(2)

These metrics apply specifically to destructive technologies designed to achieve mineralization of PFAS in concentrated IDW streams. Although such calculations can be valuable for benchmarking performance, they are not applicable to nondestructive technologies such as GAC, IX, or membrane processes. In those cases, PFAS are removed by separation or sequestration, not destruction, and mass balance calculations may be misleading.

Additionally, attempts to evaluate fluorine mass balance in complex treatment systems must consider the transformation of precursors between treatment stages. For example, PFAS precursors may convert to terminal PFAS during biological or chemical processes that precede final treatment. If sampling is limited to inlet and outlet points, this transformation can lead to under- or overestimation of PFAS removal. Given these complexities, mass balance should not be viewed as a stand-alone indicator of technology performance. To avoid misinterpretation, technology decision makers are encouraged to consider guidance from the USEPA's PFAS Treatment Efficacy Framework (TEF) (USEPA 2024) and assess technology readiness using established technology readiness levels (TRL) criteria (USDOD 2025).

For performance evaluation, standardized parameters must be established for both sequestration (for example, membrane recovery rate, media usage rate, adsorption capacity at various breakthrough levels) and destructive technologies (for example, defluorination efficiency, fluorine mass balance to determine the extent of mineralization). Analytical and process-related interferences often pose challenges in establishing a reliable fluorine balance, particularly during early development stages. Nonetheless, achieving a conclusive fluorine balance is a key performance metric linked to a technology's commercial readiness (Leeson et al. 2021).

Critical factors in economic assessments include the type of PFAS-impacted matrix (for example, groundwater, surface water, soil) and matrix characteristics (for example, total organic carbon, total dissolved solids, total suspended solids), as well as PFAS influent and target effluent concentrations. Additionally, standardized performance data, such as cost per cubic meter of treated effluent at normalized concentrations, chemical usage rates, and pH levels, must be quantified to accurately estimate capital and operational expenditures.

Integrating nondestructive and destructive treatment technologies is emerging as a promising approach for managing PFAS-impacted IDW, offering potential improvements in energy efficiency and cost-effectiveness. A crucial factor in this integration is the compatibility of certain destructive technologies (for example, sonication, oxidation-reduction methods) with the initial PFAS concentrations. Employing nondestructive technologies, such as high-pressure membranes, to concentrate the feed can enhance the performance of subsequent destruction techniques. However, accurate assessments are necessary to determine the optimal feed concentration for these destructive technologies. This aspect will ultimately dictate the operating conditions of sequestration technologies (for example, membrane recovery and concentration factors), directly impacting energy and cost efficiency (Vatankhah et al. 2023).

1.6.4 Treatment of Sediment

This section focuses on the treatment of PFAS-contaminated sediment. Information in this section was prepared to supplement the information published in **Section 12.3** and **Section 12.7**.

Sediments are impacted by PFAS through both groundwater to surface water interaction (**Section 5.1.3**) and where impacted stormwater or surface water is in contact with sediments. PFAS impacts sediments through both hydrophobic partitioning to organic carbon and electrostatic interactions between charged surfaces. These processes can affect the transfer of PFAS between surface water and sediment. Varying degrees of retention on sediments can contribute to differential transport where certain PFAS (for example, short-chain, anionic) are more rapidly transported than others.

Little information is available regarding regulations or guidance for the treatment of PFAS in sediments, but it is known that PFAS in sediments can impact the benthic community and bioaccumulation can take place, thereby impacting uptake in higher trophic species such as fish (for example, Conder et al. 2008; Pulster et al. 2022).

Contamination in sediments can be addressed either in situ, meaning where they lay (without removal), or ex situ, which typically involves dredging or excavation of impacted sediments in some form. Typically, in situ methods are less invasive and have less impact on habitat or the benthic community. Ex situ methods are typically more expensive and remove the existing benthic community. Generally, contaminated sediment remediation is complex and requires unique permitting requirements, particularly if it is being carried out in navigational areas. With regard to in situ treatment technologies, existing sediment remediation techniques are available that have been demonstrated to successfully deliver adsorptive materials to the sediments (for example, powder-activated carbon). Many of these adsorptive materials are the same as those being applied for immobilization of PFAS in soil (see **Table 12-1 Treatment Methods Table** Excel File). Sediments can also be removed and treated ex situ using methods such as soil washing. Other conventional methods for ex situ management of contaminated sediment include transporting impacted sediment to a landfill. ITRC provides other guidance (ITRC 2014) on a range of methods for managing or remediating contaminated sediment.

1.6.5 Treatment of Biosolids

This section focuses on the treatment of PFAS-contaminated sewage sludge and biosolids. It includes incineration, landfill disposal, sorption and stabilization, pyrolysis/gasification, supercritical water oxidation, hydrothermal liquefaction, and biological treatment. Additional information about Biosolids is included in **Section 1.7**.

The terms “sewage sludge” and “biosolids” are often used interchangeably. However, the USEPA provides a technical distinction between the two. Typically, the USEPA uses the term “biosolids” to refer to sewage sludge that has undergone sufficient treatment (for example, pathogen and vector attraction reduction) to meet the requirements outlined in 40 CFR Part 503—Standards for the Use and Disposal of Sewage Sludge and is intended for land application as a soil conditioner or fertilizer. “Sewage sludge” is generally reserved for untreated municipal wastewater residual that has a high solids content and may have undergone dewatering to increase the relative solids content and reduce residual volume. In common conventional wastewater treatment, large objects and readily settleable solids (primarily inorganic) are removed during the initial screening and grit removal stages. The materials removed during screening and grit removal are typically managed separately and do not become part of the “sewage sludge” residual. In general, “sewage sludge” consists of solids removed during primary settling (primary sludge) and solids removed during biologically mediated treatment processes that may include higher proportions of cell mass (that is, secondary sludge). Sewage sludge that then undergoes treatment for land application, often with the intended beneficial use as a fertilizer, is referred to as “biosolids.”

Managing PFAS impacts to sewage sludge and biosolids is an active area of focus for state and federal regulatory agencies. Multiple states have proposed regulatory frameworks for managing the land application of biosolids, and on January 14, 2025, the USEPA released the Draft Sewage Sludge Risk Assessment for PFOA and PFOS (USEPA 2025). A more detailed discussion of the regulatory landscape and other factors related to PFAS-impacted biosolids is included in **Section 1.7**.

This section focuses on the treatment alternatives that may be considered to address PFAS impacts to sewage sludge, or biosolids, or both. Conventional sewage sludge or biosolids treatment methods are widely considered ineffective in removing PFAS (Rahman et al. 2025). Specifically, the treatment technologies presented below are considered in the context of the USEPA definition of "sewage sludge," specifying the treatment of domestic wastewater (which may include contributions from industrial sources) at publicly or privately owned treatment works. This section is not intended to address sludges derived from privately owned industrial wastewater treatment works; however, some of the treatment technologies may be applicable. An effort was made to limit the discussion of treatment technologies to those that are already widely applied for sewage sludge or biosolids management or those identified by the authors as showing promise for PFAS treatment effectiveness. The list of treatment alternatives included in this section is not comprehensive (see the **ITRC disclaimer**).

Depending on the nature of the domestic wastewater treatment facility, there may be numerous sources of PFAS (for example, residential, commercial, industrial, groundwater intrusion) that contribute to PFAS loading. PFAS entering the wastewater treatment facility may be associated with solid-phase components or aqueous-phase components (dissolved) of the raw wastewater. PFAS can accumulate in biosolids via settling processes or the phase partitions processes described in **Section 5.2**.

Initially, sewage sludge and biosolids collected as a wastewater treatment residual contain a high relative water content and are often dewatered prior to final disposition. Some of the sewage sludge and biosolids treatment alternatives described below require the biosolids to be flowable, therefore a higher water content may be favorable, while others benefit from lower water content. This section does not separately address the treatment of the liquid-phase residual associated with sewage sludge and biosolids dewatering. See **Section 12.2** and **Section 12.6** for discussion of liquid-phase treatment alternatives.

This section focuses on describing sewage sludge and biosolids treatment alternatives for PFAS, serving as an extension of **Section 12.1.4.3**, and has been prepared to provide a treatment-focused discussion to supplement **Section 1.7**. Biosolids and sewage sludge treatment alternatives described below are categorized as either field-implemented or limited application and developing technologies in accordance with the framework defined in **Section 12**.

1.6.5.1 Field-implemented Biosolids Treatment Technologies

Incineration

Sewage sludge or biosolids incineration can take multiple forms in the context of PFAS treatment. Broadly, there are two applications of incineration that may be relevant to sewage sludge or biosolids PFAS treatment. First is the application of permitted sewage sludge incinerators (SSIs) historically designed and operated to serve as a terminal disposal alternative for sewage sludge or biosolids, without consideration for PFAS. Second is the application of high-temperature incineration at a permitted Resource Conservation and Recovery Act Subtitle C hazardous waste combustor, designed and operated as a terminal disposal option for hazardous wastes. In general, the application of incineration processes has demonstrated some degree of success in PFAS destruction. However, the degree to which PFAS are completely mineralized is highly dependent on the specific application (Weitz et al. 2024). Both SSI and high-temperature incineration are discussed separately below.

For additional information and resources regarding incineration, see **Section 12.4** and **Section 1.6.1**.

Sewage Sludge Incinerators (SSIs)

Biosolids incineration via permitted SSIs is a common biosolids management approach. In 2023, USEPA estimated that approximately 14% of biosolids were disposed of through incineration (USEPA 2025)

Operation and associated air emissions of SSIs are regulated by Section 129 of the Clean Air Act, titled "Solid Waste Combustion;" however, current emissions standards do not consider PFAS (USEPA 2024). Additionally, SSI air emissions are regulated under 40 CFR Part 503 Standards for the Use or Disposal of Sewage Sludge, Subpart E—Incineration, but current emissions standards do not consider PFAS.

Two common types of SSIs include multiple hearth furnaces and fluidized bed furnaces, with typical operating temperatures of approximately 300°C–500°C and 700°C–800°C, respectively (USEPA 2003; Winchell et al. 2021). Recent studies have evaluated the fate and transport of PFAS in SSIs and concluded that typical SSI implementations have variable PFAS destruction efficiencies (Seay et al. 2023; Winchell et al. 2024). Researchers have determined that additional work is necessary to better understand how the optimization of SSI processes or the implementation of additional treatment(s) (for example, thermal oxidizer) could increase SSI PFAS treatment efficiency. Thermal oxidizers are common air pollution control devices that are routinely added to thermal treatment processes to treat a wide range of organic contaminants that may be present in process air emissions. Thermal oxidizers rely on high temperature combustion processes and residence time to mineralize organic contaminants present in gas phase emissions. Through integration of energy recovery, operation of thermal oxidizers has become increasingly efficient (95-99% efficiency). Thermal oxidizers with integrated energy recovery as often referred to as regenerative thermal oxidizers (USEPA 2003).

High-temperature Incineration

High-temperature incineration at a permitted Resource Conservation and Recovery Act Subtitle C hazardous waste combustor is an established disposal alternative for a variety of PFAS-impacted wastes, spanning a wide range of physical properties (for example, liquids and solids). In addition to several other operating factors, high-temperature incineration is characterized by operating temperatures greater than 1,000°C. However, uncertainty remains regarding the ultimate fate of PFAS during permitted hazardous waste combustor high-temperature incineration processes. See **Section 12.4** and **Section 1.6.1**.

Landfill Disposal

Landfills remain a common method for disposing of sewage sludge and biosolids. In 2023, approximately 24% of the biosolids generated by POTWs in the United States was disposed of in landfills (USEPA 2025). Tolaymat et al. (2023) estimated that landfilling of biosolids contributes approximately 850 kg of PFAS mass to municipal solid waste landfills annually, approximately 11% of the 7,480 kg of extractable PFAS mass estimated to have entered municipal solid waste landfills in 2018. Due to widespread concerns about PFAS levels in biosolids, some states have begun placing limitations or bans on the use of land application as a disposal option for biosolids. For example, the State of Maine banned land application of biosolids through a bill passed by the Maine legislature in 2022. This ban resulted in 90% of the biosolids generated in the state being received by a single landfill (Brown and Caldwell 2023). Other states, primarily through the regulatory rulemaking process, have developed thresholds for PFAS levels that may limit land application options and acknowledge that such thresholds may result in additional demand for landfill disposal of biosolids (MPCA 2025). If the use of landfills for biosolids disposal increases due to limitations on other disposal options, demand may outstrip capacity for biosolids disposal in landfills in many areas, thus increasing the need for other biosolids disposal or treatment options.

Sorption and Stabilization

Sorption and stabilization is a nondestructive PFAS immobilization approach that relies on the addition of amendments to reduce the mobility of PFAS and its ability to leach from the biosolids or biosolids-amended soil into other environmental compartments (for example, groundwater, surface water, biota). Sorption and stabilization may be applied in situ to address impacts associated with historical land application of PFAS-impacted biosolids. For additional information regarding sorption and stabilization applications for PFAS-impacted solids, see **Section 12.3.1**.

The ability of sorption and stabilization amendments to effectively immobilize PFAS and the resulting impact on agricultural productivity are active areas of research. Recent studies have focused on biochar as a promising carbon-based soil amendment at PFAS-impacted biosolids land application sites (Sanchez-Hernandez et al. 2024). Compared to activated carbon, the effects of biochar on agricultural soil conditions are relatively well studied. Studies have demonstrated the ability of biochar derived from various feedstocks to sorb PFAS; however, the impact of soil conditions and other environmental factors on sorption capacity and sorption longevity are a focus area for future research (Sanchez-Hernandez et al. 2024).

Holly et al. (2024) evaluated PFAS leaching from land-applied biosolids and the effects on leaching from amending biosolids with biochar. The soil samples were collected from various sites and included silt loam, silt clay loam, sandy loam, and sandy clay loam soil types. Column leaching tests were performed on soil only, soil that had received biosolids, and soils with biosolids and amended with biochar; columns were treated weekly with simulated precipitation over a six-month period. The authors found that leachate from all treatments contained measurable PFAS concentrations (23 of 28 analytes), and the PFAS replacements 6:2 FTS and HFPO-DA were found in leachate although not in initial/untreated samples of either soil or biosolids. The authors indicated that water-holding capacity and organic carbon content of soils influenced leaching potential, and that biochar amendments reduced leaching potential of PFAS; however, this impact was highest for long-chain PFAS, whereas it had only limited impact for the short-chain (<C7) PFAS, with exceptions including PFBS, PFHxA, and PFHxS.

1.6.5.2 Limited Application and Developing Biosolids Treatment Technologies

Pyrolysis/Gasification

Pyrolysis and gasification are thermal decomposition processes that are being evaluated for the ability to destroy PFAS in impacted sewage sludge and biosolids (Garg et al. 2023). Historically, pyrolysis and gasification have been applied on organic-rich waste products with the goal of resource recovery. In general, the pyrolysis and gasification processes running on biosolids feedstock can recover resources in the solid (for example, biochar), liquid (for example, bio-oil), and gas (for example, syngas) phases that may undergo additional refinement for beneficial use. The balance of the resource phases varies between the process and operating conditions. In general, pyrolysis tends to produce more abundant liquid- and solid-phase resources and gasification produces more abundant gas-phase resources (Thoma et al. 2022; Winchell et al. 2022). The fate and transport of PFAS under varying pyrolysis and gasification process operating conditions remain an active area of research (McNamara et al. 2023).

Pyrolysis and gasification units can operate under varying conditions—typically operating at temperature ranges between 300°C and 800°C and 800°C and 1,000°C, respectively (Winchell et al. 2022). Another key distinction between pyrolysis and gasification is the amount of oxygen introduced into the reaction chamber; pyrolysis occurs in the absence or near absence of oxygen, while gasification occurs with an oxygen content less than the stoichiometric minimum for complete combustion (Winchell et al. 2022). For additional information and resources regarding the treatment mechanisms and operation of pyrolysis and gasification systems, see **Section 12.7.2** and **Section 1.6.1**.

Commercial-scale pyrolysis treatment systems for PFAS-impacted sewage sludge or biosolids are not widely implemented in the United States. Winchell et al. (2022) identified one full-scale pyrolysis and one full-scale gasification unit operating in the United States on biosolid feedstock with several additional facilities in design or under construction. Several bench-scale and pilot-scale studies have shown promise that pyrolysis can be used to reduce PFAS concentrations in biosolids, while retaining land application benefits of the biosolids as a biochar product.

Bamdad et al. (2022) completed a bench-scale pyrolysis study that documented the fate of 29 target PFAS. They observed a reduction of quantifiable PFAS in the solid biochar product stream by 97–100

wt% at a processing temperature of 500°C, and by 99.6–100 wt% at a processing temperature of 700°C. Thoma et al. (2022) completed a pyrolysis pilot study of PFAS-impacted biosolids. See **Section 1.6.1.2** for more information.

Winchell et al. (2024) evaluated the fate of biosolids-bound PFAS through a bench-scale pyrolysis unit (operating temperature of 600°C) coupled with a thermal oxidizer (operating temperature of 1,000°C) for air emissions control. Winchell et al. (2024) documented between 91.5% and greater than 99.9% reduction of targeted PFAS through the coupled pyrolysis and thermal oxidizer bench-scale system. On a molar basis, the researchers calculated removal of 99.4% of the total quantified PFAS through the system. Additionally, the researchers sampled the thermal oxidizer exhaust gas and analyzed for targeted PFAS by USEPA OTM-45. Winchell et al. (2024) noted that short-chain PFAS predominated quantifiable PFAS in the thermal oxidizer exhaust gas, ranging between 54.4% and 79.5% of the PFAS moles measured in the exhaust gas. Winchell et al. (2024) identified the need for additional research regarding the fate of PFAS in thermal oxidizer systems.

Supercritical Water Oxidation

Supercritical water oxidation (SCWO) is a destructive technology that uses unique properties of water above its critical point at 374°C and 22 MPa and the addition of an oxidizing agent (for example, air, oxygen, hydrogen peroxide) to generate a highly reactive environment. Although the exact mechanisms of PFAS destruction under SCWO conditions are not well understood, well operated SCWO systems have exhibited high rates (greater than 99.9%) of PFAS mineralization across various PFAS-impacted media (Scheitlin et al. 2023; Chiang et al. 2023). For additional information and resources regarding the treatment mechanisms and operation of SCWO systems, see **Section 12.6.3.12** and **Section 1.6.3**.

In the context of sewage sludge or biosolids treatment, SCWO is being evaluated as a destructive technology. The availability of published literature is limited regarding the application of SCWO to effectively manage PFAS-impacted sewage sludge or biosolids. However, technology developers and municipal wastewater treatment facilities (for example, Orange County California; Orlando, Florida) are actively partnering to conduct pilot testing (Orange County Sanitation District 2022; USEPA 2024). Several studies suggest the viability of SCWO as a destructive technology for PFAS-impacted biosolids based on the documented success of SCWO in mineralizing PFAS and other refractory organic contaminants in a wide range of PFAS-impacted matrixes (Chiang et al. 2023; Berg et al. 2022; Garg et al. 2023).

Effective treatment of PFAS-impacted sewage sludge or biosolids via SCWO relies on the flowability of the material. Additionally, SCWO treatment of sewage sludge biosolids is subject to similar considerations pertaining to more mature applications of SCWO, including effective pretreatment to limit scaling in the reactor and management of reactor materials against the highly reactive SCWO environment. The ultimate fate of PFAS in SCWO reactors is an active area of study, with increased focus on gaseous-phase emissions from SCWO reactors. Furthermore, the scalability of SCWO applications for full-scale biosolids management is uncertain and is the focus of additional research.

Hydrothermal Alkaline Treatment

Hydrothermal alkaline treatment (HALT) is a hydrothermal process that relies on a high-temperature, high-pressure, and high-pH (alkaline) environment to promote PFAS destruction. Diverging from SCWO, the HALT approach occurs below the critical point of water, typically around 350°C and 16.5 MPa in alkali-amended solutions (e.g., 1–5 M sodium hydroxide) (Wu et al. 2019; Hao et al. 2021). HALT reactors have demonstrated the ability to destroy a wide range of PFAS, achieving greater than 99% destruction in a continuous flow system treating AFFF-impacted fire training pit water (Pinkard et al. 2023). For additional information and resources regarding the treatment mechanisms and operation of HALT systems, see **Section 12.6.5**.

The availability of published literature is limited regarding the application of HALT to destroy PFAS in biosolids. A Water Research Foundation project is evaluating HALT technology in the context of treating PFAS-impacted biosolids (Gao 2025). Effective treatment of PFAS-impacted biosolids via HALT relies on the flowability of the biosolids material. Additionally, the scalability of HALT applications for full-scale biosolids management and potential high chemical demands (for example, alkali) is uncertain and is the focus of ongoing research.

Hydrothermal Liquefaction

Hydrothermal liquefaction (HTL) is a high-temperature, high-pressure process for converting biomass into biofuel. HTL relies on the water content of the biomass to enter a subcritical or supercritical state, depending on the reactor conditions. Water under these conditions creates a highly reactive environment, able to depolymerize macromolecules present in the biomass and convert them to smaller, hydrocarbon-like compounds that can be further refined into liquid fuel products (Toor, Rosendahl, and Rudolf 2011). Based on the elevated water content of biosolids, HTL has garnered interest for its potential to create biofuels from biosolids.

Recently, researchers have started to focus on evaluating the HTL process for its ability to mineralize PFAS present in biosolids and other sources of biomass. Based on preliminary findings, HTL has demonstrated the ability to mineralize PFAS, including refractory PFAAs; however, the extent of PFAS mineralization varies between compounds (Yu et al. 2020; Zhang et al. 2020). In a bench-scale study, Yu et al. (2020) concluded that HTL was able to achieve degradation rates of PFCAs greater than 99%, while degradation rates of PFSAs were limited, falling to 67% for 8:2 FTS and 34% for PFOS. Other researchers have focused on evaluating catalytic amendments to the biosolids or biomass to promote PFAS mineralization, with mixed results (Zhang et al. 2020; Zhang and Liang 2022).

In general, HTL has demonstrated limited effectiveness in completely mineralizing the complex mixtures of PFAS typically present in biosolids. However, additional research is ongoing regarding alternatives to optimize the HTL process for more robust PFAS mineralization efficiency.

Biological Treatment

Biological treatment processes are commonly applied to reduce pathogens and stabilize biosolids for land application scenarios. The USEPA identifies aerobic digestion, anaerobic digestion, and composting as biologically mediated treatment processes for biosolids stabilization (USEPA 1993). Several studies have investigated the ability of common biologically mediated biosolids stabilization approaches to destroy PFAS and have generally concluded that these biological processes are ineffective at mineralizing recalcitrant PFAAs (Garg et al. 2023; Kim Lazcano et al. 2019; Li et al. 2022; Kumar et al. 2023). However, these studies have documented the transformation of polyfluorinated PFAA precursors present in the biosolids material during these biologically mediated stabilization processes, which is generally consistent with the findings of other biodegradation studies of PFAS discussed in **Section 12.6.4**.

Looking more broadly at biologically mediated treatment processes for PFAS-impacted biosolids, alternative approaches, such as phytoremediation, are being evaluated (Zhang and Liang 2022; Zhang, Tran, and Liang 2022; Wen et al. 2016). Additional research is needed to better understand the potential applicability of biologically mediated processes for biosolids treatment.

1.6.6 Updated and Recent and Relevant Technology Review Papers

This section provides information about updated and recent technology review papers focusing on PFAS treatment technologies and supplements the information published in **Section 12** and Table 12-1 Treatment Methods Table.

- Overview: Meegoda et al. 2022. A review of PFAS destruction technologies. International Journal of Environmental Research and Public Health 19.
- Liquids: DiGuiseppi et al. 2024. Available and emerging liquid treatment technologies for PFAS. Remediation 34(3).
- Thermal: Longendyke et al. 2022. PFAS fate and destruction mechanisms during thermal treatment: A comprehensive review. Environmental Science: Processes & Impacts 24, 196-208.

1.7 Priority Topics for Biosolids Land Application

Section Number	Topic
1.7.1	**Introduction: Application of Biosolids to Lands Supporting Animals and Crops**
1.7.2	**Conceptual Site Model**
1.7.3	**Assessing Potential Risk from Agricultural Impacts**
1.7.4	**Plant Uptake**
1.7.5	**Uptake by Animals**
1.7.6	**Conclusion**

These Priority Topics are focused on per- and polyfluoroalkyl substances (PFAS) in biosolids applied to land as fertilizer and include discussion of the fate and transport, leaching, and plant and animal uptake of PFAS following biosolids application. Biosolids-related information is referenced in multiple sections of the PFAS-1 Guidance Document (https://pfas-1.itrcweb.org/) including wastewater treatment residuals as a source in **Section 2.6.4**. Fate and transport topics such as partitioning, leaching, and transformation are briefly discussed in **Section 5**. **Section 5.6** discusses uptake to plants across multiple site types. **Section 6.2.3** describes reported PFAS levels in land-applied soils, and biosolids. Related information is found in new Priority Topics in **Section 1.4** which includes human and ecological effects information and **Section 1.6.5** which discussed treatment of biosolids.

Publicly owned treatment works (POTWs) are present in communities around the world treating wastewater and generating biosolids on a continuous basis. Biosolids are produced from sewage sludge that is derived from domestic wastewater (which may include contributions from industrial sources) at POTWs or privately owned wastewater treatment plants. Biosolids do not typically include sludges derived from privately owned industrial wastewater treatment works, although those byproducts may also be licensed for land application. Land application has been a common practice since the 1970s in the United States (USEPA 1972). Although a large fraction of biosolids is land-applied, a relatively small fraction of US farmland is fertilized with biosolids (Beecher et al. 2022).

Biosolids and their connection to PFAS in soil, groundwater, crops, livestock, and other animals, and potential human health exposures, are a growing area of research, and public awareness has increased around this issue. For example, a review by Ehsan et al. (2024) highlighted biosolids as one of several significant sources of PFAS in soil and noted that accumulation in plants and uptake into ecological food chains are potential concerns and topics of ongoing research. In a study by Pepper et al. (2021), PFAS were detected in soils with historical biosolids applications, although concentrations were relatively low (up to 4.1 µg/kg for perfluorooctane sulfonic acid (PFOS)).

General media articles also reflect increased public awareness of PFAS in agricultural settings and food. For example, Kirchner (2024) reported on PFAS testing of "off the shelf" milk and discussed cases in Michigan and Maine where the source on farms was related to fields fertilized with biosolids. Regulatory programs have also acknowledged the potential impact of land application sites. The US Food and Drug Administration is evaluating PFAS in food supplies; biosolids are acknowledged as one of many pathways through which PFAS may be introduced to the food supply (USFDA 2025), along with environmental contamination (presence in water) or presence in cookware. Following the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) designation of widely used PFAS as hazardous substances, the US Environmental Protection Agency (USEPA 2024) recognized that land application of biosolids should be excluded along with several other categories from Superfund site consideration.

The terms "sewage sludge" and "biosolids" are often used interchangeably. However, the USEPA makes a technical distinction between the two. Typically, the USEPA uses the term "biosolids" to refer to sewage sludge that has undergone sufficient treatment (for example, pathogen and vector attraction reduction) to meet the requirements outlined in USEPA 40 CFR §§ 503 "Standards for the Use or Disposal of Sewage Sludge," and is intended for land application as a soil conditioner or fertilizer. "Sewage sludge" is generally reserved for untreated municipal wastewater residual that has a high solids content and may have undergone dewatering to increase the relative solids content and reduce residual volume. In conventional wastewater treatment, large objects and readily settleable solids (primarily inorganic) are removed during the initial screening and grit removal stages. The materials removed during screening and grit removal are typically managed separately and do not become part of the "sewage sludge" residual. In general, "sewage sludge" consists of solids removed during primary settling (primary sludge) and solids removed during biologically mediated treatment processes that may include higher proportions of cell mass (secondary sludge). "Sewage sludge" that then undergoes treatment for land application, often with the intended beneficial use as a fertilizer, is referred to as "biosolids." For clarity in this section the term "biosolids" will be used to refer to treated sewage sludge. the term "biosolids" will be used to refer to treated sewage sludge.

In the United States, biosolids can be divided into two primary classes based on pathogen density, as measured by the presence of indicator organisms (for example, Salmonella and fecal coliform). Class A biosolids have stricter guidelines for pathogen content, as these can be applied directly to fertilize food crops, to a lawn, or a home garden, or when biosolids are sold or given away in a bag or other container for application to the land. Class B biosolids can be used on agricultural land with specific crop and harvest restrictions. Class B biosolids are also spread on forested land, pastures for animals, and reclamation sites (Boczek et al. 2023; Beecher et al. 2022). Whereas Class A and B biosolids require

distributors to meet some permitting requirements, biosolids treated to meet all the requirements in USEPA 40 CFR §§ 503.10(e), (f), and (g) are defined as Class A EQ (exceptional quality). These are typically sold or given away in consumer quantities that are exempt from land application regulations. Typical approaches for treating sludge to meet biosolids criteria do not target PFAS.

Biosolids are briefly discussed in several sections—for example, **Section 2.6.4** and **Section 6.2**. These Priority Topics summarize the current understanding of the science of PFAS in biosolids focused on the land application end use for this material. Land application of biosolids represents a potential PFAS release mechanism to the environment, including through leaching and uptake. Up to 60% of biosolids in the United States may be going to beneficial reuse (USEPA 2025).

1.7.1 Introduction: Application of Biosolids to Lands Supporting Animals and Crops

Biosolids contain a high ratio of nutrients and organic carbon to volume, making them a desirable product for agricultural fertilizer. The application of biosolids on agricultural land as a low-cost fertilizer is a common practice. However, the presence of PFAS and other contaminants such as microplastics and pharmaceuticals and personal care products has increased the scrutiny of land application of biosolids (Xia et al. 2005; Jones-Lepp and Stevens 2007; Carsella et al. 2022; Marchuk et al. 2023). Spreading rates for agricultural sites in the United States are regulated by 40 CFR Parts 503.12, 503.13, and 503.14. These regulations outline annual pollutant (non-PFAS) loading rates that, in addition to agronomic requirements, dictate application rates. In 2012, it was reported that Western European countries land spread about 41% of biosolids produced (Kelessidis and Stasinakis, 2012). Land application rates increased through the 1980s prior to regulation (USEPA 2000). Data for 2022 indicate 56% of biosolids were land applied. In addition to land application, the United States incinerates 16% of biosolids, landfills 27%, and uses alternate methods of disposal for the remaining 1% (USEPA 2023).

Based on a survey of US states reported in April 2025 (ECOS 2025), with respect to state actions addressing PFAS in biosolids, Maine has banned land spreading of biosolids, Connecticut has banned use and sale of biosolids that contain PFAS, and several other states have or are planning to issue guidance or regulations. For example, New Hampshire requires biosolids to be sampled for PFAS before spreading with a goal of using the data to support reduction of PFAS concentrations in biosolids (ECOS 2023).

A recent survey of biosolids management globally (Saliu and Sauvé 2024) found that China produced nearly 8 million tons dry weight of biosolids annually, compared to 4.75 million tons in the United States in 2019. Other countries, including India, Japan, Vietnam, South Korea, and Germany, showed annual production of approximately 2 million tons dry weight in the survey (Saliu and Sauvé 2024). Most developed countries around the world report application of biosolids to agricultural land or composting as a primary outlet for managing organic waste. Europe overall is similar to the United States with a rate of about 50%. China land applied approximately 29%, Australia and New Zealand applied approximately 89% to lands, and some utilities in Colombia and Chile reported similar rates of 65% and 75%, respectively, for the years reported (Saliu and Sauvé 2024).

Several methods have been employed to apply biosolids on agricultural lands, reclamation sites, forested areas, and residential properties (including gardens). Low percent solid biosolids have 2%–6% dry weight and are sprayed onto the ground surface and tilled into the soil or injected into the shallow subsurface. Dewatering processes can reduce the water content to 75%–80%, creating a semisolid material that can be spread using conventional agricultural equipment (for example, manure spreaders). To reduce contact with the material, land application may be followed by mixing surface-applied biosolids into the shallow subsurface, a process known as incorporation (USEPA 2025).

1.7.2 Conceptual Site Model

The PFAS and biosolids conceptual site model (CSM) is a written and illustrative description of the potential release sites and pathways based on known environmental and site information and presents several unique aspects compared to typical CSMs. **Figure 1-28** presents a general CSM for biosolids at land application sites. For typical biosolids from POTWs, PFAS can be sourced from upstream PFAS-impacted industrial, commercial, and residential wastewaters. Some of the PFAS in the wastewater impacts the generated sludge and ultimately the biosolids. Biosolids application for beneficial use in agriculture is commonly regulated, managed, and permitted at the state level. PFAS-impacted biosolids resulting from PFAS discharge to a wastewater treatment plant (WWTP) may be applied at one or a few locations or at hundreds of farm fields such that distribution can be very widespread.

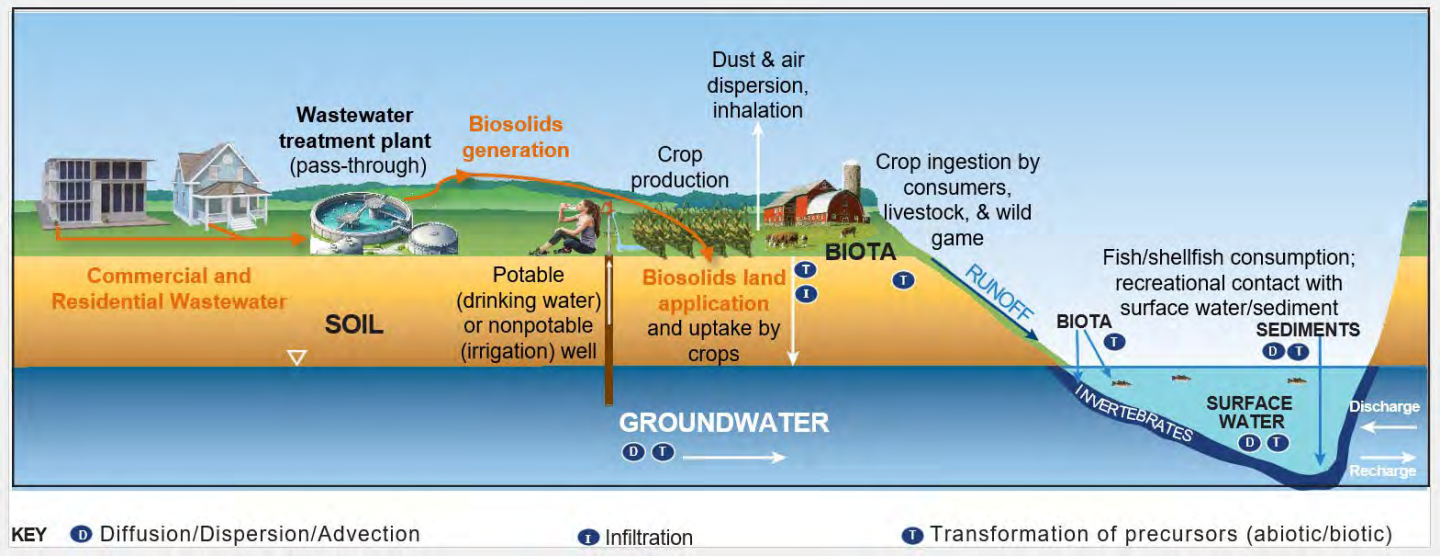

Figure 1-28. Conceptual site model at biosolids land application sites.

The application of biosolids containing PFAS on farm fields can impact several types of receptors via different exposure routes:

- Drinking water wells can be impacted from PFAS leached from biosolids and transferred through the vadose zone to groundwater.
- Agricultural crops can uptake PFAS from biosolids, as discussed in **Section 1.7.4**.
- Livestock and wild game can ingest PFAS from biosolids through several pathways, as discussed in **Section 1.7.5**, including consumption of contaminated well water; consumption of silage, grass, and hay from farm fields; or in the case of poultry, from consumption of insects and invertebrates living on or in soil contaminated by biosolids.
- Surface water and sediments can be impacted by runoff and erosion, where uptake to fish or other biota may occur.
- Soil with PFAS impacts from biosolids may be ingested and dust may be inhaled.

The fate of PFAS in biosolids includes diffusion, adsorption, dispersion, and advection during migration in soil, groundwater, surface water, and sediment. PFAS may also be dispersed in air—for example, by windblown particles. Through these pathways, PFAS precursors may transform to perfluoroalkyl acids

(PFAAs). Biosolids themselves are high in organic carbon and can retain PFAS, particularly longer chain PFAS and sulfonates, resulting in long, slow release and extending the natural migration and attenuation of PFAS. Biosolids application sites may also have some PFAS impacts not from biosolids, such as anthropogenic background from atmospheric deposition to soil.

1.7.2.1 Factors Influencing PFAS Mobility in Soils

PFAS mobilized from surface soil after biosolids application enter the unsaturated zone of soil above the groundwater in the vadose zone. Behavior of PFAS in the vadose zone is a major topic of interest because it has been shown that PFAS can be retained in this compartment for years to decades (Sharifan et al. 2021). This is important because retention in the vadose zone can translate to a long-term PFAS source to groundwater.

Climate/location and soil properties can influence PFAS transport in the vadose zone at biosolid application sites. Site-specific and climate-related factors, such as precipitation amount and frequency, depth to water, and infiltration rates, will affect the rate at which the system is flushed (Guo, Zeng, and Brusseau 2020; Brusseau 2020). Soil properties such as cation and anion exchange capacity, pH, carbon content, and soil texture will also affect contaminant transport through the vadose zone (Nguyen et al. 2020). See **Section 5.2** for additional details. Land-applied biosolids can influence these factors and affect PFAS transport. For example, microbial weathering processes can influence decomposition of the biosolids, in turn impacting partitioning of the PFAS and enhancing degradation of precursors (Lewis et al. 2023). Biosolids treatments prior to land application may also affect PFAS transport. Sludge stabilization has been found to decrease the sorption capacity for PFAS relative to secondary sludge and differences in partitioning behavior of PFAS have been observed depending on whether the sludge is aerobically or anaerobically digested (Ebrahimi et al. 2021).

PFAS interacts with climate and soil factors based on physical-chemical interactions on a microscale. Most research in this area is on PFAAs, which are recognized to be affected by hydrophobic effects, electrostatic interactions, and interfacial behaviors, such as sorption at air-water and NAPL-water interfaces. These are discussed in detail in **Section 5.2.4.1** and **Section 5.2.5** and summarized in the context of biosolids sites below.

PFAAs tend to associate with the organic carbon fraction of soil, with sorption to organic carbon generally increasing with an increase in perfluorinated carbon chain length, which is also associated with increased hydrophobicity (Higgins and Luthy 2006; Guelfo and Higgins 2013; Sepulvado et al. 2011; Campos Pereira et al. 2018). Given the relatively high organic carbon content in biosolids, organic carbon partitioning is likely an important factor for considering PFAS transport and fate at biosolids sites. One study (Evich et al. 2025, 2025) of two agricultural sites with a history of sludge application found that organic matter had a greater influence on mobility of long-chain versus short-chain PFAS. PFAS concentrations in agricultural soil are also found to be correlated with soil organic matter and pH (Oviedo-Vargas et al. 2025). Studies have shown that in the context of PFAS partitioning in biosolids, protein fractions and, to a lesser extent, lipid fractions, were also important solid-specific properties to consider (Ebrahimi et al. 2021).

Another factor with potential influence on PFAS behavior in land-applied soils is the presence of microplastics (MP) in biosolids (Siddiqui 2024). Evaluation of land application sites has correlated use of biosolids with increases in MP in soil (Crossman et al. 2020; Tran et al. 2023; Adhikari et al. 2024), and PFAS are known to be associated with MP through direct degradation of fluoropolymers and through sorption and desorption processes (Lohmann et al. 2020, Salawu et al. 2024). This linkage is a topic of ongoing research and could represent an additional factor affecting fate and transport in soil. More information on PFAS and MP is included in **Section 1.8**.

Solid-phase and solution chemistry plays a role in affinity of PFAAs for the solid phase. Changes in pH potentially impact electrostatic processes by altering surface charges, or possibly the ionic nature of the PFAS (Nguyen et al. 2020), and higher amounts of polyvalent cations, such as calcium, iron, and magnesium, can also affect electrostatic interactions and increase sorption of PFAAs (Higgins and Luthy, 2006 ; McKenzie et al., 2016). See **Section 5.2.3.2**. Data from Evich et al. (2025, 2025) showed that electrostatic interactions at mineral surfaces exerted greater influence on short-chain PFAS sorption than on longer chain PFAS sorption, which was driven by interaction with the air-water interface and organic carbon.

Because PFAAs are surfactants, they have been shown to reside in the bulk phase and to align themselves at the interfaces between phases, such as at the air-water interface and NAPL-water interface. Air-water interfacial sorption is likely a large contributor to vadose zone retention (Sepulvado et al. 2011; Ahrens and Bundshuh 2014; Sharifan et al. 2021). As discussed in **Section 4.2.7**, the surfactant properties of some PFAS may result in aggregation into micelles.

Transport of PFAS through the vadose zone after surface releases is an evolving topic, and there are still many uncertainties with PFAS vadose zone retention both generally and specifically for biosolids sites. For additional details on these processes, see **Section 5** and the latest vadose zone fate and transport research in **Section 1.3.1**.

1.7.2.2 Nature and Extent of PFAS at Land Application Sites

PFAS, including precursors, can enter the wastewater stream from numerous sources, including residential, commercial, and industrial wastewaters. **Section 6.2.3** discusses the reported concentrations of PFAS found in biosolids material across different time periods and from different sources or treatment plants. The concentration variability is directly related to the source inputs at each facility. The variable biosolid concentrations in combination with application rates, years of application, and other factors all contribute to different levels of impact observed at land application sites (USEPA 2025). Research is ongoing to evaluate PFAS impacts at land application sites and to assess the extent of impacts to soil and other media.

For example, Alvarez-Ruiz et al. (2024) reported on a study from a group of fields with a 38-year history of land application, in this case from a wastewater treatment plant that serves mainly domestic sources along with a hospital, dentist, and dry cleaner. Approximately 5,700 m^3 of 4%–5% solids biosolids were injected annually at the study site. The authors reported soil core concentrations across several orders of magnitude with total PFAS of 1,700 ng/g in the top 30 cm, decreasing to approximately 2 ng/g at 120 cm–150 cm. In a control field where no application occurred, the maximum total PFAS was approximately 1 ng/g. The authors discussed detections of several PFAS classes that may act as precursors, such as polyfluoroalkyl phosphoric acid diesters (diPAPs) and fluorotelomer carboxylic acids (FTCAs).

Maine Department of Environmental Protection (MEDEP) recently issued an updated summary report based on statewide sampling of private water supplies and soil at biosolids application sites, septage sites, and landfills (MEDEP 2025) and found that domestic water supplies exceeding the Maine Interim Drinking Water Standard of 20 ng/L for a sum of six PFAS were typically within 1,000 feet of those sites. The statewide study also showed that in Maine at land application sites where average total PFAS soil levels are 20 ng/g or less, the average detected total PFAS in private water supplies is below 50 ng/L, and across the state for all wells tested near land application sites, only 20% exceed the Maine Interim Standard. The data distribution for the 2,919 residential well samples collected statewide as of November 2024, in relation to all biosolids sites tested, is presented in **Figure 1-29**. based on concentrations in ng/L.

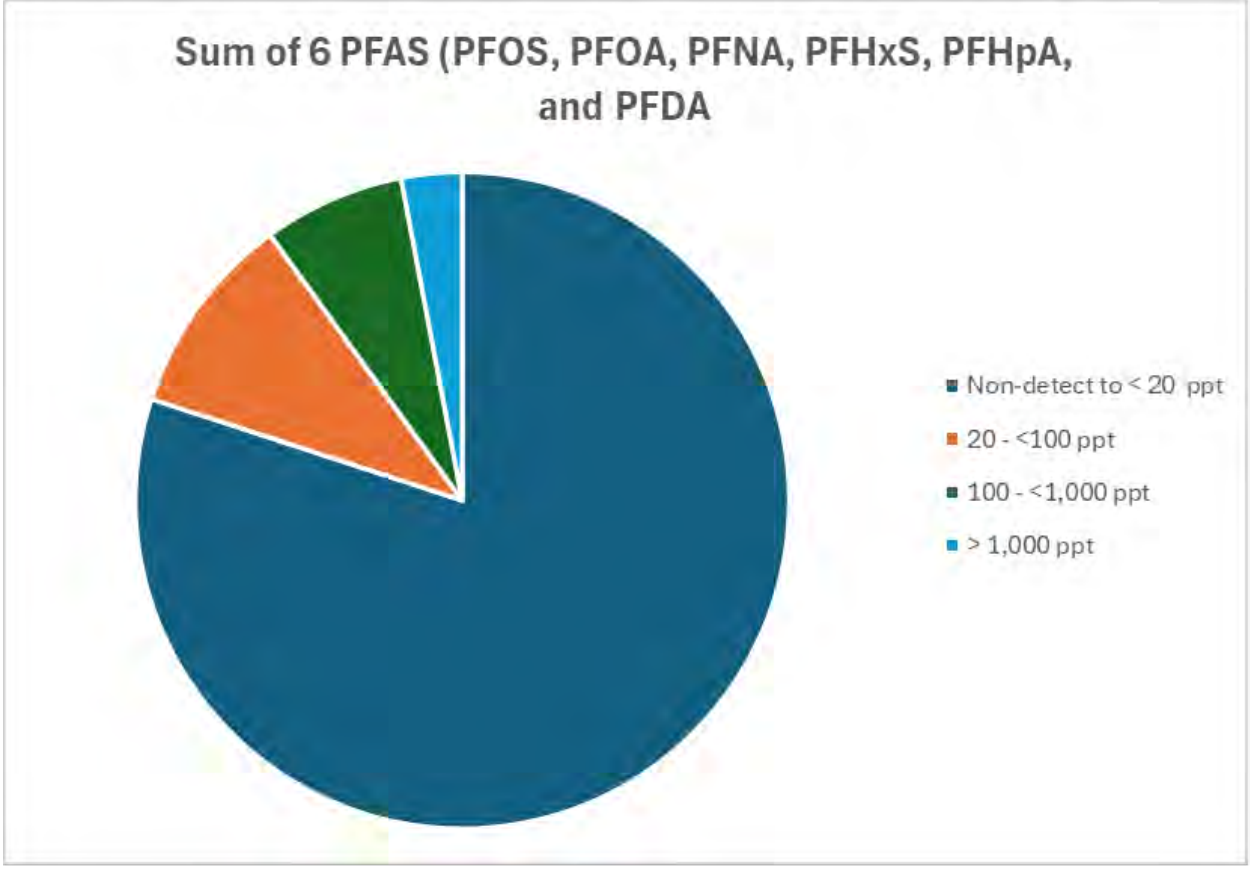

Figure 1-29. Data distribution for residential well samples near biosolids sites in Maine (concentrations in ng/L).

Source: Figure generated by Chris Evans, MEDEP, based on data from the Second Biennial Report (ME DEP 2025) , used with permission.

There are many sources of PFAS to agricultural fields, aside from biosolids, that may increase concentrations in soil and groundwater. These sources may include manure from contaminated farms, commercially available fertilizers and pesticides, contaminated irrigation well water, and rainwater deposition (see **Section 2.5** and **Section 2.6**). Other potential sources may be windblown dust from adjacent contaminated fields (Borthakur et al. 2022) or anthropogenic background atmospheric deposition to soil (see **Section 6.2.1**). The relative contribution of cumulative inputs to the total mass of PFAS present in any given field will be very site-specific and dependent on the history of the site and its location relative to other sources.

PFAS tend to remain in the soil as a long-term source to other environmental media. Soil cores collected from multiple study sites show vertical migration of PFOA to depths of up to 9 m with most of the PFAS mass remaining in the top 30 cm (Johnson 2022). Ratios of long- to short-chain perfluorinated compounds decrease with depth due to the retention of longer chains in surface soils (Washington et al. 2010; Sepulvado et al. 2011; Borthakur et al. 2021). Oviedo-Vargas et al. (2025) studied 10 farms with varied biosolids application and found concentrations decreased with depth and lower concentrations were correlated with increased chain length in the deeper 15 cm–30 cm interval. Polyfluorinated precursors (for example, N-methylperfluorooctane sulfonamidoacetic acid, N-MeFOSAA) have been found in surface soils at concentrations over 60 µg/kg but are detected at lower concentrations or not at all at greater depths due to their transformation into perfluorinated compounds and greater retention in surface soils due to their differences in physical-chemical properties (Sepulvado 2011). Pepper et al. (2021) also

found that PFAS concentrations declined with depth and that precursors such as N-MeFOSAA were detected in biosolids but not in soils following land application, suggesting that transformation occurred.

Extensive research has been conducted on the leaching of PFAS to groundwater (see **Section 5**). Although most early research focused on aqueous film-forming foam (AFFF) sites, there is increasing interest in biosolids and land application sites. Although some states have documented extensive impacts to groundwater near land application sites (ME DEP 2025), other studies have not found that leaching of PFAS to groundwater is significant (Peter and Lee 2025). Leaching of PFAS from soil will occur at higher rates in areas with shallow groundwater and high amounts of water percolating through the soil due either to precipitation or irrigation (Pepper, Kelley, and Brusseau 2023). Site-specific leaching rates can be estimated using laboratory tests (see **Section 1.5.1**), such as Leaching Environmental Assessment Framework (LEAF) or Synthetic Precipitation Leaching Procedure (SPLP), however, the accuracy of such test methods, which is complicated by biosolids physical and chemical properties, requires further research (Navarro et al. 2024).

Discharge to nearby surface water is also an important consideration. Peter and Lee (2025) identified PFAS in a stream hydrologically linked to a field receiving biosolids in a study in Indiana, with maximum perfluorooctanoic acid (PFOA) and PFOS concentrations of 10.8 and 3.7 ng/L, respectively. A recent study of 10 farms in Pennsylvania with 2 to 26 years of biosolids application (Oviedo-Vargas et al. 2025) found max concentrations of PFOA and PFOS in surface water of 250 ng/L and 110 ng/L, respectively. These are lower concentrations by 1–2 orders of magnitude than what has been reported where industrially impacted biosolids were used (Lindstrom et al. 2011) but highlight that leaching or runoff to surface water is an important factor for PFAS migration at these sites.

1.7.2.3 Potential New Classes of PFAS in Biosolids that May Require Non-targeted Analysis

Occurrence data for PFAS in biosolids, including PFAAs and select precursors, are provided in **Section 6.2.3**.

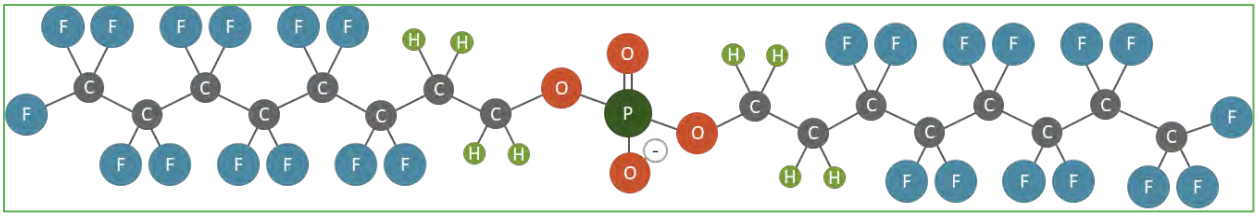

Figure 1-30. 6:2 polyfluoroalkyl phosphoric acid diester (6:2 diPAP).

Multiple studies have shown that standard PFAS target analyte lists are not reporting the full extent of PFAS present in wastewater or biosolids. Analytical techniques may include non-targeted analysis (NTA), which can be used to identify PFAS beyond those included in the conventional analyte list, and various "total PFAS" analytical methods (see **Section 11.2** and **Section 11.4.3** for additional information on NTA instrumentation and procedures). NTAs have identified primary classes of precursors that comprise significant fractions of PFAS in biosolids, including diPAPs, perfluorophosphonic acids (PFPAs), and various classes of cationic and zwitterionic precursors. Of these, 6:2 diPAP (**Figure 1-30**) has been the predominant PFAS detected in biosolids in multiple studies (Thompson et al. 2023; Schaefer et al. 2023; Lazcano et al. 2019), and diPAPs have been identified as potential perfluoroalkyl carboxylic acids (PFCA) precursors when applied under field conditions (Lämmer et al. 2022). Alternative non-targeted methods that have estimated total PFAS also suggest that unidentified precursors tend to account for much of the PFAS presence in biosolids. Associated studies are summarized below. Conventional sampling of biosolids or associated land-applied soils, for example, as conducted under regulatory requirements, would typically be limited to the analyte list included in USEPA Method 1633A (or similar methods) and

may not include these non-targeted analytes. See **Section 2.2** for more information about PFAS chemistry and **Section 11.2** for more information about analytical methods.

A 2023 study (Thompson et al. 2023) evaluated PFAS content at eight facilities in untreated sewage sludge samples and in biosolids after treatment for pathogen removal . Treatment methods included composting, anaerobic digestion, lime treatment, and heat treatment (90°C–120°C). The sum of PFAS concentrations ranged from 182 µg/kg to 1,650 µg/kg. Of detected PFAS, diPAPs were the predominant compounds, comprising an average of 54% ± 15% of total detected PFAS. PFAAs accounted for a relatively small fraction of the total PFAS detected; prior to treatment for pathogen removal, precursors comprised 82% ± 11% of total detected PFAS. Pathogen treatments had varying impact on the PFAS composition. Most treatments resulted in substantial increases in short-chain PFCAs while impacts of treatment on long-chain PFCAs and PFSAs were variable and were generally minor compared to variations in other compounds. Interestingly, concentrations of diPAPs increased following heat treatment. A primary source of diPAPs in wastewater, and associated biosolids, has been identified as toilet paper (Thompson et al. 2023).

Schaeffer et al. (2023) analyzed PFAS content in wastewater influent/effluent and biosolids at 38 treatment plants; targeted PFAS analysis was supplemented with the total oxidizable precursor (TOP) assay and NTA. TOP assay results indicated that unidentified precursors comprised 21%–88% of total fluorine. NTA identified several classes of precursors present in waste streams. Predominant among these precursors, PFPAs and diPAPs were detected in 100% and 92% of biosolids samples, respectively.

Multiple studies have evaluated fluorine nuclear magnetic resonance (^{19}F-NMR) as a useful tool for evaluating total PFAS (for example, Camdzic et al. (2023); Lewis et al. 2023; and Gauthier and Mabury 2023). Camdzic et al. (2023) evaluated ^{19}F-NMR as an alternative method for quantifying total PFAS in wastewater. In this study, ^{19}F-NMR was compared to TOP assay and liquid chromatography with high resolution mass spectrometry (LC-HRMS). ^{19}F-NMR detected 63% and 65% more PFAS than TOP assay and LC-HRMS, respectively, suggesting that TOP assay and LC-HRMS techniques may underreport total PFAS. Furthermore, ^{19}F-NMR was able to identify ultrashort-chain PFAS (ultrashort PFAS), such as trifluoroacetic acid (TFA), that might not be included in conventional target PFAS analytical methods. Limitations for ^{19}F-NMR include higher detection limits and difficulty in resolving complex PFAS mixtures. Lewis et al. 2023 used ^{19}F-NMR to screen sorbent materials for PFAS uptake. Gauthier and Mabury (2023) measured ^{19}F-NMR spectra for hundreds of PFAS and used the resulting data to evaluate the total PFAS presence in an environmental sample from a site impacted with AFFF and published the resulting ^{19}F-NMR spectra database for use in other projects.

Lazcano et al. (2019) used liquid chromatography–quadrupole time-of-flight (LC-QToF) to evaluate precursor content in biosolids after conventional treatment processes—including heating, composting, blending, and thermal hydrolysis—were applied to remove pathogens and select organic constituents. In this analysis, diPAPs were the most commonly detected precursors, detected in all samples. Fluorotelomer sulfonates and carboxylates (FTSAs and FTCAs, respectively) were also detected. Of the treatment methods evaluated for pathogen removal, heat treatment and composting had the greatest effect on transformation of precursors into PFAAs.

As an additional consideration, fluorinated pharmaceuticals are frequently present in wastewater streams and may complicate evaluation of total PFAS. In particular, extractable organic fluorine (EOF) data are often represented as “total PFAS” but may also include fluorinated pharmaceuticals. Ruyle et al. (2025) evaluated wastewater influent and effluent from eight US POTWs and found that PFAA and PFAA precursors estimated from the TOP assay accounted for only 24%–37% of EOF, whereas mono- and polyfluorinated pharmaceuticals made up 62%–75% of EOF. Polyfluorinated pharmaceuticals containing -CF3- or -CF2- moieties accounted for the majority of EOF (53%–58%). In terms of utility, the study suggested that EOF is useful as a screening tool for organofluorine presence, although total PFAS did not correlate well with EOF results. Spaan et al. (2023) found fluorinated pharmaceuticals to account for

approximately 22% of identified compounds in EOF, compared to approximately 5% for PFAA and PFAA precursors, in WWTP sludge from Sweden. Fluorinated pharmaceuticals may or may not be considered PFAS, depending on the definition used for PFAS. The definition distinction may have implications in terms of future considerations for regulating PFAS as a class, but PFAS measured using targeted analysis were present in all waste streams (Ruyle et al. 2025). At this time, data gaps associated with fluorinated pharmaceuticals include toxicology and ecotoxicology for the complex chemical mixtures, as well as their behavior in the environment once land-applied on farmland.

1.7.2.4 Assessment of PFAS at Land Application Sites

When assessing PFAS related to biosolids land application, it is critical to understand the history of the site, rates of application, area licensed, and inputs to wastewater treatment that may have changed over time, affecting both concentrations and types of PFAS. Gewurtz et al. (2024) evaluated the concentration trends and fate of 42 PFAS compounds throughout the treatment processes (influent, effluent, and biosolids) of multiple wastewater treatment plants in Canada. Results of this study indicated widespread presence of both short- and long-chain PFAS. Highest PFAS concentrations were generally detected in WWTPs receiving landfill leachate. Except for PFOS, concentrations of long-chain PFCAs decreased over approximately a decade in influent, effluent, and biosolids, coincident with the phaseout of certain PFAS in industrial production, whereas short-chain PFCA concentrations increased over time in influent and effluent (although not in biosolids, where they were infrequently detected), reflecting increased industrial use of replacement compounds. PFAS patterns in biosolids generally differed from the patterns observed in influent and effluent samples, which may be from enhanced sorption to solids in the sludge material. In biosolids samples, long-chain PFCAs, PFOS, long-chain precursors, and intermediate transformation products were detected the most frequently, in over 60% of samples, while PFOS, perfluorobutanoic acid (PFBA), and 5:3 FTCA (a short-chain precursor) were detected at the highest concentrations. Across WWTPs, higher PFAS concentrations were generally observed for facilities using anaerobic and aerobic sludge digestion; Gewurtz et al. (2024) postulated that this difference may be due to precursor transformation as well as a reduction of volatile solids in sludge, which further concentrates PFAS.

To assess whether PFAS in soil at a land application site is a potential risk to drinking water or farm operation, an accurate characterization of PFAS concentrations in soil is required. Heterogeneity is a significant concern when characterizing soils in an area of land application, particularly where there is a long history with multiple amendments or applications from different sources, or a variety of crops grown across the property. Heterogeneity of source material and site soil conditions contributes to field heterogeneity. Variable application rates based on the nutrient requirements of different crops are also a potential factor across different fields where the same fertilizer source is in use. For example, corn requires higher fertilizer inputs than pasture or other crops, such as wheat or oats (USDA 2023; Ketterings and Workman 2022), so those fields may have higher associated levels of PFAS based on the higher fertilizer application rates. Studies of nitrogen, potassium, and phosphorus distribution show that concentration variation within fields may be 4x to 10x despite an agricultural goal of uniform concentrations (Fu et al. 2013; Mancini et al. 2024). Fu et al. (2013) also discussed the influence of pastured animal behavior and field access points on land application of manures or fertilizers.

Research into nutrient variability conducted to improve optimization of fertilization needs also provides insight into potential underlying variability of PFAS related to land application. Marcaida et al. (2025) documented spatial variability of pH, phosphorus, and potassium in corn fields based on grid-based soil data. They found that grid cell density impacted interpreted spatial distribution of the parameters tested and subsequent fertilization recommendations. Virk et al. (2024) completed a similar study illustrating the influence of grid size selection of 1-, 2.5-, 5-, 7.5-, and 10-acre cells on evaluations of field variation of pH, phosphorus, and potassium. An earlier study (Cambardella and Karlen 1999) used grid-based sampling to assess variations in soil nutrient parameters, including pH and total organic carbon, in an “organic” field fertilized in part with biosolids and a field farmed with conventional practices. Cambardella and Karlen (1999) concluded that greater variability in the organic field suggested that a smaller grid cell

size was required to assess fertilization needs, and soil cores showed variation with depth from 0 to 30 cm at each grid cell. Data showed, for example, that organic carbon decreased from about 51 g/kg to 33 g/kg on average across the field. Based on the potential relationship of PFAS sorption to pH, organic carbon, and other soil parameters (as in **Section 1.7.2.1**), as well as potential variations related to heterogeneous distribution of biosolids when applied, the findings indicate that design of sample plans for PFAS in these settings should consider these factors.

Assessment of risk to groundwater or from uptake to crops or animals at land application sites is often based on a risk evaluation of a relatively large area with inherent variability as described above. Incremental sampling methodology (ISM) is one way to assess potential heterogeneity and limit its effects when collecting soil data from sites where the objective is to determine a representative value for that area or decision unit. These methods are detailed in multiple sources, including USEPA (2019), ITRC (2020), and Clausen, Georgian and Bednar (2013).

At least three states—Hawai'i, Maine, and Michigan—are currently implementing either full or partial ISM or ISM-like field management protocols for projects that involve evaluation of PFAS impacts to field areas. These states have either modified standard ISM or ISM-like sampling protocols to account for PFAS-specific heterogeneity concerns or are using ISM-based sampling protocols to obtain sampling results more representative of the populations than grab or simple composite sampling techniques.

Hawai'i's Hazard Evaluation and Emergency Response Office Technical Guidance Manual, which specifies the use of multi-increment sampling, has been updated to include PFAS as a Contaminant of Potential Concern (HI DOH 2024). The Technical Guidance Manual Table H-1 lists PFAS as an example of Highly Leachable, Non-Volatile Contaminants. The Technical Guidance Manual has added USEPA Region 4 Operating Procedure LSASDPROC-205-R4 "Field Equipment Cleaning and Decontamination," which includes a note stating, "Equipment utilized for PFAS sampling will not be cleaned in the field" (USEPA 2020; HI DOH 2024). Michigan's Department of Environment, Great Lakes, and Energy (EGLE) reports the routine use of multi-increment sampling for PFAS investigations, including those specifically for biosolids. Michigan EGLE has posted a number for field reports presenting the results of the ISM sampling (MI EGLE 2021). MI EGLE (2021) evaluated ISM and composite sampling as part of their site investigations. Their current ISM approach is summarized in MI EGLE (2024). As of September 2025, Maine had not published their methods or findings for public review.

USEPA has not formally released guidance for ISM and PFAS, and there are potential concerns related to laboratory processing of samples. The Department of Defense (DoD) recently released a white paper listing several concerns with application of ISM to PFAS sites in general, primarily focused on the sample preparation and handling at the laboratory (DoD EDQW 2025). Details related to specific concerns about using ISM, particularly if attempting to strictly follow USEPA Method 1633A for testing and USEPA Method 8330B for laboratory sample processing, are included in **Section 1.5.5**. Additional work is needed to validate this approach for PFAS and land application sites, and project teams need to carefully consider the site data quality objectives and goals of the work.

1.7.2.5 Treatment Options for PFAS in Biosolids

Research is ongoing to develop treatment options for biosolids prior to disposal or land application. Other studies are evaluating technologies to eliminate PFAS prior to biosolids production, via treatment of wastewater prior to generation of sewage sludge or industrial pretreatment prior to discharge to a WWTP. The Michigan EGLE Industrial Pretreatment Program PFAS Initiative reduced PFAS in treated wastewater discharge and biosolids by requiring certain POTWs to identify industrial sources that generated wastewater with PFAS concentrations exceeding screening criteria (11 or 12 ng/L for PFOS). For industrial sources required to mitigate PFAS, mitigation measured included application of pretreatment (typically using granular activated carbon [GAC]), PFAS-containing source removal, leak mitigation, or reducing the volume of landfill leachate accepted. Concentrations of PFOS were reduced in all nine plants

that required pretreatment, and reductions were greater than 90% in seven of nine treatment plants (MI EGLE 2020). Additional research is ongoing into remediation or treatment of agricultural soils impacted by PFAS from historic land application and associated leaching to groundwater and plant and animal uptake at those sites. See **Section 1.6.5** for information on these studies.

One side effect of some potential treatment options is that the nutrient value of the resulting material may no longer be desirable as fertilizer, which will affect distribution of treated biosolids or could affect continued agricultural or forestry use of treated land. For example, thermal or chemical treatments may negatively affect soil fertility in an agricultural site (Sanchez-Hernandez et al. 2024).

Studies have evaluated treatment options to reduce PFAS mobility or bioavailability in soils with land-applied biosolids. For example, Holly et al. (2024) conducted column studies evaluating PFAS leaching from land-applied biosolids and the effects on leaching from amending biosolids with biochar. Results indicated that leachate from all treatments contained measurable PFAS concentrations, and biochar amendments reduced leaching potential of PFAS, with greatest impact noted for long-chain PFAS. Additional details are provided in **Section 1.6.5**.

1.7.3 Assessing Potential Risk from Agricultural Impacts

Due to widespread use of PFAS in industrial manufacturing and consumer products and their ability to pass through conventional wastewater treatment processes and partition to the solid fraction, elevated concentrations of diverse PFAS have been widely identified in biosolids, generating concern for the environmental and human health risks associated with land application on agricultural fields and potential for uptake into plants and animal products consumed by humans (see the conceptual site model, **Figure 1-28**). In January 2025, USEPA released a draft risk assessment for PFOA and PFOS in biosolids (USEPA 2025). This document summarized a screening-level assessment and a refined risk assessment focused on people living on or close to land application or surface disposal sites, who almost exclusively consume food and animal products and drinking water from land where biosolids were applied. This draft risk assessment does not reflect risk for the public, which has diverse food sources, and does not consider cumulative exposure from multiple pathways or other sources.

The draft risk assessment quantitatively estimates potential human exposure and risk to PFOS and PFOA under four modeled scenarios: 1) farm scenario with pasture-raised livestock, 2) farm scenario growing fruits and vegetables, 3) land reclamation scenario for restoring grazed pastureland, and 4) surface disposal site scenario. A series of modeling approaches was conducted including farms with one application of biosolids at a rate of 10 dry metric tons per hectare over 40 consecutive years of application at this rate. Preliminary findings (USEPA 2025) of the refined model, which calculated risk under median or central tendency conditions, suggest there may be human health risks exceeding USEPA's acceptable thresholds for scenarios where land-applied biosolids contained 1 part per billion (ppb) of PFOA or PFOS, which is considered on the low end of measured U.S. biosolid concentrations, near current detection limits. This initial evaluation showed risk for all pathways assessed, including consumption of water, milk, crops, and meat products such as beef and chicken eggs. The draft risk calculations are not considered to be conservative estimates because they model only risks associated with biosolids containing 1 ppb of PFOA or PFOS, reflect median exposure conditions, do not include other exposure sources of PFOA or PFOS, and do not account for the combined risk of PFOA and PFOS together or exposures from PFOA and PFOS precursors. See the draft risk assessment document (USEPA 2025) for complete details on modeling approaches and risk calculations.

The document highlights the importance of site-specific factors such as hydrogeology, climate, agronomic practices, and human behavioral patterns and their impacts on potential risks. USEPA (2025) is planning the next National Sewage Sludge Survey to collect PFAS data from sewage sludge at 200–300 treatment plants nationwide, in conjunction with a POTW influent study to assess wastewater inputs. This information will help inform assessment of current biosolids inputs to the modeled scenarios

(USEPA 2025). The conceptual site model (**Figure 1-28**) illustrates the potential pathways of concern related to PFAS and biosolids when applied to the land. The following sections summarize in further detail the uptake of PFAS to plants and animals and the modeling that may help predict when there is a risk from that uptake.

1.7.4 Plant Uptake

The research on PFAS interactions with plants is extensive, exploring a range of topics including uptake from various types of soils and covering a variety of herbaceous plant species as well as trees. Some key issues of interest regarding plant uptake of PFAS include the need to understand whether the nature and magnitude of uptake from biosolids-amended soils is different from that of nonamended soils, and whether there is a difference in accumulation between crops that are grown in biosolids-amended soils for consumption by livestock (for example, silage, hay, forage) versus crops grown for human consumption (for example, fruits, produce). A key metric used to estimate uptake and accumulation by plants is the bioconcentration factor (BCF), sometimes referred to as the bioaccumulation factor (BAF) or transfer factor (TF), which is defined as the PFAS concentration in plant (mass/mass), in dry weight or wet weight, divided by the PFAS concentration in soil (mass/mass), in dry weight. It is important to be aware how these units are expressed for plants and soils when reporting and using uptake factors.

Uptake of PFAS from different types of soils into both agricultural and nonagricultural plants is summarized in **Section 5.6** and **Table 5-2**. It includes general studies on uptake from soils in PFAS-contaminated sites and greenhouse studies, as well as studies that are more focused on sewage-amended and biosolids-amended agricultural soils, the latter of which is relevant to this topic. The Draft Sewage Sludge Risk Assessment for PFOA and PFOS released by USEPA in January 2025 includes a review of available data on crops grown in biosolids-amended soils and observed differences in uptake factors reported in greenhouse studies versus field studies (USEPA 2025). The USEPA review and the ITRC summary (**Table 5-2**) note some important factors and apparent trends in BCFs to consider when evaluating plant uptake of PFAS from biosolids-amended soils and in agricultural settings. The bioconcentration of PFAS from biosolids-amended soils depends strongly on the physical-chemical properties and concentrations of PFAS, the soil properties, and species and physiology of the plants, as outlined below.

1.7.4.1 Reported BCFs for Plant Uptake

Most studies that report BCFs for plants focus on uptake of the terminal PFAA, which generally show increasing accumulation in plant tissues with a decrease in perfluorinated carbon chain length (see **Section 5.6.2**). Few studies have investigated uptake and biotransformation of precursor PFAS in plant tissues. It should be noted that interpretation of BCFs for PFAA may be influenced by the presence of diverse mixtures of precursor PFAS in biosolids-amended soils that can undergo degradation via microbial activity in the soil or within the plant-specific root exudates or other plant compartments (Wen et al. 2018; Wen et al. 2021; Bizkarguenaga et al. 2016).

PFAS uptake and accumulation is typically greater in the vegetative portions of plants (foliage, stems, roots), than in the reproductive parts (seeds, fruits). Plant uptake may also be impacted by aftermath growth with mixed evidence of potential high uptake of PFAS in subsequent cuttings of plants such as grass (Stahl et al. 2009). A study conducted by the state of Maine showed that cuttings of plants such as grass and hay had higher uptake of PFOS in the secondary cuttings compared to the initial growth season (Simones et al. 2024). The BCFs selected in the draft USEPA review (2025) for PFOS and PFOA (Table 13 in that document) fall within a range of 0.07–1.3 for selected crop types, classified as forage, fruit, root vegetables, silage, and aboveground vegetables. The majority of the BCF values for 14 different PFAS compounds, as compiled in the ITRC summary (**Table 5-2**), fall within a range of 0.1–10, and vary with chain length, species, and study methodology. USEPA also provides a modeling approach for estimating

crop concentrations of PFOS and PFOA in produce and feed, based on estimated soil concentration within the tilling depth, plant type-specific BCFs, and plant tissue-specific moisture adjustment factors.

1.7.4.2 Influence of PFAS Properties

PFAS with lower chain lengths and higher solubilities can enter the soil solution and tend to have greater uptake potential in plants. Short-chain compounds tend to accumulate at higher concentrations in leafy vegetables and fruits, whereas long-chain compounds tend to accumulate more in roots. Several studies have found that PFCAs accumulate at higher rates than PFSAs. Shilling Costello and Lee (2020) found that precursors and other emerging classes of PFAS may represent important long-term sources when retained in rhizomes or root zones. They summarized several studies where precursors were present in soil while intermediate and terminal degradation products were concentrated in shoots or roots. The authors also noted that potted plant and field studies often yield different BCFs in part based on factors related to air-water interface and degree of saturation in those settings. For more information about how PFAS properties influence their fate and transport, see **Section 5**.

1.7.4.3 Effects of Treatment Plant Processes on PFAS Uptake

Broadbent et al. (2023) evaluated potential use of drinking water treatment residuals (DWTRs) as biosolids amendments that could reduce the rate of PFAS uptake in plants (phytoavailability) grown on biosolids-amended soils. DWTRs are byproducts of drinking water treatment using coagulants that are typically rich in calcium (calcium hydroxides), iron (iron sulfates or chlorides), or aluminum (aluminum hydroxides); these substances are currently used to immobilize excess nutrients and other contaminants and have been found in other studies to sorb PFAS and reduce their mobility in the environment (for example, Hearon et al. 2022). Broadbent et al. (2023) conducted phytoavailability studies for an agricultural scenario (tomato plants grown on biosolids) and a mine reclamation scenario (ryegrass grown in soil amended with biosolids), using Class A biosolids containing a variety of PFAS and three different DWTRs. This study found that most of the PFAS detected in biosolids were not found in plant tissue; only three PFCAs (PFBA, perfluoropentanoic acid (PFPeA), and perfluorohexane sulfonic acid (PFHxA)) were detected in all plant samples, with PFBA found at the highest concentrations. Tomato plants also were found to contain PFOA in almost all samples and generally had PFAS concentrations approximately 2–4 times higher than those in ryegrass. The authors concluded that aluminum- and iron-based DWTRs did not significantly reduce overall PFAS uptake under either scenario (except for reduced PFBA uptake in ryegrass treated with iron-based DWTR), although these results may have been influenced by relatively high concentrations of aluminum and iron and low concentrations of organic matter in the biosolids used in their experiments. Calcium-based DWTRs, however, significantly reduced the accumulation of PFBA in ryegrass and PFHxA in tomatoes, although the authors postulated that this may have been a result of pH modification.

Biochar-based sorbents may also be effective at reducing availability of PFAS. Openiyi et al. (2024) applied aluminum chlorohydrate DWTR and biochar to biosolids-amended soil columns, finding that PFAS concentrations in soil leachate from both residuals-treated soils were substantially reduced compared to untreated soils. These findings suggested that sorbents may reduce PFAS mobility and thus bioavailability.

Research evaluating the links between the processes employed by POTWs to reduce pathogens and subsequent bioavailability of PFAS following land application of biosolids is ongoing and additional work is needed to fully assess this topic.

1.7.4.4 Influence of Soil Properties

Beyond the physical and chemical properties of PFAS, environmental factors such as soil properties also play a crucial role in the uptake process by plants (Shilling Costello and Lee 2020). Research has

highlighted the influence of soil organic carbon, pH, and cation types and concentrations on PFAS sorption (Mei et al. 2021; Li et al. 2018; Campos Pereira et al. 2018). Although organic carbon generally enhances the sorption of organic contaminants in soil, its effect on PFAS can vary depending on the soil type. Higher soil pH typically reduces PFAS sorption, thereby increasing their mobility and bioavailability, though the presence of cations can complicate this relationship. Inorganic anions such as phosphate may also reduce PFAS sorption by competing for binding sites in the soil.

Nitrogen-rich amendments also may alter PFAS bioaccumulation characteristics. Adu et al. (2025) showed that uptake of PFOA, hexafluoropropylene oxide dimer acid (HFPO-DA), and 6:2 chlorinated polyfluoroalkyl ether sulfonate (6:2 Cl-PFESA) in hydroponically grown lettuce was enhanced through addition of nitrogen fertilizers, including ammonium sulfate and potassium nitrate. Wu et al. (2023) demonstrated enhanced PFAS bioavailability through addition of ammonium ion to soil. This study also showed that nitrogen amendments in soils containing PFAS resulted in a decrease in the diversity and stability of soil microbial communities. Additional research is needed to further elucidate the effects of inorganic anionic and cationic constituents.

Unique mechanisms such as PFAS retention at the air-water interface in unsaturated soils further add complexity to their transport and bioavailability (Lyu et al. 2018; Brusseau et al. 2019). When PFAS have low sorption to soil, they remain more mobile in soil water. This increased mobility raises the PFAS concentration in the soil solution, making them more bioavailable and thus more accessible for uptake by plant roots. Conversely, strong sorption between soil particles and PFAS limits the amount of PFAS in the soil water, decreasing their bioavailability and subsequently reducing the amount that plants can take up. The abovementioned environmental conditions indirectly control the amount of PFAS that remains in the soil solution versus being bound to soil particles, shaping the extent to which PFAS can enter plant systems.

Greenhouse studies of potted plants with biosolids-amended soils have often reported higher BCFs than field studies (Blaine et al. 2013). Uptake of PFAS in produce plants was also greater when grown in fields that were situated near industrial sources (potentially due to air deposition or irrigation water) (Bao et al. 2020). In general, higher PFAS concentrations in soil are correlated with higher PFAS concentrations in plants; however, the increase in concentrations may not be directly proportional. Soil organic matter has been found to sequester PFAS and limit plant uptake in some studies reviewed. However, other studies note that in field studies at locations where biosolids had been applied, there does not appear to be a significant or consistent correlation between PFOA and PFOS uptake factors and soil concentration, pH, organic matter content, or cation exchange capacity (Simones et al. 2024). More detailed discussion of these findings and trends for PFOS and PFOA is presented in the USEPA draft risk assessment (USEPA 2025). The ITRC summary compilation and review (**Table 5-2**) presents information for multiple PFAS and include both edible and nonedible plant species.

1.7.4.5 Plant Response to PFAS Exposure

In general, plant uptake from soil includes both the process of initial uptake into the roots and subsequent translocation to and accumulation in varying portions of the plant. Unlike conventional neutral organic chemicals and ionic compounds, PFAS exhibit a greater range of anionic and both lipophilic and hydrophilic behaviors (Mei et al. 2021). Studies have indicated that the uptake of PFAS in plant tissues is influenced by the physicochemical properties of the PFAS, especially the carbon chain length and functional groups, while the accumulation may be influenced by plant morphological traits such as internal organization and functioning of the root and shoot systems (Lesmeister et al. 2021; Ghisi et al. 2019; Adu et al. 2023; Wang et al. 2020; Mei et al. 2021). For instance, PFAS with longer carbon chains tend to accumulate in the roots with limited movement to the upper parts of the plant, whereas those with shorter carbon chains are more likely to translocate and accumulate in the shoots. Additionally, plants generally take up more PFCAs compared to perfluorosulfonic acids (PFSAs), when the carbon chain length is the same (Ghisi et al. 2019). The water-soluble fraction of PFAS in soil is negatively

related to PFAS carbon chain length and log Kow values, while it positively correlates with PFAS levels in plant shoots and total plant biomass (Zhang et al. 2021).

When exposed to PFAS, plants undergo growth stress and exhibit a range of responses. At the cellular and metabolic level, research has shown that PFAS exposure can cause considerable impact, including structural changes in root cell organelles and disruptions to cell walls, especially with prolonged exposure (Li et al. 2020). This physiological impact weakens the plant's resilience to environmental stresses by hindering the production of new proteins. PFAS exposure has also been linked to changes in membrane permeability in plant cells, which can impair cellular function (Lin et al. 2020). Additionally, PFAS can affect photosynthetic pigments, with the effects differing among plant species (Lan et al. 2018; Li et al. 2020; Chen et al. 2020). PFAS exposure may also trigger the production of reactive oxygen species such as hydrogen peroxide and superoxide anions, resulting in oxidative stress (Lin et al. 2020; Yang et al. 2015; Li et al. 2021; Li et al. 2021) To mitigate this stress, plants upregulate enzymatic antioxidants, such as superoxide dismutase, catalase, and peroxidase. However, when PFAS concentrations are high, these defense mechanisms can be overwhelmed, leading to decreased antioxidant production and increased plant toxicity due to disrupted nutrient uptake (Qu et al. 2010; Fan et al. 2020; Li et al. 2020; Li et al. 2020).

On a molecular level, PFAS can influence the expression of genes associated with stress responses and metabolic pathways (Li et al. 2020; Fan et al. 2020). Additionally, PFAS exposure can cause imbalances in primary and secondary metabolites in plants (Li et al. 2020). These molecular changes highlight the substantial impact of PFAS on plant physiology and biochemistry, revealing a complex interaction between PFAS and plant health, with effects that vary across different plant species.

1.7.4.6 Mechanistic Studies of Plant Uptake of PFAS

The mechanistic study on PFAS uptake by plants conducted by Wen et al. (2013) identified that protein carriers in maize roots, likely involving aquaporins (protein-based water channels in root cells) and anion channels, play a role in the uptake process of PFOA and PFOS. Further research by the same authors explored the relationship between PFOA/PFOS accumulation and the protein and lipid content in the roots of seven plant species (Wen et al. 2016). Their findings indicated that root proteins facilitate while lipids inhibit the uptake of PFOA and PFOS.

Zhang et al. (2019) later discovered that the uptake of PFAAs with a carbon chain length between 2 and 8 in wheat is primarily an energy-dependent active process mediated by carrier proteins, including aquaporins and anion channels. However, at higher concentrations in hydroponic systems (3 mg/L), ultrashort PFCAs (such as trifluoroacetic acid (TFA) and perfluoropropionic acid (PFPrA)) were transported into wheat cells passively, without the involvement of carriers. They also suggested that competition for uptake might occur among PFAS compounds that share the same transport carriers. Once PFAAs enter the wheat xylem (vascular tissue), they are distributed throughout the plant via the transpiration stream.

A similar uptake mechanism was proposed by Wang et al. (2020) for the Asian water plantain (*Alisma orientale)*, where PFOA and PFOS are initially taken up by the root cell wall. A portion of these compounds can actively pass through the cell wall and plasmalemma, likely facilitated by aquaporins and anion channels. A variety of pathways in both living (symplastic) and nonliving (apoplastic) plant tissues contribute to PFAS translocation.

1.7.4.7 Modeling Plant Uptake of PFAS

Researchers are increasingly turning to machine learning (ML) tools to predict the uptake and accumulation of PFAS in plants (Adu et al. 2024; Xiang et al. 2023; Song et al. 2023; Bagheri et al. 2020). By leveraging data from previous studies on plant uptake, these efforts have shown that key uptake indices—such as root concentration factor, shoot concentration factor, BAF, and translocation factor—

can be accurately predicted. These predictions are based on a range of input variables, including plant species, plant root protein content), PFAS functional groups, PFAS molecular weight, pKa value of PFAS, log Kow of PFAS, PFAS exposure concentration, exposure duration, soil organic carbon content, pH, soil texture, and soil cation exchange capacity.

1.7.5 Uptake by Animals

There is an abundance of information indicating that certain PFAS (such as PFOS) bioaccumulate in fish, birds, and mammals (for example, Houde et al. 2011; Giesy and Kannan 2001; Guckert et al. 2023). The use of biosolids for land application has the potential to contaminate crops and cover crops with PFAS due to uptake into plants (Blaine et al. 2013; Blaine et al. 2014; Costello and Lee 2020; Felizeter et al. 2021; Knight et al. 2021; Yoo et al. 2011) (see **Section 1.7.4**), and leach from the land-applied soil into groundwater and surface waters (see Section **5.3.3**). This in turn can lead to uptake into terrestrial organisms, including livestock and game animals that graze on contaminated farmland and ingest contaminated plants grown as forage or feedstock or contaminated water that leaches from the soil (Brake et al. 2023; Death et al. 2021; Mikkonen et al. 2023; Simones et al. 2024; van Asselt et al. 2013). The primary exposure pathways through which livestock may be exposed to PFAS from biosolid sources include diet, drinking water ingestion, and incidental ingestion of soil (see **Section 1.4.7**). Aquatic organisms such as fish may also be exposed to this contamination source due to soil leaching, runoff, or erosion into nearby surface waters (see Section **5.5**).

Few studies have investigated uptake of PFAS into livestock and game animals exposed to biosolid-impacted farm fields (Death et al. 2021; Kowalczyk et al. 2012), with some studies showing that PFAS accumulates in chickens, eggs, and other protein sources at levels that could potentially be significant with respect to human exposure (Wilson et al. 2020; Lasters et al. 2022; Mikkonen et al. 2023; van Asselt et al. 2013) (see **Section 9.1.2**). The Maine Department of Environmental Protection (ME DEP) has been investigating PFAS in farmlands in the state where sludge and septage have been applied, finding PFAS in water, soil, hay, and milk (ME DEP 2023). Testing of deer and turkey meat from areas in Maine with fields that had PFAS-impacted biosolids applied resulted in “Do Not Eat” advisories for deer and wild turkey (ME DIFW 2023). In Michigan, PFOS-containing biosolids that were applied to fields at a cattle farm resulted in PFOS detected in beef samples at levels warranting a human consumption advisory (MI DHHS 2023). Other states are just beginning to investigate impacts on livestock from biosolid sources. For additional detail on the toxicological effects of PFAS on animals see **Section 1.4**.

1.7.5.1 Modeling PFAS Uptake to Livestock at Land Application Sites

Farms impacted by PFAS, whether through contamination in soil in fields used to grow crops for animal feed, in purchased feed, or drinking water, face the challenge of PFAS moving into the food products they produce (Death et al. 2021). Models that relate PFAS levels in soil, feed, or water to potential levels in a farm’s product, such as beef, pork, cow’s milk, or chicken eggs, are instrumental to risk assessors, farmers, and agencies assisting farms dealing with PFAS. Models that accurately estimate PFAS levels in livestock animal tissue following exposure and subsequent decline in PFAS levels if exposure ceases can provide useful information on when a product may have reduced PFAS levels, what fields or water sources a farm may want to avoid using, or can assist in cropping decisions to decrease PFAS levels in feed.

Several research groups have now developed such models to estimate PFAS levels in livestock. These models generally focus on PFOS, perfluorohexane sulfonic acid (PFHxS), and PFOA and are available for dairy cows, beef cattle, swine, and chicken eggs. Mikkonen et al. (2023) developed a dynamic exposure population toxicokinetic model for beef cattle focused on estimating PFOS and PFHxS in serum, liver, and muscle tissue. This dynamic model accounts for varying PFAS exposure levels from feed, water, and soil over the lifespan of a beef cow. Based on a one-compartment toxicokinetic model, daily PFAS intake from water, feed, and soil is translated into PFAS levels in serum, liver, and muscle. A benefit of this dynamic

modeling approach is the estimation of PFAS tissue levels resulting from varying PFAS exposure due to seasonal feeding patterns and changes in feed or water sources. Chou et al. (2023) developed a physiologically based pharmacokinetic (PBPK) model to estimate PFOS, PFHxS, and PFOA levels in beef cattle or milk from dairy cows. Given a soil or water PFAS concentration, the PBPK model estimates PFOS, PFHxS, and PFOA levels in liver, kidney, and muscle of exposed beef cattle and in dairy cows' liver, kidney, muscle, and milk. This model estimates the number of days required following exposure cessation (a withdrawal interval) for a PFAS tissue level to be below a prespecified level, such as an action level or maximum contaminant level. Chou et al. (2023) provided their model as a web-based tool (Lin 2023) for estimating this withdrawal interval for a given exposure in beef cattle or dairy cows.

The German Federal Institute for Risk Assessment also developed a web-based tool for estimating PFAS tissue levels from contaminated feed or water in beef cattle, dairy cows, pigs, and chicken eggs. This web-based Contaminant Transfer Predictor, or ConTrans tool, models PFOS and PFHxS levels in beef cattle blood, liver, and muscle, and for dairy cow's blood, liver, muscle, and milk. The modeling for beef cattle and dairy cows in the ConTrans tool is largely based on the dynamic model developed by Mikkonen et al. (2023). For swine the tool provides estimates for seven individual PFAS (PFBS, PFHxS, PFHpS, PFOS, PFHxA, PFHpA, and PFOA) in blood, fat, liver, kidney, and muscle tissue based on the swine exposure model developed by Numata et al. (2014) and Siemen et al. (2017). For chicken eggs, the tool provides estimated levels of PFBS, PFHxS, PFOS, PFHxA, PFOA, and perfluorononanoic (PFNA) in eggs with specified levels in feed. The chicken egg estimations are based on studies of PFAS exposure from contaminated feed (Kowalczyk et al. 2020) or drinking water (Wilson et al. 2021). Although these models in their development have used measured PFAS data in tissues, such as milk, beef, and serum, at impacted farms for validation and confirmation of their model estimates, application of the various models at farms with known PFAS exposures with comparisons to tissue biomonitoring data will be useful in assessing their accuracy and predictive power.

For more standard risk assessment practice in developing soil or water screening levels for livestock, exposure pathway equations from the USEPA Preliminary Remediation Goals for Radionuclides (PRGR) or Human Health Risk Assessment Protocol for Hazardous Waste Combustion Facilities can be modified and implemented using PFAS-specific parameters (USEPA 2005; USEPA 2024). The general model with these equations is consistent daily exposure under assumed steady state conditions to relate PFAS levels in soil or water to levels in an animal tissue, such as beef muscle, cow's milk, or chicken eggs. For example, the Maine Center for Disease Control and Prevention (Maine CDC 2020) modified PRGR equations for soil screening levels for a soil-to-cow's-milk pathway to derive a soil screening level for PFOS (Maine CDC 2020). These types of models are useful for setting screening levels to determine whether more investigation at a farm may be warranted and when a farm product may need to be tested for PFAS.

1.7.6 Conclusion

As described in these Priority Topics and referenced sections in the PFAS-1 Document, biosolids represent an important potential PFAS source consideration due to the large volumes generated daily at wastewater treatment plants around the world. PFAS in biosolids present major challenges to municipalities that are generating biosolids but are passive receivers of upstream sources of PFAS. The widespread land application of biosolids as fertilizer may represent a risk from factors such as subsequent PFAS leaching to groundwater, uptake to crops used for food or animal feed, and resulting accumulation in terrestrial and aquatic organisms. The strong retention and slow leaching of PFAS in vadose zone soils means that historical sources from decades-old practices can impact human health and environment in the present day.

Many factors influence PFAS leaching, transport, and uptake, including site-specific geology and hydrogeology, PFAS concentrations, presence of precursors and non-targeted PFAS, and the frequency and rates of land application. Ongoing research into fate and transport of PFAS in agricultural settings,

rates of uptake into crops and both wild game and domestic animals consumed for food, and continuing efforts to reduce PFAS concentrations in the wastewater stream will be important considerations when evaluating whether biosolids warrant attention on a site-specific basis.

1.8 Priority Topics for PFAS and Microplastics

Section Number	Topic
1.8.1	**Composition and Definitions**
1.8.2	**Co-sources of PFAS and Microplastics**
1.8.3	**Sampling and Analysis**
1.8.4	**Fate and Transport**
1.8.5	**Risk Assessment**
1.8.6	**Treatment**
1.8.7	**Regulatory and Guidance Considerations**
1.8.8	**Changing Weather Patterns**

These Priority Topics discuss the available information about the interconnections between PFAS and microplastics (MP). The unique issues around MP and PFAS (for example, heterogeneity, persistence, and toxicity concerns at low levels) warrant additional study of the potential interaction of these two groups of contaminants when they occur in the same environmental matrix. Additionally, there are significant interaction issues noted in literature on fate, transport, and bioavailability (see **Section 1.8.4**).

This section focuses mainly on the interactions and co-occurrence of PFAS and MP. For the detailed discussions on PFAS and MP exclusively, refer to the PFAS Technical and Regulatory Guidance Document **(PFAS-1)** and the Microplastics Technical and Regulatory Guidance Document **(MP-1)**, respectively.

Information about Strategic Environmental Research and Development Program (SERDP) projects for PFAS and Microplastics can be found at **https://serdp-estcp.mil/**.

1.8.1 Composition and Definitions

ITRC has defined “microplastics” as particles that are greater than 1 nanometer (nm) and less than 5,000,000 nm (or 5 millimeters [mm]) in their longest dimension and consist of solid polymeric materials to which chemical additives or other substances may have been added. This definition includes microfibers (**Section 1** in MP-1). Polymers that are derived in nature (for example, cellulose, amber, proteins, wool, or silk) that have not been chemically modified, other than by hydrolysis, are excluded from this definition (MP-1). This definition is similar to that developed by the State of California (CA SWRCB 2020).

Plastic particles less than 1,000 nm in their longest dimension are also referred to as nanoplastics (NP). Although the definition of NP is still being debated, it is generally accepted in scientific literature that they are produced by the fragmentation of MP (or larger particles), measure between 1 nm and 1,000 nm in length, and demonstrate a colloidal behavior. MP can be classified as primary or secondary. Primary MP are small plastic particles manufactured for a particular use. Primary MP include microbeads for use in various applications, including laboratory testing and agriculture (Bangs 1996; Ugelstad et al. 1992; Langlet et al. 2024), as well as small plastic beads, or nurdles, for use in industrial processes (**Figure 1-31**). Secondary MP are small plastic fragments that are created by the breakdown, degradation, or weathering of larger plastics, such as water bottles and bags (Arthur, Baker, and Bamford (eds.) 2009).

This breakdown is from physical, chemical, or biological processes, or some combination of those processes.

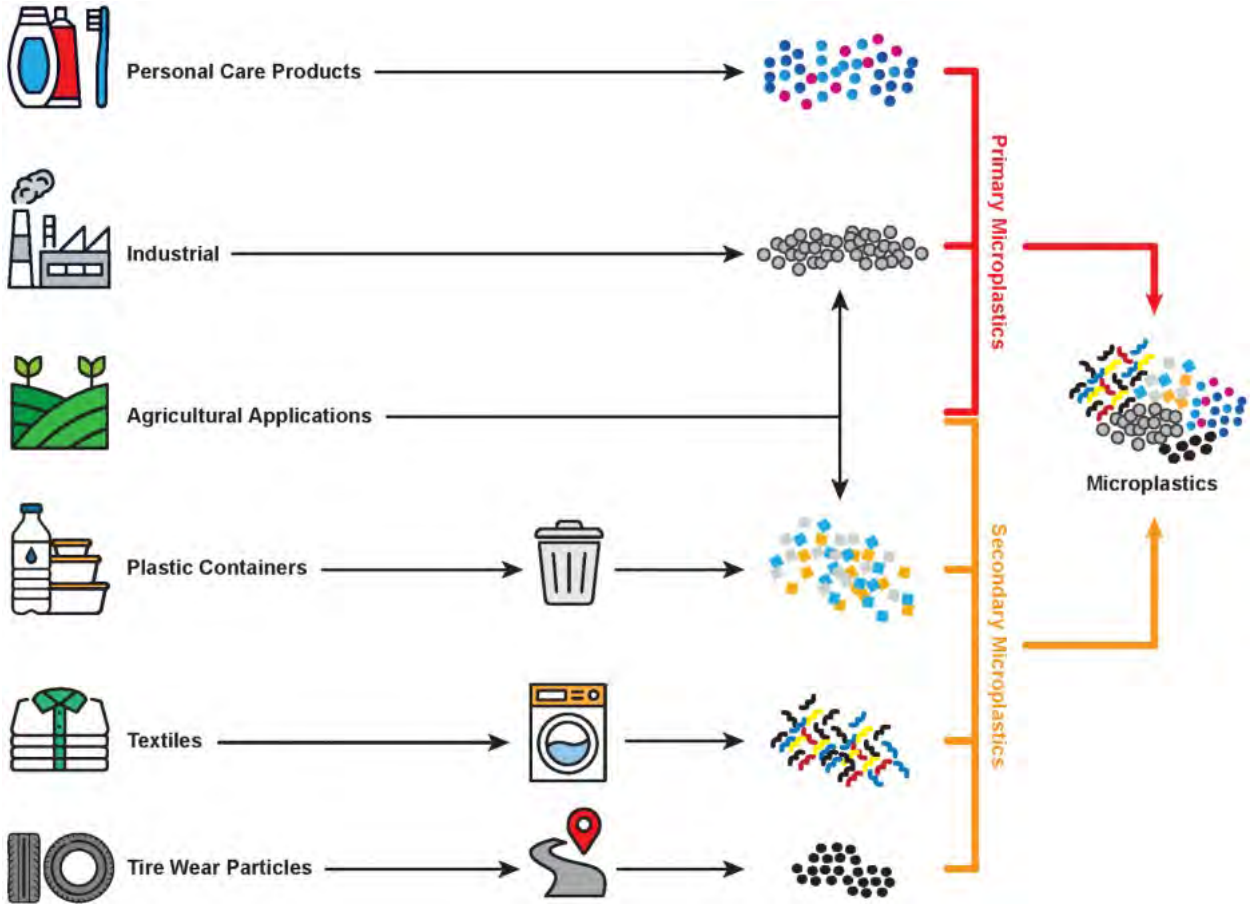

Figure 1-31. Primary and secondary microplastics.

*Source: Figure 2-2.**MP-1**, Jonathan MacDonald.*

PFAS include a wide variety of molecules with different physical and chemical properties and molecular weights with perfluoroalkyl moieties as common structural features. This variety of PFAS with diverse properties is organized in the form of a PFAS family tree (**Figure 2-4**) that includes two primary classes: polymers and nonpolymers. In plastic products, additives and processing agents are often added to enhance the properties of the plastics, while nonpolymer PFAS is one of the important processing aids. The nonpolymer PFAS processing aids may be found as impurities in some fluoropolymer products. More information is included in **Section 2.2.2.1** in PFAS-1. Nonpolymer PFAS are most commonly detected in the environment and typically referred to simply as PFAS. Polymeric PFAS such as, fluoropolymers, side-chain fluorinated polymers, and poly- or perfluoropolyethers (Lohmann et al. 2020) can break down into MP (Cook and Steinle-Darling 2021). Some plastics are polymer PFAS (for example, polytetrafluorethylene (PTFE)), or contain nonpolymer PFAS, or both. These polymer PFAS may be primary MP or may be present as secondary MP in the environment, or both (Bergmann et al. 2017; Ebnesajjad 2013; Cook and Steinle-Darling 2021). Both PFAS and MP are families of contaminants, with thousands of different species and additives, respectively, which result in a wide range of physical and chemical properties.

1.8.2 Co-sources of PFAS and Microplastics

Plastics and PFAS are often applied in the same products to improve their stability and durability, and these products release both contaminants into the environment through their manufacturing processes, uses, and disposal (Gaines 2022, Weis and Alava 2023). Polymeric PFAS materials used in commerce (for example, personal protective equipment, outdoor equipment) that are subject to weathering and physical stress have the potential to release PFAS-containing MP to the environment (Peaslee et al. 2020; Schellenberger et al. 2022). Some food packaging materials are coated with PFAS due to its functional properties to repel oil, grease, and water (Curtzwiler et al. 2021). These food contact materials could potentially release and transfer MP and PFAS into the food chain, profoundly impacting human health and the environment (Perkins 2021; Parashar, Mahanty, and Hait 2023; Koelmans et al. 2016). Alternatively, PFAS and MP can occur in separate upstream sources, which then result in PFAS sorbing to MP that could continue to flow together through environmental systems or trophic chains (**Section 2** in MP-1; **Section 5.1** in PFAS-1) (Parashar, Mahanty, and Hait 2023; Koelmans et al. 2016).

Despite the co-occurrence of PFAS and MP in various systems, predicting where these contaminants will primarily be concentrated is challenging. Because both PFAS and MP are heterogeneous classes of contaminants that possess a range of physical chemical properties, the fate of both depends heavily on both the properties of the MP and PFAS, as well as the environmental system in which they are found (see also **Section 1.8.4**). For example, effluent from wastewater treatment plants (WWTPs) is known to be a source of MP and PFAS to ecosystems (Liu et al. 2021; Nguyen et al. 2022). At the same time, PFAS and MP are found in the sludge or biosolids generated from WWTPs (Nguyen et al. 2022; Ziajahromi et al. 2021). The removed PFAS and MP in different treatment processes of WWTPs are transported to landfills (Nguyen et al. 2022). Landfills have been demonstrated to receive MP and PFAS from WWTPs, especially in the waste solids (Prada et al. 2024; Ma et al. 2025). However, the leachate coming from these landfills can also contain both PFAS and MP that are then sent back to WWTPs or released to the environment (Rahman, Sultan, and Alam 2023; Prada et al. 2024). Furthermore, numerous products and materials containing these contaminants are improperly discarded at the end of life, allowing the release of MP and PFAS into the environment (Coffin, Reeves, and Cassidy 2023; Lohman et al. 2020).

1.8.3 Sampling and Analysis

This sampling and analysis section focuses on issues relating to the co-occurrence/co-measurement of MP and PFAS. No standard methods exist for the measurement of PFAS sorbed on MP. For sampling and analysis guidance on MP and PFAS, including methods, issues, and uncertainties, consult **Section 3** in MP-1 and **Section 11** in PFAS-1. Understanding the interactions around adsorption and subsequent bioavailability of PFAS from microplastics needs further research. Several issues on co-occurrence have been identified in review literature (for example, Parashar, Mahanty, and Hait 2023). Sampling and analysis issues for PFAS and MP include:

- Does PFAS to sorb to microplastics and how does that influence sampling and analysis?
- Are microplastics a source of small molecule PFAS arising either from manufacturing residuals or from side-chain PFAS polymer degradation (Li et al. 2017)?
- Do MP behave the same as natural non-MP solids during sampling and analysis on the issues of PFAS partitioning and sampling representativeness?

Studies have indicated that MP can adsorb contaminants, such as PFAS, from the surrounding environment and act as carriers of these contaminants. This can alter the bioavailability and toxicity of these substances to human health and the environment. This interaction complicates efforts to assess the overall impact of these pollutants and underscores the need for comprehensive studies and sampling and analysis guidelines to address their combined effects. As discussed in **Section 1.8.2**, due to the

widely different physical and chemical properties of MP and PFAS, their co-occurrence measurement involves separate analyses for MP and PFAS, bringing in increased uncertainty.

One academic study by Scott et al. (2021) measured PFAS sorbed on MP; indicating the ability to successfully measure sorbed PFAS. Scott et al. (2021) also found that PFAS sorption on MP was significantly higher in the field than in laboratory studies. They wrote that this sorption was "greatly enhanced by the presence of inorganic and/or organic matter associated with these materials in the environment" (Scott et al. 2021).

In 2024, the US Environmental Protection Agency (USEPA) released a new methodology for detecting low levels of PFAS on high-density polyethylene (HDPE) plastic containers (USEPA 2024). This was developed by USEPA after learning of potential PFAS contamination for certain mosquitocide products and the fluorinated HDPE containers they were stored in (see **Table 2-7** in PFAS-1). The new method can identify 32 specific PFAS directly from the container walls. This allows industries, such as pesticide manufacturers, to test containers before use, ensuring that contamination is minimized (USEPA 2024; USEPA 2024). Although this method is validated for extraction of PFAS from a bulk plastic of one kind only, it is an example of an analytical method for measurement of certain PFAS from plastics.

Side-chain fluoropolymers (especially fluorotelomer-based) where the PFAS-containing moiety is attached to the polymer backbone, rather than being part of the backbone, are known as a significant source of fluorotelomer alcohols and perfluoroalkyl carboxylates in the environment (Li et al. 2017; Lohmann and Letcher 2023). As the plastics abrade in the environment into MP, the side-chain PFAS are subject to cleavage and reaction to form PFAS such as fluorotelomer alcohols (FTOHs), perfluoroalkyl carboxylic acids (PFCAs), and sulfonamides. In addition, previously uncharacterized PFAS have also been identified and measured as arising from other types of side-chain fluoropolymers (Chu and Letcher 2017). Many gaps still exist in the sampling and analyses of these types of MP-PFAS interactions, but they have been hypothesized as a significant source of PFAS (Li et al. 2017).

1.8.4 Fate and Transport

Information sources on the fate and transport of PFAS comingled with MP are still limited in the scientific literature. The fate and transport of PFAS has been well documented (see **Section 5** and **Section 1.3** in PFAS-1). This section focuses on the fate and transport of MP as it relates to the potential for PFAS transport. An understanding of role of MP in the overall fate and transport of PFAS is emerging. However, the detailed science is still being investigated, which would support quantitatively explaining the role of MP in fate and transport of PFAS. Significant research is still needed to understand these relationships.

The environmental fate and transport of PFAS is strongly influenced by their physical and chemical properties. Considering that PFAS represent thousands of chemicals and their transformation products, one would expect to observe a wide range of different fate and transport behavior, which adds complexity to characterizing and quantifying their environmental fate. Research based on the understanding of a select number of well-studied PFAS, however, enables an appreciation of various factors that are important when attempting to study their environmental fate and transport (see **Section 5** and **Section 1.3** in PFAS-1). Characteristics of MP that are important to understand include the size, shape, density (polymer composition), and surface functionality (see **Section 2** in MP-1). For example, relatively large MP (>1 mm), which have densities >1, will have higher deposition rates in both air and water as compared to 1 micron-size MP with densities around 1. Some caution is warranted, however, because these generalizations can be influenced by the environmental system properties into which MP are released. Thus, similar to PFAS, MP complexity results in significant challenges when assessing their fate and transport individually or when co-occurring with PFAS.

Until recently, the majority of MP studies focused on water column and soil environments using virgin plastic materials. By comparison, current research is focused on understanding the fate, transport, and

distribution of NP and MP within water, soil, sediment, and air matrixes, and introducing real-world confounding factors such as ultraviolet (UV) and physical weathering, biofilm formation, and natural organic matter sorption along the surface and pore regions of weathered plastics. It is due to these real-world factors that MP can have a potentially increased capacity as transport vectors for contaminants, such as PFAS and metals, and pathogenic microorganisms in the environment (Wang, Guo, and Xue 2021). The role and contribution of PFAS adsorption to MP as a transport vector is complex and currently not well understood compared to other factors influencing the fate and transport of PFAS.

Salawu, Olivares, and Adeleye (2024) reported long-chain PFAS, such as perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS), have been observed to be the "most abundant PFAS adsorbed to MP," referencing Cheng et al. (2021) and Navarathna et al. (2023). PFOS and PFOA, for instance, have also been observed to sorb to naturally occurring particulate and dissolved organic carbon, and in some instances electronic interactions between these chemicals and different soil minerals can be observed (see **Section 5** in PFAS-1). In general, the long-chain PFAS may increase the mobility of longer polymer MP, such as PTFE, in the subsurface (Zhao et al. 2025).

Atmospheric transport and deposition of PFAS and MP result in their accumulation in aquatic systems, which is the result of direct (wet/dry deposition) and indirect (surface runoff) deposition (Kurwadkar et al. 2022; Huang et al. 2021). Although most studies have concentrated on atmospheric deposition to water and soil, recent research has shown that MP, combined with emerging contaminants such as PFAS, can be re-released into the atmosphere from marine and soil environments due to strong winds or water turbulence (Borthakur et al. 2022; Allen et al. 2022). For example, there is clear evidence of MP being deposited from land to the ocean (Ryan et al. 2023; Amelia et al. 2021). However, some evidence implies MP re-emittance in onshore winds and sea spray mist, facilitating ocean-to-atmosphere transmission (Allen et al. 2022). A 2020 study, based on a short-term pilot project (on the French Atlantic coast), provided analytical results from air samples of MP in the marine boundary layer and indicated the potential for MP, enriched with other pollutants, to be released from the marine environment into the atmosphere (Allen et al. 2020). Given that various PFAS have been reported to adsorb onto MP in aquatic environments (Bere et al. 2023; Scott et al. 2021), MP can become enriched with PFAS and potentially be reintroduced into the atmosphere from water. Some of these atmospheric transmission processes are being studied.

Section 2 in MP-1 includes information about environmental distribution, fate, and transport of MP, including degradation of plastics once released to the environment. As noted, secondary MP are generated through chemical, physical, and biological degradation of larger plastic products in the environment. The plastic degradation processes are important in determining the fate and effects of MP in environmental media. Most plastics are subjected to abiotic (for example, mechanical, thermal, and photodegradation) and biotic degradation processes involving chemical, physical, and biological reactions. Zhang et al.(2021) is a review article that summarizes literature on the degradation processes of plastics and generation of MP in the environment.

Mechanical degradation (**Section 2.9.1** in MP-1) is the breakdown of plastics due to external forces. In the environment, external forces can come from the collision and abrasion of plastics with rocks and sands caused by wind and waves. Freezing and thawing of plastics in aquatic environments can also result in the mechanical degradation of polymers (Niaounakis 2015; Pal et al. 2018; Alimi et al. 2021; Acharjee et al. 2022). The wider literature suggests that the release of MP stems from thermal and mechanical degradation; as such, MP release is likely to be exacerbated if hard or sharp utensils are used with plastic and PTFE-coated cookware or these materials are heated to higher temperatures. Sobhani et al. (2020) found that MP can be generated from daily activities, such as cutting plastics using scissors or knives and tearing or twisting to open plastic containers, bags, tapes, and caps. Depending on the condition of the plastic materials' stiffness, thickness, density, and size, Sobhani et al. (2020) reported the generation of 0.46 to 250 MP/cm. Generation of MP depends on the composition of the original plastic,

its use, and where it is used. Plastic debris represents a complex issue, in that the degradation and weathering of plastic debris may represent an important source of secondary MP.

Thermal degradation (**Section 2.9.1**, in MP-1) refers to the breakdown of plastics due to energy input stemming from elevated temperature. Plastics can undergo thermo-oxidative reactions at high temperature. When sufficient heat is absorbed by the polymer to overcome the energy barrier, the long polymer chains can be broken, generating radicals (Pirsaheb, Hossini, and Makhdoumi 2020; Peterson and Hubbart 2021).

Photodegradation (**Section 2.1.2** in MP-1) in the natural environment as facilitated by UV irradiation is a known and important pathway for plastic weathering and fragmentation. Barthelemy et al. (2024) investigated UV irradiation in addition to mechanical stress, such as sediment abrasion and water motion, on plastic fragmentation in intermittent rivers and ephemeral streams. The team determined that plastic fragmentation increases with the duration and severity of drying episodes between rainstorms. Additionally, reservoirs with long hydraulic residence times, such as the Great Lakes (Fuschi et al. 2022), and thermal stratification (Zhang et al. 2023) could play a significant role in bioaccumulation and the persistence of NP and MP.

Biotic degradation (**Section 2.9.2** in MP-1) can occur in the environment through a variety of processes. Some organisms (for example, bacteria, mealworms) in soils can degrade specific polymers (Gu 2003; Yang et al. 2015). Other studies have reported physical breakdown of plastics by organisms through chewing or digestive fragmentation (Cadée 2002; Cau et al. 2020; Dawson et al. 2018; Jang et al. 2018; Mateos-Cárdenas et al. 2020; Porter, Smith, and Lewis 2019).

Fragmentation and weathering can increase the surface area, roughness, morphology, and functional groups available for sorption of chemicals to MP. Further, the formation of biofilms and adsorption of natural organic matter changes the surficial hydrophobicity of MP, potentially leading to changes in fate and transport behavior in the environment (Yu et al. 2024) and potentially leading MP to act as a sink for contaminants (Bhagwat et al. 2021). Scott et al. (2021) studied the interaction of MP and PFAS in natural lakes and in a controlled laboratory environment. The results indicated that the adsorption of PFAS by MP was increased (up to 259 times) by the presence of inorganic and organic matter from the lake water as compared to the laboratory environment. One study by Bhagwat et al. (2021) monitored the long-term aging of plastic in the marine environment. Over the course of 10 years, the team identified that mechanical and UV weathering coupled with biofouling of HDPE sleeves encasing wooden poles in an Australian oyster aquaculture farm exhibited higher concentrations of metaloids, polycyclic aromatic hydrocarbons (PAHs), and PFAS in the plastic-associated inorganic and organic matter. A second study by Bhagwat et al. (2021) determined that increased PFOS adsorption to aged microfibers (from polypropylene, polyethylene, nylon, and polyester ropes) in a marine environment was due to the higher surface area and the changed characteristics facilitated by biomass accumulation compared to the virgin samples. Shi et al. (2023) compared the adsorption for virgin and weathered MP in freshwater, using two long-chain and two short-chain PFAS and two common microcystins (a class of cyanotoxins). In contrast to the findings by Bhagwat et al. (2021) and Scott et al. (2021), Shi et al. (2023) found that “up to 50% adsorption of PFOS was observed for virgin PVC compared to 38% for weathered PVC.” Shi et al. (2023) concluded that “natural weathering of MP surfaces may decrease adsorption by introducing hydrophilic oxygen-containing functional groups, and adsorption is driven by specific polymer types and dominated by hydrophobic interactions.”

MP aging occurs in natural environments (Xiao et al. 2023), changing their physical and chemical properties through a range of processes, including mechanical degradation, photodegradation, chemical degradation, and freeze-thaw cycles, as mentioned above. Aged MP demonstrated increased capacity for heavy metal adsorption (Xie et al. 2025). Understanding the adsorption mechanisms of heavy metals onto aged MP is crucial for evaluating the interactions among MP, PFAS, and heavy metals (Xie et al. 2025).

As mentioned, MP can provide a unique substrate for microorganisms. Wang et al. (2021) studied MP that have biofilms on them and found that MP with biofilms sorb a larger concentration of organic pollutants compared to MP without biofilms. The MP that have biofilms can transport organic pollutants and attached microorganisms in the environment. MP are quickly and easily colonized by microorganisms and subsequently form biofilms that influence additional sorption by natural organic matter, metal ions, pollutants, and pathogenic bacteria. Additionally, MP facilitate bacterial antimicrobial resistance due to their higher propensity for facilitating biofilms (Gross et al. 2025). Biofilm cells attached to MP had elevated resistance to drugs, which can promote antibiotic-resistant bacteria and infections in the environment and healthcare settings (Gross et al. 2025).

Agricultural soils are a source of MP because of biosolids amendments (Yu et al. 2023). Yu et al. (2023) determined that polyester fibers affected soil physical properties differently compared to polypropylene granules because of their very different shapes. These differences may have an effect on soil physical properties at higher MP concentrations. A study by Borthakur et al. (2022) also looked at PFAS and MP in biosolids and indicated that aged MP could affect PFAS adsorption on MP.

To date, there is limited research on the distribution, fate, and transport of MP comingled with PFAS in the environment, although SERDP identified projects to investigate this topic; more information is on their website **https://serdp-estcp.mil/**. Similarly, little research has been done on the combination of atmospheric deposition of PFAS and MP in urban systems.

1.8.5 Risk Assessment

This section provides an overview of the available information relevant to risk assessment considerations for the co-exposure of PFAS and MP. As an overview of the knowledge related to the specific co-exposure and health effects of MP and PFAS, this section refers to detailed information for evaluating PFAS toxicity (**Section 7** in PFAS-1) and the application for risk assessments (**Section 9** in PFAS-1), as well as information on exposure and toxicity (**Section 4** in MP-1) and risk assessment (**Section 4.7** in MP-1) about MP without consideration of PFAS.

Robust information is currently lacking about the potential interactive effects of MP and PFAS on exposure and health effects for both wildlife and humans. Thus, the risk assessment science on PFAS-MP interaction is best characterized as uncertain due to the small number of available empirical studies on this topic. Although the potential for co-exposure to PFAS and MP in various media has been discussed in some recent review articles (Siddiqui 2024; Soltanighias et al. 2024; Dai et al. 2022), these articles focused on modeled or proposed interactions of these contaminant classes with limited quantitative information about co-occurring exposures to and combined toxicity from MP and PFAS. Similar to other contaminant mixtures, study design limitations for evaluating even a small number of possible mixture combinations are challenging when using historical or contemporary testing methods. This problem is compounded by the diversity of both the PFAS and MP families, and the potential varying blends of their constituents that may be occurring in different environments. As discussed in **Section 7.1.5** in PFAS-1, approaches for quantitative risk assessment of PFAS mixtures alone are still limited by insufficient data, but some approaches are being investigated within the primary literature (original research articles and review studies) or as risk management strategies by regulatory or public health agencies.

From an exposure standpoint, interactions between MP and PFAS can potentially influence fate and transport in the environment (see **Section 1.8.4**), indicating a need to investigate the subsequent impacts on relevant exposure pathways for risk assessment. The potential for PFAS and MP to co-occur and interact within exposure media has been poorly studied and documented, creating a level of uncertainty that may drastically increase the likelihood for either over- or underestimation of exposure. Although concerns about co-occurring exposures to PFAS and MP across various media and receptors (aquatic and terrestrial wildlife, as well as humans) have been expressed (Dai et al. 2022; Siddiqui 2024; Yu et al.

2024; Kang et al. 2024), they are difficult to quantify, in part, due to the widely varying physical and chemical properties of and diversity of constituents in both groups of contaminants.

Regarding human health risk assessment or mammalian model studies (rat or mouse studies) typically used to derive human health benchmarks, toxicity information for the combined exposure to PFAS and MP is almost entirely limited to in silico estimations or secondary literature (review articles). Compared to the literature available for PFAS and MP as separate classes of contaminants, not co-exposures, almost no primary literature for epidemiological, animal, in vitro, or in silico studies exists that may be used to adequately characterize biological responses to co-exposures of PFAS and MP. With respect to human epidemiology, there is a significant lack of studies evaluating the combined effects using exposed populations; however, some efforts have been made to postulate potential effects through computer modeling (Du et al. 2023; Enyoh et al. 2023) Given the diversity of both PFAS and MP, others have suggested that the interaction of PFAS with plastic additives may affect the toxicity of certain additives on female reproduction based on computational modeling approaches to toxicity assessment (Du et al. 2023). Limited studies are available for animal models that assess the effects of specific PFAS combined with typically laboratory-grade types of MP. For example, in a single mammalian study evaluating PFAS and polystyrene MP (10 µm) , altered bioaccumulation of perfluorobutane sulfonic acid (PFBS) was reported in the liver, and associated changes in molecular markers of liver function were observed (Jiang et al. 2025). Additional studies using animal or in vitro models exist, but the differences in specific PFAS, types of MP, exposure routes, and concentrations complicate evaluation of consistent effects across the limited literature at this time (for example, O'Connor et al. 2024; Lv et al. 2025; Zhang et al. 2025; Zhou et al. 2025; Zou et al. 2025). Currently, there are no quantitative human health risk assessment methodologies for evaluating combined exposure to PFAS and MP as mixtures. There are currently no human health–based toxicity factors (for example, reference doses (RfDs) or cancer slope factors (CSFs), see **Section 7** in PFAS-1) or adjustment factors for specifically evaluating co-exposures of PFAS and MP.

Similar to human health, there are no finalized toxicity factors for combined exposures to MP and PFAS of ecological receptors (aquatic and terrestrial receptors). As previously discussed, MP may pose risks due to their physical, chemical, morphological, and adsorbed contaminant properties and could influence PFAS-related exposure and subsequent risks. This creates a significant challenge for developing toxicity studies for evaluating ecological risks for a small combination of MP and PFAS, let alone the broader families for both contaminant classes that are reasonably expected to co-occur in the environment. The physically mediated adverse effects of MP are influenced primarily by their physical particle characteristics (such as particle size, shape) and behavior. Furthermore, the potential different responses (additive, antagonistic, or synergistic) to varying combinations of PFAS and MP constituents are of interest to toxicologists. For example, one combination exposure study on medaka (Japanese rice fish) embryos attributed embryotoxic effects to PFOS and not MP (polyethylene, 4–6 µm) or their interaction (Le Bihanic et al. 2020). Other studies using aquatic invertebrates *(Daphnia magna)* reported both additive and synergistic effects on fecundity following exposure to PFOS, PFOA, and combination with polyethylene terephthalate (38–50 µm) (Soltanighias et al. 2024). For a terrestrial receptor (earthworms), Sobhani et al. (2021) reported that polyvinyl chloride (PVC)-MP (<125 µm) enhanced the uptake, bioaccumulation, and reproductive toxicity of PFOS and PFOA. The limited number of studies across taxonomic groups and lack of studies for specific PFAS-MP mixtures all contribute to a high degree of uncertainty for characterizing or quantifying risks to ecological receptors. Currently, each class of contaminant has been evaluated separately for exposure of and risks to ecological receptors. Detailed information for these risk assessments is provided in **Section 4.6** in MP-1 and **Section 7.2** and **Section 16** in PFAS-1.

Additional research on PFAS-MP interaction and effects to human and ecological receptors from varying blends of constituents from these classes is needed for conducting robust data-driven risk assessments for human health and ecological receptors. The current challenges for producing high-quality data across

the diverse families of MP, PFAS, and their potential real-world mixtures have limited efforts to quantify both human health and ecological risk at this time.

1.8.6 Treatment

The widespread production and use of PFAS, as well as the many sources of PFAS release to the environment, have resulted in trace levels of PFAS in most environmental media worldwide. Although MP exist as particulate matter in aqueous streams at a wide range of particle sizes, PFAS are more often found in the dissolved phase. Although several technologies exist that can treat PFAS or MP in aqueous media, there is a challenge for a singular technology when the goal is to remove both sets of contaminants, which have different inherent properties. SERDP has identified projects to investigate treatment of PFAS and MP; more information is on their website **https://serdp-estcp.mil/**.

MP can present a favorable medium to complex with (adsorb) contaminants, including PFAS such as PFOS and FOSA, via electrostatic or hydrophobic interactions (Alimi et al. 2018; Salawu, Olivares and Adeleye 2024; O'Donovan et al. 2018). These potential interactions demonstrate the need for effective treatment solutions targeting both sets of contaminants.

The development of treatment technologies for these two groups of contaminants is rapidly evolving, but at different levels of maturity. Although treatment of PFAS has been studied more extensively (**Section 12** in PFAS-1), MP treatment technologies are still being developed (**Section 6.2** in MP-1). Effective treatment technologies targeting both contaminant groups have not been accomplished at full-scale, and the literature is limited on effective efforts completed at the pilot- and bench-scale. However, comprehensive literature reviews (Ali et al. 2023; Satyam and Patra 2024) regarding the challenges and remediation of MP from different media could be very useful. Considering the co-existence of MP and PFAS, co-removal advanced technologies in a treatment train approach are highly desirable to effectively remove both MP and PFAS from affected environmental matrixes. Conceptually, individual technologies exist in the developmental stage (laboratory-scale) targeting both contaminants and should be investigated further (Tang and Hadibarata 2021; Pico et al. 2022; Nasir et al. 2024).

1.8.6.1 Field-implemented Treatment Train Approaches for the Removal of Microplastics and PFAS

Water Matrixes

Conventional treatment of wastewater is relatively effective as a bulk removal mechanism for MP. Results vary depending upon the source water, size and type of MP encountered, and the methodology employed by investigators (for example, enumeration per unit volume versus mass per unit volume, size cutoff due to analytical detection methodology). Overall, conventional water treatment methods have shown favorable removal efficiencies for MP. Grit chambers, settling and clarifying mechanisms, coagulation and flocculation, dissolved air flotation, and sand or mixed media filtration have all demonstrated significant removal efficiencies (Talvite et al., 2017; Pivokonsky et al. 2018; Ali et al. 2021), although direct comparison of removal efficiencies between studies that have a different minimum size cutoff (for example, 1 µm vs 20 µm) is difficult. Currently, it is difficult to speculate on specific quantitative efficiencies and metrics, because further studies are needed. Although conventional wastewater treatment technologies are not designed for PFAS removal, if PFAS have complexed with MP, it is likely that both sets of contaminants would be removed, along with the PFAS removed by complexing with organic matter present in the wastewater. There is a significant research gap in these areas, and further conclusive studies are needed. Based on our understanding, full-scale studies demonstrating removal efficiencies for PFAS and MP have not been completed. 5). Additionally, consideration must be given to the final fate of the contaminants (see **Section 1.8.2** and **Section 1.8.4**). If retained in the residuals from wastewater treatment (sludge or biosolids), understanding the final disposition of the residuals is important if land application is planned, to avoid re-release of contaminants to the

environment. Finally, when considering the volumes of water in treatment processes and the MP remaining in treated effluent, wastewater remains a significant contributor of MP to the environment. Murphy et al. (2016) found that approximately 65 million MP particles are released post-treatment each day from a municipal wastewater treatment plant that processes approximately 7 million gallons per day. Dong et al. (2025) evaluated reported PFAS concentrations at WWTPs in California and found "more than 80% of WWTPs exhibit an increased sum of 39 PFAS [identified in the study] concentrations in the effluent, with over half of these facilities facing a significant risk of surpassing a 70 ng/L threshold for PFAS levels in wastewater."

Removal of PFAS from aqueous solutions has been demonstrated in many studies using separation and adsorbent technologies (See **Section 12** and **Section 18** in PFAS-1). Nanofiltration and reverse osmosis processes have been shown to be effective for membrane applications, while granular activated carbon and single-use and regenerable anion exchange resins are effective PFAS adsorbents as demonstrated in bench-, pilot-, and full-scale evaluations (Boo et al. 2018; Johnson et al. 2019; Kempisty, Xing, and Racz 2018; Liu and Sun 2021; Ross et al. 2018; Zhang, Zhang, and Liang 2019). Novel medias such as cyclodextrin and modified organoclays have also demonstrated the ability to remove PFAS from aqueous waste streams (Kempisty, Xing, and Racz 2018; Yan et al. 2020). Similarly, when operated efficiently, these technologies would conceptually remove both PFAS and MP, but it is unclear at this time whether they will be effective. Granular activated carbon, ion exchange media, novel adsorbents, and any filterable pretreatment media will act as a filter and remove MP in addition to dissolved PFAS. **Section 12.8** and **Figure 12-7** in PFAS-1 discuss integrated water treatment solutions and pre-treatment technologies for PFAS treatment trains. Similar to wastewater treatment technologies, residuals management associated with backwashing and spent media should be considered to avoid reintroduction of contaminants into the environment.

By combining these proven treatment techniques of separation and filtration of conventional wastewater treatment and PFAS removal technologies, a more comprehensive approach can be deployed. The treatment train would integrate wastewater treatment technologies for removal of MP potentially combined with PFAS while the PFAS adsorbent or separation technologies would synergistically remove MP via filtration mechanisms.

Additional technologies that could be combined to form an effective treatment train are discussed in **Table 6-3** in MP-1 and **Section 12** in PFAS-1.

Solid Matrixes

Treatment technologies for PFAS in solid matrixes have been studied and demonstrated at full-scale (**Section 12.3** in PFAS-1), whereas MP treatment technologies in solid matrixes has not been widely studied (**Section 6.2.2** in MP-1). Literature for evaluating the simultaneous removal of PFAS and MP in solid media, such as soil, sediments, and biosolids, was found to be limited during writing of this section. A recent study evaluated the treatment of PFAS, MP, and pharmaceuticals and personal care products (PPCPs) present in biosolids from municipal wastewater via pyrolysis conversion into biochar (Keller et al. 2024). The study employed pyrolysis at an existing operating facility to destroy these contaminants and produce biochar as a valuable byproduct. Contaminants removal was over 99.9% for PFAS and PPCPs, and between 91% and 97% for MP. The production of biochar, which revealed no PFAS detections and less than 1.4 particles of MP per gram of biochar (less than 250 µm particle size), could constitute an economic benefit from the process of treating biosolids. However, the net benefit of converting biosolids into biochar must be compared against the net benefit of using biosolids for land application. **Section 1.6.5** in PFAS-1 presents information about treatment of biosolids.

1.8.6.2 Developing Technologies for Effective Microplastic and PFAS Removal

Water Matrixes

Electrochemical Treatment

Electrochemical oxidation is a promising zero-sludge process that has been used to remove both PFAS and MP from water. The technology applies electrical potential across electrodes, creating two mechanisms for contaminant destruction. The first is the formation of hydroxyl radicals that nonselectively oxidize encountered organic species, to include PFAS and polymer bonds (Liang et al. 2022). The second mechanism involves direct oxidation of a contaminant at the anode surface. Pilot- and bench-scale efforts have demonstrated success with varying levels of effectiveness (Kiendrebeogo et al. 2021; Ning et al. 2023). Water quality characteristics such as conductivity need to be considered to understand and optimize treatment effectiveness. High conductivity may result in the formation of perchlorate, bromate, or other undesirable products, while low conductivity solutions may negatively affect kinetics and increase treatment time and costs (Radjenovic et al. 2020; Radjenovic et al. 2022).

In addition to electrochemical oxidation, other electrochemical approaches such as electrocoagulation are being explored; under this mechanism, cations produced by a metal electrode bind to the MP and coagulate them into larger particles (Ning et al. 2023). Nevertheless, full-scale application of electrochemical technologies continues to develop with no known full-scale treatment deployed specifically targeting both MP and PFAS.

Foam Fractionation

Foam fractionation systems have been designed and operated to remove PFAS from water streams (**Section 12.2.3** and **Section 18**, in PFAS-1) and total suspended solids from water streams (Pfeiffer, Baptiste, and Wills 2024). It follows that, at least conceptually, separation of MP from water using foam fractionation might be effective. However, this has not yet been demonstrated. Dissolved air flotation, which is a separation technology conceptually similar to foam fractionation, has been tested for removal of MP from water (De Somer et al. 2024; Saczek et al. 2024; Monira and Pramanik 2025; Wang et al. 2021; Pit et al. 2025).

Solid Matrixes

Information on developing technologies for the simultaneous treatment of PFAS and MP is not available at this time. PFAS treatment technologies, such as stabilization and soil washing, for solid matrixes are mature and available (**Section 12.3** in PFAS-1), whereas there are no fully demonstrated treatment technologies for MP in solid media (**Section 6.2.2** in MP-1).

1.8.7 Regulatory and Guidance Considerations

Several regulations at the state, federal, and international level govern MP. Similarly, there are current and developing regulations pertaining to PFAS across these geographies. For specific information pertaining to MP regulations, see **Section 5** in MP-1. For specific information about the regulatory landscape around PFAS, see **Section 8** in PFAS-1.

Several regulations mention both PFAS and MP together as emerging contaminants. Although they are mentioned together, they are not evaluated or considered as to relevance or impact related to co-existence in the environment. As an example, the Clean Water and Drinking Water State Revolving Fund Provisions of the Bipartisan Infrastructure Law (USEPA 2022) provide $5B to reduce exposures to PFAS and other emerging contaminants (such as MP) from public drinking water and wastewater systems. Several states, as a result, have included both PFAS and MP similarly in their State Chemicals of Concern

(CEC) programs. ITRC summarized State CEC Monitoring programs in the **CEC Monitoring Programs Fact Sheet**.

1.8.8 Changing Weather Patterns

There is limited information on changing weather patterns impacting environmental fate of PFAS and MP in the current literature. Changing weather patterns can impact transformation rates of PFAS and MP among the environmental media (Gander 2025; Hung et al. 2022). Transfer of PFAS from "air to surfaces, water to sediments, and ice to water [is] affected by changes in ambient temperatures … snow, rainfall, and the cryosphere" (Hung et al. 2022). Rising global temperatures influence the movement, concentration, and impact of pollutants such as PFAS and MP in water bodies and groundwater (Gander 2025). Increased temperatures remobilize persistent organic pollutants from melting sea ice into the Arctic Sea water and back to the atmosphere (Hung et al. 2022). MP and persistent organic pollutants in the melting Arctic Sea ice are released into the Arctic marine ecosystem and can potentially expose marine life and indigenous populations (Galgani, Hanke, and Maes 2015; Hung et al. 2022). The breakdown of MP into carbon dioxide (CO_2) and methane (CH_4) during degradation increases the release of greenhouse gases in the environment. It also disrupts the natural carbon and nitrogen cycles in the environment, leading to increased emissions of greenhouse gases (Gander 2025). In addition, MP absorb sunlight, which can contribute to the melting of snow and ice (Gander 2025). Ingestion of MP reduces phytoplankton growth and the ability of phytoplankton to absorb atmospheric carbon dioxide (Raju et al. 2021; Gander 2025).

Extreme rainfall events due to changing weather patterns increase leaching of pollutants to groundwater and surface waters and enhance deposition of pollutants in floodplains and low-lying urban areas (Gander 2025). Urban stormwater runoff can release significant amounts of MP to the receiving waters (Paterson, Miller, and Lin 2024). Monsoonal rains can increase leaching of MP from pesticides used in agricultural areas to aquifers (Gander 2025). Severe flooding can cause overflow of wastewater treatment plants and unplanned releases of contaminated water into the environment (Gander 2025). Additionally, changing weather patterns modify microbial communities and microbial degradation rates, which impact the degradation rates of persistent organic pollutants in the environment (Hung et al. 2022).

2 PFAS CHEMISTRY AND NAMING CONVENTIONS, HISTORY AND USE OF PFAS, AND SOURCES OF PFAS RELEASES TO THE ENVIRONMENT

This section provides a basis for the discussion of PFAS in the environment by presenting foundational information about its discovery, commercial use, health and environmental awareness, chemistry, and terminology.

Section Number	Topic
1.1	**Priority Topics for History, Use, and Naming Conventions (2025)**
2.1	**Environmental Significance**
2.2	**Chemistry, Terminology, and Acronyms**
2.3	**Emerging Health and Environmental Concerns**
2.4	**PFAS Reductions and Alternative PFAS Formulations**
2.5	**PFAS Uses and Products**
2.6	**PFAS Releases to the Environment**

In 1938, Roy J. Plunkett at the DuPont Company's Jackson Laboratory discovered polytetrafluoroethylene (PTFE) while conducting commercial experiments with chlorofluorocarbon refrigerants (**Science History Institute 2017**).

Since the 1950s, many products commonly used by consumers and industry have been manufactured with or from PFAS, as the unique physical and chemical properties of PFAS impart oil, water, stain, and soil repellency, chemical and thermal stability, and/or friction reduction to a range of products. These products have applications in many industries, including the aerospace, semiconductor, medical, automotive, construction, electronics, and aviation industries, as well as in consumer products (such as carpets, clothing, furniture, outdoor equipment, food packaging), and firefighting applications (**3M Company 1999**; **Buck et al. 2011**; **KEMI 2015**; **USEPA 2017**).

The number of PFAS and their uses have expanded over the years. It has been estimated that the PFAS family may include more than 12,000 chemical substances (**USEPA 2020**). A 2021 inventory of PFAS identified more than 4,700 PFAS with Chemical Abstracts Service (CAS) Registry Numbers that could have been, or may be, on the global market (**OECD 2021**), although the uses of each of these PFAS may not be known (**KEMI 2015**). Publicly available health and toxicity studies are limited to only a small fraction of PFAS, and modern commercially available analytical technologies typically identify and quantify only about 50–60 PFAS, but these lists are increasing. An industry survey, reported in Buck et al. (**2021**), noted that only 256 of the 4,700 PFAS with CAS Registry Numbers are commercially relevant, with others of lesser environmental significance but potentially still occurring in the environment. However, it should be noted that (1) the results of this survey reflect responses from only three major global producers of PFAS that use the fluorotelomerization manufacturing process, (2) the results of this survey do not include any producers that use the electrochemical fluorination manufacturing process; and (3) some of the information provided by the participating companies was flagged as confidential business information.

Scientific, regulatory, and public concerns have emerged about potential health and environmental impacts associated with chemical production, product manufacture and use, and disposal of PFAS-containing wastes. These concerns have led to efforts to reduce the use of or replace certain PFAS, such as certain long-chain perfluoroalkyl carboxylates, long-chain perfluoroalkane sulfonates and their

precursors, including two widely produced, commonly encountered, and most studied compounds: perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) (**USEPA 2016**; **WA DER 2017**). Refer to the Environmental Media Values Table Excel file, the Regulatory Programs Summary Table Excel file, and **Section 8** for updated regulatory actions, and **Section 13** for stakeholder perspectives.

PFAS have followed a similar pattern of emergence and awareness exhibited by many other anthropogenic environmental contaminants. **Figure 2-1** provides a general timeline of PFAS emergence and awareness that includes categories of 1) synthesis/development, 2) commercial production, 3) health concerns, 4) environmental detection, and 5) reduction/alternatives. There may be evidence of some activities occurring before or after dates provided in this timeline; the intent of the figure is to capture the years of significance for each category.

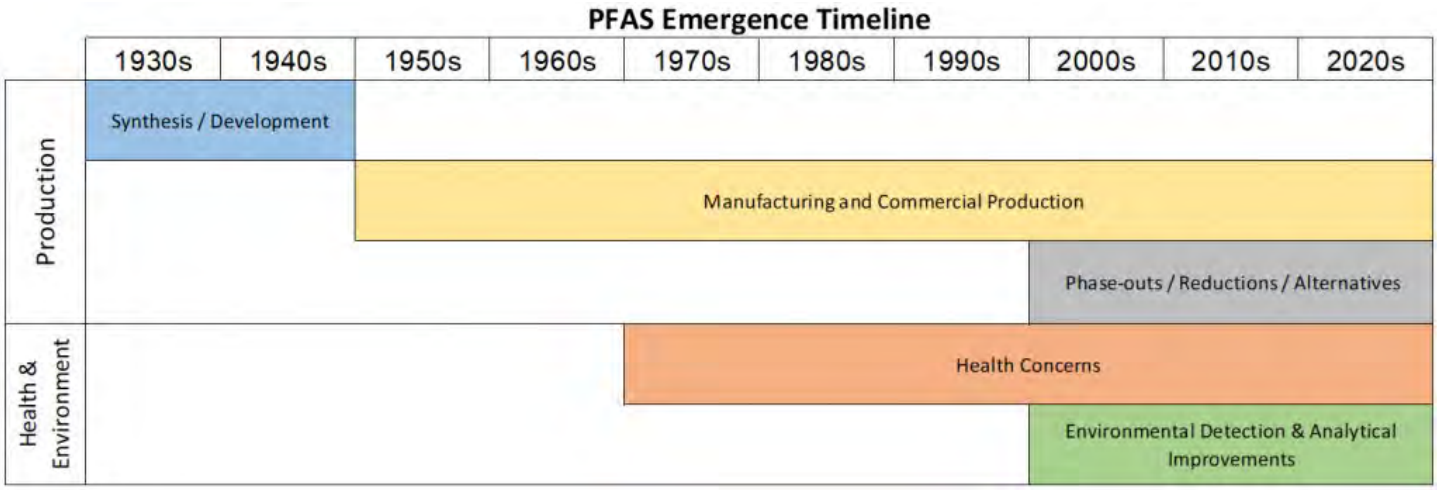

Figure 2-1. General timeline of PFAS emergence and awareness.

Graphic provides general indication of PFAS emergence and awareness by decade. Specific activities and events are described in more detail within this chapter. "Reductions/alternatives" refers to reduction in production/use and includes other PFAS that have replaced legacy chemistry.

Source: J. Hale, Kleinfelder. Used with permission.

The objective of this section is to lay a foundation for identifying potential PFAS sources in the environment.

2.1 Environmental Significance

PFAS have been and still are widely used, but not all types and uses of PFAS result in the same level of environmental impact and exposure. When considering potential environmental impacts from PFAS, it can be useful to be as specific as possible not only about the particular PFAS involved, but also where and how they are released to the environment. For example, a stable, insoluble fluoropolymer such as PTFE may pose little environmental/ecological or health risk once it is in a product. However, potentially significant environmental releases of other PFAS historically or currently used in the manufacturing process (for example, perfluoroalkyl acids [PFAAs], GenX, ADONA) have occurred. Such considerations may help to focus investigation resources on major sources. Addressing PFAS in a holistic manner is an emerging subject (**Cousins et al. 2019**) that may be helpful considering data are not available, for example, on the environmental fate and transport, environmental toxicity, or bioavailability, for all individual PFAS chemicals.

Figure 2-2 illustrates a conceptual PFAS lifecycle beginning at PFAS synthesis (raw materials). These raw materials are then used in a variety of manufacturing processes and industrial/commercial applications to create commercial and consumer products that contain or are treated with PFAS. Throughout this life cycle, variable types and amounts of PFAS may be released to the environment from manufacturing waste streams, fugitive emissions, spills, disposal of PFAS-containing or -treated materials, and general wear and tear of consumer products. Sometimes the intended use of the PFAS product (for example, firefighting foams) requires direct release to the environment. PFAS from a host of sources also may be conveyed through and aggregated in wastewater treatment plant effluent and sludges, creating sources of releases to the environment. The volume, concentration, and mixture of PFAS released to the environment varies based on the source (process, material, or product), release mechanism(s), and environmental controls employed throughout this life cycle. Exposure to PFAS may occur as (1) direct interaction with the manufacturing process, (2) professional or intensive use of PFAS-containing materials, (3) use of or contact with commercial and consumer products containing PFAS, or (4) exposure (human or ecological) to environmental media that have been impacted by PFAS. The relative significance of these exposures will also vary widely.

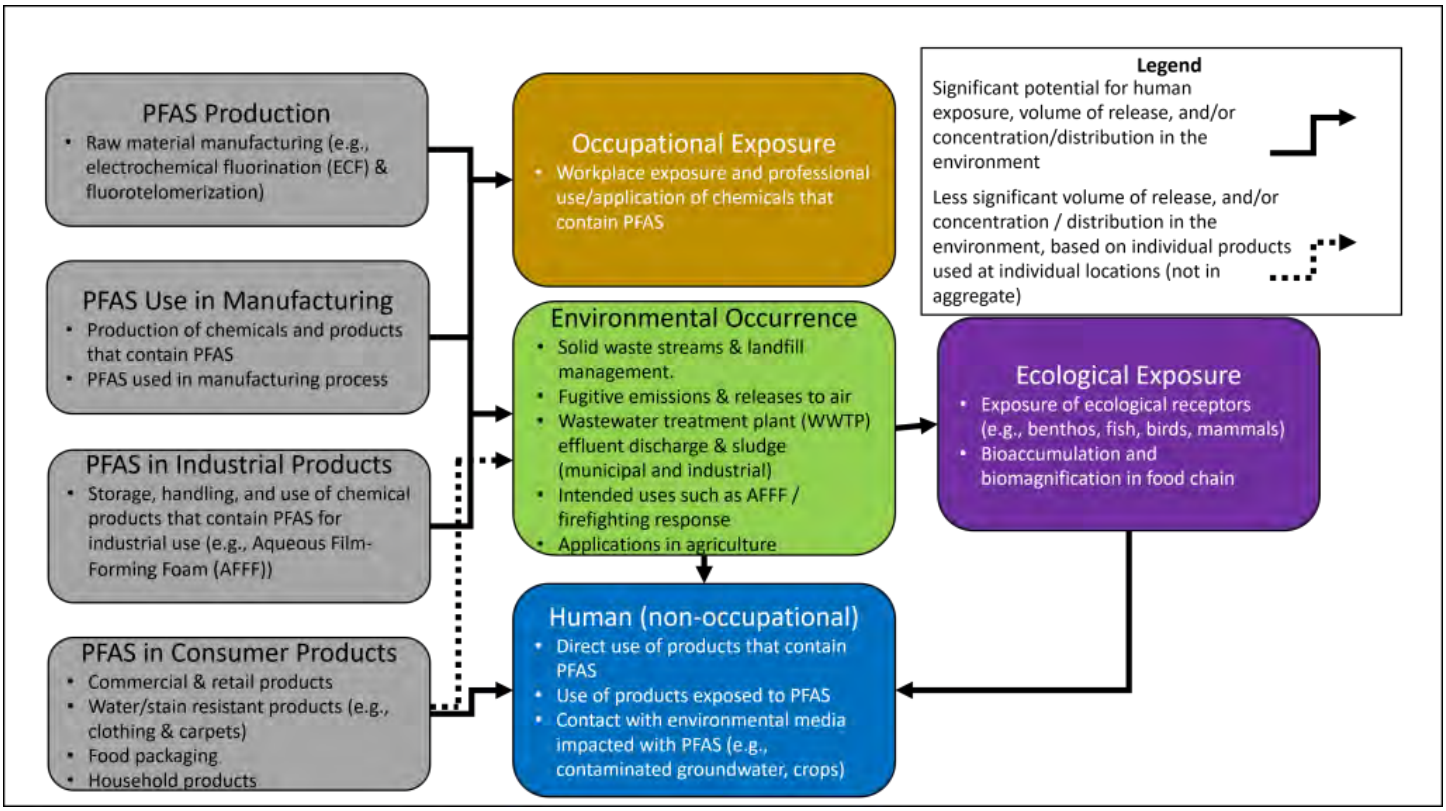

Figure 2-2. Generalized PFAS uses and relative exposure and environmental impact potential from PFAS life cycle.

This figure is not exhaustive with regard to all sources or release mechanisms from those sources. Multiple sources may exist at a site, and the relative potential of exposure and environmental impact may vary based on several considerations. Due to the widespread use of PFAS in commercial and consumer products, other minor point source or diffuse releases of PFAS to the environment may occur during use and disposal of some PFAS-containing products. Although these may result in locally significant environmental impacts, these releases typically affect smaller geographic areas and have lower total PFAS mass than major sources, such as PFAS chemical manufacturing, PFAS use in certain industries, and some applications of certain firefighting foams.

Different PFAS products and sources differ in their relative environmental significance, volumes released, distribution mechanisms, area affected, and relative concentration of impacted media. For instance, nonpolymer PFAS used in Class B firefighting foam may impact a moderate area near the source and may exhibit high concentrations in impacted media. In contrast, a similar volume of nonpolymer PFAS air emissions from a fluoropolymer manufacturing facility may be more widely dispersed and present at lower concentrations in impacted media.

The type of PFAS involved also determines the relative environmental significance. Nonpolymer PFAS (both per- and polyfluorinated) and some side-chain fluorinated polymer PFAS are likely to pose greater risks when released to the environment than certain fluoropolymer sources, such as the fluoropolymers PTFE, fluorinated ethylene-propylene (FEP), perfluoroalkoxy polymer (PFA), and ethylene tetrafluoroethylene (ETFE). These fluoropolymers are considered to be polymers of low concern (**Section 2.2.2.1**) because they are relatively stable, insoluble in the environment, and not bioavailable (**Henry et al. 2018**). However, environmental impact from the production or manufacturing uses of fluoropolymers can pose a significant risk if emissions are not properly controlled at the industrial site. Also, releases to the environment from the disposal of fluoropolymers cannot be ruled out, as nonpolymer PFAS (such as the PFAAs used as polymerization aids) may be found at trace levels as impurities and byproducts in some fluoropolymer products (**3M Company 1999**). Many fluoropolymers may be resistant to transformation. For example, in one study, PTFE did not significantly transform under certain incineration conditions (**Aleksandrov et al. 2019**). However, research suggests side-chain fluorinated polymers are likely to break down to nonpolymer PFAS over time (**Li et al. 2018**). For example, commercial fluorotelomer-based polymers (a kind of side-chain fluorinated polymer) have been documented to biotransform under environmental conditions (**Washington et al. 2015**) and to abiotically transform by hydrolysis under environmental and consumer-use conditions (**Washington and Jenkins 2015**). For additional information on transformation of polyfluorinated PFAS, see **Section 5.4**; transformation of PFAS polymers is discussed in **Section 5.4.5**.

Finally, another consideration regarding environmental impacts is the issue of anthropogenic (human-caused, not naturally occurring) ambient or anthropogenic “background” levels of PFAS. As discussed in **Section 6**, the long duration of PFAS use and their release from many types of sources may have resulted in low-level contamination of environmental media worldwide. Cousins et al. (**2022**) compares concentrations in environmental media to proposed guidelines from USEPA, Denmark, the Netherlands, and the European Union. The implications of ambient levels of PFAS should be considered in evaluating exposures and risk levels, establishing site action levels and cleanup goals, and identifying PFAS sources.

2.2 Chemistry, Terminology, and Acronyms

The Priority Topics for History, Use, and Naming Conventions include information about less-studied PFAS (see **Section 1.1.3**), ultrashort PFAS, cyclic PFAS, volatile PFAS, and fluorinated gases.

This section focuses on chemistry, terminology, names, and acronyms for those PFAS most commonly reported in the environment, identified in scientific literature, and those PFAS most commonly tested for by current analytical methods. Other important classes of PFAS are introduced. This section also introduces the chemical manufacturing processes that influence the types of PFAS that are found in the environment.

The definition of PFAS continues to evolve to reflect continued study of these compounds and takes different forms depending on the regulatory body, operational criteria used, and the intended scope and application of the included list of chemicals. There is no universally accepted definition of PFAS. However, in general, PFAS are compounds characterized as having carbon atoms linked to each other and bonded to fluorine atoms at most or all of the available carbon bonding sites.

Table 2-1 provides examples of several definitions of PFAS (**Hammel et al. 2022**) developed by several authoritative agencies and researchers. In addition, **Schymanski et al. (2023)** describes a user-friendly resource to explore >7 million PFAS and >21 million fluorinated compounds in the National Institutes of Health (NIH) PubChem database by establishing the "PFAS and Fluorinated Compounds in PubChem" Classification Browser (or "PubChem PFAS Tree").

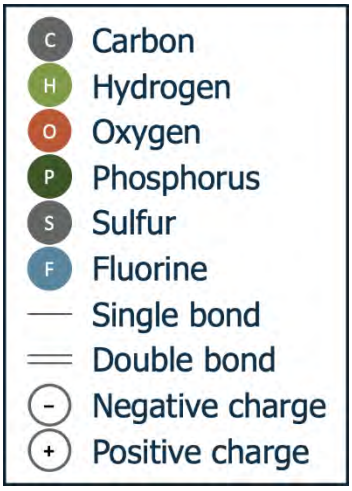

Table 2-1. Examples of PFAS definitions/Working Descriptions (Hammel et al. 2022, Table 2)(CC BY-NC-ND 4.0).

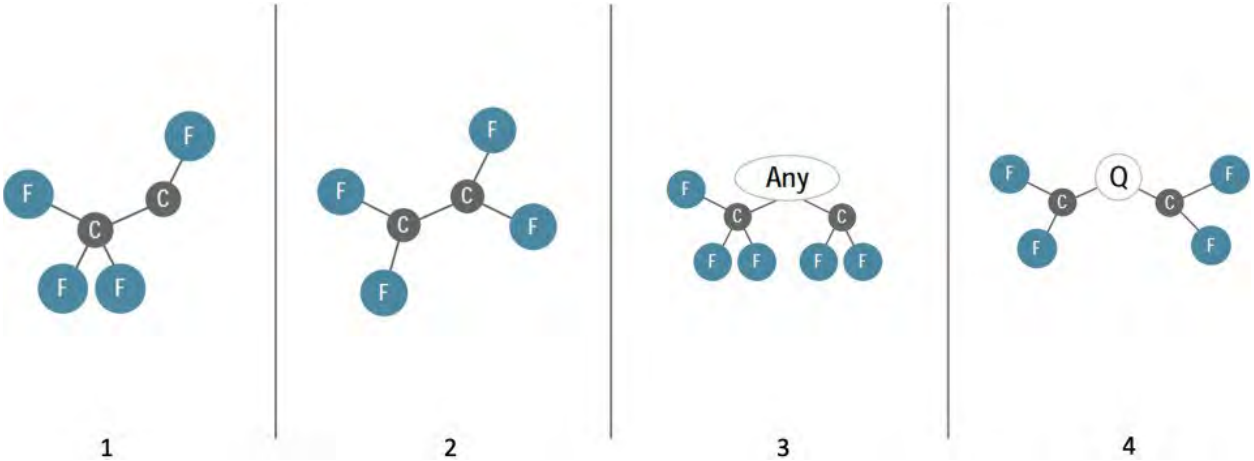

Source of Definition	Year Defined	Definition	Additional Comments
Buck et al.	2011	"highly fluorinated aliphatic substances that contain one or more carbon (C) atoms on which all the hydrogen (H) substituents (present in the nonfluorinated analogues from which they are notionally derived) have been replaced by fluorine (F) atoms, in such a manner that they contain the perfluoroalkyl moiety C_nF_{2n+1}–."	**Buck et al. (2011)** is an open-access paper that provides a detailed explanation of PFAS terminology, classification, and origins, and recommends specific and descriptive terminology, names, and acronyms for PFAS.
OECD	2021	"PFASs, including perfluorocarbons, that contain a perfluoroalkyl moiety with three or more carbons (i.e., $-C_nF_{2n}-$, n ≥ 3) or a perfluoroalkylether moiety with two or more carbons (i.e., $-C_nF_{2n}OC_mF_{2m}-$, n and m ≥ 1)."	Updated in 2021
OECD	2021	"fluorinated substances that contain at least one fully fluorinated methyl or methylene carbon atom (without any H/Cl/Br/I atom attached to it), i.e., with a few noted exceptions, any chemical with at least a perfluorinated methyl group ($-CF_3$) or a perfluorinated methylene group ($-CF_2-$) is a PFAS."	**OECD (2021)** expanded the **Buck et al.(2011)** definition to include chemicals that contain the $-C_nF_{2n}-$ moiety in addition to the $C_nF_{2n+1}-$ moiety, which encompasses chemicals with both ends of the carbon-fluorine chain connected to a hydrogen or a functional group, as well as cyclic analogs of linear PFAS.
Gluge et al.	2020	In addition to substances containing C_nF_{2n+1}, where n ≥ 1, it also "includes (i) substances where a perfluorocarbon chain is connected with functional groups on both ends, (ii) aromatic substances that have perfluoroalkyl moieties on the side chains, and (iii) fluorinated cycloaliphatic substances. Additionally, "polymeric PFAS with the $-CF_2-$ moiety and non-polymeric PFAS with the $-CF_2-CF_2-$ moiety [excluding] non-polymeric substances that only contain a $-CF_3$ or $-CF_2-$ moiety, with the exception of perfluoroalkylethers and per- and polyfluoroalkylether-based substances. For these two PFAS groups, substances with a $-CF_2OCF_2-$ or $-CF_2OCFHCF-$ moiety are also included."	**Glüge et al. (2020)** acknowledged the **Buck et al. (2011)** and **OECD (2018)** definitions while also considering the definition of PFAS to include: • substances in which a perfluorocarbon chain is connected with functional groups on both ends • aromatic substances that have perfluoroalkyl moieties on the side chains • fluorinated cycloaliphatic substances.

Source of Definition	Year Defined	Definition	Additional Comments
TURA Program, Massachusetts (**TURA 2023**)	2023	"Certain PFAS not otherwise listed includes those PFAS that contain a perfluoroalkyl moiety with three or more carbons (e.g., $-C_nF_{2n}-$, n ≥ 3; or $CF_3-C_nF_{2n}-$, n ≥ 2) or a perfluoroalkylether moiety with two or more carbons (e.g., $-C_nF_{2n}OC_mF_{2m}-$ or $-C_nF_{2n}OC_mF_{2m}-$, n and m ≥ 1), wherein for the example structures shown, the dash (–) is not a bond to a hydrogen and may represent a straight or branched structure, that are not otherwise listed."	
USEPA OPPT	2021	"a structure that contains the unit R-$CF_2-CF(R')(R")$, where R, R', and R" do not equal "H" and the carbon-carbon bond is saturated (note: branching, heteroatoms, and cyclic structures are included)."	Chemicals for review under TSCA to evaluate human health and environmental risks
NDAA, WA, CA, VT, ME	2019, 2020, 2021	Organic chemicals containing at least 1 fully fluorinated carbon atom	Authorities whose legislation defines PFAS as a class of fluorinated organic chemicals containing at least one fully fluorinated carbon atom.
USEPA CCL5	2022	"For the purposes of CCL5, the structural definition of per- and polyfluoroalkyl substances (PFAS) includes chemicals that contain at least one of these three structures: (1) $R-(CF_2)-CF(R')R"$, where both the CF_2 and CF moieties are saturated carbons, and none of the R groups can be hydrogen; (2) $R-CF_2OCF_2-R'$, where both the CF_2 moieties are saturated carbons, and none of the R groups can be hydrogen; (3) $CF_3C(CF_3)RR'$, where all the carbons are saturated, and none of the R groups can be hydrogen."	The USEPA CCL5 definition is less inclusive than the OECD definition, but it is more inclusive than the USEPA TSCA definition.
MPART	2023	PFAS means per- and polyfluoroalkyl substances that contain the perfluoroalkyl moiety with two adjacent fully fluorinated carbons, $R-(CF_2)-C(F)(R')R$", or perfluoroalkyl ether moiety, $R-(CF_2)-O-(CF)(R')R$", where R, R', and R" represent any functional group or atom except hydrogen (H). This includes perfluoroalkyl substances with $R-CF_2-CF_2-R'$ and CF_3-CF_2-R units or perfluoroalkyl ether substances with $R-CF_2-O-CF_2-R'$, and CF_3-O-CF_2-R units.	MPART has not agreed to a PFAS definition, but has accepted this working description of PFAS, which is subject to change. This working description borrows from the OECD 2021 and the EPA TSCA definitions of PFAS. In 2024, the Subgroup is examining this working description closer and is considering physicochemical and toxicological properties.

Definitions of PFAS: **Buck et al. (2011)** definition: "highly fluorinated aliphatic substances that contain one or more carbon (C) atoms on which all the hydrogen (H) substituents (present in the nonfluorinated analogues from which they are notionally derived) have been replaced by fluorine (F) atoms, in such a manner that they contain the perfluoroalkyl moiety CnF2n+1 –."
OECD (2021) definition: "fluorinated substances that contain at least one fully fluorinated methyl or methylene carbon atom (without any H/Cl/Br/I atom attached to it), i.e., with a few noted exceptions, any chemical with at least a perfluorinated methyl group (–CF3) or a perfluorinated methylene group (–CF2–) is a PFAS."

The USEPA's CompTox Chemicals Dashboard (CompTox Chemicals Dashboard (epa.gov)) provides a large publicly available resource for PFAS structures and predicted properties (**Williams et al. 2017**; **Williams et al. 2022**). This effort has taken two approaches to defining PFAS. The first, denoted PFASMASTER (**USEPA 2020**), was based on a simple join, or combination, of publicly available lists of PFAS chemicals reported by other entities, such as the **OECD (2018)** report. The second approach applied a small set of structure filters to the entire EPA DSSTox database (currently exceeding 1,200,000 substances), resulting in a list containing more than 8,000 PFAS structures, denoted PFASSTRUCTV3 (**USEPA 2020**); the 2022 version is PFASSTRUCTV5 (**USEPA 2022**) containing more than 14,000 structures. Please check USEPA's CompTox Chemicals Dashboard for the most current version. The 2022 PFASMASTER file exceeds 12,000 substances and includes both PFAS structures (from PFASSTRUCV5) and structures and non-structurable chemicals (such as mixtures and polymers) from combining several public PFAS lists. Hence, the structure-based filters used in this effort expand the PFAS definition beyond the **Buck et al. (2011)** and **OECD (2021)** definitions and are designed to fully encompass publicly available PFAS lists, as well as to be inclusive of small, fluorinated chemicals of potential concern to USEPA. The 2022 PFASSTRUCTV5 uses a combination of four substructural filters (see **Figure 2-3**) and/or a threshold of 30% fluorine without hydrogen based on molecular formula count (not weight). The substructural filters (shown in **Figure 2-3**) are designed to be simple, reproducible and transparent, yet general enough to encompass the largest set of structures having sufficient levels of fluorination to potentially be considered PFAS. (**USEPA 2022**).

Note: Q can be any of the following atoms: B, O, N, P, S or Si.

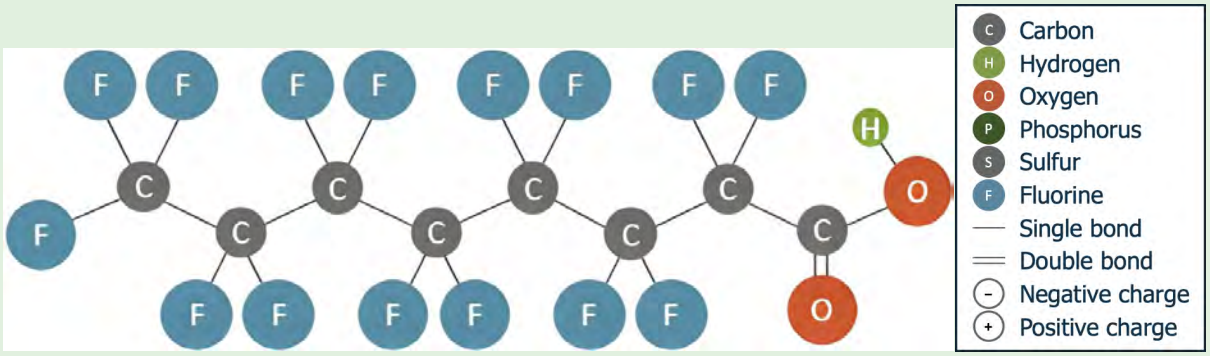

Figure 2-3. Four Substructural Filters of PFAS Used in Development of USEPA's CompTox Dashboard for PFAS (USEPA 2022) (see legend above figure).

Whereas some PFAS definitions such as provided by USEPA's CompTox Dashboard are designed to be broadly inclusive, definitions used in regulatory applications often must be more circumscribed and

precisely worded. Examples of definitions used in regulatory applications include those used by USEPA TSCA and the USEPA Drinking Water Contaminant Candidate List 5 (CCL5); see **Table 2.1**. Information about state regulatory programs for PFAS is included in the Regulatory Programs Summary Table. For example, the state of Maine defines PFAS as substances that include any member of the class of fluorinated organic chemicals containing at least one fully fluorinated carbon atom (**Maine State Legislature 2021**).

General Concepts of Organofluorine Chemistry for PFAS

Organofluorine Chemistry: A branch of organic chemistry involving organic molecules with a carbon-fluorine bond. Organofluorine molecules have many commercial uses. They include PFAS, such as PFOA, shown below:

Example PFOA molecule, acid form (see legend right of figure).

Gray spheres represent carbon atoms linked together in a chain; there are eight of them, so "octane" is used in the name. Blue spheres represent fluorine atoms bonded to carbon atoms. Red spheres represent oxygen atoms. Green sphere represents a hydrogen atom that dissolves away in water, which makes this an acid. Fluorine atoms are attached to all possible bonding sites, making this perfluorinated. If some of the fluorine atoms were replaced by other atoms (such as oxygen or hydrogen), it would be polyfluorinated. Without the hydrogen, the "head end" takes on a negative charge and can bond to things through electrostatic attraction. The fluorine "tail end" is strong and stable, giving it lipid- and water-repelling properties, but also making it persistent in the environment.

Isomer: A molecule with the same molecular formula as another molecule, but with a different chemical structure. Isomers contain the same number of atoms of each element, but have different arrangements of their atoms. See **Figure 2-16** for an example; linear and branched PFOS contain the same number of carbon, fluorine, oxygen, and sulfur atoms, but these atoms are arranged differently depending on whether it is a linear or branched isomer of PFOS.

Homologue Groups and Homologous Series: A group of organic compounds, usually listed in order of increasing size, that has a similar structure (and therefore also similar properties) and whose structures differ only by the number of carbon atoms in the chain. For example, all of the linear and branched isomers of PFOS would be in the C8 homologue group, while all of the linear and branched isomers of perfluorohexane sulfonic acid (PFHxS) would be in the C6 homologue group. The C_4-C_{12} PFSAs are a homologous series of perfluoroalkane sulfonates.

Throughout Section 2, the **Buck et al. (2011)** definition has been used for simplicity of discussion in the depiction of naming conventions of PFAS.

2.2.1 Naming Convention Considerations

There is confusion among the environmental community and the public due to overgeneralization when describing PFAS and the lack of consistent naming of specific PFAS. The use of consistent naming conventions would reduce confusion and support clearer communication (**Buck et al. 2011**; **Wang et al. 2017**).

"PFAS," not "PFASs": The acronym "PFAS" stands for "per- and polyfluoroalkyl substances." No single chemical within the PFAS family can be both perfluorinated and polyfluorinated, so by definition "PFAS" is plural and a small "s" is not needed. Some authors elect to add a small "s" to this acronym (PFASs) to emphasize the fact that it is plural, but it is not needed. When referring to a single chemical within the PFAS family, it is more accurate to simply name that specific chemical.

Consistent naming also helps to distinguish PFAS from other organic compounds that contain fluorine. As defined in the literature, PFAS may include only one fluorinated aliphatic (carbon chain) substance. Alkyl/aliphatic groups are fully saturated carbon chains, which can be either cyclic, non-cyclic, branched or unbranched. Alkyl and aliphatic can be used interchangeably. Depending on the definition, PFAS may or may not include fluorinated compounds that contain aromatic (carbon ring) features in their structures (for example, active pharmaceutical ingredients, crop protection agents, or chlorofluorocarbons [refrigerants]) (**Gaines, Sinclair, and Williams 2023**; **Glüge et al. 2020**; **Hammel et al. 2022**). The inclusion of aromatic components in a chemical structure in the PFAS classification varies depending on what definition is applied. As **Gaines, Sinclair, and Williams 2023** describes, including aromatics in a PFAS definition confounds things as the "PFAS" acronym includes the word "alkyl" that does not include aromatics. The authors go on to say that the "A" in PFAS could also be used to mean both aliphatic and aromatic, but this could also cause confusion as PFAS have not been used widely with this interpretation.

The use of nonspecific acronyms, such as perfluorinated compound (PFC), has hampered clarity of investigative results. The acronym "PFC" is poorly defined in the scientific literature, but typically refers to "perfluorinated compounds." "PFC" is widely used in the climate community, referring to perfluorocarbons, which are a subset of PFAS. PFC does not include "polyfluorinated substances," which are increasingly recognized as important contaminants at many PFAS sites.

CAS numbers are another helpful tool for clearly identifying the chemical that is being referenced; however, care must be taken in selecting the correct CAS number to avoid confusion regarding the chemistry and behavior of the chemical being described. Some PFAS may exist in various ionic states, such as acids, anions (negatively charged), cations (positively charged), and zwitterions (both positively and negatively charged dipolar molecules), and each has its own CAS number (and some have no CAS number). The ionic state determines electrical charge and physical and chemical properties, which in turn control fate and transport in the environment (**Section 5**) and potential human health and ecological effects (**Section 7**). The ionic state of individual PFAS can result in significantly different physical and chemical properties (**Section 4**), such as solubility, volatility, and bioaccumulative potential.

International Union of Pure and Applied Chemistry (IUPAC) (https://iupac.org) nomenclature may also be used for identifying PFAS chemicals. The IUPAC nomenclature system is typically used in more formal literature such as patents. Examples of the IUPAC naming convention are provided below.

- PFOA: 2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-Pentadecafluorooctanoic acid
- PFOS: 1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-heptadecafluorooctane-1-sulfonic acid

Some chemicals in the PFAS family can exist in various ionic states (for example, acids, anions, cations), which have important implications for their chemical and physical properties. In most cases for PFAAs, this section uses the anionic form of a given PFAS name, as this is the state in which most PFAAs exist in the environment.

In the future, it may be necessary to expand the current naming conventions and acronym approaches to ensure that standardized naming is available for additional members of the PFAS family of compounds.

2.2.2 Introduction to the PFAS Family

PFAS are comprised of a wide variety of molecules with different physical and chemical properties and molecular weights with perfluoroalkyl moieties as common structural features, as noted by **Cousins et al. (2020)**, who identified specifically:

> *"…the PFAS class comprises distinct substances with very different structures and properties: high-molecular-weight polymers and high-molecular-weight non-polymers; neutral, anionic, cationic and zwitterionic substances; solids, liquids, and gases; highly reactive and non-reactive (inert) substances; soluble and insoluble substances; and volatile and involatile substances. In the environment, some PFAS are mobile and others immobile, and some bioaccumulate while others do not."*

This variety of PFAS with diverse properties is organized in the form of a PFAS family tree (**Figure 2-4**) that includes two primary classes: polymers and nonpolymers. Each class may contain many subclasses, groups, and subgroups, some of which are shown in the figure. This document focuses primarily on those nonpolymer PFAS most commonly detected in the environment and those PFAS that may be significant as "precursors" that can transform to more persistent forms.

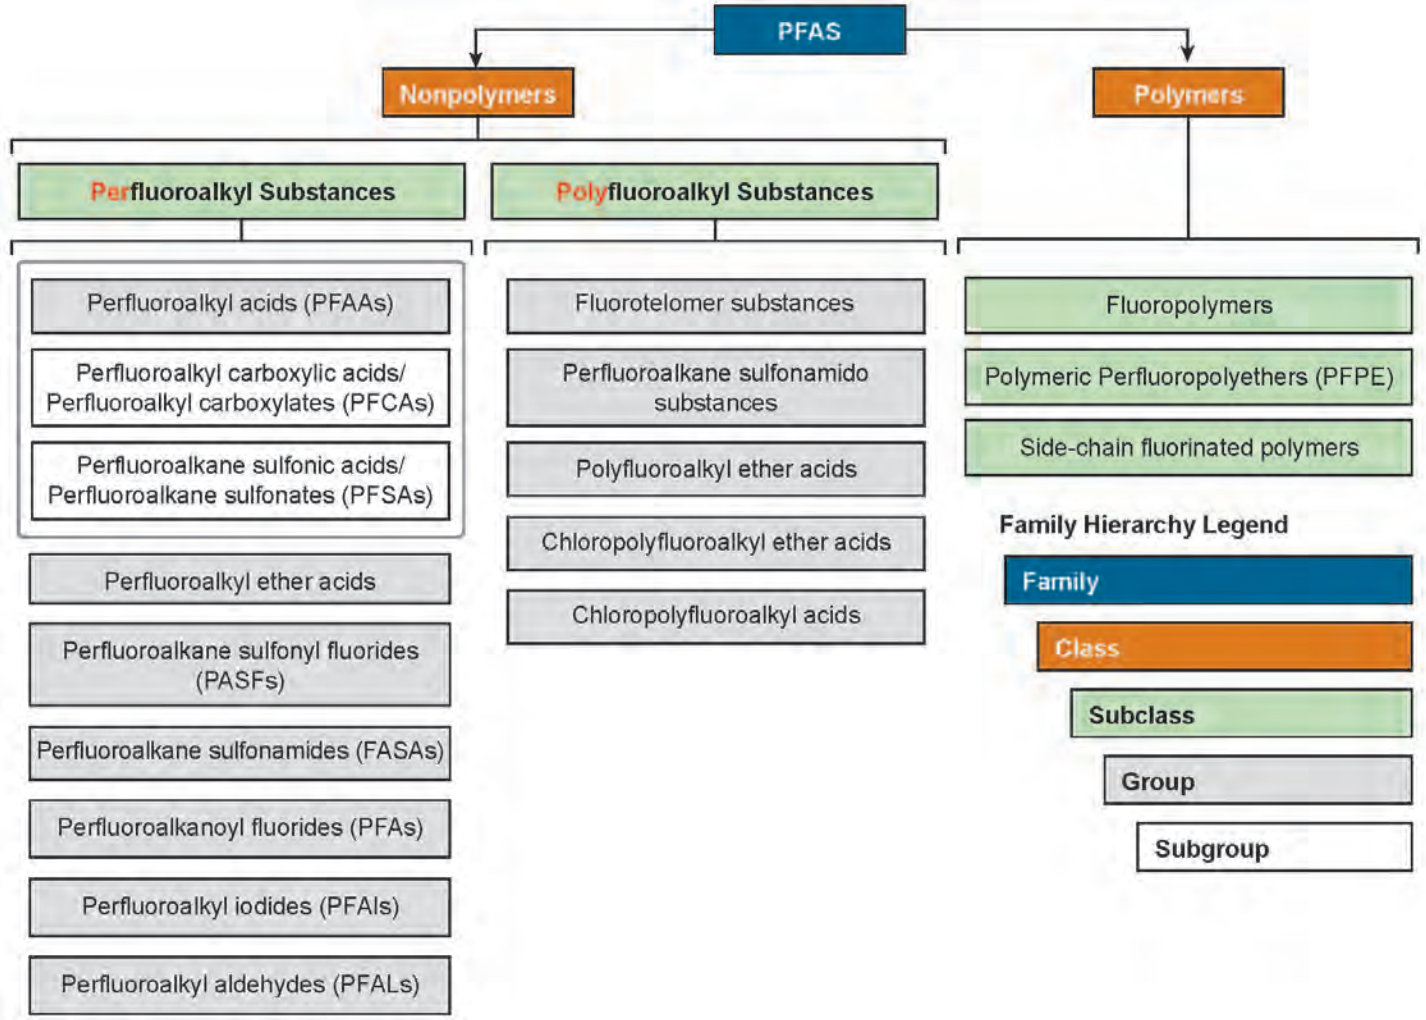

Figure 2-4. The PFAS family.

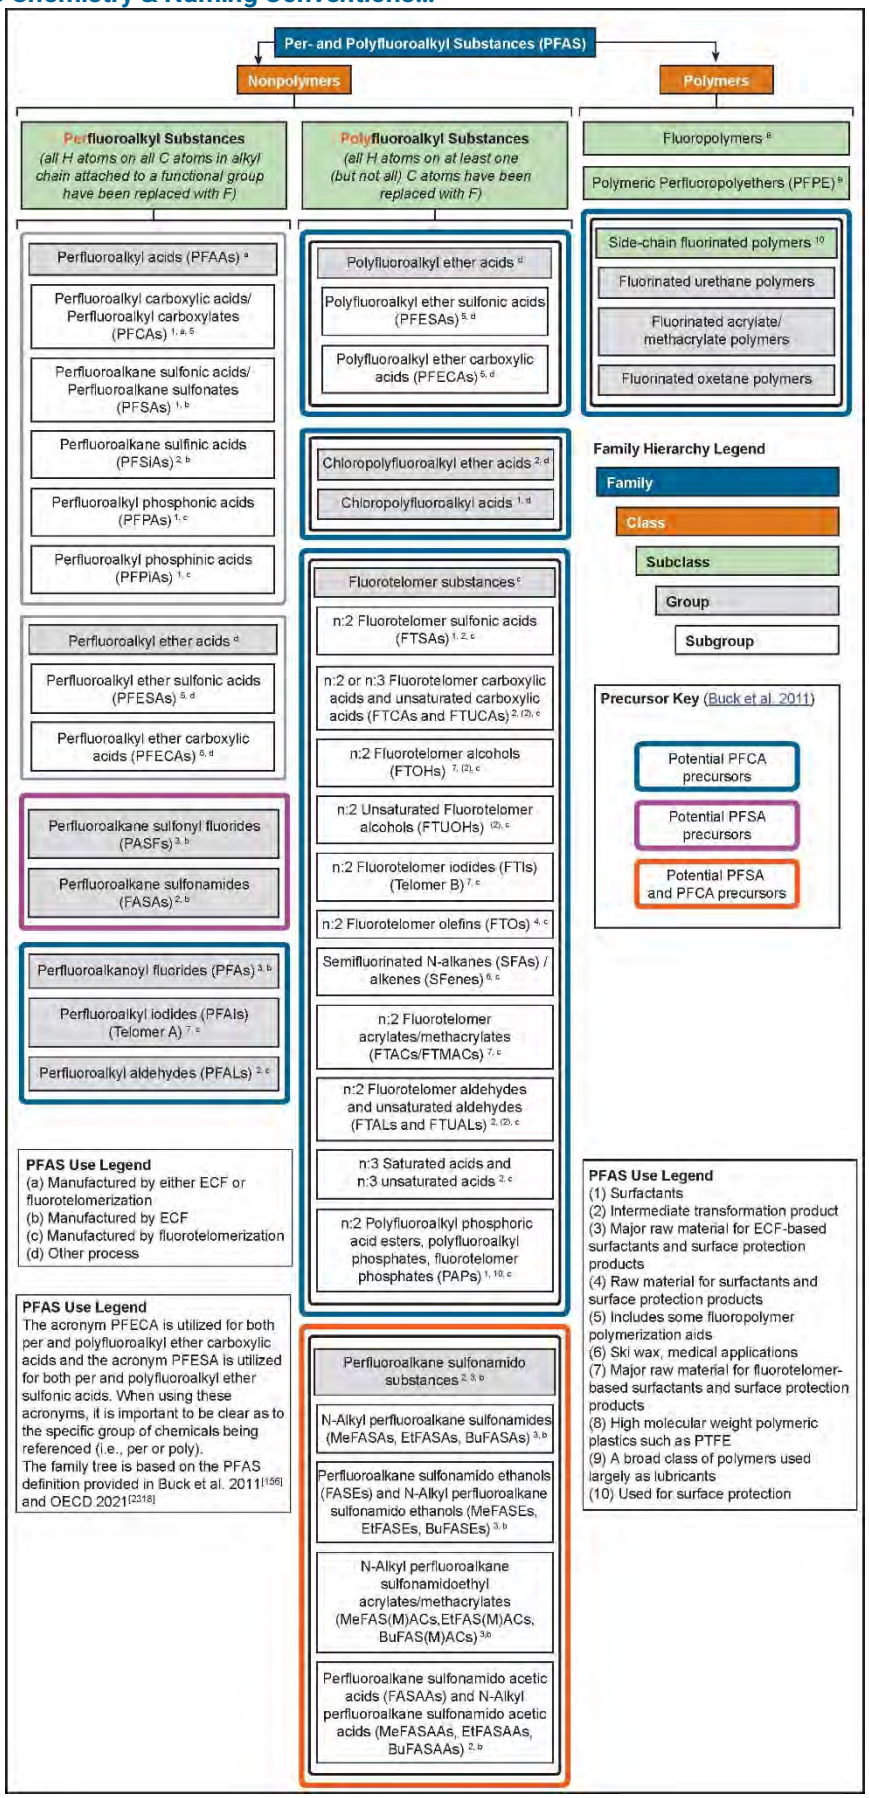

Figure 2-5. PFAS family tree. *Adapted from a graphic provided courtesy of Paul Caprio, EA Engineering.* A stand-alone **PDF version of Figure 2-5** is available.

The family tree is further expanded in **Figure 2-5**, based on nomenclature provided in **Buck et al. (2011)**, Organization for Economic Co-operation and Development **OECD (2015)**, and **Wang et al. (2017)**, with further introduction to some of these chemicals provided later in this section. Future updates to the family tree and nomenclature are expected to be necessary given the evolving public knowledge of these compounds. For example, other PFAS without analytical standards are being identified using nontarget analyses by research laboratories (**Section 11**). These PFAS do not necessarily have associated CAS numbers but are being identified by molecular structure. Naming conventions and categories of PFAS are developed as a means to communicate, manage, and address this class of many chemicals, which can include alternate naming conventions and a variety of rationales for assigning categories.

2.2.2.1 Polymer PFAS

Polymers are large molecules formed by combining many identical smaller molecules (or monomers, which are shorter chain molecules with no repeating units) in a repeating pattern.

The PFAS polymer class includes fluoropolymers, polymeric perfluoropolyethers, and side-chain fluorinated polymers (**Henry et al. 2018**; **Buck et al. 2011**; **Wang et al. 2013**):

- Fluoropolymers contain a carbon-only polymer backbone with fluorines directly attached to the carbon. Fluoropolymers include polymers like PTFE, ETFE, copolymer FEP, and PFA, which were historically made using processing aids ammonium perfluorooctanoate (APFO) or sodium perfluorooctanoate (NaPFO), which are salts of perfluorooctanoic acid (PFOA). Fluoropolymers also include polyvinylidene fluoride (PVDF), which was historically made using ammonium perfluorononanoate (APFN), the ammonium salt of perfluorononanoic acid (PFNA) (**OECD 2015**; **Buck et al. 2011**).

- The specific fluoropolymers PTFE, FEP, ETFE, and PFA have been referred to as "polymers of low concern" in two studies. **Henry et al. (2018)** notes that these specific fluoropolymers have high molecular weight and are extremely stable and PTFE has been demonstrated not to be bioavailable (**Henry et al. 2018**). Polymers of low concern are reported to pose little environmental or health risk once in a consumer product, and based on this, **Henry et al. (2018)** suggested that "polymers of low concern" should be considered separately from other PFAS when evaluating risk. An additional study (**Korzeniowski et al. 2023**) describes the composition, uses, performance properties and functionalities of 14 fluoropolymers, including fluoroplastics and fluoroelastomers, and presents data to show that they satisfy the widely accepted polymer hazard assessment criteria to be considered polymers of low concern (PLC). Further, the study results show that fluoropolymers are a distinct and different group of PFAS and should not be grouped with other PFAS for hazard assessment or regulatory purposes.

- However, during the manufacture of some fluoropolymers, nonpolymer PFAS are used as processing aids and may be found as impurities in some fluoropolymer products (**3M Company 1999**; **CalEPA 2018**; see **Section 5.4.5**). For this reason, in order to prevent potential releases of nonpolymer PFAS processing aids (see APFO and NaPFO discussion above) and short-chain polymeric byproducts/impurities, such as unreacted monomers, environmental controls are necessary during the manufacturing and further processing of fluoropolymers. However, it should be noted that another study (**Lohmann et al. 2020**) found that there was insufficient evidence to consider fluoropolymers as being of low concern for environmental and human health and that group of fluoropolymers should not be given a blanket exemption from regulatory review. According to **Lohmann et al. (2020)**, the assessment and management of fluoropolymer products should consider the complete life cycle, including associated emissions during production and disposal.

- Polymeric perfluoropolyethers (PFPE) contain a carbon and oxygen polymer backbone with fluorines directly attached to carbon. Relatively little is known about these chemicals in the environment.

- Side-chain fluorinated polymers contain a nonfluorinated polymer backbone, off of which fluorinated side chains branch. These PFAS include fluorinated urethane polymers, fluorinated acrylate/methacrylate polymers, and fluorinated oxetane polymers. A few side-chain fluorinated polymers can become precursors for PFAAs, (**Section 2.2.3.1**) by transformation, when the point of connection of a fluorinated side chain on a polymer is broken to release a PFAA, or by release of fluorinated monomer residuals, or both.

2.2.2.2 Nonpolymer PFAS

Nonpolymer PFAS encompass two major subclasses: perfluoroalkyl substances and polyfluoroalkyl substances, which include many groups and subgroups of chemicals. **Figure 2-6** provides general classification and chemical structures, examples of each group and/or subgroup, and examples of the primary uses of some of the nonpolymer PFAS highlighted in **Figure 2-4** and **Figure 2-5**.

Nonpolymer PFAS were selected as the focus of this document because:

- they are included in most laboratory PFAS analyte lists (**Section 11**)

- they are the PFAS most commonly detected (to date) in humans, biota, and other environmental media and appear to be relatively more abundant at PFAS investigation sites (**Section 6**)

- data may be available regarding potential human health and ecological effects from environmental exposure for some of these chemicals (**Section 7**)

- state or federal standards or guidance values may exist or be under development for some of these chemicals (**Section 8**).

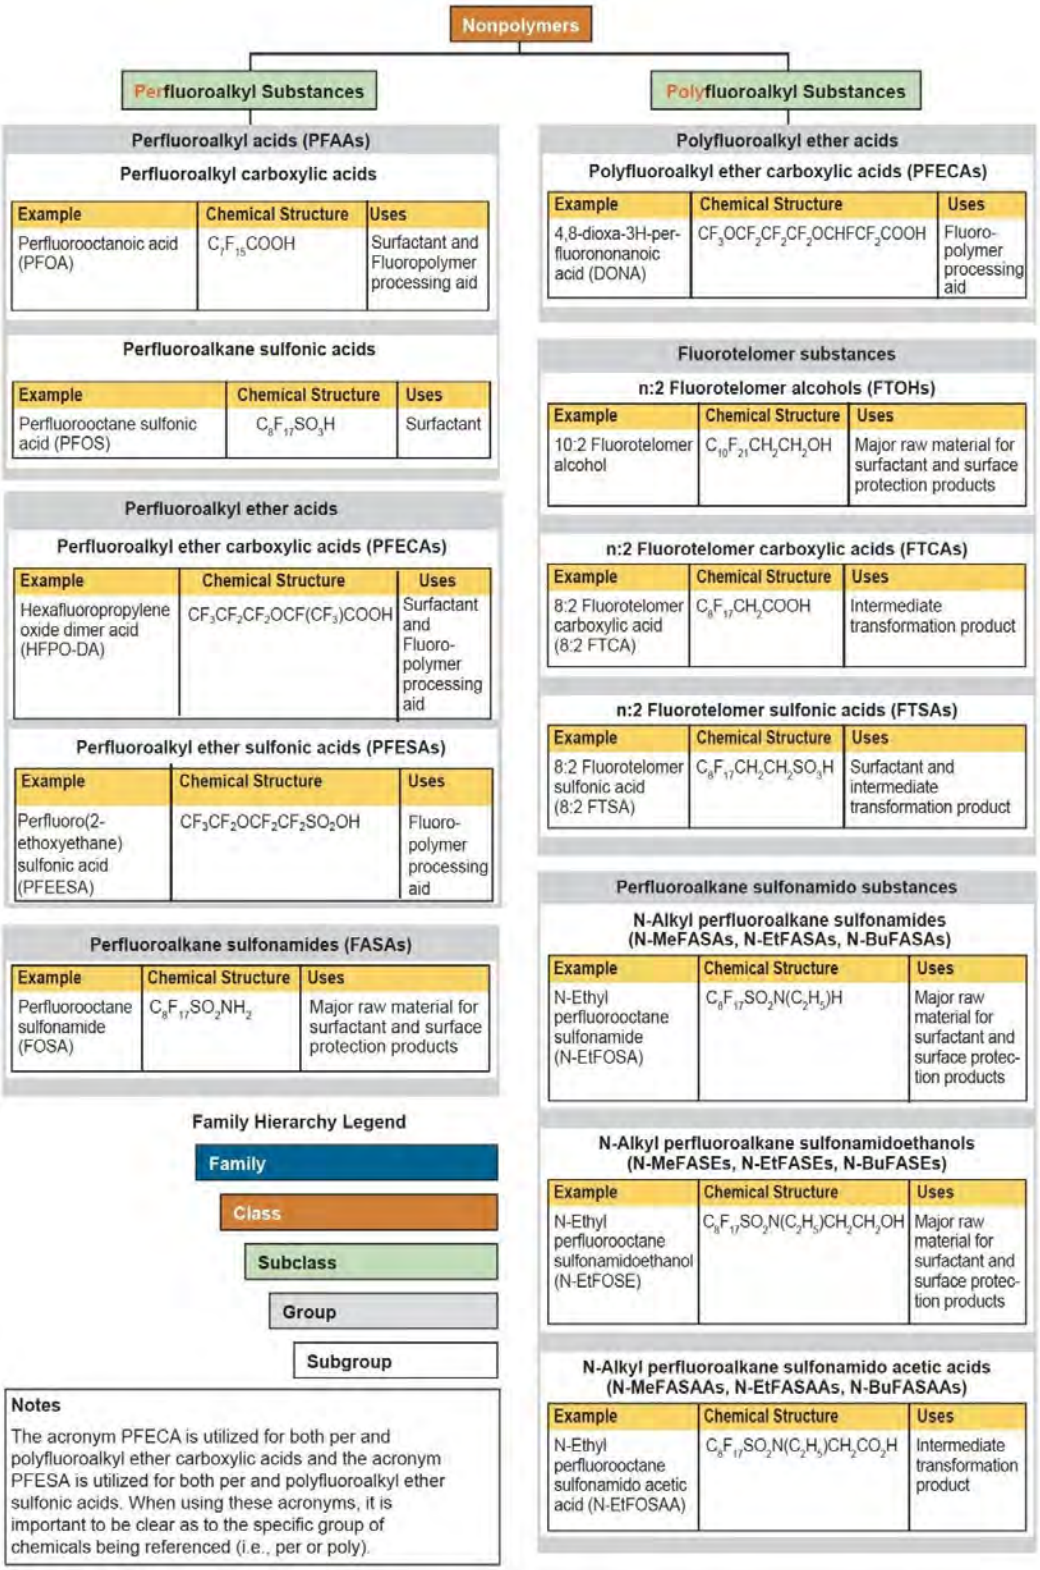

Figure 2-6. Examples of some nonpolymer PFAS subclasses discussed in this document.

2.2.3 Perfluoroalkyl Substances

Perfluoroalkyl substances are fully fluorinated alkane molecules that include (but are not limited to):

- perfluoroalkyl acids (PFAAs) and
- perfluoroalkane sulfonamides (FASAs).

The basic chemical structure is a chain (or *tail*) of two or more carbon atoms with a charged functional group (or *head*) attached at one end. The functional groups commonly are carboxylates or sulfonates, but other forms are also detected in the environment. Fluorine atoms are attached to all possible bonding sites along the carbon chain of the tail, except for one bonding site on the last carbon where the functional group head is attached. This structure, which is illustrated in **Figure 2-7** for PFOS and PFOA, can be written as:

$$C_nF_{2n+1}\text{-R}$$

where "C_nF_{2n+1}" defines the length of the perfluoroalkyl chain tail, "n" is >2, and "R" represents the attached functional group head. Note that the functional group may contain one or more carbon atoms, which are included in the total number of carbons when naming the compound.

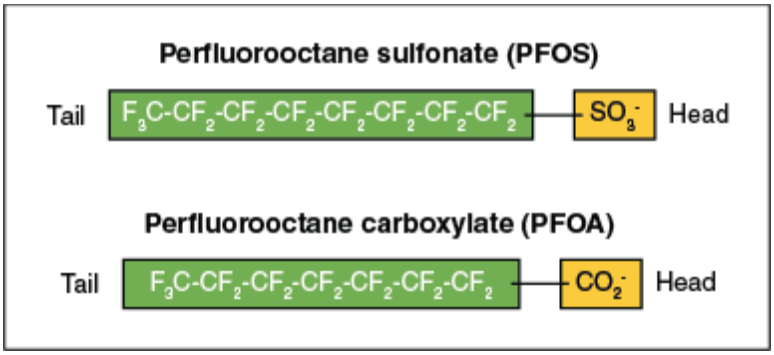

Figure 2-7. The tail and head structure of PFOS and PFOA molecules.

2.2.3.1 Perfluoroalkyl Acids (PFAAs)

PFAAs are some of the least complex PFAS molecules. They are essentially non-degradable under normal environmental conditions. Biotic and abiotic transformation of many polyfluoroalkyl substances may result in the formation of PFAAs. As a result, PFAAs are sometimes referred to as "terminal PFAS" or "terminal transformation products," meaning no further transformation products will form from them under environmental conditions. Polyfluoroalkyl substances that transform to create terminal PFAAs are referred to as "***precursors***." Longer chain PFAAs are not known to biotransform to shorter chain PFAAs.

The PFAA group is divided into two major subgroups (as shown in **Table 2-2** and **Figure 2-4**).

- ***Perfluoroalkyl carboxylic acids*** (PFCAs), or perfluoroalkyl carboxylates, are used commercially and can be formed as terminal transformation products of select precursor polyfluoroalkyl substances, such as fluorotelomer alcohols (FTOHs). An example PFCA is PFOA.
- ***Perfluoroalkane sulfonic acids*** (PFSAs), or perfluoroalkane sulfonates, also are used commercially and can be formed as terminal transformation products of select precursor polyfluoroalkyl substances, such as perfluoroalkane sulfonamido ethanols (FASEs). An example PFSA is PFOS.

Other subgroups of PFAAs are introduced below. Some of these are compounds that are receiving increasing attention, are being added to commercial laboratory target analyte lists, and are being detected in the environment. Other PFAAs include:

- perfluoroalkane sulfinic acids (PFSiAs), associated with the electrochemical fluorination (ECF) process and also occurring as intermediate environmental transformation products
- perfluoroalkyl phosphonic acids (PFPAs) and phosphinic acids (PFPiAs), associated with the fluorotelomerization process and used as surfactants

PFAAs are the group of PFAS that make up the majority of PFAS typically included in commercial laboratory target analyte lists and are the primary PFAS for which federal or state health-based guidance values have been established. As a result, PFAAs tend to drive site investigation and remediation decisions, so it is helpful to understand the naming conventions for this class. Many of the commonly detected PFAAs are denoted using the following structural shorthand acronym:

PFXY where:
PF = perfluoro
X = the carbon chain length (using the same naming conventions as hydrocarbons based on the number of carbons (for example, B for butane or 4 carbons, Pe for pentane or 5 carbons)
Y = the functional group (for example, A = carboxylate or carboxylic acid and S = sulfonate or sulfonic acid)

Table 2-2 illustrates how this naming structure works for the PFCAs and PFSAs, which collectively are referred to as PFAAs.

Table 2-2. Basic naming structure and shorthand for PFAAs.

X	Y	Acronym	Name	Formula	CAS No.[1]	DTXSID[2]

NA = not available
[1]Older nomenclature may use butyrate or butyric acid.
[2] Link to DTXSID: **CompTox Chemicals Dashboard (epa.gov)** (helpful to use as a means of finding structural depictions and availability of other public data)

Note that for PFCAs, the total number of carbons used for naming the compound includes the carbon in the carboxylic acid functional group (COOH). For example, although PFOA has seven carbons in its

fluoroalkyl tail, all eight of the carbons in the molecule are used to name it, hence *perfluorooctanoate*. But in terms of chemical behavior, PFOA would be more analogous to seven-carbon perfluoroheptane sulfonate (PFHpS) than to eight-carbon perfluorooctane sulfonate (PFOS).

Table 2-2 shows the PFAA names and formulas in both the anionic (also referred to as "deprotonated" or negatively charged) and acid (also referred to as protonated or neutral) forms. The anionic form is the state in which PFAAs are found in the environment, except in very rare situations (for example, extremely low pH). The anionic and acid forms of PFAA names are often incorrectly used interchangeably (for example, perfluorooctane sulfonate and perfluorooctane sulfonic acid), and the same acronym (in this case, PFOS) applies to both forms. However, as discussed below and in **Section 4**, their physical and chemical properties are different, and it is important to know which form is being described.

Until recently, PFCAs and PFSAs have been the subgroups most commonly tested for in the environment; however, a wide range of PFAS with other functional groups exists for which the same "PFXY" shorthand shown above may or may not apply. For naming conventions for these compounds, please refer to **Buck et al. (2011)**.

Long-Chain Versus Short-Chain Distinction

PFAS, predominantly PFAAs, are sometimes described as *long-chain* and *short-chain* as a shorthand way to categorize PFCAs and PFSAs that may behave similarly in the environment; however, it is important not to generalize about PFAA behavior based only on chain length. As recent research suggests, other factors besides chain length may affect bioaccumulation potential of PFAS (**Ng and Hungerbühler 2014**).

According to the **OECD (2013)**:

- *Long-chain* refers to:
  - PFCAs with eight or more carbons (seven or more carbons are perfluorinated)
  - PFSAs with six or more carbons (six or more carbons are perfluorinated)
- *Short-chain* refers to:
  - PFCAs with seven or fewer carbons (six or fewer carbons are perfluorinated)
  - PFSAs with five or fewer carbons (five or fewer carbons are perfluorinated)

Table 2-3 illustrates the differences in the short-chain and long-chain PFCAs and PFSAs.

Table 2-3. Short-chain and long-chain PFCAs and PFSAs.

Number of Carbons	4	5	6	7	8	9	10	11	12
PFCAs	Short-chain PFCAs				Long-chain PFCAs				
	PFBA	PFPeA	PFHxA	PFHpA	PFOA	PFNA	PFDA	PFUnA	PFDoA
PFSAs	PFBS	PFPeS	PFHxS	PFHpS	PFOS	PFNS	PFDS	PFUnS	PFDoS
	Short-chain PFSAs		Long-chain PFSAs						

Anions Versus Acids

As noted above, the names for the anionic and acid forms of PFAAs are often used interchangeably, but it is critical to know which form is being discussed because of differences in their physical and chemical

properties and behavior in the environment (**Section 6**). Some important things to keep in mind regarding the anionic versus acid forms are:

- Most PFAAs are present in environmental and human matrices in their anionic form. For example, PFOS is present in the environment in the anionic form, perfluorooctane sulfonate.
- Although laboratories may be reporting PFOA or PFOS using the acid form of their name, they are actually measuring the anionic form (for example, perfluorooctanoate or perfluorooctane sulfonate), as this is the form that exists in the environment.
- The acid form and their associated cationic salts have CAS numbers, while the anionic forms may not (**Table 2-2**). For example, PFOS can exist as different salts (cationic), including sodium, lithium, potassium, or ammonium. Each of these salts will have a different CAS number:
    - PFOS, acid form CAS No.: 1763-23-1
    - PFOS, potassium salt CAS No.: 2795-39-3
    - PFOS, ammonium salt CAS No.: 29081-56-9
- When the salt or acid exists in water or other liquids, it will dissociate (lose its hydrogen or associated ion), and the salt or acid will break off and form the **anion** (for example, COO– or SO3–). **Figure 2-8** illustrates the dissociation of PFBA.

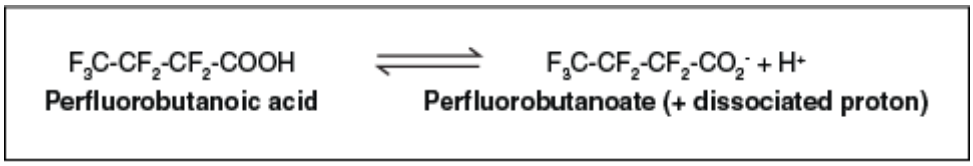

Figure 2-8. Dissociation of PFBA.

It is most important to distinguish between the acid form and anionic form when reporting the physical and chemical properties. The discussion of PFAS properties in this guidance document generally refers to the anionic form; it will be specifically called out if the acid form is being discussed.

A Note About PFAS Naming in Laboratory Reports (see Section 11)

*Even though PFAAs occur as anions in the environment, some laboratories report all of their results in the acidic form, while others may report PFCAs as acids (for example, **perfluorooctanoic acid**) and PFSAs as anions (for example, **perfluorooctane sulfonate**). Different naming conventions in laboratory reports have led to confusion regarding exactly which form of the PFAA the labs are measuring. Although the lab is measuring the concentration of PFAA anions present in the sample, where the results are reported as an acid, the lab has adjusted for the H+ cation (which has so little mass, this does not affect the resulting concentration). It should be noted that the standards used by laboratories to perform analyses may be prepared from PFAA salts, as is often the case for sulfonate standards. If so, the lab must adjust the reported concentration to account for the mass of the counterion (typically Na+ or K+). The calculation to do this is described in section 7.2.3 of EPA Method 537 (USEPA 2009) and section 15.2 of EPA Method 1622 (USEPA 2024).*

2.2.3.2 Perfluoroalkane Sulfonamides (FASAs)

FASAs, such as perfluorooctane sulfonamide (FOSA), are products and/or intermediates from the ECF process for surfactants and surface protection products. FASAs can transform to form PFAAs such as PFOS.

2.2.3.3 Other Perfluoroalkyl Substances

Other perfluoroalkyl substances shown on **Figure 2-4** and **Figure 2-5** include:

- perfluoroalkane sulfonyl fluorides [PASFs, such as perfluorooctane sulfonyl fluoride (POSF) and perfluorobutane sulfonyl fluoride (PBSF)], and perfluoroalkanoyl fluorides (PAFs), associated with the ECF process
- perfluoroalkyl iodides (PFAIs) and perfluoroalkyl aldehydes (PFALs), associated with the fluorotelomerization process
- perfluoroalkyl ether acids, including perfluoroalkyl ether carboxylic acids (PFECAs) and perfluoroalkyl ether sulfonic acids (PFESAs)

As discussed in **Section 2.4**, some PFECAs have been developed or used as replacements for other PFAS that are phased out of production and use. This includes GenX chemicals (see **text box**). Other emerging fluorinated replacement PFECAs more recently detected in the environment, such as perfluoro-2-methoxyacetic acid (PFMOAA), are described in **Sun et al. (2016)**.

GenX Chemicals

A PFECA, commonly referred to by the trade name "GenX," has been used by one manufacturer as a replacement for APFO (PFOA) as a surfactant and polymerization aid in the production of their PTFE product. GenX actually refers to the GenX processing aid technology, while the major chemicals used include:

- hexafluoropropylene oxide (HFPO) dimer acid (HFPO-DA, CAS No. 13252-13-6, also known as 2,3,3,3-tetrafluoro-2-(1,1,2,2,3,3,3-heptafluoropropoxy)propanoic
- its ammonium salt (ammonium, 2,3,3,3- t [$CF_3CF_2CF_2OCF(CF_3)COO^-NH_4^+$, CAS No. 62037-80-3, als

(Wang et al. 2013; Buck 2015; USEPA 2018).

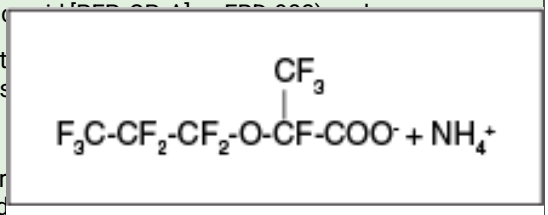

Figure 2-1. Example replacement chemistry structure for GenX Ammonium Salt.

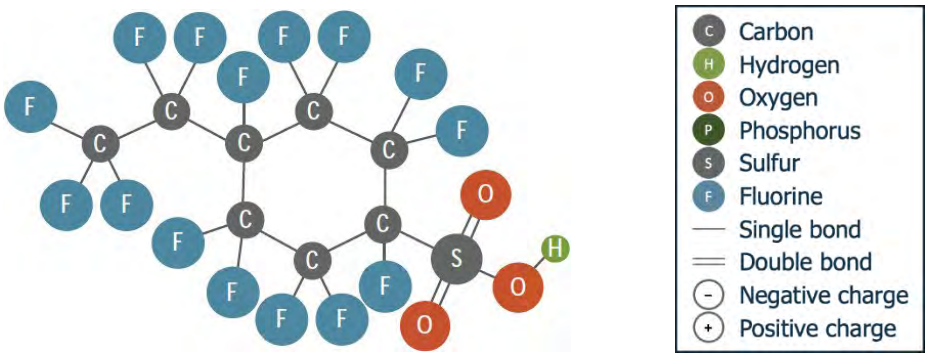
Prior to their use in PTFE production, GenX chemicals were pr processes (NC DEQ 2018). From the GenX Toxicity Assessment d manufacture other HFPO-DA derivatives, fluoropolymers a agrochemical, semiconductor, and pharmaceutical applications. can be formed from reaction of HFPO-DA.

Further discussion of the GenX chemicals is provided in Section 2.4.6. The chemical structure of the ammonium salt is shown in Figure 2-9.

In addition to linear and branched structures, certain cyclic structures have much in common with the noncyclic PFAS and are consistent with the definitions/descriptions provided above. As an example, **Figure 2-10** illustrates the structure of perfluoro-4-ethylcyclohexanesulfonate, also perfluoro-p-ethylcyclohexylsulfonic acid (PFECHS), which some classify as a PFAS (**MPART 2020**). It is used in airplane hydraulic fluids and has been found both in the environment (**Kaboré et al. 2018**; **Howard and Muir 2010**; **De Silva et al. 2011**; **Lescord et al. 2015**; **Houde et al. 2016**) and in human blood (**Miaz et al. 2020**). The characteristics of PFECHS include:

- fully fluorinated six-carbon ring
- nonaromatic
- sulfonate active group
- perfluorinated two-carbon tail

PFECHS fits the **Buck et al. (2011)** description by having a fully fluorinated aliphatic tail of one or more carbon atoms attached to a charged functional group head. **Section 1.1.3.2** includes more information about cyclic PFAS.



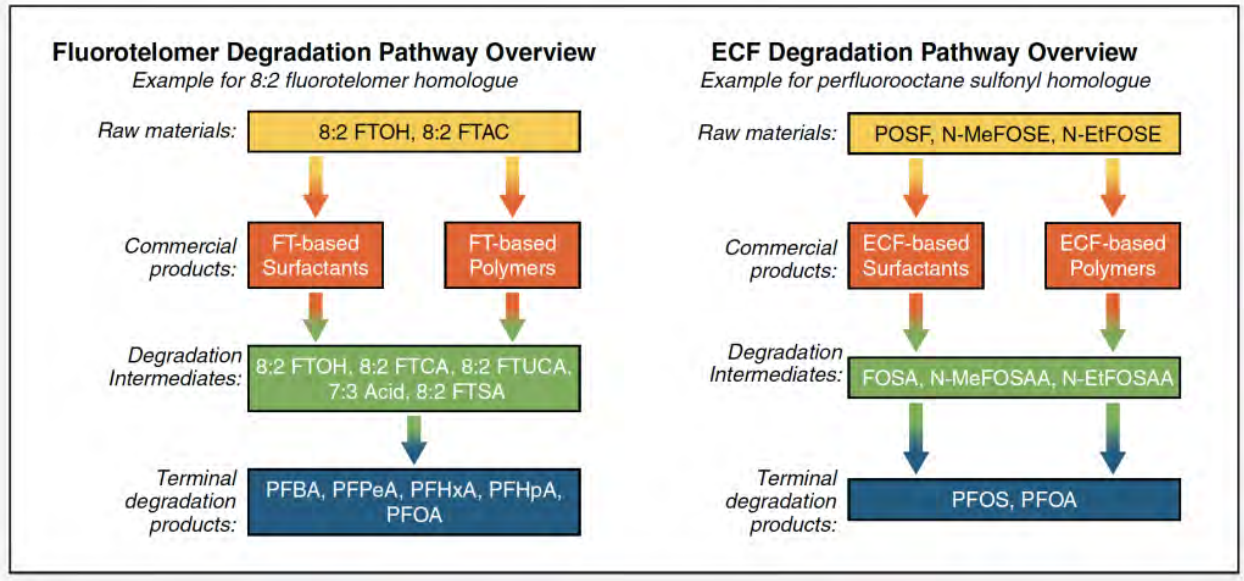


Figure 2-10. Illustration of perfluoro-p-ethylcyclohexyl sulfonic acid structure (see legend right of figure).

2.2.4 Polyfluoroalkyl Substances

Polyfluoroalkyl substances including some side-chain fluorinated polymers are increasingly being identified as important to understanding the occurrence, fate, and transport of PFAS at release sites and in the environment (**OECD 2013**; **Butt, Muir, and Mabury 2014**; **Liu and Mejia-Avendaño 2013**; **Wang et al. 2011**; **Mejia-Avendaño et al. 2020**). **Figure 2-4** and **Figure 2-5** highlight the groups of polyfluoroalkyl substances that, to date, have most commonly been detected at PFAS sites (see **Barzen-Hanson et al. 2017**; **OECD 2018**). Of the approximately 4,700 PFAS identified in the OECD (**2018**) study, about 90% were potential precursors to PFAAs.

(Note that transformation of POSF-based products is for the terrestrial environment, but transformation into lower homologues of PFCAs and PFSAs in the atmosphere is also possible, see references in the paragraph above.)

Figure 2-11. Example polyfluoroalkyl substance transformation pathways.

Polyfluoroalkyl substances are distinguished from perfluoroalkyl substances by not being fully fluorinated. Instead, they are aliphatic substances for which all hydrogen atoms attached to at least one (but not all) carbon atoms have been replaced by fluorine atoms, in such a manner that they contain the perfluoroalkyl moiety CnF2n+1 (**Buck et al. 2011**), see **Figure 2-6**.

The carbon-hydrogen (or other nonfluorinated) bond in polyfluoroalkyl molecules creates a "weak" point in the carbon chain that may be susceptible to biotic or abiotic transformation. As a result, many polyfluoroalkyl substances that contain a perfluoroalkyl CnF2n+1 moiety are potential precursor compounds that have the potential to be transformed into PFAAs.

Figure 2-11 provides examples of transformation pathways for environmentally relevant polyfluoroalkyl precursors derived from two PFAS production methods, fluorotelomerization and ECF, respectively (**Buck et al. 2011**; **Liu and Mejia-Avendaño 2013**; **Butt, Muir, and Mabury 2014**; **Martin et al. 2006**). Note that these figures include some PFAS not discussed in this guidance document, but described in **Buck et al. (2011)**. Refer to **Section 5.4** and **Section 1.3.3** for further information on transformation processes, noting that not all transformation products will be formed through every environmental transformation process.

2.2.4.1 Fluorotelomer Substances

Fluorotelomer substances are polyfluoroalkyl substances produced by the fluorotelomerization process. As shown in **Figure 2-11**, the transformation of fluorotelomer-based substances is a potential source of PFCAs in the environment, but not PFSAs (**Buck et al. 2011**).

Fluorotelomer-based polyfluoroalkyl substances are named using an "n:x" prefix where "n" indicates the number of fully fluorinated carbon atoms (n > 2) and "x" indicates the number of carbon atoms that are not fully fluorinated (x > 1). An example of a polyfluoroalkyl substance is shown in Figure 2-12, which also illustrates the "n:x" naming convention.

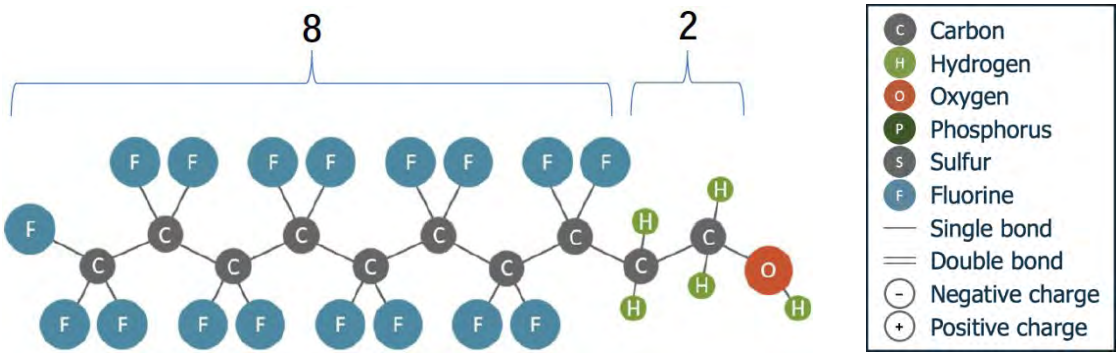

Figure 2-12. Example of a polyfluoroalkyl substance (see legend right of figure).

Some of the fluorotelomer substances most commonly detected in the environment to date are as follows (**Section 6**):

- *Fluorotelomer alcohols* (FTOH): The n:2 fluorotelomer alcohols (n:2 FTOHs) are key raw materials in the production of n:2 fluorotelomer acrylates and n:2 fluorotelomer methacrylates (**Buck et al. 2011**).

- *Fluorotelomer sulfonic acids* (FTS): The n:2 fluorotelomer sulfonic acids (n:2 FTSs) have been detected in environmental matrices at sites where aqueous film-forming foam (AFFF) has been used, and also in wastewater treatment plant effluents and landfill leachate. FTSs are precursor compounds and can undergo aerobic biotransformation to form PFCAs (**Buck et al. 2011**).

- *Fluorotelomer carboxylic acids* (FTCA): These compounds form through the biotransformation of FTOHs (**Figure 2-11**; (**Buck et al. 2011**; **Mejia-Avendaño et al. 2016**) and have been detected in landfill leachate. Note that the –COOH functional group on these fluorotelomer compounds

means they may have either an even or odd number of carbons, so they may have n:2 or n:3 prefixes.

Other fluorotelomer (FT) substances are shown in **Figure 2-5** and **Figure 2-6**.

2.2.4.2 Perfluoroalkane Sulfonamido Substances

The subgroups of perfluoroalkane sulfonamido substances shown in **Figure 2-5** and discussed below have been detected in the environment and humans (**Buck et al. 2011**). Perfluoroalkane refers to the fully fluorinated carbon chain tail, but these compounds also contain one or more CH2 groups in the head of the molecule attached to the sulfonamido spacer (**Figure 2-13**). They are either used as raw materials for surfactant and surface treatment products, or they are present as intermediate transformation products of these raw materials. As shown in the transformation pathways in **Figure 2-11**, some perfluoroalkane sulfonamido substances have been found to transform to PFOS (**Mejia-Avendaño and Liu 2015**). Environmentally relevant perfluoroalkane sulfonamido substances include:

- *N-Alkyl perfluoroalkane sulfonamides* (N-alkyl FASAs) are raw materials used for surfactant and surface treatment products that include N-methyl perfluorooctane sulfonamide (N-MeFOSA) and N-ethyl perfluorooctane sulfonamide (N-EtFOSA) (**Buck et al. 2011**)

- *Perfluoroalkane sulfonamido ethanols* (FASEs) and *N-alkyl perfluoroalkane sulfonamido ethanols* (N-MeFASEs, N-EtFASEs, N-BuFASEs) are raw materials for surfactant and surface treatment products (**Buck et al. 2011**). **Figure 2-13** illustrates the structure of N-EtFOSE

- *Perfluoroalkane sulfonamido acetic acids* (FASAAs) and *N-alkyl perfluoroalkane sulfonamido acetic acids* (N-MeFASAAs, N-EtFASAAs, N-BuFASAAs) are intermediate transformation products of FASEs, N-MeFASEs, N-EtFASEs, and N-BuFASEs (**Figure 2-11**) (**Buck et al. 2011**)

- *N-alkyl perfluoroalkane sulfonamidoethyl acrylates/methacrylates* (N-MeFAS(M)ACs, N-EtFAS(M)ACs, N-BuFAS(M)ACs)

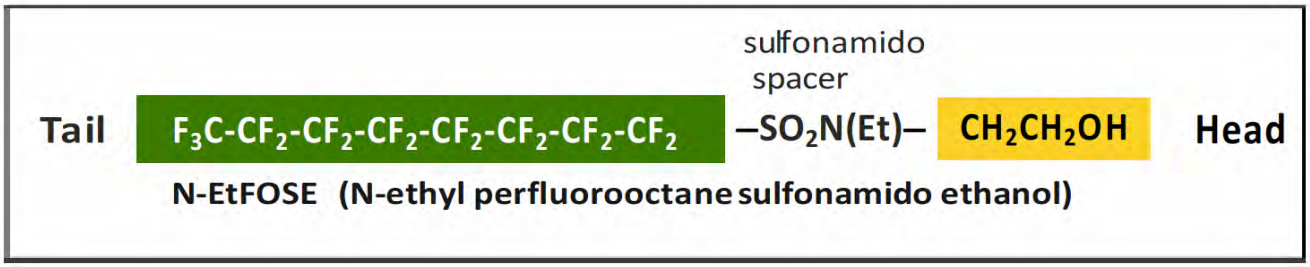

Figure 2-13. Example of a perfluoroalkane sulfonamido ethanol (FASE).

2.2.4.3 Other Polyfluoroalkyl Substances

Other polyfluoroalkyl substances shown in **Figure 2-5** include:

- polyfluoroalkyl ether acids, including polyfluoroalkyl ether sulfonic acids (PFESAs) and polyfluoroalkyl ether carboxylic acids (PFECAs)

- chloropolyfluoroalkyl ether acids
- chloropolyfluoroalkyl acids

As discussed in **Section 2.4.6**, some PFAS have been developed or used as replacements for other PFAS that are phased out of use and production.

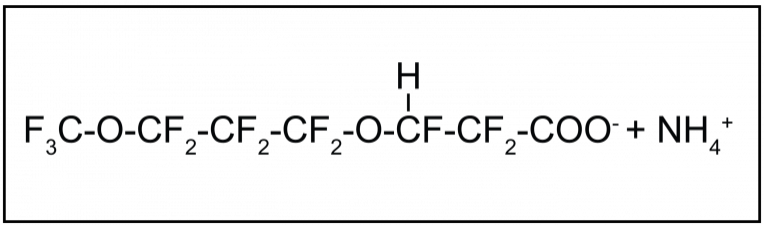

Figure 2-2. Chemical structure for ADONA ammonium salt.

One replacement compound for the use of PFOA as a polymerization aid in the production of PTFE is a polyfluoroalkyl ether carboxylic acid: ammonium 4,8-dioxa-3H-perfluorononanoate (CF3OCF2CF2CF2-OCHFCF2COO–NH4+ (CAS No. 958445-44-8), commonly referred to by the trade name ADONA (**Gordon 2011**). The chemical structure is shown in **Figure 2-14**.

Other replacement polymerization compounds for the manufacture of PTFE and polyvinylidene fluoride (PVDF) include polyfluoroalkyl ether acids, also referred to as cyclic or polymeric functionalized perfluoropolyethers (PFPEs) (**Wang et al. 2013**). A sample chemical structure of a chloropolyfluoroalkyl ether acid is shown in **Figure 2-15**.

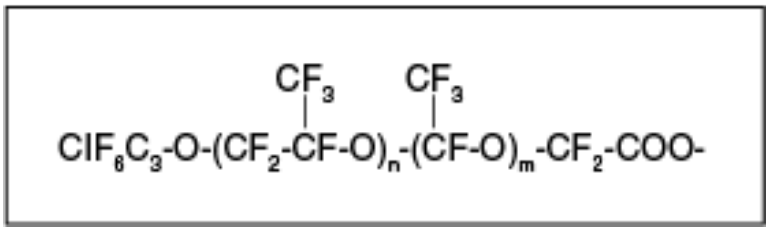

Figure 2-3. Sample chemical structure for a chloropolyfluoroalkyl ether acid.

2.2.5 Chemical Manufacturing

To differentiate among PFAS in understanding a conceptual site model for environmental risk assessment, it is important to know about the chemical manufacturing processes. The various manufacturing processes produce different types of PFAS, such as linear and branched isomers (as discussed in this section), which may affect the environmental fate, treatment, toxicology, and site forensics for these chemicals. The type of PFAS that might be formed by the transformation of precursor PFAS at or related to an environmental release site also may depend on the manufacturing process (refer to the family tree in **Figure 2-5**).

2.2.5.1 Processes

Two major processes, *electrochemical fluorination (ECF)* and *fluorotelomerization*, have been (and are) used to manufacture PFAS that contain perfluoroalkyl chains: side-chain fluorinated polymers, PFAAs and polyfluoroalkyl surfactants (**USEPA 2003**; **Benskin, DeSilva, and Martin 2010**; **KEMI 2015**; **OECD 2018**). The fluorotelomerization process may also be characterized as "oligomerization," as it involves, for example, using tetrafluoroethylene (TFE) monomer and adding one to nine TFE monomers to form a perfluoroalkyl chain (**Kissa 2001**; **Rao and Baker 1994**). ECF and fluorotelomerization can be used to create some of the same PFAS, as shown on **Figure 2-5**. PFSAs are produced only using the ECF process, whereas PFCAs can be produced by both ECF and fluorotelomerization (**USEPA 2003**; **CONCAWE 2016**).

More than 600 intermediate processes have been used to further produce certain PFAS and the associated final products. Further discussion of the intermediate processes may be found in the general scientific literature and numerous textbooks specifically written about fluorinated organics and fluoropolymers (**Banks, Smart, and Tatlow 1994**).

Electrochemical Fluorination (ECF)

The Simons ECF process was licensed by 3M in 1945; 3M subsequently built an ECF pilot in 1949 and started commercial production in 1951 (**3M Company 1999**) In the ECF process, an electric current is passed through a solution of an organic feedstock and liquid anhydrous hydrogen fluoride, which causes the hydrogen atoms to be replaced by fluorine atoms, thereby creating carbon-fluorine bonds (**3M Company 1999**; **USEPA 2003**; **Buck et al. 2011**). ECF is used to create perfluoroalkane sulfonyl fluorides (PASFs), which are the building blocks for other sulfonyl-based PFAS, as well as perfluoroalkyl carboxylate derivatives. These ECF-synthesized PFAS can contain a variable mixture of linear and branched perfluorinated isomers, as well as other homologues, byproducts, and impurities (**USEPA 2003**; **Buck et al. 2011**). The variable composition is caused by the process conditions, raw materials, and equipment used by the ECF process (**3M Company 1999**; **CONCAWE 2016**). Subsequent processes (for example, hydrolysis, base neutralization) are then used to refine the compounds (**USEPA 2003**).

Historically, the ECF process was primarily used to produce POSF which was then used to make PFOS-based materials. PFOS is often a terminal transformation product of POSF-based compounds. ECF was also used to produce perfluorooctane carbonyl fluoride which was then used to produce PFOA and other derivatives (for example, using perfluorooctane carbonyl fluoride to produce PFOA and its salts, such as APFO). As part of the phaseout of production of select long-chain PFAS in the United States, 3M has ceased using ECF to make certain long-chain PFAS, such as POSF-based compounds (PFOS and PFHxS) and PFOA (**Buck et al. 2011**; **Section 2.4.1**). 3M's phaseout did not include other, shorter chain PFAS-based products, such as those based on PBSF (**3M Company 2018**).

Fluorotelomerization

A typical fluorotelomerization process involves the reaction of perfluoroethyl iodide (PFEI, CF_3CF_2-I) with tetrafluoroethylene (TFE, CF_2=CF_2) to yield a mixture of even-numbered carbon linear perfluoroalkyl iodides (C_nF_{2n+1}-I, n= 4, 6, 8, 10, etc.), commonly known as "Telomer A." Telomer A is then reacted with ethylene to make "Telomer B" (fluorotelomer iodide, $C_nF_{2n+1}CH_2CH_2$-I, n= 4, 6, 8, 10, etc.). Telomer B is reacted to make fluorotelomer alcohols (FTOHs, $C_nF_{2n+1}CH_2CH_2$-OH, n= 4, 6, 8,10, etc.) Telomer A, Telomer B, and FTOHs are the basic raw materials used to manufacture fluorotelomer-based surfactant (nonpolymer) and polymer products (**Kissa 2001**; **Rao and Baker 1994**).

As part of the USEPA 2010/2015 Stewardship Program (**USEPA 2018**; **Section 2.4.3**), eight major global fluoropolymer and fluorotelomer manufacturers phased out production of long-chain fluorotelomer-based products that were potential precursors to PFOA and other long-chain perfluoroalkyl carboxylic acids (PFCAs). Today, the major global fluorotelomer manufacturers are reported to have refined their processes and predominantly manufacture short-chain (C6) fluorotelomer-based products (**American Chemistry Council 2021**). Some manufacturers outside of the United States (for example, China, India) have not phased out long-chain PFAS production (**Song et al. 2018**).

Fluorotelomerization has been primarily used to produce linear (straight-chain) PFAS isomers with an even number of carbon atoms (**Buck et al. 2011**), although some sources indicate that the process can also produce compounds with an odd number of carbons and branched chains (**Lindstrom, Strynar, and Libelo 2011**; **Danish EPA 2015**).

2.2.5.2 Linear and Branched Isomers of PFAS

Many PFAS may be present as mixtures of linear and branched isomers (**Figure 2-16**) depending on the manufacturing process that was used. These structural differences are important because they may

affect how the compounds behave in the environment and may provide an indicator of their source. Structural differences are described below:

- A *linear isomer* is composed of carbon atoms bonded to only one or two carbons, which form a straight carbon backbone. There can be only one linear isomer in a Cn homologue (compounds with the same number of carbons in their tail) series.

- In a *branched isomer*, at least one carbon atom is bonded to more than two carbon atoms, which forms a branching of the carbon backbone. There can be many isomers per Cn homologue series.

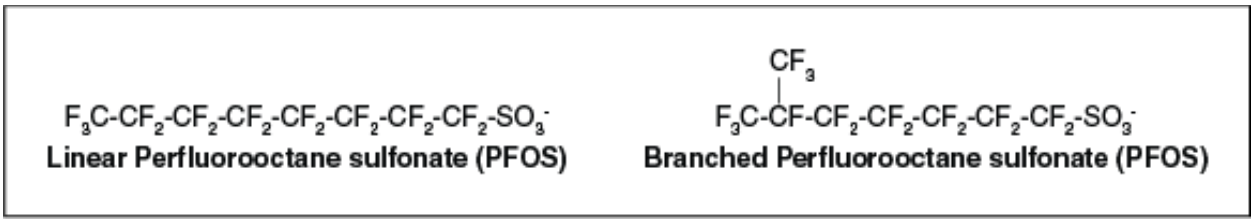

Figure 2-16. Linear and one branched isomer of PFOS.

For simplicity, both linear and branched isomers are abbreviated using the same acronym in this document. Note that other nomenclature conventions further identify PFAS by labeling linear isomers (for example, n-PFOS) and branched isomers based on the location of the branch in the carbon chain (for example, 5m-PFOS) (**Benskin, DeSilva, and Martin 2010**).

The formula "C_nF_{2n+1}-" (where n is greater than or equal to 3) includes linear and branched isomers. For example, PFOS and PFHxS are routinely present in environmental samples as a mixture of linear and branched isomers (**Beesoon et al. 2011**; **Beesoon et al. 2012**; **Benskin, DeSilva, and Martin 2010**).

Table 2-4. Manufacturing processes and potential PFAAs produced.

Manufacturing Process	Commonly Found Polyfluorinated Substance (Precursors)	Potential PFAAs Produced
Fluorotelomerization	FTS[1]	Linear PFCAs[3]
	FTCA[2]	Linear PFCAs[3]
	FTOH	Linear PFCAs[3]
Electrochemical fluorination	FASE	Branched and linear PFCAs Branched and linear PFSAs
	FASAA	Branched and linear PFCAs Branched and linear PFSAs

[1]Fluorotelomer sulfonic acid: for example, may be found at AFFF sites
[2]Fluorotelomer carboxylic acids: for example, 5:3 FTCA may be found in landfill leachate
[3]Under certain instances, can produce mixture of linear and branched PFCAs

Accurate quantification of PFAS that are mixtures of linear isomers and branched isomers in environmental matrices can be difficult (**Riddell et al. 2009**). However, the relative contributions of isomers may be useful in understanding sources of PFAS and the age of the source, because the production of isomers varies by manufacturing processes. For example, as discussed above, the fluorotelomerization process has been primarily used to produce mostly linear PFAAs, whereas the ECF process produces a mixture of linear and branched PFAA isomers (**Table 2-4**). Refer to **Section 10.5** for

more information on PFAS source identification. The presence of linear and branched isomers may also have implications for partitioning, transport, and bioaccumulation (**Section 10.5.1.1**).

2.3 Emerging Health and Environmental Concerns

Like other emerging contaminants, knowledge and concern about PFAS in the environment have evolved through a series of phases discussed in this section:

- discovery and/or synthesis of PFAS (**Section 2.2.5**), followed by growth in commercial production and use (**Section 2.5**)
- emerging health and environmental concerns, including:
  - awareness of potential health impacts (**Section 2.3.1**)
  - analytical developments (**Section 2.3.2**)
  - detection in the environment (**Section 2.3.3**)
  - growing awareness and concern (**Section 2.3.4**)
- subsequent efforts to reduce use of contaminants of concern and/or replace the contaminants of concern with alternate technologies and chemicals, accompanied by health and environmental questions about those chemicals (**Section 2.4**)

2.3.1 Awareness of Potential Health Impacts

Occupational studies in the 1970s found detections of some PFAS in the blood of exposed workers, and further studies in the 1990s reported detections in the blood of the general human population (**Buck et al. 2011**). In recent years, the presence of several long-chain PFAAs (PFOA, PFOS, PFNA, and PFHxS) have been measured in the low parts per billion (ppb, equivalent to nanograms per milliliter (ng/ml)) range in the blood serum of almost all residents of the United States and other industrialized nations (**Kato and Calafat 2015**; **CDC 2022**). These PFAS are present whether or not people were exposed in the workplace, likely due to the widespread use of PFAS in consumer products and industries (**Kannan et al. 2004**; **Kärrman et al. 2006**; **Olsen et al. 2003**). However, there have been decreasing concentrations of long-chain PFAAs in people's blood serum, likely due to the voluntary reductions in production, especially PFOA and PFOS; refer to the CDC data presented in **Figure 2-17**. Further information and discussion of studies and human health effects can be found in **Section 7.1**.

Unit	Mass per liter (L)	Mass per milliliter (mL)
1 part per million (ppm)	1 mg/L	1 µg/mL
1 part per billion (ppb)	1 µg/L	1 ng/mL
1 part per trillion (ppt)	1 ng/L	1 pg/mL

Notes: mg = milligrams, µg = micrograms, ng = nanograms, pg = picograms
1 ppm = 1,000 ppb = 1,000,000 ppt

These findings led to increased awareness of PFAAs in the environment, associated human exposure, and the potential for health effects. Occupational workers may be more highly exposed, and at risk, than other populations (**ATSDR 2018**). Laboratory studies using animals and epidemiological studies of human populations show that exposure to some PFAS may be associated with a wide range of adverse human health effects (**USEPA 2016**; **USEPA 2016**; **ASTDR 2021**). Toxicity studies have mostly focused on PFOS and PFOA, as well as some other long-chain PFAAs (**Section 7.1**). More recently, the toxicology of other PFAS, such as fluorotelomers and shorter chain PFAAs, as well as replacement PFAS chemicals (such as GenX chemicals, **Section 2.4.6**), have received increased attention (**CONCAWE 2016**; **USEPA 2016**; **USEPA 2021**).

ATSDR is undertaking a national, multi-site PFAS health study to evaluate the health impacts of PFAS in drinking water (**ATSDR 2020**). The study was authorized by the National Defense Authorization Acts of 2018 and 2019. According to ATSDR, "The information learned from the multi-site study will help all communities in the U.S. with PFAS exposures, including those that were not part of the study." The multi-site health study builds on the Pease Health Study at former Pease Air Force Base in Newington, NH, which effectively serves as a pilot program. The health study is intended to provide a better understanding of the cause and effect relationship between PFAS at various concentration and specific health outcomes based on adults and children. The study is expected to improve upon epidemiological studies with limited information about exposure factors.

In addition to the PFAS health study, ATSDR conducted PFAS Exposure Assessments at 10 locations in the United States. The 10 locations selected had PFOA and PFOS in the public drinking water that had previously exceeded the EPA 2016 health advisory level of 70 ng/L and/or other state guidelines. Through the Exposure Assessments, ATSDR was able to estimate exposures to PFAS in these communities and compare those exposure estimates to measured levels in blood collected from participants. Results of these Exposure Assessments are published in ATSDR's Final Report (**ATSDR 2022**).

The Centers for Disease Control (CDC) has been including biomonitoring for specific PFAS in blood serum in its National Health and Nutrition Examination Survey (NHANES) surveys of the U.S. general population since 1999-2000, and the latest NHANES PFAS data are from 2017-18 (**CDC 2022**). Blood serum levels of some PFAS in NHANES monitoring have decreased over time, as shown in **Figure 2-17**.

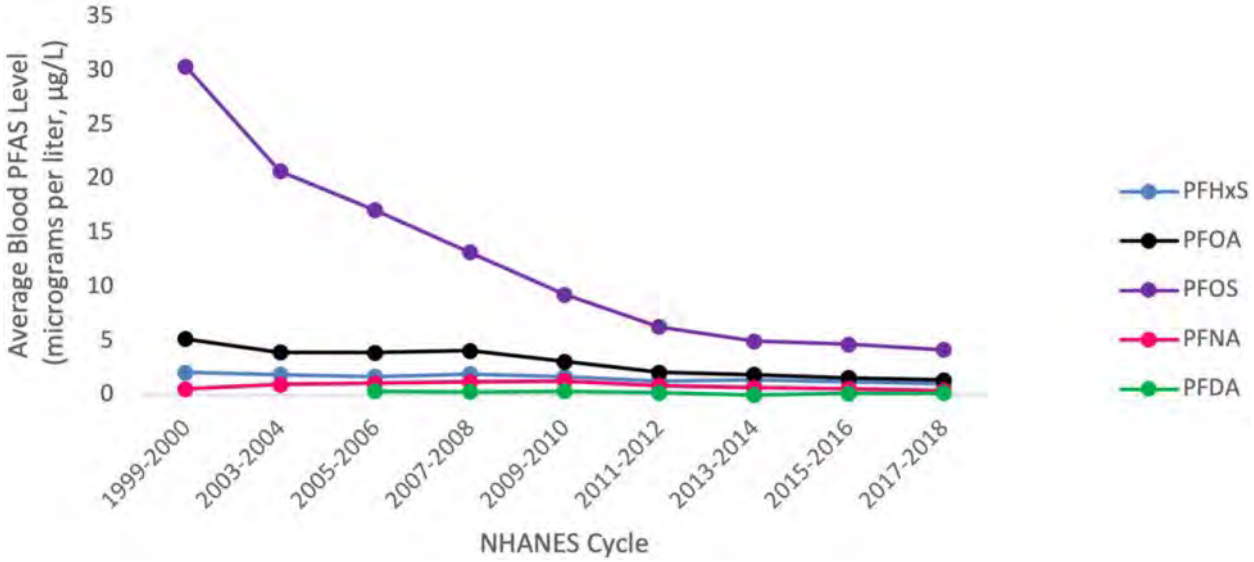

Figure 2-17. Blood Serum Levels of Specific PFAS Frequently Detected in the U.S. General Population (NHANES) Over Time (data from CDC 2022).

2.3.2 Analytical Developments

Early detection of PFAS in environmental media was hindered by the analytical capability challenges arising from the unique surface-active properties of PFAS (**Giesy and Kannan 2001**; **3M Company 2000**). Since the 2000s, methods have been, and continue to be, developed with lower detection limits (for example, parts per trillion [ppt]) in water, that are commensurate with levels of potential human health effects. The number of commercial laboratories that offer PFAS analysis is increasing. Analytical methods continue to be developed and improved to test a variety of media and additional PFAS; these continue to improve our knowledge of PFAS in the environment and potential human health effects.

Since the early 2000s, three analytical methods have been developed, validated, and published by USEPA for the analysis of PFAS in drinking water. These include Methods 537, 537.1, and 533 (**USEPA 2020**). These methods were developed for finished drinking water from groundwater and surface water sources. According to USEPA, these methods were developed for accuracy, precision, and robustness and have been through multi-lab validation and peer review (see **Section 11**). USEPA notes that Method 537 was used extensively during Unregulated Contaminant Monitoring Rule 3, described below. In December 2019, USEPA published Method 533: Determination of Per- and Polyfluoroalkyl Substances in Drinking Water by Isotope Dilution Anion Exchange Solid Phase Extraction and Liquid Chromatography/Tandem Mass Spectrometry (**USEPA 2019**). While each method includes analytes not included in the other, the analytes targeted by Method 533 include shorter-chain PFAS and fluorotelomers (see **Section 11.2.1.1**). Methods 537.1 and 533 have both been validated for the analysis of HFPO-DA (a component of the GenX processing aid technology). The PFAS analytes associated with Methods 537.1 and 533 are listed in Table 2-5 (**separate PDF**) and categorized according to the family tree hierarchy. The USEPA has also published USEPA Method 1633 that tests for up to 40 PFAS in eight environmental media (**USEPA 2024**). For further information on USEPA analytical methods, refer to **Section 11**.

The number of PFAS that can be identified and quantified by analysis has also evolved over time, with longer lists of compounds and changing commercial availability linked to evolving health and environmental concerns. Early focus was on PFOA and PFOS, but nationwide testing of drinking water supplies under the USEPA's Third Unregulated Contaminant Monitoring Rule (UCMR3) led to four additional PFAAs (PFHpA, PFNA, PFBS, PFHxS) gaining greater attention. More information about UCMR3 is provided in **Section 6.3**, and a summary of the occurrence data for the six PFAAs analyzed during UCMR3 is provided in **Section 8.2**. UCMR5 is occurring in 2023–2025 and includes 29 PFAS using USEPA Methods 533 and 537.1. UCMR5 includes all large systems serving over 10,000 people, all small systems serving 3,300 to 10,000 people, and 800 randomly selected small systems serving less than 3,300 people (**USEPA 2021**).

Many state regulatory agencies now request or require testing for an expanded list of long- and short-chain PFAAs, and some potential precursors to PFAAs, such as fluorotelomers. Other polyfluoroalkyl substances are also receiving increased attention, as illustrated in **Figure 2-18**. Many of these PFAS are also summarized in **Figure 2-6**.

Other analytical methods and approaches are available to detect and quantify PFAS not included in the standard methods mentioned above, including nontarget analysis, total organic fluorine, and total oxidizable precursor assay (see **Section 11**).

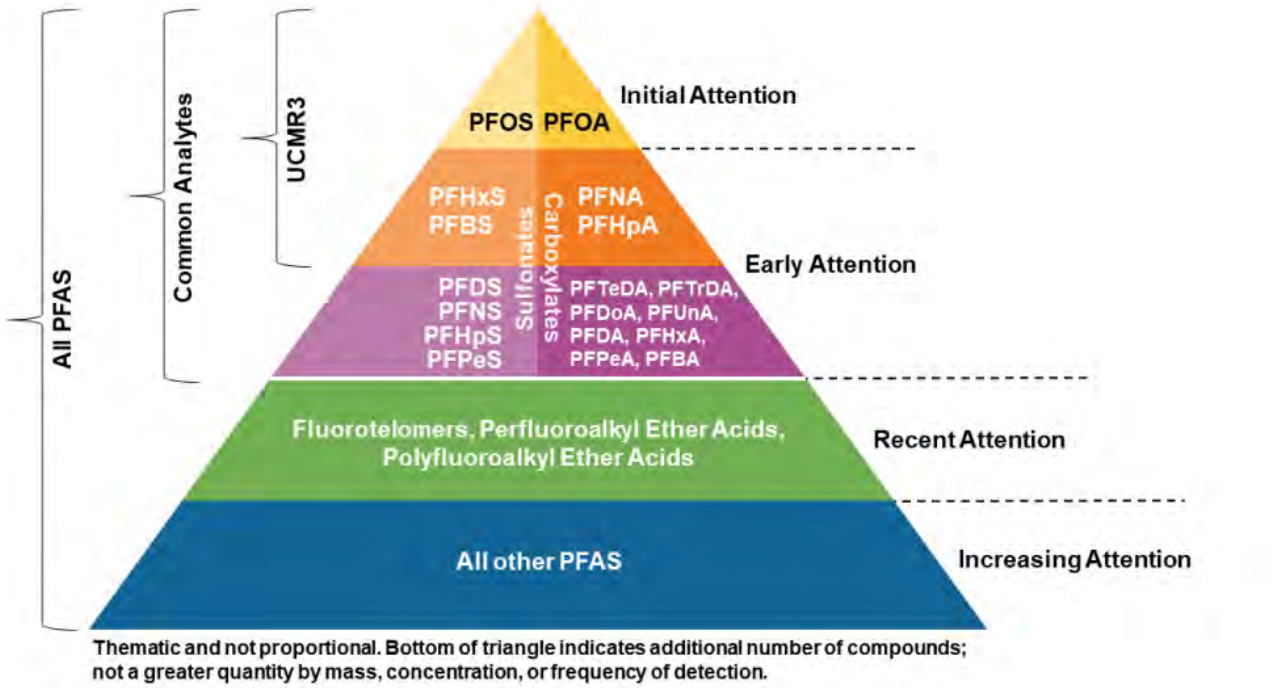

Figure 2-18. Emerging awareness and emphasis on PFAS occurrence in the environment.

2.3.3 Detection in the Environment

Although some PFAS have been manufactured since the 1950s, PFAS were not widely documented in environmental samples until the early 2000s, as PFAS testing was not widely available until that time. Since the early 2000s, however, the occurrence of PFAS in the environment has been a very active area of research. The occurrence of certain PFAS has been reported in a wide variety of matrices, including sediments, surface water and groundwater, and wildlife (**Kannan et al. 2004**; **Yamashita et al. 2005**; **Higgins et al. 2007**; **Rankin et al. 2016**). UCMR3 sampling detected PFAS in 4% of drinking water supplies across the country, including in 33 states, three territories, and one Native American community (**Hu et al. 2016**). However, the Hu et al. study used a non-final download of the UCMR3 dataset, so final statistics may be different. Initially, investigations focused mainly on major releases from manufacturing sources and significant PFAS uses such as firefighting foam application sites.

In recent years, with more sensitive analytical methods available, studies have detected PFAS (especially PFAAs) in locations throughout the globe, even in areas well beyond where they were initially used or manufactured (**Houde et al. 2011**). Detections of certain PFAS in the environment in various media are detailed in **Section 6**, and ecological effects are described in **Section 7.2**.

2.3.4 Growing Awareness and Concern

Societal awareness and concern about PFAS have increased since regulatory activity began in the early 2000s. Societal awareness and response are documented in the form of scientific progress and health advisories, regulatory actions, and legal actions. Major milestones for these activities within the United States are summarized in **Figure 2-19**. Other milestones, such as the growth of knowledge and investigation at major manufacturing and DOD sites in various U.S. states, are not discussed here.

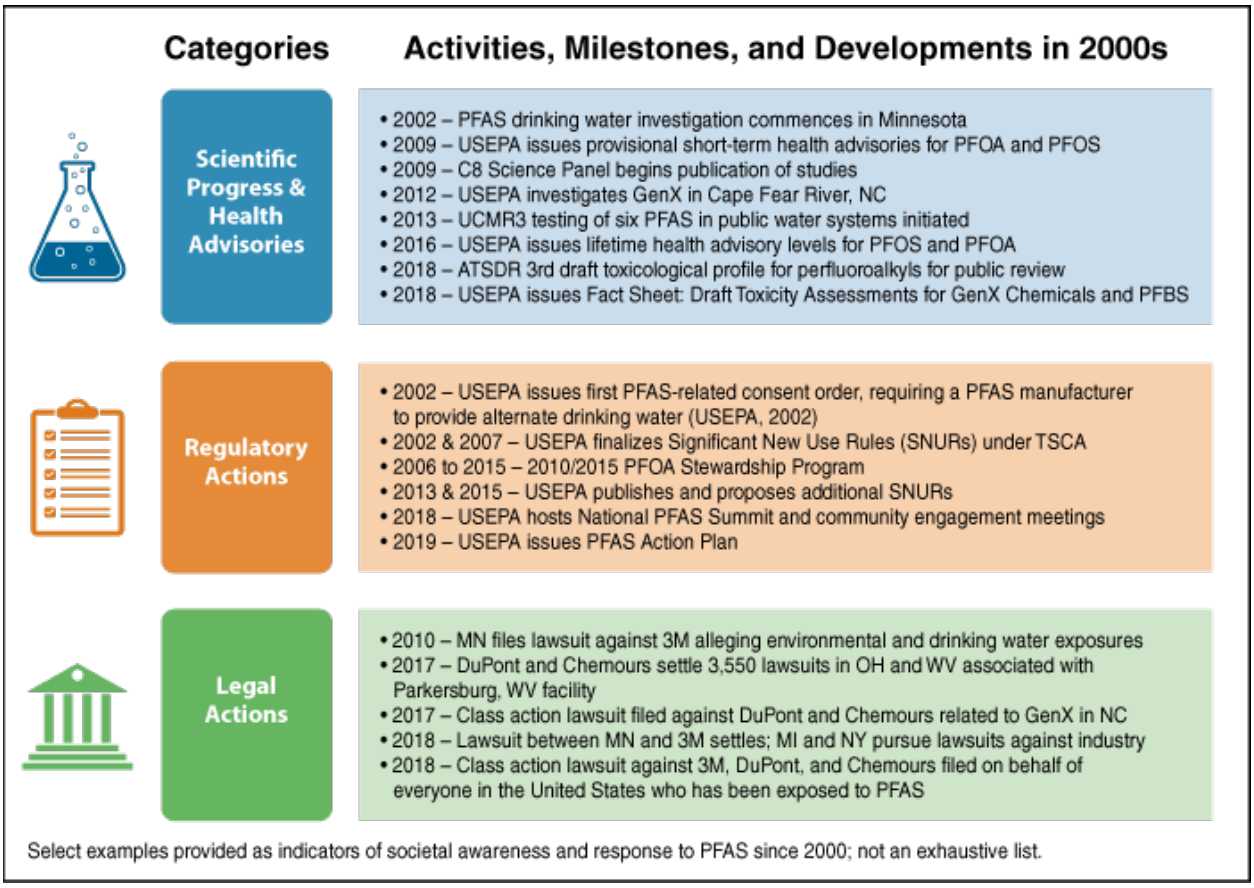

Figure 2-19. Growing awareness and concern 2000-2019.

2.4 PFAS Reductions and Alternative PFAS Formulations

Concern regarding the persistence, bioaccumulation, and possible ecological and human health effects of long-chain PFAAs has led manufacturers to use replacement PFAS chemistries, which include reformulating or substituting longer chain substances with generally shorter chain perfluoroalkyl or polyfluorinated substances that should not transform to long-chain PFAAs, or replacing manufacturing processes with nonfluorinated chemicals or alternate methods (**USEPA 2006**; **OECD 2017**). Manufacturing reductions and phaseouts are described in this section.

2.4.1 3M Voluntary Phaseout of Certain Long-Chain PFAS

In early 2000, 3M was the principal worldwide manufacturer of PFOA and POSF-derived PFAS (for example, PFOS) (**Buck et al. 2011**). This represented about 80–90% of global POSF-based production (**Prevedouros et al. 2006**), with 3M the sole U.S. manufacturer of PFOS (**USEPA 2003**). In 2000, 3M announced a voluntary, unilateral phaseout (this only applied to 3M) of POSF-derived PFAS, which at the time represented more than 95% of the company's perfluorooctanyl production (**3M Company 2000**). The 3M phaseout included the six-, eight-, and ten-carbon PFSAs (PFHxS, PFOS, and PFDS) and related precursors, as well as PFOA (**Buck et al., 2011**). 3M reportedly completed most of the phaseout by the end of 2002, with the remaining phaseout completed by 2008 (**USEPA 2017**; **3M Company 2017**).

At the time of the phaseout, 3M's POSF-derived PFAS were used in several applications:

- ~41% for paper and packaging protectors

- ~36% for textiles, leather, and carpet treatment and fabric protectors
- ~19% as industrial surfactants, additives, and coatings (including electroplating and etching surfactants, household additives, insecticides, and other applications)
- ~3% in firefighting foam (**3M Company 2000**).

The paper and packaging protectors included POSF-based side-chain fluorinated polymers and phosphate diesters (**Wang et al. 2013**).

PFOA produced by 3M was primarily used as a fluoropolymer processing aid, with only about 3% of PFOA production used for other applications: mostly in antistatic coatings in medical films, with limited quantities used for electronics applications (for example, to create a humidity barrier on printed circuit boards and to coat precision bearings with silicone oil) (**3M Company 2003**).

This phaseout applied only to 3M, and only to select PFAS. 3M subsequently used (and reportedly continues to use) ECF to produce PBSF-based PFAS (for example, the four carbon PFSA: PFBS) (**OECD 2013**; **Wang et al. 2015**). Any new manufacture and/or import of the PFAS phased out by 3M requires USEPA review based on the Significant New Use Rules (SNURs) described in **Section 2.4.2**. Based on the 2012 Chemical Data Reporting effort, no company reported manufacture or import of PFOS into the United States (reporting was required for quantities greater than 25,000 pounds) (**USEPA 2018**).

When 3M stopped producing PFOA in the early 2000s, it is reported that the manufacture of PFOA was continued by other domestic and international producers using fluorotelomerization (**USEPA 2003**; **Wang et al. 2014**). Domestic PFOA production was later phased out by the eight major domestic producers, as described in **Section 2.4.3**. Global production is summarized in **Section 2.4.4** and **Section 2.4.5**.

In December 2022, 3M issued a press release stating the company would discontinue the manufacturing of PFAS and the use of PFAS in its products by the end of 2025. This will include discontinuing the manufacturing of all fluoropolymers, fluorinated fluids, and PFAS-based additive products and the use of PFAS across their product portfolio.

2.4.2 USEPA Significant New Use Rules (SNURs)

In conjunction with these voluntary reductions and phase-outs, USEPA used its authority under the Toxic Substances Control Act (TSCA) to finalize SNURs between 2002 and 2020 to require notification to USEPA before any manufacture (including import) of select PFAS, which include, but are not limited to, some of the PFAS included in 3M's voluntary phaseout of PFOS and related chemicals (**Section 2.4.1**). The July 2020 SNUR restricts products containing certain PFAS that have been phased out from being imported into the United States (**USEPA 2021**). According to USEPA (**2021**), this SNUR levels the playing field for companies that had already voluntarily phased-out the use of long-chain PFAS under EPA's PFOA Stewardship Program. As of February 2023, 1,422 PFAS are on the TSCA Chemical Substance Inventory, a list of all existing chemical substances that are either currently or have historically been manufactured (including imported) or processed in the United States. Of these, 711 are considered "active" in commerce, meaning they were manufactured (including imported) or processed over the 10-year period ending June 21, 2016, or more recently. Updates to the TSCA inventory are published generally on a quarterly basis, including the number of chemicals on the "active" inventory (**USEPA 2023**). USEPA has reviewed more than 300 of the commercially active PFAS under the New Chemicals Program and regulated about 200 PFAS with consent orders and/or new chemical SNURs (**USEPA 2021**). A new proposed SNUR has been added regarding 300 PFAS that "have not been manufactured (including imported) or processed for many years and are consequently designated as inactive on the TSCA Chemical Substance Inventory" (**USEPA 2023**).

2.4.3 USEPA PFOA Stewardship Program

In January 2006, USEPA initiated the 2010/2015 PFOA Stewardship Program (**USEPA 2006**). Most PFOA produced in 2003 (around the time of the phaseout described in **Section 2.4.1**) was used as a processing aid in the manufacture of fluoropolymers, such as PTFE (**USEPA 2003**), and this was likely still the case at the time the stewardship program began.

The eight major manufacturing or processing companies that participated in the program are reportedly those that manufactured or processed the majority of these chemicals, including Arkema, Asahi, BASF Corporation (successor to Ciba), Clariant, Daikin, 3M/Dyneon, DuPont, and Solvay Solexis (**USEPA 2018**). There may be other manufacturing or processing companies that did not participate in the program (**USEPA 2015**). USEPA indicated that the eight participating companies successfully met the program goals, meeting a 95% reduction by 2010 in global facility emissions and product content, and eliminating production (100% reduction) of PFOA, certain longer chain PFCAs (higher homologues such as PFNA and PFDA), and related PFOA precursors (for example, 8:2 FTOH) by 2015 (**USEPA 2017**). Even though the program goals were met by the eight companies, the ongoing use of PFOA stock and imported materials has not been fully restricted (**USEPA 2018**). Products manufactured and imported prior to 2015, and materials with ongoing uses, may still contain these PFAS (**USEPA 2018**), and PFOA may be present as a trace contaminant in some other PFAS and fluoropolymer products (**3M Company 2003**). As discussed in **Section 2.4.5**, production is ongoing in other nations. Additional information on current US regulatory activities can be found in **Section 8.2**.

2.4.4 Stockholm Convention on Persistent Organic Pollutants

The Stockholm Convention on Persistent Organic Pollutants (POPs) is a United Nations treaty signed in 2001 aimed at reducing or eliminating the production, use, and release of key POPs. POPs are defined as synthetic, organic compounds that, to varying degrees, resist photolytic, biological, and chemical transformation (**KEMI 2004**, **2015**; **USEPA 2017**). Chemicals listed as POPs satisfy screening criteria for persistence, bioaccumulation, long-range environmental transport, and adverse effects (**Stockholm Convention 2001**). The Stockholm Convention targets PFAS in these ways:

- In 2009, *Annex B of the Stockholm Convention* (which restricts production and use) was amended to include PFOS (and its salts and POSF), because it is persistent in the environment and is not known to transform at any environmental condition. Currently, the United States has not ratified the amendment (**KEMI 2017**). Annex B is not an outright ban; it allows certain approved uses and exemptions of POPs. Prior to 2019, approved, ongoing uses for PFOS under Annex B included select applications in photoimaging, semiconductor coatings and etching agents, metal plating, insect baits, chemically driven oil production, aviation hydraulic fluids, some medical devices, and color printer electronic parts (**UNEP 2008**, **2009**).

- Additionally, the following amendments and recommendations have been made:

    - In May 2019, Annex B was amended to discontinue several of the previously allowed ongoing uses (**UNEP 2019**).

    - Annex A was amended in May 2019 to prohibit and/or eliminate the production and use of PFOA (its salts and PFOA-related compounds), with certain exemptions (**UNEP 2019**).

    - the POPs Review Committee recommended in October 2019 to list PFHxS (and its salts and related compounds) in Annex A without specific exemptions (**UNEP 2019**)

2.4.5 Global Manufacture and Use of PFAS

PFAS are still manufactured globally, despite some PFAS (most notably PFOA and PFOS) no longer being produced in the United States, Europe, and Japan; for further information, see OECD's Country Information page on the OECD Portal on Per and Poly Fluorinated Chemicals (**OECD 2017**), "Risk Reduction Approaches for PFASs" (**OECD 2015**), and "Toward a New Comprehensive Global Database of Per- and Polyfluoroalkyl Substances" (**OECD 2018**). In addition to the domestic reductions discussed in **Section 2.4.1** and **Section 2.4.3**, some of the phase-outs and restrictions are summarized below.

In 2017, the South Australia state government took initial steps to develop legislation banning environmentally harmful foams, such as Class B firefighting foams containing PFAS (**SA EPA 2017**).

Canada embarked on an Environmental Performance Agreement with four major manufacturers to phase out PFOA and related compounds from 2010 to 2015 (**CEPA 2006**). In 2008, Canada prohibited the use of most PFOS, with select exemptions such as use of existing stocks of PFOS-based firefighting foams, and then added PFOS to the Virtual Elimination List in 2009 and to the Prohibition of Certain Toxic Substances Regulations in 2016 (**CEPA 2018**). By 2016, Canada prohibited the import, manufacture, use and sale of PFOS, PFOA, and other long-chain PFCAs (and salts and precursors), with limited exemptions (**CEPA 2018**), and subsequently in 2018, Canada proposed further modification to those restrictions (**Government of Canada 2018**).

In 2009, the European Union (EU), through the European Chemicals Agency (ECHA), regulated PFOS as a POP, and use of PFOS is limited to certain restrictions (**Vierke et al. 2012**). In 2017, the EU banned the sale, use, and import of PFOA, its salts and PFOA-related substances through Annex XVII of the European Chemicals Regulation (REACH), with phase-outs occurring through 2032 and certain allowed uses. ECHA is currently considering restrictions for other long-chain PFCAs, their salts and precursors, as well as other compounds, such as PFHxA (**ECHA 2018**). On February 7, 2023, ECHA proposed restrictions on PFAS as a class; this proposal was prepared by Denmark, Germany, the Netherlands, Norway, and Sweden (**ECHA 2023**).

In Japan, there are restrictions on the manufacture, import, export, and use of PFOS and its salts (**OECD 2015**).

The global reduction anticipated with the U.S. phaseout of PFOA has potentially been offset by increased production of PFOA and related PFAS in China, India, and Russia (**OECD 2015**). PFAS manufacture began in China in the 1980s (**World Bank 2017**, **2017**), and PFOS production in China increased coincident with the long-chain PFAA phaseout in the United States (**CONCAWE 2016**; **OECD 2015**). In 2016, PFOS and its derivatives were still being produced in Germany, Italy, and China (**TTE 2016**), but by early 2017, China was the only known producer of PFOS. China has ratified the Stockholm Convention on POPs and was awarded a grant from the Global Environment Facility (GEF) in 2017 to support the reduction of PFOS in China (**World Bank 2017**). China has developed some guidance for restriction and limitations of some PFAS (**OECD 2015**). In Brazil, EtFOSA, which is a precursor to FOSA and PFOS and used in the pesticide sulfluramid, which is still being produced on an industrial scale, is allowed as an approved use by the Stockholm Convention (**Löfstedt Gilljam et al. 2016**). **Section 1.1.2.2** includes information about PFAS use in pesticides.

There does not appear to be a comprehensive reference publicly available to document the individual PFAS and the quantity of PFAS produced over the years. This is possibly because these data are proprietary or because quantities produced did not meet USEPA reporting requirements under TSCA, but could also be due to modifications to chemistries and products over the years (**Lindstrom, Strynar, and Libelo 2011**), complexity of the issue, and the general lack of publicly available data (**OECD 2018**). That said, some estimates of production and emissions of select PFAS have been made based on the limited available data.

Prevedouros et al. (2006) estimated global emission of PFCAs at about 3,500–8,000 tons between the 1950s and 2002, with approximately 80% of emissions related to fluoropolymer manufacture (and use), based on overall annual production estimates of:

- APFO (ammonium salt of PFOA)-about 335–525 tons per year between 1951 and 2002
- APFN (ammonium salt of PFNA)-about 60–225 tons per year between 1975 and 2004
- POSF (building block for PFOS)-about 9,550 tons per year from 1960 to 2002.

Other production and emissions estimates for PFCAs are available from **OECD (2015)** and **Wang et al. (2014)**, and for PFOS and PFOS precursors from **Armitage et al. (2009)** and **Paul, Jones, and Sweetman (2009)**. **OECD (2015)** called for a new, comprehensive survey to evaluate both historical and ongoing emissions.

2.4.6 PFAS-Based Replacement Chemistry

With the emerging awareness of potential health and environmental impacts of some PFAS and related limitations on production of some PFAS, such as the SNURs (**Section 2.4.2**) and 2010/2015 PFOA Stewardship Program (**Section 2.4.3**), manufacturers began efforts to replace the use of long-chain PFAS chemistries with nonfluorinated chemicals, alternate technologies, and/or other, shorter chain PFAS (**Wang et al. 2013**). For example, decorative chrome plating typically now uses less toxic chromium III instead of chromium VI so that PFAS are not needed (**Wang et al. 2013**).

Some of the replacement chemicals are said to achieve the same performance effectiveness of some of their predecessors. A carpet manufacturer has found that performance of fluorine-free alternatives is "equivalent or superior to the fluorinated treatments" pg. 66, (**CalEPA 2018**). Conversely, a 2015 study concluded that there are no nonfluorinated alternatives that provide equivalent technical performance in textiles (**Danish EPA 2015**). Refer to **Section 3** for a discussion of PFAS-free AFFF that meets U.S. Department of Defense performance specifications.

Several studies suggest some of the alternate PFAS chemistries may or may not be less hazardous than the long-chain predecessors, although publicly available information on most replacement chemicals is limited (**Wang et al. 2015 RIVM 2016**; **OECD 2015**). Documentation regarding the USEPA's review of hundreds of "shorter chain-length PFAS telomeric" substitutes is available under the TSCA New Chemicals Program (**OECD 2013**; **USEPA 2017**), and other documentation regarding replacement PFAS chemistries is available from the **Performance Fluoropolymer Partnership (2021)** and **American Chemistry Council (2021)**. Draft toxicological evaluations have been provided for public comment by the USEPA for GenX chemicals and PFBS (**USEPA 2018**, **2018**) with the PFBS Toxicity Assessment finalized in 2021 (**USEPA 2021**), and the GenX Toxicity Assessment finalized in 2021 as well (**USEPA 2021**) . For further discussion of toxicity documentation for select PFAAs and replacement chemistries, see **Section 7**.

Although a full discussion of such PFAS chemistries is not possible here, it is important to be aware of the trend toward shorter chain chemistries, as some of these PFAS increasingly may be detected in the environment. Some replacement PFAS have been detected in the environment and generated public concern and regulatory actions; however, information on significant environmental contamination by replacement PFAS is limited, and most are not detected by standard analytical methods (**Wang et al. 2013**). Some PFAS used as replacement chemicals, such as HFPO-DA and ADONA (used as replacements for APFO/PFOA in PTFE manufacture), and F-53B (11-Chloroeicosafluoro-3-1455 oxaundecane-1-sulfonic acid [11Cl-PF3OUdS or F-53B Minor], 9-Chlorohexadecafluoro-3-1456 oxanonane-1-sulfonic acid [9Cl-PF3ONS or F-53B Major]) (used as a replacement for PFOS in plating), have recently

been added to USEPA Method 537.1 (**USEPA 2018**). Certain treatment processes used to remove these chemicals from waste streams may not be as effective as with longer chain PFAS (**Sun et al. 2016**).

Alternate PFAS chemistries are being used to replace long-chain PFAAs that have been phased out of production and/or use. In many cases, although similar legacy PFAAs were manufactured and used by many companies, these same companies have transitioned to the use of many different types of other PFAS as alternative chemicals. Many of these replacement PFAS are structurally similar to their long-chain predecessors, and are typically also manufactured using electrochemical fluorination (ECF) or fluorotelomerization (**Wang et al. 2015**; **CONCAWE 2016**). Some of these fluorinated substitutes may transform to form short-chain PFAAs. Some short-chain PFAAs, PFECAs (both per and poly), and related chemicals were manufactured as early as the 1980s, or earlier (**Wang et al. 2015**). Some PFAS used to replace long-chain PFAS are presented below (**Hori et al. 2006**; **OECD 2007**; **Herzke, Olsson, and Posner 2012**; **Buck 2015**; **Wang et al. 2013**; **Wang et al. 2014**; **Wang et al. 2015**; **KEMI 2015**; **Sun et al. 2016**; **Holmquist et al. 2016**):

- short chain homologues of the long-chain PFAAs, including PBSF-based derivatives (for example, 4-carbon chain PFBS in lieu of POSF-based six-, eight-, and ten-carbon chain compounds) in many applications, including surface treatment
- perfluorohexane sulfonyl fluoride (PHxSF, which can transform to PFHxS and is considered to be phased out in the United States) as an alternative to PFOS, primarily in China
- fluorotelomer-based products such as FTOH, for example, those with a six-carbon perfluorohexyl chain, including 6:2 fluorotelomer-based compounds in AFFF formulations and other six-carbon fluorotelomer-based products, side-chain fluorinated polymers, and PFPE products for surface treatment of food contact materials
- per- and poly-fluoroalkyl ether acids used as polymerization aids in manufacture of fluoropolymers, such as GenX chemicals (perfluoroalkyl ether acids) and ADONA (polyfluoroalkyl ether acids) used as a replacement for APFO in the manufacture of PTFE, as well as other types of perfluoroalkyl ether acids, also referred to as cyclic or polymeric functionalized PFPEs as a replacement for APFN in the manufacture of polyvinylidene fluoride (PVDF)
- 6:2 fluorotelomer-based compounds, a PFBS-based compound, and PFAS known as F-53 and F-53B in lieu of PFOS in metal plating applications.

2.5 PFAS Uses and Products

This section provides information on PFAS uses (**Section 2.5.1**), potential PFAS use or occurrence in some specific products (**Section 2.5.2**), and PFAS certifications (**Section 2.5.3**). Each section includes a table summarizing available information. The tables are not exhaustive.

The Priority Topics for History, Use, and Naming Conventions include information about less-publicized PFAS Sources (see **Section 1.1.2**) including hydraulic fluids and pesticides. Other less-publicized sources are presented in **Table 1-1**, which supplements **Table 2-7**. The Priority Topics for Human and Ecological Health Effects include information about potential PFAS exposures from consumer products (see **Section 1.4.2**). The Priority Topics for Sampling and Analysis include information about testing consumer products for PFAS (see **Section 1.5.4**).

2.5.1 PFAS Uses

PFAS have been produced on a commercial scale since the 1950s, and production continues today. The unique physical and chemical properties of PFAS impart oil, water, stain, and soil repellency, chemical and temperature resistance, friction reduction, and surfactant properties to a wide range of products, some of which are considered essential to health, safety, or modern life (**Glüge et al. 2020**). **Glüge et al. (2020)** categorized PFAS by uses according to industry application and practical use and identified more than 200 uses for more than 1,400 individual PFAS.

Table 2-6 provides a general (not exhaustive) introduction to some of the uses of PFAS chemistries that are, or have been, marketed or used (**3M Company 1999**; **Poulsen et al. 2005**; **OECD 2006**; **Washington State Department of Ecology 2021**; **OECD 2011**; **OECD 2013**; **Fujii, Harada, and Koizumi 2013**; **OECD 2015**; **Performance Fluoropolymer Partnership 2021**; **Henry et al. 2018**). The specific applications for all PFAS are not well documented in the public realm. For example, of the 2,000 PFAS identified in a 2015 study, only about half had an associated listed use (**KEMI 2015**). Further discussion of select uses that may be associated with potentially significant environmental releases are provided in **Section 2.6**.

As discussed in **Section 2.2.2.1**, most polymer PFAS are considered to pose relatively less risk to human health and the environment than some nonpolymer PFAS. For this reason, **Table 2-6** distinguishes between these two major classes of PFAS and where they are used in various industries and products. **Glüge et al. (2020)** provided a detailed listing of PFAS by use category/subcategory, function, and properties; however, it is not organized according to polymer versus nonpolymer PFAS used in these instances.

The major industries and applications summarized in the table are described in more detail in **Section 2.6.1**.

Table 2-6. Sample historical and current uses of PFAS.

Industry / Application	PFAS Type	Documented Use and Examples of Some PFAS
Aviation and Aerospace	Polymer	Mechanical components made of fluoropolymers (such as PTFE and Perfluoroalkoxy tubing, piping, seals, gaskets, cables, and insulators)
	Nonpolymers	Hydraulic fluid additives made from PFSA salts (such as PFOS at about 0.1%) to prevent evaporation, fires, and corrosion
Automotive	Polymer	Mechanical components made of fluoropolymers, including wiring and cable, fuel delivery tubing, seals, bearings, gaskets and lubricants, and some polymer coatings on carpets
	Nonpolymers	Surface treatment for textiles, upholsteries, carpets, leather and exterior surfaces
Biocides (Herbicides and Pesticides)	Polymer	None reported
	Nonpolymers	Active ingredients such as short-chain sulfonamides in plant growth regulators and herbicides, and EtFOSA (sulfluramid) in ant and termite baits; inert enhancing ingredients in pesticides; PFPAs and PFPiAs as anti-foaming agents in solutions
Biotechnology	Polymer	Polymers used for reaction vessels, stirrers, and other components, filtration, and moisture barrier
	Nonpolymers	Cell cultivation by delivery of oxygen and other gases and ultrafiltration and microporous membranes to prevent bacterial growth.
Building and Construction	Polymer	Fluoropolymer membranes and coatings (such as PTFE, PVDF, and/or side-chain fluorinated polymers) in architectural materials (like fabrics, roofing membranes, metals, stone, tiles, concrete, radomes); adhesives, seals, caulks; additives in paints (for example, low- and no-VOC latex paints), varnishes, dyes, stains, sealants; surface treatment agent and laminates for conserving landmarks
	Nonpolymers	Additives in paints, coatings, and surface treatments (PASF- and fluorotelomer-based compounds, ammonium salt of PFHxA)

Industry / Application	PFAS Type	Documented Use and Examples of Some PFAS
Cable and Wiring	Polymer	Coatings and jacketings made of fluoropolymers (such as PTFE and PVDF) for weathering, flame, and soil resistance, with cables used in many applications, including communication facilities, antennae, and computer networks
	Nonpolymers	None reported
Chemical Industry	Polymer	Fluoropolymers used to coat chemical tanks and pipes to enhance corrosion and high temperature resistance, as sealing and gasket materials for chemical processing, and for filtration media used in chemical manufacturing processes and emissions controls
	Nonpolymers	Fluoropolymer processing aids, stabilization and binder for certain chemicals, elimination of imperfections, and provide inert reaction media
Cosmetics/Personal Care Products	Polymer	Dental floss, toothpaste, dental creams, tooth powders, throat lozenges, chewing gums, sunscreens, cosmetics, and micro powders used in creams and lotions.
	Nonpolymers	Cosmetics, shampoos, nail polish, eye makeup, denture cleaners, eye drops, contact lenses, and others
Electronics	Polymer	Fluoropolymers (such as PVDF and PTFE) used in insulators, solder sleeves, printed circuit boards, cell phones, computers, speakers, and transducers
	Nonpolymers	Flame retardants for polycarbonate resin (such as the potassium salt of PFBS)
Energy	Polymer	Fluoropolymer films (such as FEP, PVDF) to cover solar panel collectors, electrolyte fuel cells, PTFE expansion joint materials for power plants, filtration of fly ash from stack emissions
	Nonpolymers	Fuel cell and battery electrolyte (such as the lithium salt of PFAAs)
Explosives, Propellants, Guns, and Ammunition	Polymer	Fluoropolymers (PTFE) applied to guns for lubrication and antidegradation during long term storage, tungsten-iron-fluoropolymer shot alloys (replacement for lead in hunting waterfowl and coots), fluoropolymer use in visual flares, warheads, incendiaries, and others
	Nonpolymers	PFCAs used in energetics, infrared flares, ignitor pyrolant, coating of reactive metallic powders, combustion behavior modification and other processes
Firefighting/Safety	Polymer	Fluoropolymers used in firefighting equipment and protective clothing (such as those woven with PTFE). Other polymer coatings using side-chain fluorinated polymers
	Nonpolymers	Coatings and materials used as water repellents and some Class B foam (may contain PFCAs, PFSAs, and fluorotelomer-based derivatives), vapor suppression for flammable liquids (for example, gasoline storage)
Food Processing	Polymer	Fluoropolymer fabrication materials (such as PTFE) (liners for trays, ovens, grills)
	Nonpolymers	May be used as coatings on food packaging
Household and Cleaning Products	Polymer	Nonstick coatings (fluoropolymers such as PTFE); aftermarket treatment for textiles, upholsteries, carpets, and leather (such as Fluorotelomer-based side-chain fluorinated polymers); sewing machine presser feet; glass
	Nonpolymers	Aftermarket treatment for textiles, upholsteries, carpets, and leather (such as PASFs; floor polishes (such as the ammonium salt of PFDA), coatings, and floor finishes (PFPAs and PFPiAs) and cleaning agents and alkaline cleaners; automobile waxes; may include PFAAs, PASF- and fluorotelomer-based derivatives, anti-reflective coatings, dry cleaning agent (PureDry®) replacement for perchloroethylene
Medical Products	Polymer	Fluoropolymers (such as PTFE) used in surgical patches, cardiovascular grafts, raw materials for human body implants (such as catheters, stents, sutures, device surface coatings, needles, and other) given biocompatibility and extremely low coefficient of friction, dialysis membranes, anesthesia, machine components (o-rings, filters, tubing, and other)
	Nonpolymers	X-ray film, stain- and water-repellent protective medical fabrics (like surgical drapes and gowns) created from PASF- or fluorotelomer-based (meth)acrylate polymers and polyurethanes, burn wound care cleaning product, oxygen and oxygen carriers used to improve therapeutic outcomes
Metal Plating	Polymer	None reported
	Nonpolymers	Wetting agent, mist suppression for harmful vapors, and surfactants (may include potassium, lithium, diethanolamine and ammonium salts of PFOS or 6:2 FTS)
Oil Production	Polymer	Lining of gas pipes
	Nonpolymers	Marketed for and potential instances of use in oil well production
Mining	Polymer	None reported
	Nonpolymers	Instances of surfactants used in ore mining flotation and leaching, improve separation of materials, and concentration of ore by destruction of mineral structure

Industry / Application	PFAS Type	Documented Use and Examples of Some PFAS
Nuclear Industry	Polymer	Lubricants used for valves and centrifugal bearings in enrichment processes
	Nonpolymers	None reported
Oil and Gas Industry	Polymer	Lining of gas pipes and insulation of cable and wire during drilling, and membranes for filtration
	Nonpolymers	Marketed for and potential instances of use in oil well production to change the permeability of the target formation, reduce viscosity for transport, prevent evaporative loss during storage, tracers
Paper and Packaging	Polymer	Oil and grease and water repellent to paper, paperboard, molded pulp products (including food contact materials), and LDPE bags; examples include side-chain fluorinated polymers in which the PASF- or fluorotelomer-based alcohols or their acrylate or methacrylate esters are attached on side chains; PFPEs
	Nonpolymers	Phosphate ester salts (esterification of PASF or Fluorotelomer-based alcohols with phosphoric acid
Pharmaceutical Industry	Polymer	Polymers used for reaction vessels, stirrers, and other components, filtration, and moisture barrier
	Nonpolymers	Processing aids in the manufacture of microporous particles, additives and ingredients in certain types of medicine for drug delivery
Photographic Industry	Polymer	None reported
	Nonpolymers	Photographic processing aids to reduce air bubbles and prevent foaming, wetting agents, stabilizers, and antistatic agents, prevent spots, and create uniform edge in multilayer coatings, anti-reflective agents
PFAS Production	Polymer	None reported
	Nonpolymers	Emulsion polymerization processing aids for fluoropolymers (such as PTFE, FEP, PFA, PVDF), (co)monomer of side-chain fluorinated polymers; (co)monomer of fluoropolymers and to make fluoroelastomers; may use salts of long-chain PFCAs (such as PFOA and PFNA), salts of short-chain PFCAs (such as PFHxA), or PFECAs
Photolithography & Semiconductor	Polymer	Equipment raw materials (such as PFA) for molded wafer baskets to handle corrosive liquids and gases, use as fluids in mechanical vacuum pumps
	Nonpolymers	Photolithography (such as using PFOS) in manufacture of semiconductor chips
Plastics and Rubber	Polymer	Fluoropolymers (such as PTFE) are used as processing aids, as a raw material in plastics and rubber production, and as an intermediate material. Used in molded material production to enable easy release and reduce imperfections, polymer processing aids
	Nonpolymers	Surface tension reduction for foams, etching of plastic, and production of rubber
Recreational and Musical Equipment	Polymer	Fluoro waxes used to reduce wear and abrasion on: stringed sports equipment (for example, tennis racquets) and stringed instruments; fishing rods and reels; lubricants; piano keys; ski wax
	Nonpolymers	None reported
Recycling and Material Recovery	Polymer	None reported
	Nonpolymers	Fluorosurfactants are used to recover metals, including rare earth metals, and n-hexane from waste gases
Refrigerants	Polymer	None reported
	Nonpolymers	Perfluorocarbons (PFCs), a subset of PFAS, used in refrigerant fluid and compressor systems for both heat transfer and lubrication
Textiles (Upholstery, Carpets), Leather, and Apparel	Polymer	Fluoropolymers (such as PTFE) are used in the construction of outdoor gear, clothing, and housewares; side-chain fluorinated polymers (such as PASF- or fluorotelomer-based (meth)acrylate polymers and -polyurethanes) may be used in oil- and water-repellent and stain release finishing and treatment coatings
	Nonpolymers	PFOA-based chromium treatment for paper and leather. Nonpolymer coatings used to treat textiles to provide oil- and water- repellent and stain release finishes
Wood Industry	Polymer	Polymeric PFAS fabric used during bleaching process, clear coating of wood substrate
	Nonpolymers	Adhesive resin on wood particle board

Information presented in this table captures potential instances of use but is not intended to indicate universal use. In addition, the table is not exhaustive of PFAS use in various industries.

2.5.2 Potential PFAS Use or Occurrence

Growing awareness of PFAS has led to both research and speculation about the use and occurrence of PFAS associated with an increasing number of consumer and commercial products, and whether such occurrences may constitute a risk to human health and the environment. **Table 2-7** provides a high-level technical assessment of such recent claims, some of which have been popularized in the news media. **Section 1.1.2** includes information about less-publicized PFAS sources, such as hydraulic fluids and pesticides. Other less-publicized sources are presented in **Table 1-1**, which supplements **Table 2-7**.

Table 2-7. Summary of Claims of PFAS Use and Occurrence.

Potential Use or Occurrence	Technical Basis	Documentation	Conflicting Perceptions on Presence of PFAS and Significance of PFAS
Cosmetics and Personal Care Products	Higher dermal absorption of PFOA from sunscreen than was previously reported for dermal absorption of PFOA: 1.6% of the applied dose was absorbed over time in a human volunteer.	Journal Articles, **Abraham and Monien 2022**; **Whitehead et al. 2021**, **2021**	One study demonstrates significant uptake of a PFAA via transdermal absorption in humans may occur via PFOA mixed into sunscreen, indicating past occurrence of PFAS in some cosmetics may have contributed to this route of exposure. Other article discusses the use of PFAS in North American cosmetics to increase their durability and water resistance.
Face Masks	Chemical analysis of PFAS in face masks and calculations of leaching to landfill leachate.	Journal Article, **Muensterman et al. 2022**	Nine varieties of masks were tested. Homologous linear PFCAs and 6:2 FTOH indicated a fluorotelomer origin. Wearing masks treated with high levels of PFAS for extended periods can be a notable source of exposure with potential human health risk. Modeled annual disposal of ~29–91 billion masks assuming 100% leaching of individual PFAS into landfill leachate indicates mask disposal would contribute an additional 6% of annual PFAS mass loads and less than 11 kg of PFAS discharged to U.S. wastewater.
Fluorinated HDPE Containers	Testing of a limited number of fluorinated and non-fluorinated HDPE containers for presence of PFAS by EPA's Analytical Chemistry Laboratory at Fort Meade (initial and follow-up testing). Leaching of PFAS from container walls to liquid contents (methanol and water) was demonstrated for fluorinated containers. Degree of leaching relates to the brand of fluorinated containers and duration of liquid storage in container. Higher amounts of PFAS were detected in methanol solvent versus water.	USEPA Memos **USEPA 2021**; **USEPA 2022**	Through the fluorination process of HDPE containers, PFAS may be formed and then partly leach into the products inside the containers. These containers are believed to explain the occurrence of PFAS in mosquito control insecticide tested by an environmental group and published by news outlets.
Food Packaging	Consumer Reports (CR) tested total organic fluorine content in multiple samples collected from 118 paper food packaging products from 24 restaurants and grocery chains. A subset of 50 products was tested by a method only identified as being "regularly used by industry, regulators, and researchers."	Consumer Reports, **Loria 2022**	The organic fluorine levels were averaged for each product. Thirty-seven products had an average organic fluorine concentration above 20 ppm, and 22 products had an average above 100 ppm. PFBA was found at the highest concentrations in the subset of 50 products analyzed by an alternate method.
Pesticides	Fluorinated pesticides may meet certain definitions of PFAS and therefore would be considered PFAS-containing.	Scientific American, **Wilcox 2022**	Article notes at least three active pesticide ingredients currently allowed by the USEPA—broflanilide, pyrifluquinazon and noviflumuron—meet its definition for a PFAS.
Pesticides	A university laboratory tested pesticide products. PFAS were detected in some of the products.	**Lasee et al. 2022**; **USEPA 2023**	USEPA's Analytical Chemistry Branch repeated the analyses for PFAS and conducted additional analyses. In USEPA's results no PFAS were detected above the method detection limits.

Potential Use or Occurrence	Technical Basis	Documentation	Conflicting Perceptions on Presence of PFAS and Significance of PFAS
Synthetic Turf	Media reports describe testing by non-profit organizations that detected PFOS on backing of older discarded turf material and 4 PFAS (PFOS, PFOA, PFHxS and 6:2-FTS) in nearby wetland water, 6:2 FTS on backing of newer turf material, and fluorine in 8 samples of grass blades acquired directly from distributors.	Fact Sheet, **TURI 2020** CT DPH Review, **CT DPH 2022** Lab analyses of PFAS in turf and wetland waters, **Eurofins 2019** PEER Letter of Complaint to MassDEP, **PEER 2019** **Massey and Pollard 2023** City of Portsmouth, NH Evaluation of PFAS in Synthetic Turf, **City of Portsmouth 2022** Project report, **Tetra Tech 2021** Journal article, **Lauria et al. 2022**	Staff at Connecticut Department of Public Health (CT DPH) have retrieved and reviewed the original lab reports that were the basis of the media reports for PFAS detected in newer and older fields (and nearby wetland water) and determined that the available data do not provide scientific evidence that the detected PFAS originate from the artificial turf itself; their presence in turf may be attributable to other sources of PFAS, including sample contamination. The PFAS concentrations detected in turf and in nearby waterways are within the range of "background" levels of PFAS detected in soils in remote areas and in surface waters collected near urban areas. The Portsmouth, NH study evaluated analyses of synthetic turf samples utilizing standard PFAS analyses and TOP Assay; low-levels of select PFAS detected were determined to not represent a human health risk to users of the turf. Staff at CT DPH were unable to identify lab reports of the detection of fluorine in grass blades. Negligible PFAS leachate concentrations were also noted well below applicable criteria associated with synthetic turf at the Martha's Vineyard Regional High School Athletic Fields. A study of artificial turf in Sweden determined that PFAS were detected intermittently and at low concentrations in backing (<LOD–0.63 ng of F/g; 71% DF) and filling (<LOD–0.15 ng of F/g; 18% DF) and were completely absent in blades. Studies reviewed did not show risk but not all manufacturers and products evaluated thus far.

2.5.3 PFAS Certification and Acceptability of Products

Numerous labels and certifications related to reduction or elimination of PFAS in products exist in the marketplace but there is great variation in the terms used to indicate PFAS content in products. Commonly used PFAS-related terms for products include: PFAS-free, PFOS-free, PFOA-free and Fluorine-free. However, many certifications allow a minimum limit to be present. The USEPA Sustainable Marketplace website (**USEPA 2023**) provides a useful compilation of PFAS-specific product certifications that lists the basis of the required and optional criteria. Many of the certifying organizations offer labels and criteria that may cover a wide range of chemicals and other sustainability considerations. The user should check the primary certifying organization's documentation to verify their requirements for obtaining PFAS-specific certifications.

Table 2-8 provides examples of some of the most commonly-used product labels and certifications for intentionally-added PFAS. Several definitions exist for the term "intentionally added" in legislation and regulation. Examples of "intentionally added" definitions include:

- Maryland: H275/S273 "(C) Intentionally added means the act of deliberately using a chemical in the formation of a product where the chemicals continued presence is desired in the product to provide a specific characteristic."

- Colorado: H1345(12) (a) "Intentionally added PFAS chemicals" means PFAS chemicals that a manufacturer has intentionally added to a product and that have a functional or technical effect on the product. (b) "intentionally added PFAS chemicals" includes PFAS chemicals that are intentional breakdown products of an added chemical.

- Hawaii: HB1644/S3000 "Intentionally introduced" means deliberately utilizing PFAS in the formulation of a package or packaging component where the continued presence of the PFAS is

desired in the final package or packaging component to provide a specific characteristic, appearance, or quality."

- California: A2771 "(c) Intentionally added PFAS means either (1) PFAS chemicals that a manufacturer has intentionally added to a product and that have a functional or technical effect on the product; or (2) PFAS chemicals that are intentional breakdown products of an added chemical."

Many countries and states also have enacted individual bans for PFAS, or intentionally added PFAS, in products and some trade groups have developed product-specific certifications (for example, furniture, floor care products). Due to the dynamic and evolving nature of these labeling programs and requirements, users should consult the primary reference to get the most current information.

Certifications for unintentionally added PFAS have also been issued. The European Union's ECHA program requires that PFOA cannot exceed 25 ppb and PFOS cannot exceed 10 ppm as impurities (See Annex 1, Part A, **European Union 2019**).

Table 2-8. Examples of Certifications – Intentionally Added PFAS.

Institution	Products	Criteria	Reference
USEPA Sustainable Marketplace	Comprehensive web site of multiple product categories	Links to multiple Standards and Ecolabel	https://www.epa.gov/greenerproducts/how-epas-recommended-standards-and-ecolabels-address-and-polyfluoroalkyl-substances
USEPA – Safer Choice	Industrial and consumer products	PFAS not specifically prohibited but EPA has determined that PFAS no longer meet the Safer Choice standard; **Exceptions** allowed; will be specifically called out as not meeting the standard in March of 2023 **Other** labels also listed	https://www.epa.gov/greenerproducts/how-epas-recommended-standards-and-ecolabels-address-and-polyfluoroalkyl-substances
FDA	Food-contact equipment & packaging	Authorized **limited** PFAS use for certain categories of food contact products	https://www.fda.gov/food/chemical-contaminants-food/authorized-uses-pfas-food-contact-applications
Green Screen	PFAS-free AFFF, cleaners and degreasers, furniture and fabrics, food service ware, and textiles	Separate limits for intentionally added PFAS **(0-100 ppm)** versus contamination as Total Organic Fluorine **(1-100 ppm)**, which vary by product category.	https://www.greenscreenchemicals.org/resources/entry/pfas-free-preferred-products

PFAS-Central	Referrals to PFAS-free products	Based on declared **company policy**, no independent verification	https://pfascentral.org/perch/resources/products/pfas-free-products-list-eligibility-one-pager.pdf

2.6 PFAS Releases to the Environment

This section summarizes sources of PFAS releases to the environment that have the potential for significant environmental impact, based on the type and magnitude of the release, and the types and concentrations of PFAS associated with that release. These sources are sites where PFAS could be, or are known to have been, released to the environment, even if the site is not the location where the PFAS were generated or used. Refer to **Section 2.1** for a discussion of the relative significance of releases and source control, as not all of these facilities will have, or have been documented to have, PFAS releases, and not all releases are of the same magnitude. "In the absence of high-quality testing data, PFAS contamination could be presumed" (**Salvatore et al. 2022**) at major sources and certain facilities as mentioned below. In addition, USEPA has developed an online database called the PFAS Analytic Tools that provides access to different sources of information about potential PFAS sources, drinking water sampling data, occurrence in environmental media, among others (**USEPA 2023**).

These major sources are located both in the United States and abroad, and include:

- industrial facilities that produce PFAS or process PFAS, or facilities that use PFAS chemicals or products in manufacturing or other activities (**Section 2.6.1**)
- areas where fluorine-containing Class B firefighting foams are stored, used, or released (**Section 2.6.2**)
- waste management facilities, such as landfills (**Section 2.6.3**)
- wastewater treatment residuals and areas of biosolids production and application, with more significant impacts associated with industrial wastewater discharges (**Section 2.6.4**).
- commercial inputs like schools, hotels, and box stores that can discharge high concentrations, linked to commercial cleaning activities like floor treatments (**Section 2.6.1.7**)

The fate and transport processes and distribution of PFAS in the environment are discussed in **Section 5**. Media-specific occurrence data are discussed in **Section 6**. Information about risk assessment, and human and ecological receptors is included in **Section 9**. Discussion of conceptual site model (CSM) components for each of the PFAS release categories listed above are included in **Section 10.2**.

2.6.1 Major Manufacturing and Industry Sources

Industrial source sites include primary and secondary manufacturing facilities. Primary manufacturing facilities are those where PFAS-containing products are synthesized and made into products or chemical feedstocks, or where PFAS are used as processing aids in fluoropolymer production. PFAS processing aids are not intended to be in the final product, but may be present at trace quantities (**3M Company 2003**; **Buck et al. 2011**).

Secondary manufacturing facilities may use fluoropolymers and PFAS-based materials produced at primary manufacturing facilities as part of industrial processes, such as the application of coatings to finished products. In some industrial settings, PFAS have been used for worker safety purposes, such as using 6:2 FTS or PFOS-based materials to suppress harmful mists during electroplating activities (**Section 2.6.1.3**).

USEPA (2021) includes PFAS manufacturers and PFAS formulators in the organic chemicals, plastics, and synthetic fibers (OCPSF) point source category, which includes a broad range of sectors, raw materials, and unit operations that may manufacture or use PFAS. PFAS manufacturers are defined as

facilities that manufacture PFAS through electrochemical fluorination, fluorotelomerization, or other processes. PFAS formulators are defined as facilities that blend, convert, or integrate PFAS feedstocks with other materials to produce new commercial or intermediate products. **USEPA (2021)** identified six OCPSF PFAS manufacturing facilities and seven OCPSF PFAS formulators located in Illinois, Alabama, New Jersey, North Carolina, West Virginia, Minnesota, Pennsylvania, Ohio, Virginia, and Michigan.

PFAS composition and release mechanisms will vary for each facility. The composition of PFAS released from industrial facilities depends on the type of PFAS produced or used by the facility.

The general PFAS release mechanisms and pathways at industrial facilities are illustrated in CSM **Figure 2-20** and include wastewater and stormwater discharges; on- and off-site disposal of solid wastes; accidental releases such as leaks and spills; and stack and fugitive emissions. Stack emissions may result in aerial deposition of PFAS to soil and surface water (with subsequent leaching and infiltration to groundwater) related to the facility (**Davis et al. 2007**; **Shin et al. 2011**), as well as short- and long-range air transport of PFAS. Industrial facilities may also contain areas where fire training or fire response using AFFF has occurred, AFFF storage areas, and AFFF fire suppression systems inside buildings. Like many AFFF release sites, industrial sites may also have releases of co-contaminants (solvents, petroleum products, etc.) that could potentially influence fate and transport of PFAS.

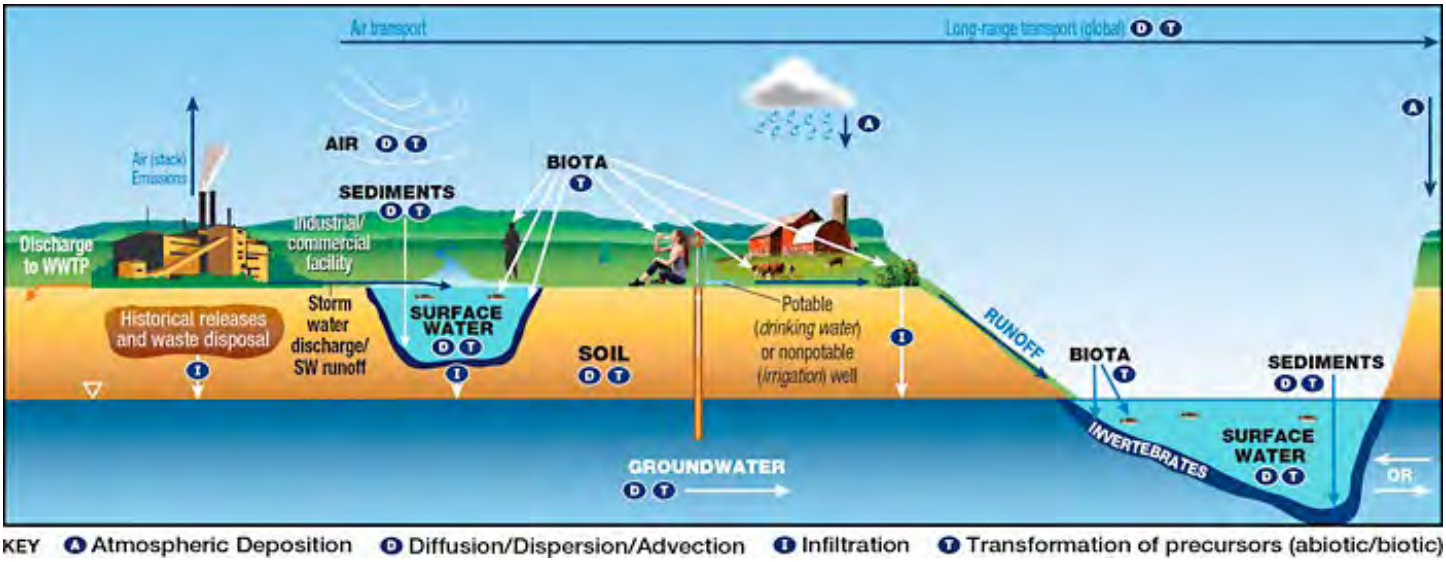

Figure 2-20. CSM for industrial sites.

Source: Adapted from figure by L. Trozzolo, TRC, used with permission.

The following subsections provide further details regarding potential sources of PFAS releases to the environment from PFAS use in manufacturing or industrial processes; these are not presented in order of the potential for significance of a release.

2.6.1.1 Building and Construction

Similar to other products, the chemical attributes of PFAS have led to advancements in building and construction materials. One particular application has been in composite wood and oriented strand board (OSB). Over the last 50 years, wood-based materials have used numerous additives for product strength and durability. A recent study performed on wood samples and OSB found primarily short-chain PFCAs and PFOA at concentrations ranging from 1.38 to 13.9 micrograms per kilogram (µg/kg) (**Bečanová et al. 2016**). Furthermore, wood fiber insulation has been shown to contain high amounts of PFHpA and other 5- to 8-carbon chain PFCAs (**Bečanová et al. 2016**). Many manufacturers use urea- or phenol-

formaldehyde due to their performance and low cost; however, the composition of the resins used by many manufacturers is proprietary.

Other materials, including certain types of building insulation (phenolic foam) have shown high amounts of PFOS. Additionally, PFAS (predominantly C8–C20 gamma-omega-perfluorotelomer thiols with acrylamide) have been used in the production of lightweight concrete, concrete sandwich panels, and lightweight concrete blocks (**Bečanová et al. 2016**; **Posner et al. 2013**). The prevalence of these building materials in the construction of fire training areas, AFFF storage facilities, and other areas potentially exposed to PFAS led to potential issues with demolition waste. The porous nature of these materials (for example, concrete, brick) could lead to PFAS adsorption/absorption, representing a potential source of PFAS when disposed in landfills or recycling facilities (**Australia Government DOD 2021**).

PFAS, including fluoropolymers such as PTFE, are used in the manufacture of architectural fabrics, such as those used in the construction of roof domes, including large stadiums and transportation facilities (**Performance Fluoropolymer Partnership 2021**; **Glüge et al. 2020**).

PFOS-related chemicals have several uses in paint and varnishes. They can be used as wetting, leveling, and dispersing agents, and have also been used to improve gloss and antistatic properties. Additionally, they can be used as additives in dyestuff and ink. Furthermore, they can be used as pigment grinding aids or as agents to combat pigment flotation problems (**KEMI 2004**; **RPA 2004**). Fluorosurfactants are commonly used in coatings application for substrate wetting, leveling, reduction of surface tension, oil repellency, and dirt pickup resistance (**Danish EPA 2015**; **Posner et al. 2013**).

Information received from different suppliers within the paint and varnish industry suggests that fluorinated surfactants in general are much more expensive alternatives compared to other surfactants. Therefore, fluorosurfactants are used only for special purposes in paint and varnishes, where it is necessary to gain such a low surface tension that no other (nonfluorinated) alternatives can achieve (**Danish EPA 2015**).

Studies pertaining to PFAS in building materials continue to be published. The Green Science Policy Institute recently published a report that summarizes currently available studies for the purposes of informing those in the building and construction industry of the presence of PFAS and eliminating unnecessary uses (**Fernandez, Kwiatkowski, and Bruton 2021**).

2.6.1.2 Cable and Wiring

In the 1950s the wire and cable industry began to use extruded grades of PTFE. This is a suspension polymerization process, which does not require surfactants, unlike dispersion polymerizations (for example, Teflon-coated pans). Melt extrusion is the process by which most fluoropolymers are applied to wires. For instance, FEP, PFA, and PVDF are heated to 260°C and then melt extruded over wire to continuous lengths. The equipment used for melt-processable fluoropolymers requires temperature sensitivity of 427°F. PTFE is processed via paste extrusion for coating PTFE over wires due to its high melting point (**ASTSWMO 2015**; **Kotthoff et al. 2015**; **Lau et al. 2007**; **Lindstrom, Strynar, and Libelo 2011**; **Oliaei et al. 2013**; **Renner 2001**; **Trudel et al. 2008**). For more information on the safe handling of fluoropolymer resins during processing, see the **Plastics Industry Association (2019)** guidance document.

2.6.1.3 Metal Finishing and Plating

Electroplating is a process that uses electric current to apply a metal coating to the surface of an object. Metallic ions in an acidic electrolyte solution are used in the electrochemical deposition of metal coatings to the surface of the cathode (**USEPA 1996**).

PFAS, particularly PFOS, have been used as mist suppressants that are added to metal plating and finishing baths to prevent air emissions of toxic metal fumes. **USEPA 2021** estimates that approximately half of the 1,339 chromium electroplating facilities in the United States still apply PFAS-based mist and fume suppressant. PFAS-containing chemicals may also be used in this industry as wetting agents, to reduce mechanical wear, and as surface coatings for reduced corrosion / enhanced appearance (**USEPA 2021**). **Glüge et al. (2020)** identified PFAS use in chrome, nickel, copper, tin, and zinc plating for lowering surface tension. In the United States, amendments to the National Emissions Standards for Hazardous Air Pollutants (NESHAP) under the Clean Air Act included a requirement to phase out the use of PFOS-based fume suppressants (a fume suppressant that contains 1% or greater PFOS by weight) in chromium electroplating by 2015 (**USEPA 2012**). Some countries (including the United States) have phased out the use of PFOS in some electroplating operations, adopting the use of other fluorotelomers (for example, 6:2 FTS) as a substitute in hard chrome plating operations (**Danish EPA 2015**; **KEMI 2015**) or changing decorative chrome plating operations to employ the less toxic trivalent chromium. PFAS known by the trade name F-53B have been used as metal plating mist suppressants in China (**USEPA 2021**; **Bao et al. 2019**). The toxicology of F-53B is reviewed in **Section 17.2.6.1** (note that toxicological research may use different nomenclature for F-53B, namely 6:2 chlorinated polyfluoroether sulfonate (6:2 ClPFESA) and 8:2 ClPFESA (**Munoz et al. 2019**). Non-fluorinated fume suppressants are also now available.

Many different types of electroplating solutions can be used in plating activities, including hard and decorative chrome plating; chromic acid anodizing; nickel, cadmium, or lead plating; metal plating on plastics; and alkaline zinc plating. Chrome electroplating is the most significant contributor as it relates to PFAS use. In this process, PFAS are used as surfactants to reduce the surface tension of the electrolyte solution. Historically, PFOS was commonly used at a concentration of 5–10% to limit the development of bubbles and the emission of hexavalent chromium aerosols to workplace air, thereby reducing the potential hazard to workers posed by hexavalent chromium (**USEPA 2009**) (**OSHA 2013**) (**Danish EPA 2015**).

Studies show use of PFAS in these settings can result in high concentration wastewater discharges (**USEPA 2009**) and air emissions. Once the electrolyte solution can no longer be used, it may be treated to remove chromium and other metals, but PFOS and other PFAS may be present in effluent and deposited in sewage sludge (**Danish EPA 2015**). Investigations in Minnesota traced PFOS releases from one chrome plating operation to a wastewater treatment plant (WWTP) where elevated levels of PFOS were detected in the biosolids, effluent water, and fish in the receiving surface water (**ATSDR 2008**). Air emissions from another Minnesota chrome plater were found to have accumulated on the roof of the facility and from there contaminated stormwater and snow melting from the roof, which in turn contaminated the groundwater, a nearby surface water system, and fish (**MPCA 2016**). In another study in Minnesota looking at PFAS air and deposition monitoring, elevated PFAS were found in the vicinity of a chromium plater (**MPCA 2022**).

According to a study in Michigan by the Michigan Department of Environment, Great Lakes, and Energy (EGLE), 320 metal finishers that had a history of using fume suppressants were found to have PFOS in wastewater effluent. The report noted that 15% of metal finishers were discharging to WWTPs at concentrations greater than screening criteria (12 ppt PFOS) and 5% were discharging greater than 1,000 ppt PFOS (**MI EGLE 2020**). Of the metal finishers discharging PFOS above screening criteria, 89% used hexavalent and/or trivalent chromium in their current or past processes. Chrome platers in Michigan were determined to be in compliance with the NESHAP and many replaced PFOS with a fume suppressant containing 6:2 FTS. Some chrome platers did not use PFOS-containing chemicals to control fumes and have not been found to be sources of PFOS to WWTPs. Nearly half of the chrome platers regulated under the NESHAP used mechanisms other than chemical fume suppression. It was concluded that current effluent containing PFOS from facilities that have complied with NESHAP originates from historical use of PFOS-containing fume suppressants.

2.6.1.4 Industrial Surfactants and Fluoropolymer Production

PFAS have been, and currently are, instrumental as surfactants in industrial and commercial production. In the recent past, some information pertaining to specific surfactant uses of PFAS has become publicly available, though much information still remains unavailable. Most well documented is the historical use of PFOA as a processing aid in the manufacturing of PTFE, where APFO is used to help mix together the chemicals needed to combine units of tetrafluoroethylene (TFE) to make PTFE. Similarly, APFN, the ammonium salt of perfluorononanoic acid (PFNA), has also been used in the production of PVDF. PVDF polymers that are produced with the aid of APFN are sold in solid phase, with notable residual APFN concentrations (100–200 ppm) (**Prevedouros et al. 2006**).

Since the voluntary phaseout of PFOA and related PFAS chemistries, replacement chemistries such as ADONA and the GenX process chemicals are now used in the production of fluoropolymers.

The PFAAs used as polymerization aids may occur as impurities/residuals in some fluoropolymer products, as discussed in detail in **Section 2.2.2.1**.

PFAS are also used in the manufacturing of plastics and fluoropolymers, rubber, and compression mold release coatings. These have applications in tubing, piping, drums, molds, and resins (**Poulsen et al. 2005**; **Prevedouros et al. 2006**).

2.6.1.5 Paper Products and Packaging

Since the 1960s, PFAS have been used as grease-proofing agents on food contact materials (FCM) to prevent oil, grease, and moisture from foods from leaking through the packaging. This includes coated paper and cardboard such as pizza boxes, microwavable popcorn bags, parchment paper, fast food wrappers, paper cups, pet food bags, and other items (**Rao and Baker 1994**; **Hekster, Laane, and De Voogt 2003**; **Poulsen et al. 2005; Trudel et al. 2008**; **Buck et al. 2011**).

The U.S. Food and Drug Administration (FDA) currently approves more than 90 unique monomer and polymer PFAS in FCMs (**USFDA 2016**). In January 2016, the FDA rescinded approval for three families of long-chain PFAS used in FCMs, but these had been voluntarily removed from the market in 2011. N-MeFOSE and N-EtFOSE were historically used to produce surface coatings for textiles and paper products (**Zaggia and Ameduri 2012**). PFAS currently used in FCM include polyfluorinated polyether-based polymers and shorter chain PFAAs (**Wang et al. 2015**; **Schaider et al. 2017**). See **Section 8.2** for additional information regarding a voluntary phaseout of 6:2 FTOH.

The most common PFAS detected in U.S. fast food wrappers include PFCAs (for example, PFOA and PFHxA), PFSAs (for example, PFBS), and fluorotelomer sulfonates (for example, 6:2 FTS) (**Schaider et al. 2017**). Six of 20 FCM tested were found to contain detectable levels of PFOA even though in 2011 U.S. manufacturers had voluntarily agreed to stop distributing FCM that were manufactured using PFOA via an FDA initiative. The methodology was not sensitive enough to detect if the PFAS were intentionally added to the packaging material or if they were attributed to unintentional background levels (**Schaider et al. 2017**). Refer also to **Section 2.4.3** on the USEPA 2010/2015 PFOA Stewardship Program, which discusses the phaseout of PFOA and potential sources of PFOA that may remain in commercial and consumer products.

2.6.1.6 Photolithography/Semiconductor Industry

The Priority Topics for History, Use, and Naming Conventions include information about semiconductor industry uses of PFAS (see **Section 1.1.1**).

The semiconductor industry historically has used PFOS for their surface-active properties in the fabrication of imaging devices such as digital cameras, cell phones, printers, and scanners (**Poulsen et al. 2005**). Studies have shown semiconductor waste streams containing the PFAAs PFBS, PFHxS, PFOS, PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnA, and PFDoA (**Lin, Panchangam, and Lo 2009**). Similarly, in photolithography processes, PFOS has been used predominantly in applying top-layer antireflective coatings (TARCs), bottom antireflective coatings (BARCs), and etchants. Smaller quantities of PFOS and longer-chain PFAS have been used in wet etchants, film developers, cleaners, protective coatings, and color filters (**SIA 2008**), with ongoing uses permitted (**Section 2.4**).

2.6.1.7 Textiles, Leather, and Apparel (Including Carpet and Furniture)

Surface treatment of textiles, leather, carpet, and furniture upholstery with PFAS to make them stain, oil, and water repellent occurs both before (that is, at the factory) and after consumer acquisition for ongoing stain, oil, and water repellency (**Prevedouros et al. 2006**; **Ahrens 2011**; **Herzke, Olsson, and Posner 2012**). Aftermarket PFAS-containing stain-repellent products for carpets allow consumers to treat carpets and textiles at home (**Renner 2001**; **Hekster, Laane, and De Voogt 2003**). Losses to the environment can be related to dry cleaning and laundering activities (**Poulsen et al. 2005**; **3M Company 2000**).

Home textiles, including furniture and carpeting, as well as aftermarket PFAS surface treatment products, are also sources of long-chain perfluorinated chemical exposure (**Guo et al. 2009**). Textile coating operations may use water-emulsion or powdered feedstocks that contain greater proportions of PFCAs compared to PFSAs (**Lassen et al. 2015**; **Gremmel, Frömel, and Knepper 2016**). According to California EPA (CalEPA) **CalEPA 2018**, pg. 12, "The PFAS polymers used in carpets, rugs, and other textiles can contain various amounts of mobile residual raw materials, impurities, or transformation products, including PFAAs and other PFAA precursors such as fluorotelomer alcohols (FTOHs) and perfluoroalkyl sulfonamide alcohols." Releases to the environment could occur from disposal of carpet cleaning wastewater (**CalEPA 2018**). Physical degradation of some consumer products (such as PFAS-treated textiles and carpets, as well as paper) may be a source of PFAS in house dust (**Björklund, Thuresson, and de Wit 2009**). The weathering of certain textiles can also be the causes of potential releases of PFAS (**Schellenberger et al. 2022**; **van der Veen et al. 2020**).

It should be noted that many treated home textiles and carpets are now manufactured with alternatives to long-chain PFAS; however, these products can have a long useful life, making it possible that items previously treated with long-chain PFAS are still in use (**Brooke and Nwaogu 2004**). A 2009 study of over 100 consumer products conducted by the USEPA and Arcadis indicated that pretreated carpet, treated upholstery and textiles, as well as other floor treatments, are likely the largest source of PFAS receptor exposure in American homes (**Guo et al. 2009**).

Other studies have since shown nonpolymeric PFAS in leather samples and outdoor textiles to impart water, oil and stain resistance; applications include protective clothing, outerwear, footwear, umbrellas, tents, and sails (**OECD 2013**; **Walters and Santillo 2006**; **Kotthoff et al. 2015**). Durable water repellent (DWR) is a fabric surface finish that creates a protective barrier. It is typically added at the factory, but is also available to consumers for apparel maintenance (**Brooke and Nwaogu 2004**). The finishes/treatments are applied to materials in mills/tanneries and as aftermarket applications by professionals or do-it-yourself consumers as aqueous dispersions. In some aftermarket applications, they are applied as solutions in hydrocarbon-based or halogenated solvents (**OECD 2013**).

2.6.1.8 Other Potential Commercial or Domestic Sources of PFAS Releases to the Environment

There is the potential for everyday uses of PFAS to result in relatively smaller releases of PFAS to the environment. Of note, these may include, but are not limited to leaching from materials to media (for

example, well construction and plumbing materials), discharges to on-site wastewater disposal systems from use of household products and cosmetics, discharges from car washing and waxing, and use of ski waxes (professional ski wax technicians may have significant inhalation exposures to PFAS (**Nilsson et al. 2013**). Snowmelt and surface waters (**Kwok et al. 2013**), as well as snow, soil, and groundwater (**Carlson and Tupper 2020**), near ski areas may have measurable PFAS impacts.

2.6.2 Class B Fluorine-Containing Firefighting Foams

Some Class B firefighting foams designed for extinguishing flammable liquid hydrocarbon fires and vapor suppression may contain fluorine. These foams can be a major source of local PFAS release to the environment, with the CSM included in **Figure 2-21**.

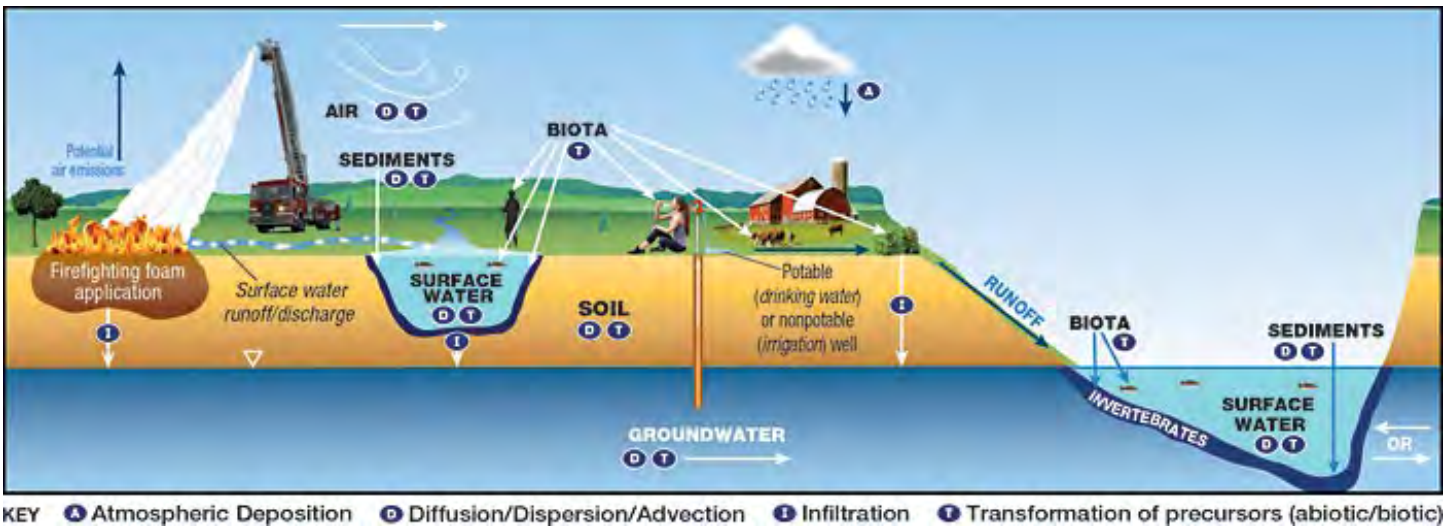

Figure 2-21. CSM for fire training areas.

Source: Adapted from figure by L. Trozzolo, TRC, used with permission.

Class B firefighting foams are commercial surfactant solutions that have been (and continue to be) stored and used for fire suppression, fire training, and flammable vapor suppression at military installations and civilian facilities and airports (**Hu et al. 2016**), as well as at petroleum refineries and bulk storage facilities, and chemical manufacturing plants and storage facilities (**CONCAWE 2016**). Additionally, local fire departments in communities have used and may maintain quantities of firefighting foam in their inventories for use in training and emergency response. Facilities that manufactured firefighting foams and landfills that received firefighting waste are also potential sources. Refer to **Section 3** and **Section 1.2** for more detailed information about firefighting foams.

2.6.3 Solid Waste Management Facilities

Environmental releases associated with the use of PFAS-containing products are primarily related to management of solid waste (for example, disposal of used items in a landfill or other legacy disposal areas). Other solid waste facilities, such as scrap yards and metal salvage facilities, might also be a potential source of release to the environment. Some PFAS are considered hazardous waste by some states (**Section 8**). Additional information pertaining to disposal of PFAS and PFAS-containing materials at MSW landfills can be found in the 2020 USEPA Interim Guidance on the Destruction and Disposal of Perfluoroalkyl and Polyfluoroalkyl Substances and Materials Containing Perfluoroalkyl and Polyfluoroalkyl Substances (**USEPA 2020**).

Landfills can be sources of PFAS because they are the ultimate repositories for PFAS-contaminated industrial waste, sewage sludge from wastewater treatment facilities, and waste from site mitigation, as well as for PFAS-bearing consumer wastes, such as goods treated with hydrophobic, stain-resistant coatings (**Busch et al. 2010**; **Eggen, Moeder, and Arukwe 2010**). But the type and concentration of PFAS vary greatly among landfills, due to variations in the waste streams. Industrial waste can be a significant source of PFAS in landfills (as well as in wastewater and biosolids), particularly those that accept waste from facilities involved in the production or application of PFAS (**Oliaei et al. 2013**). Although MSW will contain PFAS due to its presence in so many consumer products, it generally is expected to have lower concentrations than landfills that accept industrial waste. Given the production timeline of PFAS, industrial, commercial, and consumer products and waste disposed since the 1950s are potential sources of PFAS release to the environment. As PFAS manufacturing processes change with time, the resulting type and composition of waste streams also change. PFAS production and use began several decades before the enactment of federal and state regulations governing waste disposal; as a consequence, environmental and drinking water impacts from disposal of legacy PFAS industrial and consumer waste have been documented (**Oliaei, Kriens, and Weber 2010**; **Shin et al. 2011**; **MPCA 2017**).

Figure 2-22 illustrates common elements of CSMs associated with the potential release scenarios at waste management facilities.

2.6.3.1 Landfill Construction

Landfills are either lined or unlined (**Figure 2-22**). Municipal solid waste (MSW) landfills constructed since the 1990s are required by federal or state regulations to install a composite liner, a layer of compacted soil, and a leachate collection system (40 CFR 258.40). Although some states may have implemented construction standards at an earlier date, most landfills constructed before the 1990s were not required to have synthetic flexible membrane liners, compacted soil liners, or leachate collection systems, causing waste to be in direct contact with underlying soil or groundwater. Hazardous waste (Subtitle C) landfills have similar design requirements for the liner system, though an additional composite layer and leak detection layer are required (40 CFR 264.301). Construction and demolition (C&D) landfills or nonmunicipal solid waste landfills are subject to the requirements specified in 40 CFR 257 Part A (and if they intend to accept very small quantity generator waste, they are also subject to 40 CFR 257 Part B). Minimum design criteria for landfill liners are not specified in 40 CFR 257. Therefore, new C&D and

nonmunicipal solid waste landfills may be permitted and constructed (or new cells added to existing facilities) without synthetic liners. Some states may have more restrictive requirements. Therefore, unlined landfills (and legacy disposal areas not classified as landfills) have a higher potential of contributing PFAS to groundwater (**Oliaei et al. 2013**). Properly constructed and operated modern landfills provide one of the few available disposal/management options for PFAS-containing waste, including wastewater solids, remedial/treatment waste, and consumer products. The USEPA Interim Guidance on the Destruction and Disposal of Perfluoroalkyl and Polyfluoroalkyl Substances and Materials Containing Perfluoroalkyl and Polyfluoroalkyl Substances provides further discussion about the use of landfills for management of PFAS-containing wastes, the potential for PFAS to be released to the environment from landfills, and the additional research and data that are needed to further assess the effectiveness of managing PFAS discharges and emissions from all landfills (**USEPA 2020**).

Landfills are currently required to use a daily cover or alternate daily cover. It is acceptable for alternative daily cover to include materials such as sludge, sludge-derived products, shredded automotive parts, spray-on foams, and other materials (**Pohland and Graven 1993**) that are possible sources of PFAS. Landfill caps reduce infiltration of water to waste and may reduce the overall mass of PFAS entering the environment from a landfill, but more research on their effectiveness is needed (**Hamid, Li, and Grace 2018**).

Leachate from some MSW landfills has been shown to be a source of PFAS release to the environment (**Busch et al. 2010**; **Eggen, Moeder, and Arukwe 2010**), although the fate and transport processes for PFAS through landfills into leachate are not well understood at this time. The processes for managing leachate have implications on the ultimate fate and transport of PFAS. If landfill liners or leachate collection systems fail, PFAS may directly enter the environment. Leachate collected from landfills is typically treated on site or transported to either a WWTP or evaporation ponds. Modern landfills with properly constructed and operated liner and leachate collection systems should generally protect the underlying groundwater from PFAS releases. Leachate treatment by WWTPs is common prior to discharge to surface water or distribution for agricultural or commercial use (**Lang 2016**). However, standard WWTP technologies are generally ineffective at reducing or eliminating PFAS (**Hamid and Li 2016**; **Ahrens et al. 2016**; **CRC CARE 2017**). As a result, the discharge of landfill leachate, even if treated at WWTPs, can be a significant source of release of some PFAS to the environment (**Ahrens et al. 2016**; **CRC Care 2017**). Although landfill leachate PFAS concentrations can be relatively high, landfill leachate discharged to WWTPs for treatment generally is considered a relatively minor source to the environment because the volume of leachate generated annually and sent to a WWTP for treatment is low compared to the flow volume in most WWTPs (**Busch et al. 2010**; **Masoner et al. 2020**; **MWRA 2019**). On a site-specific basis, the impact of leachate on combined wastewater influent PFAS mass loading can vary depending on the relative volumetric contribution of leachate to combined influent flows and the nature of the landfilled waste materials (**Masoner et al. 2020**). Furthermore, USEPA's Effluent Guidelines Program Plan, (**USEPA 2023**) states "EPA evaluated discharge data from over 200 landfills from across the country and found PFAS present in the leachate at over 95 percent of the landfills. PFAS detections included 63 different PFAS with average concentrations for an individual compound as high as 14,000 parts-per-trillion (ppt)." However, in a limited study of five wastewater treatment facilities in Florida, **Masoner et al. (2020)** did not identify differences in the effluent PFAS loading of wastewater treatment facilities that received landfill leachate relative to those that did not, suggesting the PFAS load present in wastewater treatment effluent is attributable to numerous sources. A similar finding was noted by **MWRA (2019)**, though only PFOA and PFOS were investigated.

As part of EPA's final Effluent Limitations Guidelines Plan 15, **USEPA (2023)** announced its plans to proceed with a rulemaking to address PFAS discharges from landfills; refer to **Section 16.6** for more information on this rulemaking.

2.6.3.2 Waste Age

Landfills containing sources of PFAS may continue to release PFAS to leachate at slow but relatively steady rates for decades following initial placement. In modeled anaerobic landfill reactors, most of the release is attributed to biological, not physical, mechanisms, indicating that the low solubility of the compounds is not solely responsible for slow release rates from landfills (**Allred et al. 2015**; **Lang et al. 2016**). Legacy industrial waste landfills may constitute a major source of PFAS release to the environment (**ATSDR 2008**, **2012**).

2.6.3.3 PFAS Composition

PFAS composition and concentration in leachates vary depending on waste age, climate, and waste composition (**Allred et al. 2015**; **Lang et al. 2017**). Relative concentrations of PFAS in leachate and groundwater from landfills are different from those at WWTPs and AFFF-contaminated sites. PFAS with fewer than eight carbons tend to dominate landfill leachate because they are less hydrophobic and therefore more likely to partition to the aqueous phase (**Huset et al. 2011**; **Higgins and Luthy 2007**). In particular, 5:3 fluorotelomer carboxylic acid (FTCA) is a common and often dominant constituent of PFAS found in landfills and is released from carpet in model anaerobic landfill reactors. This compound could prove to be an indicator of PFAS in the environment originating from landfills (**Lang et al. 2017**, **2016**).

PFAS may also be released to the air from landfills, predominantly as fluorotelomer alcohols (FTOHs) and perfluorobutanoate (PFBA). In one study, total PFAS concentrations were 5–30 times greater at landfills than at background reference sites (**Ahrens et al. 2011**). PFAS release rates vary with time for a given waste mass, with climate (for example, rainfall) as the apparent driving factor for the variations (**Lang et al. 2017**; **Benskin et al. 2012**). Gas collection systems commonly employed at modern landfills should reduce possible PFAS emissions to air.

2.6.4 Wastewater Treatment and Wastewater Treatment Residuals and Biosolids

The Priority Topics for Biosolids Land Application (see **Section 1.7**) include information that supplements the Biosolids information included here.

Consumer and industrial use of PFAS-containing materials, including disposal of landfill leachate and firefighting foam, may discharge PFAS-containing wastewater to municipal and industrial WWTPs (**Lin, Panchangam, and Lo 2009**; **Ahrens et al. 2009**) private septic systems (see **Section 1.3.2**), or other wastewater disposal systems.

2.6.4.1 Wastewater Treatment

WWTPs receive PFAS from a host of sources conveyed thru and aggregated in effluent and sludges, which can provide the following pathways for PFAS releases to the environment (**Figure 2-22**):

- point source discharges of effluent
- leakage or unintended releases from surface impoundments and structures
- air emissions
- management (for example, land application) and disposal (for example, landfilling, incineration) of biosolids (https://www.epa.gov/biosolids), wastewater solids and sludges, and other byproducts generated during the treatment process (**Section 2.6.4.2**). Refer to **Section 12** for more information on incineration.

The composition of PFAS in these media is a function of the different sources to the WWTP influent and the WWTP processes (**Chen, Lo, and Lee 2012**; **Oliaei, Kessler, and D. Kriens 2006**; **Frömel et al. 2016**; **Schultz et al. 2006**), including:

- type and concentration of PFAS received by the WWTP
- biological and chemical transformation of polyfluorinated substances (that is, precursor PFAS) to intermediate and terminal transformation products, such as PFAAs
- physical or chemical partitioning, or both.

In addition to PFAAs, fluorotelomer sulfonates, and sulfonamides, another family of PFAS precursor compounds, polyfluoroalkyl phosphate monoesters (PAPs) and polyfluoroalkyl phosphate diesters (diPAPs) (particularly 6:2 and 8:2 PAP; and 6:2 and 8:2 diPAP) have been documented in wastewater treatment plant (WWTP) samples and especially biosolids (**Eriksson, Haglund, and Karrman 2016**; **Fredriksson et al. 2022**; **Kim Lazcano et al. 2020**; **Lee et al. 2014**). This family of PFAS precursors plays an important role since they are typically found at much higher concentrations than commonly measured PFAS (**Aro et al. 2021**; **Fredriksson et al. 2022**; **Moodie et al. 2021**; **Schaefer et al. 2022**) and they have been shown to biotransform to PFAAs (**Eriksson, Haglund, and Karrman 2016**). **Fredriksson et al. (2022)** reported diPAPs accounting for 66% of the total concentrations of PFCAs precursors in sludge samples with the sum of diPAPs reaching up to 632 µg/kg, consistent with findings by **Schaefer et al. (2022)**. As a result of precursor biotransformation, the concentrations of PFAAs can increase from influent to effluent, while the concentrations of these PFAS precursors decrease (**Chen et al. 2018**; **Dauchy et al. 2017**; **Houtz, Wang, and Park 2018**).

PFAS occurrence is reported in small municipal wastewater treatment plants with only domestic sources (**Sinclair and Kannan 2006**). PFAS in non-industrial wastewater is attributed to environmental transformation of polyfluorinated microfibers that might be released by different sources, for example, water-resistant clothing during laundry (**Schellenberger et al. 2019**), food packaging (**Choi et al. 2019**; **Schaider et al. 2017**), human excretion after oral exposure (**Ma, Zhu, and Kannan 2020**; **Worley et al. 2017**), and tap water (**Andrews and Naidenko 2020**; **Filipovic and Berger 2015**).

Thompson et al. (2022) suggested that domestic wastewater accounts for most of the PFAS load in WWTPs while historically industrial discharges was believed to cause the majority of the PFAS releases from WWTPs.

Conventional sewage treatment methods used in WWTPs do not efficiently remove PFAAs (**Ahrens et al. 2011**; **Schultz et al. 2006**). Even WWTPs with advanced treatment technologies (such as granular activated carbon (GAC), powdered activated carbon (PAC), or reverse osmosis (RO)) may not fully remove all PFAS if these systems were not designed with the intent to remove PFAS in addition to other targeted contaminants. Some PFAAs are frequently detected in WWTP effluent (for example, PFOA and PFBS), with concentrations of some PFAS up to hundreds of ng/L (**Tavasoli et al. 2021**). **Ahrens et al. (2011)** and **Hamid and Li (2016)** suggested that WWTP effluent can be a major source of PFAAs to surface waters.

Evaluation of full-scale WWTPs has indicated that conventional primary (sedimentation and clarification) and secondary (aerobic biotransformation of organic matter) treatment processes can change PFAS concentrations and subgroups. For example, studies have shown increased concentrations of PFAAs in effluent, presumably from transformation of precursor PFAS (**Schultz et al. 2006**), and the possible creation of PFAAs from the oxidation of polyfluorinated precursors during the treatment process (**Oliaei, Kessler, and D. Kriens 2006**; **Frömel et al. 2016**; **Houtz, Wang, and Park 2018**).

PFAS may be concentrated in wastewater solids (for example, sewage sludge) generated throughout the wastewater treatment process (**Schultz et al. 2006**). PFAS may also be present in septage (solids removed from septic systems). Depending on waste management and disposal practices, land

application or landfill disposal of wastewater solids, biosolids, or septage could potentially contaminate the environment.

Hu et al. (2016) suggested that the presence of WWTPs in an area could be predictive of the presence of PFOS and PFOA in drinking water. PFOS and PFOA are two of the most frequently reported PFAS in wastewater (**Hamid and Li 2016**) in addition to other relevant PFAS such as diPAPs (**Schaefer et al. 2023** and **Thompson et al. 2023**); see **Section 6.2.3** for more information. Using WWTP effluent-impacted surface water as a source of drinking water can, in turn, recycle the PFAS back to the WWTP, recirculating PFAS in the water cycle (**Hamid and Li 2016**).

At some WWTPs, studies have shown concentrations of PFAS in ambient air at WWTPs to be 1.5–15 times greater than background reference sites (**Hamid and Li 2016**). **Hamid and Li (2016)** noted that these elevated air concentrations of total PFAS include polyfluoroalkyls and that this has important implications considering the potential for their long-range transport and subsequent transformation to recalcitrant PFAAs. PFAS distribution (primarily PFAAs and FTOH, with higher concentrations of FTOH) changes based on the specific PFAS sources in the effluent and the type of treatment methods employed at the WWTP.

Michigan EGLE has a program for evaluating PFAS in WWTP influent, effluent, and biosolids including conducting studies to better understand the fate and transport of PFAS from land application of biosolids (**MI EGLE 2021**). This included sampling of WWTP influent, effluent, and associated sludge or biosolids at 42 WWTPs and sampling of soils, groundwater, and surface waters at eight biosolids land application sites. The land application sites that received biosolids with "typical" levels of PFAS generally exhibited non-detectable to low concentrations of PFAS in soils and surface waters. The sites that received biosolids with higher PFAS levels that EGLE considered to be "industrially-impacted" showed higher concentrations of PFAS in the soils, surface water and groundwater with some results exceeding certain Michigan criteria. Results from the broad biosolids sampling were used to develop an Interim Biosolids Land Application PFAS Strategy (**MI EGLE 2024**), which in conjunction with the other State initiatives, allowed the majority of WWTPs to maintain the option to land apply biosolids while maintaining protectiveness. Restrictions were placed on land application of biosolids containing PFAS above certain criteria. Additional information about the MI EGLE biosolids programs are linked from their web site (**https://www.michigan.gov/egle/about/organization/Water-Resources/biosolids/pfas-related**).

Human exposure to PFAS can occur from wastewater through leaching into groundwater from biosolids land application or landfill operations, bioaccumulation into food or unplanned/planned potable reuse (**Ahrens et al. 2011**; **Glover, Quinones, and Dickenson 2018**; **Hu et al. 2016**; **Lindstrom et al. 2011**). More information about human exposures to PFAS is included in **Section 9.1.2**.

2.6.4.2 Biosolids Production and Application

Biosolids or "sewage sludge" are products of liquid separation from solids in wastewater treatment systems which undergo further physical chemical treatments to produce nutrient-rich products. Biosolids are residuals that have been treated thermally and/or chemically to meet state and federal standards to allow beneficial reuse. Biosolids are managed through beneficial reuse with land application (agriculture, turf grass, land reclamation) or composting (fertilizer) or disposed of by landfilling, incineration, or other form of surface disposal (**NACWA 2023**). Biosolids must meet state and federal requirements prior to land application in agricultural and reclamation sites. Land application of biosolids can offer economic and waste management benefits to municipalities and farmers (**Stulp 1995**). It should be noted that biosolids are not wastewater solids, industrial-derived sludges, or sludges that are the untreated solids/sludge removed during the process of treating wastewater.

PFAS presence in wastewater treatment residuals generated at municipal WWTPs is the result of widespread presence in engineered and natural systems, including numerous consumer products and certain industrial processes. The residuals can contain varying levels of PFAS commensurate with sewer shed characteristics, one of which is the type of and degree of influence that industrial dischargers have on municipal WWTPs. Several studies have reported results of testing of biosolids for PFAS (**MI EGLE 2022**). PFAS (measured as PFCAs and PFSAs) have been found in domestic sewage sludge (**Higgins et al. 2005**; **Yoo et al. 2009**), and PFAS occurrence in biosolids is reported to be prevalent and nationwide (**Venkatesan and Halsden 2013**).

PFAS are not known to be intentionally added to biosolids during processing or application since WWTPs are largely considered passive recipients of these chemicals.

There are a number of methods currently used to manage biosolids. According to **USEPA (2023)**, around 43% of biosolids are land applied (typically as agricultural fertilizer), 42% landfilled, 14% incinerated, and 1% are stored or deep-well injected in the United States. The National Biosolids Data Project (https://www.biosolidsdata.org/) similarly reports about half of the biosolids are land applied, 25% are disposed in landfills, and 15% managed through incineration. Given the significant proportion of biosolids land applied for agriculture, there is the potential for release of PFAS to the environment associated with biosolids production and application. A small number of states have placed restrictions on incineration of PFAS containing material until the efficiency of destruction is better understood through on-going studies. Landfilling biosolids may lead to increased PFAS in landfill leachate which must be managed or increase the potential for releases to groundwater or air. However, there may be a greater reliance on landfilling in some states as restrictions are made on other management options. Long term landfilling of biosolids would also stress existing landfill capacity. In addition, a small number of states have also restricted the land application of biosolids due to concerns related to PFAS.

Biosolids can be land applied in several ways, including subsurface injection of liquid biosolids, surface application of liquid biosolids, surface application of dewatered (semi-solid) biosolids, or application and incorporation of dewatered (semi-solid) biosolids. Once introduced to the environment through land application, PFAS may enter surface water through runoff or infiltrate to groundwater (**Lindstrom, Strynar, and Libelo 2011**). Biosolids are also dried/pelletized for direct use as a soil amendment/fertilizer and for use in fertilizer blends that are then marketed commercially. The potential effects on groundwater or surface water may depend on many factors including but not limited to the amount and composition of PFAS present in biosolids, soil properties, infiltration rate, land application practices, land use, precipitation, climate, and land slope. PFAS concentrations can be elevated in surface water and groundwater in the vicinity of agricultural fields that received PFAS-contaminated biosolids over an extended period of time (**Washington et al. 2010**). The Washington et al. study was completed in an area that received industrial wastewater discharges from several PFAS-related industrial dischargers. Other studies indicate that the potential PFAS releases from municipal biosolids (for example, those generated at WWTPs that do not receive significant inputs from industries linked to PFAS), may still impact water quality, but at an apparent lower relative impact than at the industrial-influenced biosolids application sites (**Gottschall et al. 2017**). **Pepper et al. (2021)** examined PFAS in soil in Arizona following long-term application of biosolids. The study concluded “long-term land application resulted in low incidence of soil PFAS” and “PFAS soil concentrations in irrigated agricultural plots with or without land application of biosolids were similar” (**Pepper et al. 2021**).

The most abundant PFAS found in biosolids (PFOS and PFOA) are the same as those found in WWTP effluent, although biosolids may also contain other long-chain PFAS (**Hamid and Li 2016**; **Washington et al. 2010**). Although multiple studies have reported statistically significant data showing transformation of polyfluorinated substances to PFAAs in land-applied biosolids (**Yoo et al. 2010**; **Sepulvado et al. 2011**; **Washington et al. 2010**), other evidence indicates that some polyfluorinated substances remain in biosolids-amended soils for many years to decades (**Yoo et al. 2010**; **Rich et al. 2015**; **Washington et al. 2018**).

Application of municipal or industrial biosolids as a soil amendment can result in a transfer of PFAS to soil (**Sepulvado et al. 2011**). These PFAS can then be available for uptake by some plants and soil organisms (**Yoo et al. 2011**). There are indications that PFAAs can enter the food chain through the use of biosolids-amended soil (**Lindstrom, Strynar, and Libelo 2011**; **Blaine et al. 2013**; **Blaine et al. 2014**; **Navarro et al. 2017**). It is noted, however, that PFAAs present at one municipal biosolids application site were not found in grain grown in the application plot (**Gottschall et al. 2017**). **Hamid and Li (2016)** suggested that short-chain (< C7) PFAAs in biosolids subsequently used in land applications can lead to contamination of food (**Section 5.6**). Significant data gaps exist regarding the fate and transport mechanisms associated with land application of PFAS impacted biosolids and the associated impacts to the food chain are an active area of study (see **Section 6.5**).

Refer to **Section 2.6.4.1** for information on Michigan EGLE's program for evaluating PFAS in WWTP influent, effluent, and biosolids including conducting studies to better understand the fate and transport of PFAS from land application of biosolids (**MI EGLE 2021** and **MI EGLE 2024** which includes links to field report addenda for individual application sites). The Environmental Council of the States (ECOS) collected information in November 2022 from state environmental agencies about management of biosolids and published a report of their findings (**ECOS 2023**).

3 FIREFIGHTING FOAMS

The purpose of this section is to assist aqueous film-forming foam (AFFF) users (first responders, regulators, environmental managers, and environmental professionals) who manage AFFF releases. The section includes information about the applications, environmental impacts, and regulations associated with firefighting foams.

Section Number	Topic
1.2	**Priority Topics for Firefighting Foams (2025)**
3.1	**Foam Formulations**
3.2	**AFFF Characteristics**
3.3	**Mechanisms for Release to the Environment**
3.4	**AFFF Fate and Transport**
3.5	**Forensic Analysis of AFFF**
3.6	**AFFF Procurement and Inventory**
3.7	**Foam Systems and Operations**
3.8	**Emergency Firefighting Operations**
3.9	**Immediate Investigative and Cleanup Actions**
3.10	**AFFF Disposal**
3.11	**Firefighting Foam System Replacement**
3.12	**Federal, State and International Regulations and Guidance**
3.13	**Foam Research and Development**

It should be noted that the priority of firefighters and first responders is to protect life and property. The information provided supports decision-making about firefighting using AFFF so that potential impacts to the environment can be minimized and mitigated once the fire emergency is ended, or at such time that sufficient resources are deployed to the scene to both handle the fire emergency and mitigate the environmental risks posed by AFFF use. Fluorine-free foam (F3) alternatives are also discussed; these foams are not "film-forming" and are mechanistically different than AFFF in how they work to extinguish a fire. **Figure 3-1** illustrates the life cycle considerations of AFFF. The considerations are discussed in subsequent sections.

Figure 3-1. Life cycle considerations for Class B Foams.

3.1 Foam Formulations

There are two major classes of firefighting foam, Class A and Class B foams. Class A foams are not considered in this document as

they are intended for use on Class A or wood fuel fires. They are made from hydrocarbon-based surfactants, do not contain intentionally added PFAS, and are appropriate to use for their intended purpose. They are covered under NFPA 1150 (Standard on Foam Chemicals for Fires in Class A Fuels) (**NFPA 2022**).

Class B firefighting foams are commercial surfactant solutions that are designed and used to combat Class B flammable fuel fires. PFAS (fluorinated surfactants) are the active ingredient in Class B fluorinated foams. When mixed with water and discharged, the fluorinated foam forms an aqueous film that quickly cuts off the oxygen to the fire, cools it, extinguishes the fire, and prevents the fire from relighting. Class B foams have been (and continue to be) stored and used for fire suppression, fire training, and flammable vapor suppression at military installations and civilian facilities and airports (**Hu et al. 2016**), as well as at petroleum refineries and bulk storage facilities and chemical manufacturing plants (**CONCAWE 2016**). Additionally, local community fire departments have used and may maintain quantities of firefighting foam in their inventories for use in training and emergency response. Facilities that manufactured fluorinated firefighting foams and landfills that received firefighting waste are also potential sources of PFAS in the environment.

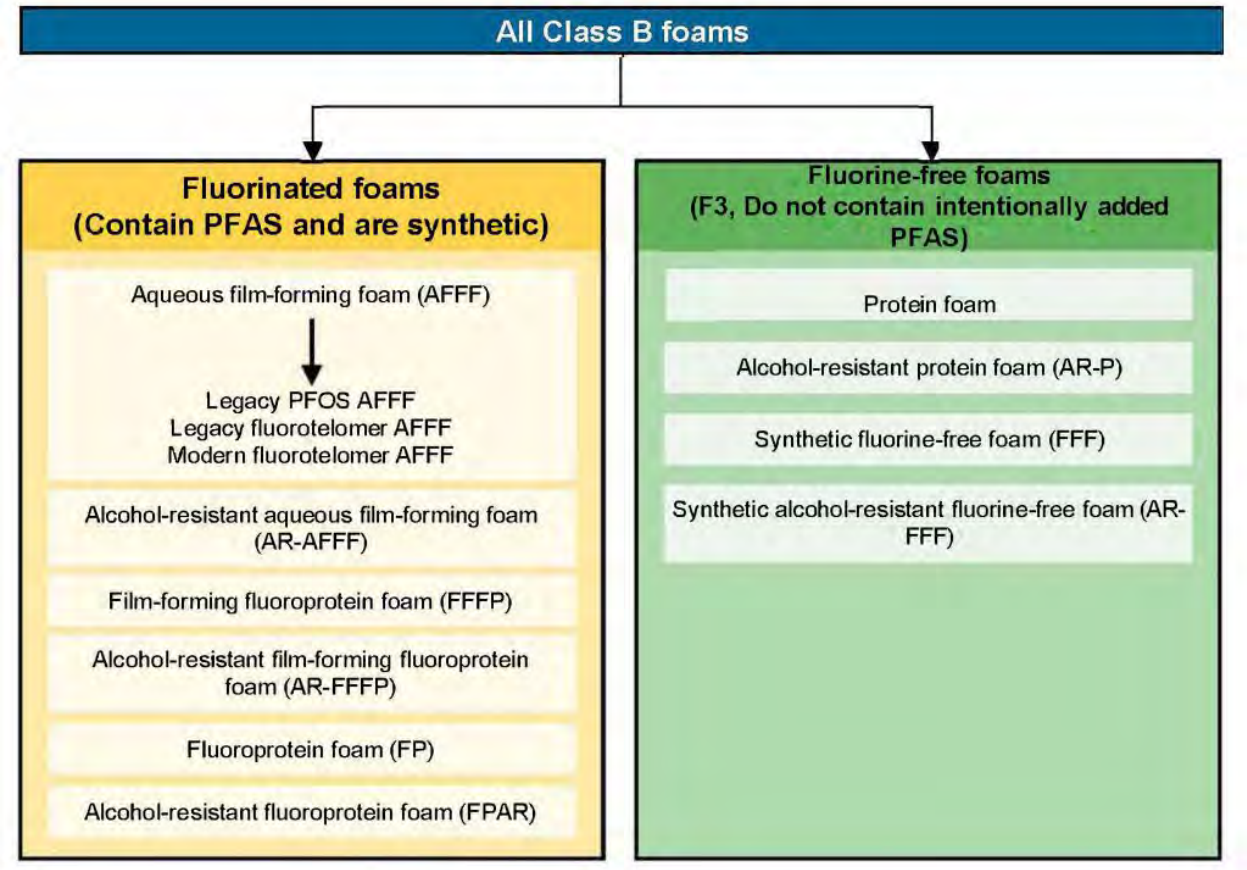

Figure 3-2. Types of Class B foams.

Source: S. Thomas, Battelle. Used with permission.

All Class B foams are not the same in composition and use different mechanisms to extinguish fires. Although not usually categorized this way from a fire protection viewpoint, they can be divided into two broad categories from a PFAS composition perspective: fluorinated foams that contain PFAS and F3 that do not contain intentionally added PFAS. **Figure 3-2** highlights the two broad categories of Class B foams and their general subcategories. Both fluorinated and fluorine-free foam examples are presented. As the

fluorine-free options continue to expand, the nomenclature and acronyms also expand. Synthetic fluorine-free foam may also be referred to as Fluorine-free foam (FFF), Synthetic Fluorine-free Foam (SFFF) or Non-fluorinated Foam (NFF). Similarly, synthetic alcohol-resistant fluorine-free foam may be referred to as Alcohol-resistant Fluorine-free foam (AR-FFF), (AR-SFFF, AF-NFF).

All Class B foams have the potential to create an adverse environmental impact if uncontrolled releases to the environment occur, particularly if the foam reaches drinking water sources, groundwater, surface water, or other natural waters. For all Class B foams, including F3, there is a potential for acute aquatic toxicity and excessive biological and chemical oxygen demand, as well as nutrient loading, depending on where the discharge occurs (see Section **3.11.1.3**). The Priority Topics for Firefighting Foams include information about recent studies of firefighting foam ecotoxicity (see **Section 1.2.2**).

This section is focused on AFFF because of its long-term and widespread use and associated impacts to human health and the environment. AFFF is of particular concern because it contains PFAS.

As discussed elsewhere in this document, many PFAS are highly persistent and mobile in the environment and are not removed by traditional drinking water treatment methods typically used by public water suppliers.

Other foams such as alcohol-resistant foams (AR-AFFF), film-forming fluoroprotein foams (FFFP), alcohol-resistant film-forming fluoroprotein foams (AR-FFFP), fluoroprotein foam (FP), and alcohol-resistant fluoroprotein foam (FPAR), as illustrated in **Figure 3-2**, also contain PFAS and similar precautions and considerations should be taken.

The fluorosurfactants in AFFF formulations can be produced either using the electrochemical fluorination (ECF) process or the fluorotelomerization (FT) process. Both ECF-derived and telomer-derived AFFF contain diverse mixtures of PFAS (**Barzen-Hanson et al. 2017**). The ECF process results in a PFAS mixture dominated by perfluoroalkyl acids (PFAAs)—both perfluoroalkane sulfonate (PFSA) and perfluoroalkyl carboxylate (PFCA) homologues, while the fluorotelomerization process exclusively produces AFFF formulations consisting of polyfluorinated compounds (**Houtz et al. 2013**). ECF-based AFFF formulations were voluntarily phased out of production in the United States in approximately 2002 (**Section 2.4.1**). Despite the phaseout, however, ongoing permitted use of legacy AFFF can still result in long-chain PFAA contamination. Several organizations (for example, U.S. Department of Defense) commenced systematic replacement of legacy PFOS AFFF with modern fluorotelomer AFFF as early as 2018, but some legacy AFFF remains in service or stockpiled at other facilities (**Section 3.11.1**).

Fluorotelomer foams have been in use since the 1970s and became the predominant foam after 2001, when the major manufacturer (3M) of long-chain ECF-based foams (legacy PFOS foam) discontinued production (**Leeson et al. 2021**). Fluorotelomerization-derived AFFF is still manufactured and used in the United States but has been reformulated with the goal to eliminate, long-chain PFAS; these foams are now referred to as modern fluorotelomer foams. Studies show ECF-based AFFF is a primary source of PFAS at AFFF-impacted sites, likely due to the longer period of ECF-based AFFF use and the relative coincidence of implementation of engineering controls for releases with increased use of fluorotelomer-based AFFF (**CONCAWE 2016**; **Anderson et al. 2016**).

To further classify AFFF products in terms of current usage and environmental considerations, they can be divided into three categories, including legacy PFOS AFFF, legacy fluorotelomer AFFF, and modern fluorotelomer AFFF (as shown in **Figure 3-2**).

- Legacy PFOS AFFFs were created in the 1960s by 3M and manufactured in the United States from the late 1960s until 2002 exclusively by 3M and sold under the brand name “Light Water” (**USDOD 2014**). 3M was the sole supplier from the mid-1960s until 1973. 3M did license some companies overseas to use their products and formulations. Legacy PFOS AFFFs contain PFOS and PFSAs such as perfluorohexane sulfonate (PFHxS) (**Backe, Day, and Field 2013**). Although

phased out of production in 2002, legacy PFOS AFFFs are the dominant source of PFAS at AFFF-impacted sites (**CONCAWE 2016**). Furthermore, because of its long shelf life, stock of legacy PFOS AFFF could exist at any given fire department today.

- Legacy fluorotelomer AFFF were manufactured and sold in the United States from the 1970s until 2016 and encompass all other brands of AFFF besides 3M Light Water or their licensed products (**Schultz et al. 2006**). Specifically from 1973 onward, several manufacturers created fluorotelomer-based AFFFs that met the Mil-Spec criteria. Although they are not made with PFOA, they contain polyfluorinated precursors (**Backe, Day, and Field 2013**; **Place and Field 2012**) that are known to transform to PFCAs, including PFOA (**Weiner et al. 2013**; **Harding-Marjanovic et al. 2015**).

Modern fluorotelomer AFFF became the predominant foam as users transitioned from legacy foams starting in 2006 through 2015 in response to the USEPA 2010/2015 voluntary PFOA Stewardship Program (**USEPA 2018**). By 2015, foam manufacturers transitioned to the production of only short-chain (C6) fluorotelomer-based fluorosurfactants. These modern fluorotelomer AFFFs, or "C6 foams," do not contain or break down in the environment to PFOS or PFOA and are currently considered to be less toxic and have reduced bioaccumulative potential compared to long-chain (C8) fluorosurfactants. But under particular environmental conditions, breakdown products of C6 foams can include PFHxA, PFPeA, and 5:3 FTCA (**Kempisty, Xing, and Racz 2018**). Modern fluorotelomer AFFF may contain smaller levels of PFOA as an unintended manufacturing impurity or byproduct.

Fluorotelomer foams, short-chain fluorotelomer foams, and C6 foams are analogous and will be referred to as "modern fluorotelomer foams." When discussing legacy PFOS or C8 foams, the term "legacy foams" will include both legacy PFOS AFFF and legacy fluorotelomer AFFF.

Legacy foams were first introduced by the naval firefighting services in 1964 (**Gipe and Peterson 1972**). The U.S. Naval Research Laboratory (NRL) began research on the development of firefighting foams in the 1960s. This led to advancements in fire suppression performance and increased firefighting safety (**US Naval Research Laboratory 2017**). In 1969, the U.S. Department of Defense (USDOD) issued military specification MIL-F-24385, which dictates the performance of all AFFF (with performance standards referred to as "Mil-Spec"). AFFFs shown to perform to MIL-F-24385 requirements are listed on the U.S. military's AFFF Qualified Product Listing (QPL). The first date AFFF was placed on this list was May 15, 1970 (MIL-F-24385 QPL/QPD History of Type 6 AFFF). DOD maintains the online qualified products database (QPD) that lists all AFFF agents that have been tested and qualified by the NRL to meet the Mil-Spec, currently referenced as MIL-PRF-24385, (**USDOD 2018**). On July 1, 2006, the Federal Aviation Administration (FAA) required that commercial airports certified under 14 CFR Part 139 purchase only AFFF that is Mil-Spec compliant (**FAA 2016**; 14 CFR 139.317). The FAA Reauthorization Act modified that requirement. In January 2023, the performance specification for F3 land-based, freshwater applications was released as MIL-PRF-32725. This latest specification requires manufacturers to certify that PFAS has not been intentionally added to the formulation and that the concentrate contains a maximum of 1 ppb of unintentionally-added PFAS (**USDOD 2023**). More information can be found in **Section 3.12.3**.

Different types of AFFF were produced to meet firefighting specifications, such as Mil-Spec, rather than formulated to contain a specified mixture of PFAS. AFFFs are a complex mixture of both known and unidentified PFAS. Multiple AFFF formulations have been produced over the years, and the exact composition of any given AFFF used or manufactured in any given year is variable (**Backe, Day, and Field 2013**). However, due to the production methods, any given AFFF formulation contains complex mixtures of PFAS, many of which can be identified only by nontargeted analytical methods (**Barzen-Hanson et al. 2017**) (see **Section 11** for information about analytical methods).

AFFF is typically formed by combining hydrocarbon surfactants, organic solvents, fluorosurfactants, polymers, and other additives (**Kempisty, Xing, and Racz 2018**). AFFF concentrates are commercially

available in 1%, 3%, and 6%. **Figure 3-3** illustrates the typical composition of a 3% AFFF concentrate; estimates are that water/diluent makes up more than 60% of the concentrate, up to 20% is solvents, and as much as 15-18% is surfactants, of which less than 2% is fluorosurfactants. When the concentrate is mixed with water, the resulting solution achieves the interfacial tension characteristics needed to produce an aqueous film that spreads across the surface of a hydrocarbon fuel to extinguish the flame or reduce the hydrocarbon vapors. This is a general estimate and composition can vary.

Figure 3-3. Typical composition of 3% AFFF concentrate.

3.2 AFFF Characteristics

As sectors and industries continue to transition from fluorinated foams to F3s and investigation and remediation activities related to AFFF continue, an understanding of current and historical AFFF products is an invaluable asset to identify and delineate potential sources. This includes, where available:

- whether an AFFF product is/was considered a modern or legacy foam and if it is/was manufactured using fluorotelomerization or electrochemical fluorination
- when an AFFF product is/was approved for use and for what specific use/application and to what specific performance standard(s)
- any other pertinent and available information on the product (for example, compatibility, composition information, equipment requirements)

Table 3-1 provided as a separate Excel file, includes the above information for specific AFFF products. The Priority Topics for Firefighting Foams include information about recent studies of firefighting foam ecotoxicity (see **Section 1.2.2**).

Some research has been conducted to specifically characterize AFFF formulations in both legacy and modern foams. **Barzen-Hanson et al. (2017)** presented information about AFFF composition over time. **Field et al. (2017)** summarized information on the commercial formulations approved for use by the DOD in a document, "FAQs regarding PFAS associated with AFFF use at U.S. military sites." **Shojaei et al. (2022)** characterized PFAS composition in Buckeye Platinum Plus C6 3% MS-AFFF (i.e., Platinum Plus C6) using targeted analysis, total oxidizable precursor assay (TOP), suspect screening, and nontargeted analysis. Results show that the sum of PFAS identified during target analysis comprised only 0.2 percent of total PFAS. 6:2 FTS and PFHxA were the most abundant target PFAS among the 12 monitored target PFAS. Suspect screening identified seven PFAS in six classes, which were largely comprised of C6 FT-based precursors (>99%). The most prevalent class was n:2 FTSAPr-DiMeAn, which may be a byproduct of fluorotelomer betaine synthesis. Nontarget analysis identified ten PFAS within nine classes of n:2 fluorotelomer sulfonamides, with 6:2 FTSAPr-AmHOPrS (CASRN 76201-56-4) being the most prevalent PFAS. PFAS composition of Platinum Plus C6 is different from the older Premium 3MS reported by Han et al. (**2021**).

ECF-based AFFFs contained primarily C6–C8 perfluoroalkyl sulfonates, with some zwitterionic C4–C6 perfluoroalkyl sulfonamides (FASAs) containing carboxylic acid and tertiary amine functionalities. Fluorotelomer-based AFFF formulations normally contained fluorotelomer thioamidosulfonates (FtTAoS) (4:2, 6:2 and 8:2) with 6:2 FtTAoS as the dominant compound, and very low perfluoroalkyl sulfonates or carboxylates (**Backe, Day and Field 2013**).

Some legacy nonfluorinated foams, notably those that are protein-based, form thick, viscous foam blankets on liquid hydrocarbon fuel surfaces. These foams are typically referred to as mechanical foams. These foams extinguish fires using strong bubble structure to smother the fire as opposed to the film and bubble structure of AFFF. More recent F3s are similar to the legacy protein foams in that they rely solely on the foam blanket to contain the fuel vapors to extinguish the fire (F3s do not produce a surfactant film on the fuel surface like AFFF). As a result, air-aspirating discharge devices may be required to optimize the capabilities of these products (**NFPA Research Foundation 2022**).

Many of the commercially available F3s have been tested to, and or listed/approved to, the legacy foam test protocols. These protocols include but are not limited to Underwriters Laboratories (UL), Factory Mutual (FM), European Standards (abbreviated EN), and International Civil Aviation Organization (ICAO) standards (**NFPA Research Foundation 2022**).

3.3 Mechanisms for Release to the Environment

Firefighting foam is applied by mixing foam concentrate and water to make the firefighting foam solution, which typically contains less than a fraction of a percent of fluorinated surfactants once in mixture. When applied to a fire, the foam solution is aerated at the nozzle, yielding finished firefighting foam. Thousands of gallons of foam solution may be applied during a given event. **Figure 3-4** illustrates the use of firefighting foam, how it may be released to the environment, and potentially affected media. Once released to the environment, AFFF can contaminate soil, surface water, sediment, and groundwater. **Section 5** includes details and references for fate and transport of PFAS in the environment.

Firefighting foams are released into the environment through various practices and mechanisms (**Anderson et al. 2016**; **Hale 2016**; **Thalheimer et al. 2017**) such as:

- low-volume releases of foam concentrate during storage, transfer, or operational requirements that mandate periodic equipment calibration
- moderate-volume discharge of foam solution for apparatus testing and episodic discharge of AFFF-containing fire suppression systems within large aircraft hangars and buildings
- occasional, high-volume, broadcast discharge of foam solution for firefighting and fire suppression/prevention for emergency response
- periodic, high-volume, broadcast discharge for fire training
- accidental leaks from foam distribution piping between storage and pumping locations, and from storage tanks and railcars.

AFFF-impacted sites often are also contaminated with petroleum hydrocarbons from unburned fuel. PFAS and hydrocarbon plumes at these sites may follow the same flow paths, though the extent of contamination may be significantly different. These co-contaminants, particularly light nonaqueous phase liquids (LNAPLs), may affect the fate and transport of AFFF-derived PFAS (**Guelfo and Higgins 2013**; **Lipson, Raine, and Webb 2013**; **McKenzie et al. 2016**), see **Section 5.2.5**. Certain air-based or in situ oxidation remedial activities aimed at treating co-contaminants may affect PFAS composition, fate, and transport as well (**McKenzie et al. 2015**). Additionally, the altered soil and groundwater geochemistry and redox conditions may result in oxidation of some PFAS precursor compounds, degrading them to terminal PFAAs (**Harding-Marjanovic et al. 2016**; **McKenzie et al. 2016**; **McGuire et al. 2014**). For additional detail on transformations of precursors see **Section 5.4** and **Section 10.4.6**.

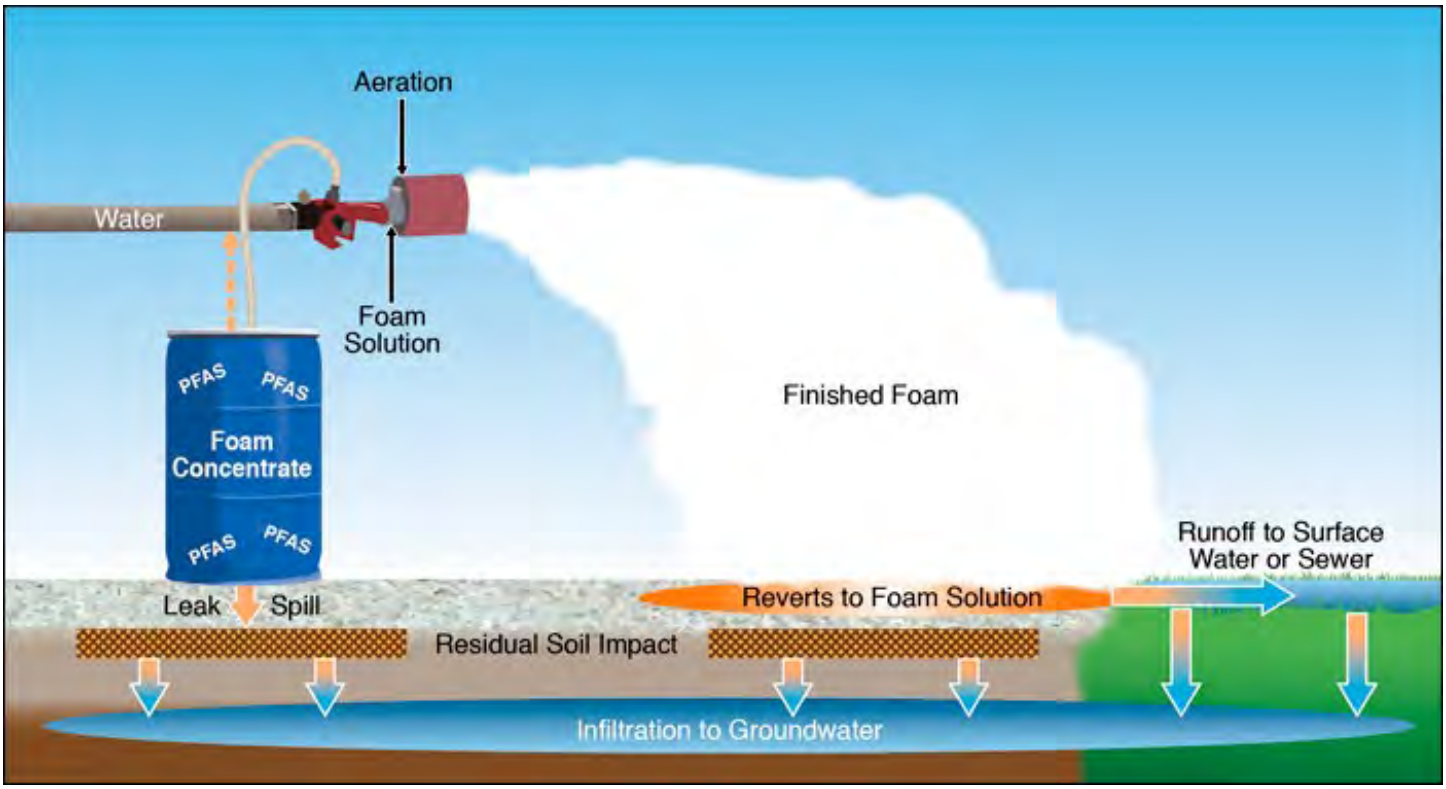

Figure 3-4. Release of firefighting foam.

Source: Adapted from figure by J. Hale, Kleinfelder. Used with permission.

The USDOD has undertaken an evaluation of potential firefighting foam contamination at its facilities nationwide (**Anderson et al. 2016**). Similar efforts have been undertaken by some states. For example, the Minnesota Pollution Control Agency (MPCA) conducted a statewide survey of firefighting foam use at training sites. Working with the State Fire Chiefs Association, the MPCA identified more than two dozen locations where Class B foams were likely used in firefighting training (**Antea Group 2011**).

Figure 2-21 illustrates common elements of CSMs associated with the potential AFFF release scenarios at fire training areas.

3.4 AFFF Fate and Transport

3.4.1 Physical and Chemical Characteristics

Factors that affect fate and transport of PFAS from AFFF releases, as concentrate or in mixture with water, include the chain lengths of the PFAS, their ionic states, the type of functional group(s), and the extent of fluorination. These factors strongly influence the extent of PFAS partitioning and transformation that occurs in the environment. The distribution and composition of legacy PFOS AFFF and legacy and modern fluorotelomer AFFF differ in the environment based on their different chemical constituents and physical and chemical properties (**MPART 2020**). It is important to consider any precursor PFAS that can transform to PFAAs over time and add to concentrations of known PFAAs in the environment, such as PFOS and PFOA. The relatively high solubilities of most PFAS in AFFF contribute to their migration rates in groundwater. Current published data and physical properties of PFAS differ and some chemical data are experimental, extrapolated, or modeled. **Section 4** summarizes some of the available physical and

chemical properties for PFAS. Tabulated values and references are included in Table 4-1 (provided as a separate Excel file).

3.4.2 Fate and Transport Processes

Fate and transport process information is used to address questions related to potential risk, conceptual site model (CSM), and treatment of PFAS. The mechanisms of partitioning, transport, and transformation of PFAS, which occur across different environmental media, are summarized in **Table 3-2** below. **Section 5** provides the detailed discussion and references.

Table 3-2. Fate and transport process considerations.

Fate and Transport Process	Description	Role in Transport
Partitioning Refer to **Section 5.2**	• Competition between hydrophobic and lipophobic C-F "tail" and nonfluorinated polar and hydrophilic head groups causes partitioning to interfaces such as: soil/water water/air water/NAPL co-contaminants	• Controls distribution in environment • Preference for air-water interface influences aerosol transport and deposition, and vadose zone transport (unsaturated conditions provide significant air water interfacial area)
Advection, Diffusion, Dispersion Refer to Sections **5.3**, **10.4**	• PFAS dispersion in groundwater is slow but greater in air and surface water • Atmospheric transport, e.g., from AFFF applications, results in deposition to soil/surface water/surfaces • PFAS are mobilized from soil to groundwater or to surface water through runoff and leaching	• Facilitate transport of PFAS in and across media • Increase contaminant distribution. Research on the potential impacts of diffusion on PFAS persistence in natural soils is ongoing. **Adamson et al. (2020)** conducted a study that estimated the relative distribution of different PFAS between high and low permeability soils at AFFF fire training area
Abiotic Transformation Refer to **Section 5.4.4.1**	• Abiotic processes that can transform precursors under ambient environmental conditions include hydrolysis, photolysis, and oxidation	• Results in chemicals with different physical and chemical properties • May alter risk • May affect treatment selection
Biotic Transformation Refer to Sections **5.4.4.2** and **5.4.4.3**	• PFOA, PFOS, and other PFAAs are resistant to microbial degradation • Biotransformation of various precursors has been reported	• Results in chemicals with different physical and chemical properties • May alter risk • May affect treatment selection

3.4.3 Fate and Transport Considerations for AFFF Remediation

Knowledge of the type of AFFF and the constituents released to the environment is critical for adequate site characterization and CSM development. Physical and chemical properties and environmental processes play key roles in identifying contaminant capture and collection methods and selection of treatment technologies. The effects of co-contaminants, such as petroleum hydrocarbons, on fate and transport of AFFF constituents is addressed in **Section 3.3** and partitioning into NAPL co-contaminants is addressed in **Section 5.2.5**. Many traditional technologies, such as air stripping and soil vacuum

extraction, which rely on volatilization, have been found to be ineffective for PFAS, which typically have low volatilities and are highly soluble. The stability and persistent nature of PFAS in the environment also make current bioremediation approaches ineffective.

Proven and developing treatment technologies for treatment of PFAS are presented in **Section 12**, which also includes details on the roles of physical and chemical characteristics and transport processes in technology selection. For example, water treatment technologies, such as GAC adsorption and ion exchange, have been proven to be effective because they rely on the hydrophobic and ionic properties of PFAS. Field-implemented technologies for soil include excavation and landfill disposal or mixing with sorbent for stabilization. The potential for leaching associated with disposal is reduced by stabilization. Many new technologies that rely on the unique properties of PFAS are under development.

3.5 Forensic Analysis of AFFF

Forensic analysis of AFFFs should be based on fingerprinting the composition of unknown samples and comparison with published fingerprints that are further discussed in this section. Many limitations must be considered in such investigations, including the changes in original manufactured product fingerprint due to precursor transformation through time, potential presence of impurities due to manufacturing processes and/or equipment used, and differences in original fingerprints for distinct manufactured batches. While there are tests that may be performed to help understand and overcome some of these limitations, every case should be based on site-specific data and historical information. For example, total oxidizable precursors (TOP) analysis may be performed to evaluate the changes in original AFFF fingerprints due to precursor transformations through time and the data should be interpreted within site-specific context considering potential deviations due to site-specific conditions. The fingerprint of AFFF products stored for long periods of time may have changed from the original PFAS fingerprint even if those products were not released and exposed to environmental conditions. Therefore, when trying to identify the type and original composition of AFFF products, multiple lines of evidence should be employed, including historical information, chemical fingerprinting via targeted PFAS analysis, TOP analysis, and total organic fluoride (TOF) content. Ultimately, nontargeted PFAS analysis may also be employed for in-depth evaluations and matching of foams with suspected sources. More information on these specific tests is provided in **Section 10.5** and **Section 11**.

Although many types of PFAS are identified in the AFFF formulations, due to the lack of analytical standards, quantitative information is not available for all identified individual PFAS, whereas qualitative detections and area counts are reported (**D'Agostino and Mabury 2014**; **Barzen-Hanson et al. 2017**; **D'Agostino and Mabury 2017**; **Ruyle et al. 2021**). There is quantitative information on the composition of a series of AFFF formulations manufactured in different years by several manufacturers, including 3M, ChemGuard, Ansul, Buckeye, and National Foam (**Annunziato et al. 2020**; **Houtz et al. 2013**; **Backe, Day, and Field 2013**; **Ruyle et al. 2021**; **Herzke, Posner, and Olsson 2009**; **KEMI, 2015**). The chemistry of AFFF is complex, consisting of anionic, cationic, zwitterionic, and neutral compounds; in addition, different formulations of AFFF from the same manufacturer may also vary in chemistries (**Backe, Day, and Field 2013**; **Houtz et al. 2013**; **Barzen-Hanson et al. 2017**). AFFF includes many fluorinated and nonfluorinated surfactants. Total surfactants are thought to range from approximately 15 to 18 percent. Some references cite about 5–10% (w/w) are nonfluorinated surfactants and 0.9–1.5% (w/w) are PFAS (**Backe, Day, and Field 2013**; **D'Agostino and Mabury 2014**). These nonfluorinated surfactants have also been detected in the AFFF-impacted groundwater (**García et al. 2019**). For forensic analysis, evaluating the source attribution of PFAS from AFFF used for emergency response or fire training operations and understanding the manufacturing history, timing of release, potential sources, degradation products, isomer profiles, and environmental partitioning of PFAS during transport are very important (**Dasu et al. 2022**; **Guelfo et al. 2021**; **Dorrance et al. 2017**).

3.5.1 Manufacturing and Chemistry

PFAS are commonly produced by two manufacturing processes: electrochemical fluorination (ECF) and fluorotelomerization. For example, legacy 3M AFFF brand name Light Water was manufactured by electrochemical fluorination, and the legacy longer chain and the new replacement shorter chain (C6) fluorotelomer-based AFFFs are manufactured by the fluorotelomerization process. More detailed information on these processes is presented in **Section 2.2.5**, and more detailed information on AFFF as it relates to these processes is presented in **Section 3.1**. Despite the recorded differences and complex composition of AFFF products, several general traits have been established in the literature based for each manufacturing processes and the final products and byproducts formed by using these two processes are different.

The ECF process results in a mixture of linear and branched fluorinated molecules of various carbon chain lengths, both even and odd carbon chains (**Buck et al. 2011**). The ratio of linear and branched isomers ranges from 70 to 80% linear and 20 to 30% branched isomers (**Kissa 2001**; **Buck et al. 2011**; **Benskin et al. 2007**). The ECF process produces varying amounts of C2–C10 PFAAs (**Backe, Day, and Field 2013**). Some of the ECF chemistries are based on perfluorooctane sulfonyl fluoride (POSF), a major raw material used to manufacture surfactants (such as perfluorooctane sulfonate (PFOS)), and other raw materials such as sulfonamides, sulfonamido alcohols, and related monomers (**Backe, Day, and Field 2013**; **D'Agostino and Mabury 2014**; **Buck et al. 2011**).

The other important manufacturing process of PFAS is the telomerization process, which mainly produces linear isomers with an even number of carbon chains as the major products, although some odd-numbered carbon chains have also been produced (**Kissa 2001**). The nomenclature of PFAS manufactured by the telomerization process includes n:2 fluorotelomers (see **Section 2.2.4.1**), where n represents the perfluorinated carbon chain length and 2 represents the nonfluorinated ethane attached to the functional group, such as alcohols, carboxylates, sulfonates, etc. (**Buck et al. 2011**). Fluorotelomers (FT) are predominantly produced in 4:2-, 6:2-, 8:2-, and 10:2-carbon chain lengths, although 12:2 has been seen in FT Mil-Spec AFFF (**Backe, Day, and Field 2013**). Fluorotelomer alcohols or iodides are commonly used as raw materials in the telomerization process to produce fluorotelomer sidechain polymers. At many of the AFFF-impacted sites, perfluorooctanoic acid (PFOA), PFOS, and perfluorohexane sulfonic acid (PFHxS) are the most prevalent PFAS detected. The phaseout of the longer chain PFAS by global manufacturers has resulted in quantifiable increase in shorter-chain concentrations and decreased concentrations of longer chains at some of the areas investigated (**Ruyle et al. 2021**).

3.5.1.1 Reported PFAS Profiles in AFFFs Manufactured Via ECF vs. Telomerization.

In spite of the recorded differences and complex composition of AFFFs, several main traits may be established among AFFFs manufactured by each mentioned process based on the literature-reported data (**Annunziato et al. 2020**; **Houtz et al. 2013**; **Backe, Day, and Field 2013**; **Ruyle et al. 2021**; **Herzke, Posner, and Olsson 2009**; **KEMI 2015**). These traits provide the basis for chemical fingerprinting of PFAS in AFFFs and environmental media.

AFFFs manufactured via ECF process (by 3M) are reported to contain both precursor PFAS (including: PFBSAm, PFPeS-Am, PFBS-AmA, PFPeS-AmA, and PFHxS-AmA) and PFSAs (which are typically predominant) and PFCAs. The AFFFs manufactured via fluorotelomerization process are reported to contain mostly precursor PFAS, with some PFCAs also being reported in some of these AFFFs (**Ruyle et al. 2021**). Upon oxidation (for example, transformation of precursor PFAS in time and due to exposure to environmental conditions), both main types of AFFFs generate PFCAs with distinct profiles described below.

- The profiles of PFCAs in ECF-manufactured AFFFs after oxidation are consistent among various manufactured batches and years and are different from the profiles reported before oxidation.

The oxidized ECF-manufactured AFFFs PFCA profiles should be more representative for environmental profiles of spilled AFFFs and have the following common traits: the predominance of PFHxA (61–75%), followed by PFBA (12–26%), and PFPeA (2–25%) (**Houtz et al. 2013**). Smaller amounts of PFOA and PFHpA are also reported in these oxidized foams.

- The profiles of PFCAs in AFFFs manufactured by telomerization generated after AFFF oxidation have several common traits among manufacturers (for example, Chemguard, Ansul, Buckeye, National Foam), which seem to be preserved along the years. These traits include the predominance of PFPeA (25–49%), followed by PFBA (19–28%), PFHxA (13–20%), and PFHpA (3–20%), and the presence of smaller amounts of PFOA (1–9%) and PFNA (1–4%) (**Houtz et al. 2013**).

- The profiles of PFSAs in manufactured (nonoxidized) AFFFs are preserved among ECF-manufactured AFFFs from different years (1988, 1989, 1992, 1993, 1998, 1999, 2001), including batches from the same years, as reported by **Houtz et al. (2013)**. The PFAS profiles of 3M-manufactured AFFFs are consistent in the strong predominance of PFOS (85–90%), followed by PFHxS (7–12%), with smaller amounts of PFHpS and PFBS also detected. Similar profiles are reported by **Backe, Day, and Field (2013)** and by **Ruyle et al. (2021)**, with the addition of PFPeS detected in small amounts.

- The profiles of PFCAs in manufactured AFFFs (non-oxidized) vary more among the reported manufactured batches and years than in the case of the PFAS profiles mentioned before. Despite these variations, several traits can be observed: In some of the analyzed AFFFs manufactured by ECF (**Houtz et al. 2013**), PFPeA predominates, followed by PFHxA and PFOA, while in ECF-manufactured AFFFs analyzed by other authors, these proportions change to some extent with the predominance of PFHxA and PFOA, and with smaller amounts of PFPeA, PFBA, and PFHpA also reported (for example, see data reported by **Backe, Day, and Field 2013**, **Annunziato et al. 2020**, and **Ruyle et al. 2021**).

In AFFFs manufactured by telomerization, only a few had PFCAs detected before oxidation and the profiles were quite variable, as reported by **Ruyle et al. (2021)**, with the predominance of PFHxA and PFBA in many analyzed foams, and the predominance of PFHpA, PFOA, and PFNA in few other foams. In several different analyzed foams, **Herzke, Posner, and Olsson 2009** reported the predominance of PFHxA and PFPeA, followed by PFOA and PFBA, with PFDcA (at comparable amounts with PFBA) reported in one foam, while smaller amounts of PFDoA were reported in another foam.

Benotti et al. (2020) reported PFAS profiles for several FT-manufactured modern AFFFs, consistent with those described here and reported by other authors mentioned before (for example, **Herzke, Posner, and Olsson 2009**), consisting predominantly of 6:2 FTS among detected precursor PFAS and PFHxA among detected PFCAs. Additionally, the **Benotti et al. (2020)** study pointed out the predominance of even-numbered PFCAs (PFBA, PFHxA) over their odd-numbered homologues in AFFFs manufactured via telomerization. Notably, this study also pointed out the presence of smaller amounts of long-chain PFCAs (including PFOA, PFDA, PFDoA) and PFSAs (PFHxS and PFOS) in the modern AFFFs that were analyzed. The authors attributed these findings to the manufacturing process from fractional distillation of feedstock or to cross-contamination during manufacturing and handling.

3.5.2 Factors Affecting the PFAS Fate and Fractionation

PFAS forensic analysis of environmental samples is often challenging as many of the PFAS-contaminated sites consist of comingled sources. Many of the AFFF-impacted sites often contain a mix of different formulations of AFFF, either from the same manufacturing source (ECF or telomer-based), or a mix of different sources. Many of the PFAS analytes exhibit a wide range of physical and chemical properties, and hence are transported from the source zones and redistributed downstream through

environmental fractionation (**Lindstrom et al. 2011**; **McGuire et al. 2014**). Higher water solubility and mobility of short-chain PFAS contribute to the relatively high concentrations of short-chain PFAAs in aqueous matrices downstream from the source areas. The isomer profiles present at the source of contamination will change and redistribute after a certain distance from the source (**Adamson et al. 2020**; **Nickerson et al. 2021**). Due to the high solid/water distribution coefficient (K_d), longer chain PFAS have a greater affinity than shorter chain PFAS to partition to sediments, sludge, and soils (**Higgins and Luthy 2006**; **Kwadijk, Korytár, and Koelmans 2010**; **Schulz, Silva, and Klaper 2020**). PFAS, due to their electrostatic nature, may also adsorb onto soils due to the soils' electrostatically charged surfaces (**Adamson et al. 2020**). Groundwater transport of PFAAs depends on the concentration, chain length, soil characteristics, partitioning behavior, and in situ precursor biotransformation followed by the redistribution of the transformation products (**Guelfo and Higgins 2013**; **McGuire et al. 2014**; **Anderson et al. 2016**). Additionally, the presence of co-contaminants and/or remediation products in the subsurface may also affect PFAS fate and transport (**Guelfo and Higgins 2013**; **McKenzie et al. 2015**; **Brusseau 2018**; **Hatton et al. 2018**) and should be considered in a forensic investigation.

All these factors indicate that the PFAS fingerprint at the source could be different compared to the downstream sample locations. Hence, forensic analysis of such complex AFFF-impacted comingled sources would require consideration of many factors and multiple lines of evidence to better understand the identification and delineation of sources. These include: (1) PFAS profiles, including PFCAs and PFSAs isomer profiles and chain-length ratios, which may differ from source, based on the environmental fractionation; (2) unique source-specific markers, which require a detailed understanding of known sources to identify a source related to a sample (**McGuire et al. 2014**; **KEMI 2015**; **Guelfo and Adamson 2018**); and (3) high-resolution mass spectrometry (HRMS) tools to help identify and characterize a broad suite of PFAS analytes to understand the source-specific markers (**D'Agostino and Mabury 2014**; **Barzen-Hanson et al. 2017**; **D'Agostino and Mabury 2017**; **Newton et al. 2017**; **Ruyle et al. 2021**). In addition to HRMS analysis, application of statistical analysis tools showed great promise in identifying sources of PFAS contamination (**Zhang et al. 2016**; **Kibbey, Jabrzemski, and O'Carroll 2020**; **Nason et al. 2021**). However, statistical analysis of any PFAS data sets should be done with caution, considering comparability between data sets in terms of sampling and analytical techniques used, as well as environmental transformations expected based on sample location and site-specific parameters. A forensic approach based on multiple independent lines of evidence increases certainty. Examples of lines of evidence that may be developed for PFAS forensic evaluation include chemical profiles of PFCAs and PFSAs, isomer profiles, signature PFAS (for example, via nontargeted analysis), historical document review, and fate and transport evaluation and modeling (see also Sections **4**, **5**, **10**, and **11**).

3.5.3 Summary of Forensic Analysis of AFFF

Employing a lines of evidence approach to identify what AFFF product or products have been used at a particular site is a useful first step during site assessment. The identification of products may help the practitioner to predict what PFAS compounds may be present, including likely precursors and degradation products. Understanding product use will improve site conceptual model development at the outset. Lines of evidence that may be used to identify AFFF products include interviews with site users, bills of lading or procurement records, and finally, analysis of environmental samples. Foam product groups (for example, legacy ECF-manufactured AFFFs, legacy fluorotelomer AFFFs, and modern AFFFs) differ in key ways as presented below.

The proprietary nature of source information, complex PFAS chemistry, and lack of analytical standards pose many challenges in understanding the source identification (see also **Section 10.5** and **Section 11.4**) and attribution at AFFF-impacted sites. Using only targeted PFAS analysis may be useful, since several common traits are evident in AFFFs and may help differentiate between AFFFs and other types of PFAS sources. However, differentiation between multiple AFFF sources may become more difficult based just on targeted analysis data (for example, PFCA and PFSA data), especially for comingled plumes away from the source area where environmental fractionation may play an important role. Nontargeted analysis

using HRMS helps in understanding the chemistry beyond the standard targeted analysis data and shows great promise in identifying and delineating PFAS contamination; however, HRMS is still a relatively new and developing tool and its results should be interpreted carefully in the context of the specific investigation. Considering multiple lines of evidence while conducting forensic investigations helps to identify PFAS source attribution and manage AFFF-impacted sites.

A series of recent publications provide data and information relevant to AFFF source evaluation, as synthesized below:

- AFFF fingerprints seem to be preserved in fish from polluted freshwater systems and were used to differentiate AFFF versus other PFAS sources in fish, namely the paper industry and long-range atmospheric transport (**Langberg et al. 2022**). Specifically, a total of 454 liver samples and 581 muscle samples from 11 fish species were investigated. The fish samples from AFFF-polluted sites had a predominance of PFOS, suggestive of legacy ECF-manufactured AFFFs. High percentages of PFOS were also observed in fish samples contaminated from the paper industry, but the PFCA profiles were distinct from those in fish contaminated by AFFFs. In fact, the profiles of PFCAs were distinct between AFFFs and the other PFAS sources (paper industry and long-range atmospheric transport). The PFCAs profiles in fish from waters contaminated from the paper industry and via long-range atmospheric transport had higher percentages of long-chain PFCAs, as compared with those from fish in waters contaminated by AFFFs. Additionally, PFUnDA/PFDA and PFTrDA/PFDoDA ratios were different between the two non-AFFF sources, being higher in the case of long-term atmospheric transport.

- **Dasu et al. (2022)** performed a comprehensive review of PFAS concentration profiles from both main direct (fluorochemical manufacturing plants, consumer products, metal-plating operations, AFFF use) and indirect sources (landfills and wastewater treatment plants). They found that both groundwater and soil at or near AFFF-contaminated sites had higher median PFOA and PFOS concentrations as compared to those from groundwater and soils near the other main studied sources. **Dasu et al. (2022)** pointed out the potential for environmental transformation of many unknown PFAS present in AFFF into persistent PFAS, acting as long-term PFAS sources. From a fingerprinting perspective, the study indicates that the commonly analyzed PFAS compounds are ubiquitously detected in environments contaminated by distinct main sources, pointing out the need for high-resolution tools such as nontargeted analysis and combined methods of total fluorine and/or extractable fluorine for better source attribution of PFAS. However, **Dasu et al. (2022)** did not include an analysis of the relative proportions of individual PFAS compounds in media contaminated by different sources, which could have forensic relevance.

- The high precision methods used by **Liu et al. (2022)** in analyzing PFAS-contaminated soil and groundwater at four Canadian airports, consisting of HRMS and an improved total oxidizable precursor (TOP) assay, may be of high utility in forensic applications. Based on these analytical techniques, 93 classes of PFAS could be investigated and characterized at these Canadian airports.

- A comprehensive study of PFAS in surface water near U.S. Air Force bases (**East, Anderson, and Salice 2021**) determined that, according to the legacy AFFF composition, a four-chemical mixture composed of PFOS, PFHxS, PFHxA, and PFOA generally accounted for >80% of the sum of all routinely reported PFAS in a sample. This observation is relevant in building AFFF-representative PFAS fingerprints.

- The predominance (90%) of 6:2 fluorotelomer sulfonate in modern AFFFs has been confirmed by **Ruyle et al. (2021)**, who developed and applied a “novel method (Bayesian inference) for reconstructing the fluorinated chain lengths, manufacturing origin, and concentrations of oxidizable precursors obtained from the total oxidizable precursor (TOP) assay” (**Ruyle et al.**

2021). These authors were able to identify 14 major fluorotelomer compounds present in modern AFFF "yielding a priority list that accounts for almost all detectable PFAS in contemporary AFFF." Testing for these fluorotelomers may help differentiate between AFFF and non-AFFF sources of PFAS.

- **Kibbey, Jabrzemski, and O'Carroll (2020)** "explored the use of supervised machine learning classifiers for allocating the source of PFAS contamination based on patterns identified in component concentrations." "The deep neural network and Extra Trees exhibited particularly high performance at classification of samples from a range of sources, [showing that] patterns exist in PFAS water sample data that can allow forensic source allocation." While these methods are complex and evolving, they show promise for PFAS allocation at complex sites.

- **Shojaei et al. (2022)** provided useful data on the chemical composition of AFFFs currently certified for use by the U.S. military. These authors used several distinct analysis techniques, including targeted analysis by HRMS, TOP, and nontargeted analysis. The study identified nine novel classes of PFAS comprising 10 individual compounds that made up ~90% of total PFAS measured in the tested foam. The combination of TOP with nontargeted analysis holds great potential for PFAS source identification.

3.6 AFFF Procurement and Inventory

This section discusses procurement and inventory of AFFF, including suggestions for storing inventory to minimize the potential for accidental releases.

3.6.1 Foam Selection and Requirements

Multiple manufacturers in the United States and abroad produce AFFF concentrate in 1%, 3%, or 6% concentrations. Most AFFF sold or in stock in the United States is either 1) listed by Underwriters Laboratory (UL) based on conformance with UL Standard 162, "Foam Equipment and Liquid Concentrates," or 2) tested by NRL and granted qualification by U.S. Naval Sea Systems Command in accordance with the Mil-Spec. Only AFFF meeting the Mil-Spec has been used in military applications and at FAA-regulated airports.

Military and FAA AFFF applications subject to Mil-Spec account for more than 75% of AFFF used in the United States (Airport Cooperative Research Program **ACRP (2017)**). Hence, the production of AFFFs has historically been driven by firefighting specifications, such as Mil-Spec, which requires a specific percentage concentration of PFAS. Current Mil-Spec AFFFs contain ≤ 1% (approx. 0.5–0.6%) fluorosurfactants after the concentrate is mixed with water to create the final foam solution used to extinguish or prevent high-hazard flammable liquid fires; however, the exact AFFF PFAS mixtures are highly variable. Non-Mil-Spec Class B foams can vary from fluorine-free to having concentrations of PFAS similar to Mil-Spec AFFF. Furthermore, where fire risk allows it, users who are not subject to Mil-Spec requirements are less likely to use foam formulations that contain PFAS given the environmental implications and increasing prevalence of F3. However, the knowledge of environmental implications of PFAS was historically lacking and is still not widely understood by first responders, and there are many historical examples of AFFF use by municipal fire departments during fire response activities.

3.6.2 AFFF Storage and Handling

AFFF concentrate is available from the manufacturers in containers ranging from 5-gallon buckets to 5,000-gallon tanker trucks. The most common method of shipping is in 5-gallon buckets, 55-gallon drums, or 265-gallon intermediate bulk containers. Shipping containers are typically not double walled but made of plastic, steel, or steel reinforced plastic tote construction to resist damage/puncture. Per National Fire

Protection Association (NFPA) 11, Section 4.3.2.3, bulk liquid storage tanks should be fabricated from or be lined with materials compatible with the concentrate, designed to minimize evaporation of foam concentrate, and stored within the listed temperature limitations (**NFPA 2016**).

In fire suppression systems, the AFFF concentrate is typically stored in either an atmospheric (nonpressurized) tank or a bladder tank (pressurized). Atmospheric tanks are single- or double- walled tanks and can supply proportioning foam concentrate pumps or venturi-based proportioners that feed the suppression system. Atmospheric tank piping arrangements may include recirculation from downstream of the pump back to the tank. The bladder tanks contain a bladder filled with foam concentrate that is squeezed by water between the shell of the tank and the bladder. As long as the bladder integrity is maintained, the foam concentrate does not mix with the shell water.

Safety data sheets are provided by all manufacturers for each specific type of AFFF. Labels on shipping containers conform to U.S. Department of Transportation (USDOT) standards. AFFF and AFFF-impacted materials (soils and absorption materials), including concentrate being disposed, rinsate, and foam supply system materials, are not currently considered to be hazardous materials under federal regulations. Some individual states have passed legislation to include PFOS, PFOA, and other PFAS on their hazardous substances list and otherwise restrict the sale and use of AFFF (for example, (**Washington Senate 2018**) (**New York State 2017**). USEPA published the designation of PFOA and PFOS as CERCLA Hazardous Substances in May 2024 (**USEPA 2024**). Regulations are discussed further in **Section 3.12**

As with any potentially hazardous substance, the best practice for storage and handling is to ensure containment until proper disposal. AFFF materials should be labeled to clearly indicate the contents of the container. It is important that all containers are kept clean so that any signs of leakage can be easily and quickly identified during container inspections, with the labeling pointed outward for easier reading.

3.7 Foam Systems and Operations

Class B firefighting foams are employed globally to fight flammable liquids fires where risk of damage to property or human life is high. These products are particularly prevalent in airport settings. This section describes common AFFF system operations, including system testing and training. Additionally, information is provided in **Section 3.11** for organizations that want to replace legacy PFOS AFFF systems with modern fluorotelomer AFFF or F3.

3.7.1 Fixed System Testing

Fixed fire suppression systems that utilize any of the foam types and application methods are permanent designs and should incorporate the containment, collection, and runoff components in the event of system discharge into the design. Examples include flammable liquid warehouse, waste treatment facility, and aircraft hangar fire suppression systems. New systems should be designed to include foam containment and collection mechanisms such that foam releases that occur during testing or activation are not released to the environment, or the AFFF can be captured for disposal. AFFF design standards require minimum durations for foam system discharge to meet the suppression/control requirements and in some cases require specific volumes of concentrates and foam solution to be contained in on-site storage tanks. Fixed AFFF proportioning systems that are connected to city water mains should be fitted with backflow preventers to protect the city water mains from potential AFFF contamination.

Codes, standards, and authorities having jurisdiction over fixed system testing, such as NFPA Standards 16 (**NFPA 2019**) and 25 (**NFPA 2017**), can require that the equipment produce a foam/foam solution that can be tested and compared to laboratory standards. System testing generates a small amount of foam that should be contained or controlled by the design to the best extent possible for proper disposal. Foam

can be wetted with fog nozzles/mist to knock down the foam and dilute it. Gentle squeegee and sweeping are required to keep the solution from aspirating during cleanup and dilution. Alternatives, such as testing with water (without foam) or testing with fluorine-free training foam or surrogate liquids having similar physical properties, may be considered to minimize disposal issues. Check applicable regulatory requirements for testing to determine frequency and type of testing required, as well as what is specifically mandated for foam type before any alternatives are considered to ensure compliance with appropriate laws.

3.7.2 Mobile Firefighting Equipment Testing

Firefighting equipment requires inspection, calibration, and testing to ensure reliability and performance to specifications. In accordance with fire protection standards (for example, NFPA Standard 412, (**NFPA 2020**) and manufacturer's recommendations, the testing of mobile firefighting equipment should be conducted routinely and documented.

Multiple pieces of equipment can be tested or inspected simultaneously. Mobile equipment, including but not limited to mobile foam extinguishers, firefighting vehicles, and marine craft, can be collected, tested, and cleaned and foam concentrate samples can be collected in a single location to minimize potential impacts. It is recommended that testing of mobile firefighting equipment is executed at purpose-built facilities specifically designed to capture and contain all generated foam and wastewater for treatment, reuse, or disposal.

Conditions during equipment testing should include secondary containment measures to ensure foam solutions can be captured and managed and environmental impact minimized. Alternatives to traditional testing methods may be considered, such as:

- using water or surrogate solutions for training
- testing equipment indoors
- spraying into drums or other containers
- testing within lined pits or spill containment equipment
- testing with closed-loop AFFF testing systems to minimize and eliminate discharge (**FAA 2023**).

Other controls include not testing during adverse weather conditions, not testing where the facility is not deemed fit for purpose, conducting a risk assessment of the activity, and minimizing foam wastewater volume generated whenever possible. As with fixed fire suppression systems, mobile equipment that complies with NFPA Standard 412 requires that the equipment produce a foam/foam solution that can be tested and compared to laboratory-analyzed solutions (**NFPA 2020**).

3.7.3 Training Exercises

Facilities should have specifically designed areas and structures to conduct training exercises involving flammable liquid fires and foam systems. The fire training areas (FTAs) should be arranged to contain/control the training site for the safety of the persons being trained. Control of training fires as well as applied foam and/or foam solutions is maintained by the facility design. The FTA should also be designed for collection/recovery of unburned fuels as well as the foam solution and fire water following the completion of training exercises. Conducting outside exercises during windy weather conditions should be avoided, as the foam solutions can be difficult to contain due to natural aspiration and windblown transport.

Past training exercises at airports and military installations employed large quantities of foam/foam solutions. To prevent further releases to groundwater, USDOD issued a policy in January 2016 requiring prevention of "uncontrolled land-based AFFF releases during maintenance, testing, and training activities.

Current USDOD policies prohibit using AFFF with PFOS for testing, maintenance, or training exercises with the exception of shipboard activities.

Consider minimizing the volume of foam used to the greatest extent possible. If permitted by the applicable regulatory requirements for training, consider entirely discontinuing the practice of using expired legacy AFFF and modern fluorotelomer AFFF as training foam. Whenever possible, seek fluorine-free alternatives for training events; consider training with water or training foam where practicable, not Class B foam, and certainly not with Class B foam containing PFAS. Any wastewater or foam generated from training activities should be kept to a minimum and foam spraying should be restricted to target areas only (not sprayed over wide areas). Preplanning responses that deploy AFFF can identify weaknesses in both AFFF use strategies and in fuel and fire water runoff and containment. This can also identify the need for calling mutual aid early to assist with containment tactics.

Training protocols with F3s must be established. While F3 foam does not contain PFAS, some F3 foams may contain other additives or chemicals that could be harmful to the environment or human health. As such, any training involving F3s should also consider the mitigation measures established for AFFF.

3.8 Emergency Firefighting Operations

Fire response planning in advance can identify various options for firefighting and contingency planning for fire wastewater capture. Where possible and as setup allows, consider containing and recovering AFFF used for emergencies for disposal. Use mutual aid resources to assist with containing the fuel and fire water runoff should your department not have the resources available to fight the fire emergency and contain the runoff (**Section 3.7**). Although federal law currently does not prohibit the use of existing stocks of legacy AFFF, any discharge of foam containing PFAS to public waters can be considered a release of a "pollutant or contaminant" under the Comprehensive Environmental Response Compensation and Liability Act (CERCLA), 42 U.S. Code § 9601, and therefore may be subject to remediation requirements.

Emergency scenarios vary case by case. Industrial plant fire brigades and responding emergency crews utilize portable foam generators or monitor nozzles to apply foam to pooled flammable liquids (potential fires) or existing fires. In cases where the fire involves a fixed system, it is critical that an arrangement for containment/control of runoff is included in the design. The following are examples of how preplanning can better inform the use and containment of AFFF at an industrial facility:

Consideration should be given to parts of facilities not protected by the fixed foam system that could be subject to AFFF application in the event of an emergency incident and opportunity for containment of foam.

- Industrial processes have many components, and only portions of the process are protected by the fixed foam systems. For example, a scrubber, or filter found within industrial smokestacks, may be part of the process that is not protected by the foam system and may be outside the discharge area where design considerations have been made for containment/control. Emergency response units may be required to apply foam/water to the location of the scrubber, outside the planning boundaries, in the event the fire that originated in the process was conveyed to the scrubber unit.

- At oil refineries, F3 may be used for small incidents and fluorinated foam reserved for the large tank fires. Fluorine-free and new generation C6 foams have been tested in large-scale tests (involving up to 40 m foam travel requirements) and could be considered suitable for application to fires involving some tank sizes and the associated dike area fires. But firefighting foam use is rapidly evolving, and as such, those responsible for tank application foam selection should refer to the latest test results from any recognized independent source (for example, LASTFIRE) to determine whether F3 could meet the performance requirements.

- On some remote industrial sites, where no immediate threat to life or property exists, and given the additional resources necessary to manage the wastewater produced, the best response may be to let the fire burn instead of applying AFFF.

3.8.1 Best Management Practices (BMPs)

BMPs are key to the use of AFFF in the most environmentally responsible manner with the goal of minimizing risk from their use. It is important to establish BMPs prior to use in an emergency so that BMP equipment, procedures, and training are already in place. Although firefighting personnel may be aware that the foams they are using contain chemicals, they may not be aware of the potential environmental effects of AFFF use. Training of firefighting personnel is important to ensure BMPs are discussed and employed consistently and effectively.

Example BMPs, adapted from the Fire Fighting Foam Coalition (**FFFC 2016**) are summarized in **Table 3-3**. Table 3-3 also includes some information from Angus Fire (**2017**). Users should follow BMPs to protect themselves, others, and the environment when using AFFF and other foams. Further BMP guidance can be found in other documents, such as the Best Practice Guidance developed by the Fire Fighting Foam Coalition (**FFFC 2016**), and the **US National Fire Protection Association's NFPA 11 NFPA (2016)**. Users at DOD facilities have other BMPs to follow. Other industry associations such as American Petroleum Institute (API) have also issued BMPs (**API 2020**).

Other foams such as alcohol-resistant foams (AR-AFFF), film-forming fluoroprotein foams (FFFP), alcohol-resistant film-forming fluoroprotein foams (AR-FFFP), fluoroprotein foam (FP), and alcohol-resistant fluoroprotein foam (FPAR), as illustrated in Figure 3-2, also contain PFAS and similar precautions and considerations should be taken.

Section 3 provides supporting information for the BMPs presented in **Table 3-3**, as follows:

- Foam selection and storage are discussed in **Section 3.6** (AFFF Procurement and Inventory).
- Use is detailed in **Section 3.7** (Foam Systems and Operations).
- Planning and mitigation are covered in Sections **3.8** (Emergency Firefighting Operations) and **3.9** (Immediate Investigative and Cleanup Actions).
- Disposal is addressed in **Section 3.10** (AFFF Disposal).

Table 3-3 addresses current operating procedures for selection, storage, use, planning and mitigation. For complete change-out and transition from AFFF to fluorine-free across an entire system, detailed consideration should be made regarding performance, compatibility, decontamination, treatment, and disposal.

Table 3-3. BMPs for AFFF (and Other Foams) Selection, Storage, Use, Planning and Mitigation, and Disposal (adapted from FFFC 2016).

Life Cycle	BMP
Foam Selection	1. Public safety first. Use AFFF and other fluorinated Class B foams only in the following situations: • Class B liquid fires and/or spills with significant risks to public safety or of property loss, where specific extinguishing rates and burnback times are necessary • Facilities where AFFF is required until F3 replacement that meets Mil-Spec has been approved
	2. Evaluate whether Class B foam is needed for a specific hazard, or if an alternative product, such as an F3 can provide the needed level of protection. The proper agent to use for your hazard "must be evaluated well in advance of an emergency situation" (**FFFC 2016**).

Life Cycle	BMP
Storage	1. Develop a foam inventory and stock tracking system documenting foam composition, date of purchase, lot number, brand, and manufacturer.
	2. "Obtain and follow manufacturers' recommendations for foam concentrate and equipment" (**FFFC 2016**). The amount of foam in the system should be at least enough for the group of hazards that simultaneously need to be protected against.
	3. Designate transfer areas and store Class B foam concentrate (all foam, not only AFFF) in a covered area with secondary containment.
	4. Design storage tanks to minimize evaporation of concentrate. Label containers clearly to identify the type of concentrate and its intended concentration in solution. Keep foam within the temperature limitations provided by the manufacturer.
	5. Properly maintain foam systems to prevent accidental discharges. Conduct regular inspections of tanks, storage containers, and any associated piping and machinery. Any leaks of foam concentrate should be addressed immediately to minimize environmental impacts. Maintain records of accidental releases, including date, volume, and foam type. Be cognizant of state and local reporting requirements for releases.
	6. Corrosion is reported by some to generally not be an issue with foam concentrates, but exceptions exist. Check safety data sheets to evaluate corrosivity of your product. Manufacturers recommend stainless steel, high-density polyethylene (HDPE), or polypropylene containers for AFFF storage. Avoid using aluminum, galvanized metal, and zinc in storage tanks, piping, and handling equipment for foam concentrates (**Angus Fire 2017**).
	7. Ensure compatibility of foams per manufacturer specifications before change-outs. Do not mix different types or brands of foam concentrates unless all the foams are compatible. As an example, all foams that meet Mil-Spec 24385 are considered compatible.
Use	1. Consider the firefighter and public safety first.
	2. Eliminate the use of AFFF and other fluorinated "Class B foams for training and testing of foam systems and equipment" whenever possible. Instead, use specially designed nonfluorinated, PFAS-free "training foams available from most foam manufacturers." (**FFFC 2016**).Be aware that such training foams result in longer extinguishments and less burnback protection.
	3. If the authority having jurisdiction requires testing of equipment or training of firefighters using AFFF, training foams that do not contain fluorinated compounds are preferred and, in many cases, required. All foams, regardless of type, should be captured during training and testing.
	4. Evaluate firefighting strategy to determine if Class B foam is needed or if a Class A foam or just water can succeed in fighting the fire.
	5. Provide containment, treatment, and proper disposal of foam solution. Avoid direct release to the environment to the greatest extent possible.
	6. Collect, treat, and properly dispose of runoff/wastewater from training events or live fire events to the greatest extent possible. Prevent discharge to storm drains and surface water to the greatest extent practicable.
	7. Use appropriate personal protective equipment (PPE) when handling and using AFFF and identify how to decontaminate and or dispose of PPE materials and gear that come into contact with foam.
	8. "Follow applicable industry standards for design, installation, maintenance, and testing of foam systems" (**FFFC 2016**).
	9. Keep records of when and where foam is used to respond to incidents, including foam type, manufacturer, brand, and amount used.
	10. Make note of any sensitive receptors (for example, streams, lakes, homes, wells) identified in the vicinity of foam use and report to environmental agencies as required.
Planning and Mitigation	1. Develop and communicate documented processes for a facility or installation with the stakeholders and regulatory agencies before a release occurs. Stakeholders may include local fire department, elected officials, landowners, interested parties, and local environmental groups.
	2. Prepare runoff collection plans, equipment, and training processes for all foam and those specific to fluorinated Class B foam use.
	3. Create mitigation plans for uncontrolled releases of foam concentrate or foam solution to minimize environmental impacts (**FFFC 2016**).
	4. Quickly and thoroughly clean up any contaminated environmental media after foam release following established mitigation plans.
	5. Design new firefighting systems to accommodate F3s. Consider their different properties, modes of action, and effectiveness.
	6. Prioritize education, training, and preplanning to ensure the safest and most efficient use of foam and equipment during an incident.
Disposal	1. Proper disposal of foam is imperative. See **Section 3.10**. When available, consider disposal of AFFF inventory to state collection and disposal programs. Refer to Interim Guidance on the Destruction and Disposal of Perfluoroalkyl and Polyfluoroalkyl Substances and Materials Containing Perfluoroalkyl and Polyfluoroalkyl Substances – Version 2 (**USEPA 2024**).
	2. Terminate any donation programs for expired or unused AFFF concentrate (for example, donation to fire training school). Instead, as stated above, encourage collection/proper storage/disposal of expired or unused AFFF.
	3. Monitor developments in new treatment and disposal technologies.

3.8.2 Personal Protective Equipment

The use of personal protective equipment (PPE) is highly recommended when exposure to AFFF, as well as other firefighting foams, is anticipated. A critical aspect of PPE is ensuring the proper use of the equipment. The equipment should be used correctly, maintained, and decontaminated routinely (**Queensland Government 2021**).

During the application or immediate cleanup of AFFF foam, the use of a self-contained breathing apparatus or positive pressure–supplied air respirator is recommended to avoid respiratory exposure. Dermal exposure should also be avoided, as skin contact can result in irritation and dryness. When responding to fires, first responders should wear appropriate turnout gear, or proximity gear per their specific department requirements.

PPE cleanup after using AFFF (as well as other foams) is discussed in the next section.

3.8.2.1 Decontamination

Although PPE will prevent initial exposure to AFFF, contamination of the PPE itself can present health risks. Decontamination of the PPE and personal hygiene are crucial preventative measures in reducing or avoiding exposure to AFFF, as well as in avoiding cross-contamination. Since there is little PFAS-specific guidance on PPE decontamination, general PPE use and decontamination approaches should be used, as discussed below.

When handling AFFF concentrate or foam, it is imperative to avoid hand-to-mouth contact. After the use or cleanup of AFFF, responders should wash hands and use other decontamination procedures to remove any residual AFFF from the skin. Responders should remove contaminated clothing and launder before reuse.

PPE should be placed in a bag and container after exposure to AFFF as well as other foams. In 2014, NFPA released its latest edition of NFPA 1851: Selection, Care and Maintenance of Protective Ensembles for Structural Firefighting and Proximity Firefighting. This standard provides guidance for proper care of firefighting protective gear as well as health hazards associated with improper maintenance or contamination of protective equipment (**NFPA 2014**). The standard outlines different decontamination measures for turnout gear as well as proximity gear.

Turnout gear is the general PPE for firefighting. It should be machine washed in warm water in the normal cycle. Turnout gear should be spot treated with warm water, a soft brush, and mild detergent prior to being machine washed. When hand washing and spot treating PPE, wear protective gloves—either latex or PVC— to avoid skin contact with any residual AFFF. No fabric softener or bleach should be used. The turnout gear should never be washed in home washing machines, as this practice has the potential to contaminate personal clothing. Advanced cleaning is suggested at least on a yearly basis (**Avsec 2015**).

Although PPE decontamination prior to reuse is important, it is equally important to recognize when decontamination is not possible. In this case, the gear should be discarded in accordance with local, state, and federal regulations.

When decontaminating or laundering PPE, the disposition of the waste stream should be considered. The potential for environmental impacts due to laundering in washing machines is not well defined, but the potential does exist. Regulatory agencies should consider including decontamination procedures when working with firefighters, refinery safety personnel, and other potential first responders to develop BMPs.

3.8.3 Initial Mitigation Efforts for Firefighting Foam

Initial mitigation efforts following a release of firefighting foam include source control, containment tactics, and recovery tactics. Each is further described in this section.

Discharges of AFFF can occur during firefighting operations, system testing, equipment malfunctions, or incidental releases. In addition to foam, a large amount of water is often applied when attempting to suppress a fire. Due to the highly miscible nature of AFFF, the main objective of the initial mitigation efforts should be to reduce the footprint of contamination by limiting the spread of foam and fire water. This is often done through various containment and recovery tactics while making sure that the release has been abated and response personnel are safe.
Specific department or facility fire wastewater management considerations may be outlined in a fire response plan, which should include information such as resources available within the facility or department fire protection jurisdiction to contain and recover fire water, protect sensitive areas (for example, public and private water systems, storm drains, surface water, critical wildlife habitat), and address safety considerations when conducting water management tactics. By using the fire response plan, first responders familiar with the content can increase the potential for a successful response while reducing or eliminating any imminent or substantial threat to human health, safety, welfare, or the environment.

3.8.3.1 Source Control

In addition to AFFF application for emergency response, accidental discharge of AFFF can occur from faulty or malfunctioning equipment such as hard-lined fire suppression systems in aircraft hangars or equipment used to apply or contain foam (for example, fire engines or storage tanks). The first step in any response is to stop the accidental discharge or release at the source by disabling or shutting off the system, if possible, and then temporarily or permanently repairing the malfunctioning equipment. By controlling the source, the impact to the environment is minimized.

3.8.3.2 Containment Tactics

Due to AFFF's miscible nature, as well as the large amount of water often applied in combination with the foam, containment tactics that prevent or minimize surface water runoff are critical during and after emergency response activities. Proper containment tactics may also reduce the footprint of the affected area to make the containment and cleanup easier. Depending on resources available to response personnel and conditions of the release, tactics such as ditching, berming, diking, damming, and blocking storm drains, culverts, or other surface inlets can help to contain runoff. When using these tactics, it is important to ensure that any digging activity will not result in breaking through a confining layer that would allow contaminated water to move more quickly into the subsurface and specifically to groundwater. Several response organizations have tactics manuals available online for review, including the Spill Tactics for Alaska Responders (STAR) Manual (**AK DEC 2014**) and Alaska Clean Seas Tactics Manual (**Alaska Clean Seas 2017**). Most manuals are targeted at tactics proposed to be conducted after a release of oil or other petroleum products, but most of these tactics will also apply to AFFF releases. General guidance, similar to this section, on containment tactics to be conducted after a foam discharge has been provided by several other organizations, including the Firefighting Foam Coalition (**FFFC 2016**, **2018**) and the Queensland Department of Environment and Science (**Queensland Government 2021**).

As stated previously in this section, preplanning can greatly assist with prioritizing sensitive areas or locations that need protection during the mitigation or response effort after an AFFF discharge, as well as the resources necessary to succeed with this strategy. The containment tactics used and resources required will differ among sites. Preparedness can be increased by identifying potentially sensitive areas. Also, designing infrastructure such as aircraft hangars with foam-applying fire suppression systems so

that the discharged foam is automatically directed to storage tanks or containment structures can minimize the need for any cleanup. The DOD has provided guidance via Engineer Technical Letters (**USACE 2018**) that address containment/disposal system design for AFFF discharges from open systems (such as nozzle and deluge sprinkler systems) and closed systems (in which individual sprinkler heads are activated only by heat of a fire).

Because no single set of containment tactics is going to be applicable to all facilities or departments where a foam discharge occurs, it is important for each user to conduct preplanning to identify solutions that fit its facilities, objectives, and specific response scenarios.

3.8.3.3 Initial Recovery Tactics

Recovery tactics can differ depending on the amount of AFFF released, as well as whether the AFFF is discharged during firefighting operations or accidentally (for example, from malfunctioning equipment). Collection of large volumes of AFFF concentrate or the 1%, 3%, or 6% AFFF mixture combined with water could require the use of mechanical devices such as pumps or vacuum trucks, while absorbent material might suffice to clean up after a smaller release. The AFFF and water mixture has a low flammability and a high flash point, so there is no need to use intrinsically safe pumps or mechanical devices unless other, more flammable compounds are present in the fire water being recovered.

It may be beneficial to remove affected AFFF saturated materials such as soil and vegetation to reduce or eliminate surface or subsurface migration of potential contaminants. Removal of contaminated media may reduce or eliminate the need for additional investigation and cleanup in the future; however, focus during the initial mitigation effort should be on the more easily recoverable media such as affected waters or slurries. Initiating recovery tactics as soon as possible after a release of AFFF will greatly reduce the footprint of PFAS-contaminated materials and lower the cost of the total mitigation effort.

3.9 Immediate Investigative and Cleanup Actions

A series of immediate investigative actions can be taken after the use of AFFF at the site of a fire to determine the level, nature, and extent of the contamination. First responders should collect, to the best of their ability, information regarding the volume of AFFF discharged, its concentration, active ingredients, and discharge location information.

Information about actions to be taken after the immediate actions is included in **Section 10**, Site Characterization; **Section 11**, Sampling and Analysis; and **Section 12**, Treatment Technologies.

Traditional field-screening methods used for other types of contaminants (for example, PID field screening for petroleum) are not effective for PFAS due to their unique chemistry, generally low volatility, and lack of development of colorimetric or reactive chemistry technologies. Some efforts have been made to develop mobile analytical laboratories, which are covered in **Section 10.3.1.3** of this document.

3.9.1 Visual Site Delineation

Visual site delineation refers to outlining the affected area of contamination based on visual clues, such a visible foam and wet ground, as a guide. The extent of foam should be marked using survey tape, lathe, and pin flags placed to identify locations of AFFF contamination. This technique of determining the initial expanse of the contamination is simple to perform directly after a discharge and can be useful for reference in future testing on the site. In addition, photographs of the site taken during or immediately after the incident can be used to determine the extent of AFFF impacts.

3.9.2 The Shake Test

The shake test is an informal qualitative field-screening method that provides a visual analysis of the site contamination. The shake test can apply to both water and soil-water solutions. In the shake test, a small sample (10–25 mL) is collected on site by the field personnel and shaken. After it is shaken, if there is foaming in the sample, it should be noted and then submitted for analysis (**Transport Canada 2017**). Photographs of the samples may be helpful. If AFFF foam was used to fight the fire, then the presence of foam strongly suggests the sample may be contaminated with PFAS. This test is a good indicator for high concentration contamination. It may not be able to detect lower concentrations of contaminants, so lab testing may still be required. This may be true of soil and water samples taken around the foam application location where the shake test does not show foaming but the sample media may still have PFAS above background in it.

3.9.3 Initial Investigative Sampling

Investigative sampling is used to determine the nature and extent of contamination, including concentrations at and surrounding release areas. Initial investigative sampling can help to determine whether additional characterization is necessary, in addition to informing the need for and extent of interim or permanent remedial actions. Combining the information gained from investigative and confirmation sampling with information from a CSM will inform project managers as to whether further site characterization and remediation or mitigation efforts are needed. See **Section 5**, Environmental Fate and Transport Processes, **Section 10** and **Section 12** for additional information on the actions that may be needed following initial response.

3.9.4 Interim Removal

Following the information gathering described above, or possibly prior to initial investigative sampling, additional source control can be achieved through removal of soils that are expected to be highly contaminated. During an initial removal action intended to target PFAS hot spots, soil excavation can be guided by shake tests (**Section 3.9.2**). An interim removal is not necessarily designed or expected to remove all contamination but can help to reduce the migration of PFAS into other media, including groundwater and surface water. After this initial removal effort, it may be appropriate to hire an environmental professional to perform further mitigation efforts. To determine how to dispose of the soil, see **Section 12**.

3.9.5 Confirmation Samples

Once removal actions take place, confirmation samples are taken to confirm that an excavation or interim removal successfully removed the soil contamination that exceeds applicable regulatory or risk-based levels. If confirmation sampling determines that soil contamination still exists at levels of concern, additional removal actions or other types of remediation or mitigation may be required. The type, number, and distribution of confirmation samples is determined on a site-specific basis according to local regulatory guidance.If confirmation sampling is delayed due to weather events—for example, a rainfall event—the results from such sampling should be interpreted carefully.

3.10 AFFF Disposal

BMPs recommend that volumes of AFFF foam concentrate be carefully monitored and recorded at each storage location, from fire trucks to suppression systems to storage containers (see **Table 3-3**). Weights of other AFFF system components requiring disposal should be similarly observed. Disposal certificates for materials bound for removal should indicate volumes of AFFF concentrate or solution or weights of

system components or debris, as applicable. Total volumes or weights generated for disposal should match that indicated on disposal certificates.

Disposal of AFFF concentrate represents a significant challenge for any owner of firefighting foam concentrates. The disposal of AFFF concentrates through standard disposal options may carry risks. Practitioners should be aware of possible disposal options, best management practices, and disposal hierarchy, as explained by USEPA (**USEPA 2024**). Manufacturers' product literature and local regulatory agencies should be consulted for information regarding the specific foam concentrate to be disposed. Some disposal options that are currently available for AFFF concentrates and AFFF-impacted natural media are presented in USEPA's *Interim Guidance on the Destruction and Disposal of Perfluoroalkyl and Polyfluoroalkyl Substances and Materials Containing Perfluoroalkyl and Polyfluoroalkyl Substances* (**USEPA 2020**). The discussion in Section 3.10 is based on the 2020 version of the USEPA guidance and the reader is encouraged to review the updated 2024 Version 2 guidance. Additional information can be found in **Stoiber, Evans, and Naidenko (2020)** and **Aleksandrov et al. (2019)**.

Currently available AFFF concentrate disposal options are briefly presented below and in **Table 3-4**. Table 3-4 also presents advantages and disadvantages associated with each disposal method and new disposal technologies that were under development when this table was prepared. The disposal options that are currently available for materials impacted with dilute AFFF wastes are presented in **Section 12**, and include stabilization and landfilling, incineration, and deep well injection.

As stated in the USEPA interim PFAS destruction and disposal guidance (**USEPA 2024**), one option for addressing disposal concerns related to environmental releases of foam, byproducts, or other possible releases is to store AFFF in warehouse storage to provide time for completion of studies for destruction, disposal, or stabilization of the AFFF. Stakeholder concerns regarding AFFF waste disposal practices are presented in **Section 13.1.11**.

Each of the currently available disposal options presented below and in **Table 3-4** has different advantages and disadvantages that the practitioner should consider when deciding how to dispose of AFFF concentrates, including availability, cost, effectiveness, and potential long-term risks associated with nondestructive disposal options.

3.10.1 Stabilization and Landfill Disposal

Waste stabilization and landfilling is a nondestructive disposal methodology wherein waste, including AFFF concentrates, are mixed with stabilizing materials (for example, Portland cement) and disposed at a landfill that is licensed to accept and manage these wastes. This disposal method is nondestructive in that the waste is not destroyed but immobilized and encapsulated to prevent exposure and reduce potential mobility. Ultimately the stabilized and landfilled AFFF concentrate is managed with other wastes disposed of at the same landfill through landfill best management practices (for example, liners, leachate collection, cap management, groundwater monitoring, etc.). Stabilization and landfill disposal is an accepted waste management strategy in some states, though the long-term stability of stabilized AFFF concentrate is not well understood.

Practitioners with AFFF concentrates requiring disposal should collaborate with their local or state agency waste management personnel, as applicable, to determine current availability and acceptability of stabilization and landfill disposal as a waste management practice. AFFF concentrate bound for disposal should be properly documented (for example, a proper manifest or bill of lading) as a best practice and in compliance with state and federal transportation regulations (as discussed in **Section 3.6.2**). After the concentrate product has been disposed of, a certificate of disposal may be generated by the disposal facility, transmitted to the product owner, and retained by the disposal facility. This certificate of disposal may be transmitted to the state regulatory agency for review and maintained on file by the product owner.

3.10.2 Incineration

Incineration is a destructive disposal technology wherein AFFF concentrate is destroyed, or mineralized, through the application of heat. Heat is applied to the AFFF concentrate at incineration facilities that have the capability to manage high temperatures and residence times required to destroy AFFF concentrate, as well as vaporized combustion products (flue gases) that are captured and/or further incinerated. Most AFFF concentrate has historically been disposed of using incineration in the United States (**FFFC 2016**). However, the effectiveness of incineration, and the temperature and time conditions required to achieve complete PFAS destruction, are not well understood (**USEPA 2020**). Legal, technical, and political challenges to incinerating AFFF exist based on gaps in research on the effectiveness of incineration (**Earthjustice 2020**). For example, the New York State DEC prepared a sampling report in 2021 near one incineration facility in response to concerns about emissions from the facility (**NY DEC 2021**). USEPA researchers are currently studying PFAS incineration, sampling and analytical methods development, and industrial field sampling. Thermal stability of PFAS, the ability to fully capture and identify PFAS and their thermal decomposition byproducts, and the efficacy of emission control technologies are areas of targeted research (**USEPA 2020**). The NDAA for fiscal year 2022 (**https://www.congress.gov/bill/117th-congress/senate-bill/1605**) established a temporary moratorium on incineration of AFFF generated by DOD. The temporary moratorium began no later than 120 days after enactment of the NDAA FY22 (4/26/2022). The DOD published a memo about the temporary prohibition on April 26, 2022 (**USDOD 2022**).The DOD published a memo with interim guidance about destruction or disposal of materials containing PFAS on July 11, 2023 (**USDOD 2023**). A follow-up statement was published on July 17, 2023 about additional planning and coordination that is needed before incineration is implemented (**USDOD 2023**). Additional information is included in the DOD Incineration Report to Congress (**USDOD 2024**).

This technology is currently the only known AFFF destruction technology in widespread use, though the efficacy of incineration as an effective disposal option for AFFF concentrate is an area undergoing further study (**USEPA 2024**). More information is also included in **Section 12.4**. At the time of publication there are a number of studies ongoing to evaluate destruction temperatures and treatment time required to achieve complete AFFF destruction, the potential to generate products of incomplete combustion, flue-gas analyses to assess mobilization of AFFF concentrates, and other risk factors. Owners of AFFF concentrates requiring disposal should consider contacting their local or state agency waste management personnel, as applicable, to determine current acceptability of incineration as a disposal practice prior to disposal.

3.10.3 Deep Well Injection

Another disposal approach, available in some states, is to dispose of AFFF concentrate through deep-well injection. In some cases, disposal via landfilling of a stabilized concentrate or deep well injection at a licensed hazardous waste management facility has been used. This disposal option eliminates discharges to surface water and shallow groundwater, similar to stabilization and landfilling, but does not destroy or degrade disposed wastes. Deep well injection is an available option that is being used given the currently limited number of disposal options for AFFF concentrate. Class I deep injection wells, as defined by USEPA, accept both hazardous and nonhazardous liquid wastes (**USEPA 2019**), including AFFF waste materials such as dilute AFFF (fire water) and AFFF concentrates. The USEPA has published guidance on the requirements for the use of deep injection wells, including siting, construction, operation, monitoring, testing, record keeping, reporting, and closure (**USEPA 2019**). The USEPA has also studied the risks associated with underground injection wells (**USEPA 2001**), and these risks are documented for consideration by generators prior to disposal of AFFF concentrates through deep-well injection.

3.10.4 Potential Future Disposal Technologies

The currently available disposal options for AFFF waste are limited and carry inherent unknowns in terms of long-term reliability. This is of particular importance when considering nondestructive disposal means such as stabilization and landfill disposal and deep well injection. These unknowns translate into short- and long-term risks for the practitioner. Additional disposal options may be available in some areas (for example, deep well injection) for AFFF concentrate wastes and AFFF-impacted materials. Alternate treatment and disposal technologies are presented in **Section 12**. New treatment and disposal technologies are an active area of research and development by a number of groups; some are presented in **Table 3-4**. All technologies will require extensive evaluation to ensure they are fit-for-purpose.

Table 3-4. PFAS Waste Materials Disposal Options.

Current as of October 2022.

Current Disposal Practice	Advantages	Disadvantages
Stabilization and Landfill Disposal (**Section 3.10.1**)	1. AFFF concentrate mass is encapsulated and immobilized in a stable form 2. Disposal is at a licensed landfill with monitoring programs and leachate collection systems designed to ensure disposed mass remains controlled 3. Long-term management of the disposed waste is part of the overall landfill management and monitoring program	1. Disposed AFFF concentrate mass remains in place with no known and documented destruction mechanisms 2. Risks associated with comingled waste disposed of at the waste management facility 3. Long-term testing of stabilized PFAS waste materials under landfill conditions is limited. Some studies are available (**CONCAWE 2016**; **Oliaei et al. 2013**; **Weber et al. 2011**) 4. PFAS mass from disposed wastes can form mobile leachates, which require long-term collection, management, and disposal (**Stoiber, Evans, and Naidenko 2020**) 5. Some PFAS may be emitted by the landfill gas collection and management system
Deep Well Injection (**USEPA, 2019**; **USEPA 2024**; **Marine 2020**) (**Section 3.10.3**)	1. AFFF concentrate mass is injected deep underground in previously defined tectonically stable strata 2. Waste is injected well below drinking water aquifers, reducing potential for future impacts to drinking water resources 3. Waste immobility and lack of potential for unacceptable migration must be documented prior to waste injection 4. Long-term management of the injected waste is the responsibility of the operator while the disposal facility is in operation	1. Disposed AFFF concentrate mass remains in place with no documented destruction mechanism known 2. Waste materials are injected with no modifications or additives to reduce migration potential or enhance degradation 3. Deep well injection facilities are generally operated with limited mandated monitoring to document lack of long-term waste migration 4. The long-term stability of injected wastes is undocumented
Incineration—General (**Section 3.10.2**)	1. Incineration (at properly licensed and operated disposal facilities) is the only disposal technology currently available that has the potential to result in the destruction of PFAS 2. PFAS destruction through incineration has been documented in laboratory studies (e.g., **Aleksandrov et al. 2019**; **Khan et al. 2020**) but known studies analyzed only for a subset of PFAS 3. PFAS destruction reduces/eliminates future risk 4. Some incineration facilities maintain successful track records of operating within permit requirements based on system performance monitoring data collection	1. The efficacy and operational requirements of incineration are currently under question and require additional study (**USEPA 2020**) 2. Existing laboratory experiments on the incineration of PFAS do not address the full spectrum of potential PFAS byproducts that could form during incineration (**Stoiber, Evans, and Naidenko 2020**; **USEPA 2024**) 3. Current regional and local moratoria exist in some locations against incinerating PFAS waste. Practitioners should confirm disposal vendor licensing and operational status prior to shipping AFFF concentrate for disposal

Current Disposal Practice	Advantages	Disadvantages
Incineration—Municipal	1. Municipal incinerators are readily available and offer a comparatively low-cost disposal option if operated at sufficient temperatures and residence times and if equipped with appropriate emissions controls	1. Municipal incinerators may not be permitted to accept AFFF concentrate for disposal 2. Temperatures, residence times and emissions controls may not be adequate to fully degrade PFAS 3. Potential for partial decomposition of PFAS to shorter carbon chain-length PFAS (**USEPA 2024**) 4. Existing laboratory experiments on the incineration of PFAS do not address the full spectrum of potential PFAS byproducts that could form during incineration (**Stoiber, Evans, and Naidenko 2020**; **USEPA 2024**)
Incineration—Hazardous Waste	1. Some specialized incinerators exceed minimum temperature required 2. Some are designed to handle flue gases and scrubber wastes 3. Generators may be able to obtain a disposal certification from the incineration facility	1. Temperatures, residence times, and emissions controls may not be adequate to fully degrade PFAS at some standard commercial facilities 2. Potential for partial decomposition of PFAS to shorter carbon chain-length PFAS (**USEPA 2024**) 3. Difficulty handling high-water content wastes
Incineration—Cement Kiln	1. Temperatures and residence times in excess of minimum required (1100°C and 2 seconds) 2. Effective permanent capture of fluorine 3. No extra energy required above normal kiln processing	1. Potential for partial decomposition of PFAS to shorter carbon chain-length PFAS (**USEPA 2024**)
Experimental Disposal Technologies (Section 3.10.4)		
Electrochemical Oxidation (**Le et al. 2019**; **Ensch et al. 2020**)	PFAS is degraded in a closed-cell reactor using metallic electrodes and electrical current. Several different types of electrodes (titanium oxide, boron-doped diamond, etc.) have degraded some PFAS to varying degrees of success and several studies were underway in 2020. In previous laboratory-scale studies, PFAS destruction was achieved, though at relatively low throughput rates. This disposal technology is applicable to liquid waste streams only.	
Enhanced Contact Plasma Reactor (**Singh et al. 2019**)	PFAS are degraded in a closed system using water, electricity, and argon gas to degrade PFAS through a series of sequential destruction steps. At laboratory scale the destruction of PFAS was observed within their ability to measure, limited by analytical method detection limits. Air Force Civil Engineering Center (AFCEC) and Clarkson University were field testing this technology at Wright-Patterson Air Force Base, Ohio in 2020.	
Alkaline Hydrothermal Treatment (HaLT) (**Wu et al. 2019**)	Perfluorooctane sulfonate (PFOS) and potentially other PFAS are degraded through the application of hydrothermal conditions (condensed water at high temperature [200–350 °C] and high pressure [2–16.5 MPa]) to solutions amended with NaOH. Initial studies document PFOS destruction within 90 minutes. Expanded laboratory studies continue to investigate efficacy over a broader range of PFAS compounds.	
Supercritical Water Oxidation (**SERDP-ESTCP 2020**)	Supercritical water oxidation at high temperature (greater than 373 °C) and high pressure (greater than 22 MPa) has been demonstrated to degrade PFAS. Battelle Memorial Institute has patented a process called PFAS Annihilator to apply this technology for the destruction of PFAS. In addition, an ESTCP-supported study at Duke University began in May 2020 to demonstrate the efficacy of this technology at higher throughput rates (approximately 907 kg of waste material per day).	

3.10.5 Fire Water and Flush Water Containing PFAS

Fire water produced during training or emergency response, as well as flush water produced during the rinsing of firefighting systems and equipment, may be managed and disposed of as a generated waste because these waters contain dilute concentrations of PFAS. Practitioners may consult with local regulatory agency personnel ideally prior to the generation of fire- and flush water so that there is a good understanding of local laws and regulations governing disposal. Standard practices for foam containment and cleanup should be developed prior to use such that response teams have the needed equipment and training before an event occurs; **Table 3-1** provides additional information for BMPs. Some fire water disposal options are focused on reducing the volume of wastewater through concentration and disposal of the generated concentrate via incineration, landfilling, stabilization, or other mechanisms. See **Section 3.10.1** for comments related to these disposal methods. Widely used treatment methods, as presented in **Section 12** are as follows:

- granular activated carbon treatment

- discharge to and treatment at a wastewater treatment plant
- pumping AFFF-impacted fire water into watertight, secure containment basins and allowing the water phase to evaporate, leaving behind a solid or semi-solid material containing the AFFF concentrate. The remaining material is then disposed of at a certified waste management facility (**USDOD 1997**). This method is an option only in some localities and where climatic conditions are favorable.

3.11 Firefighting Foam System Replacement

The Priority Topics for Firefighting Foams include updates to the information in this section (see **Section 1.2.3**). The updates include information about transition planning of foam systems from AFFF to F3 and a summary of available guidance. One case study was added to the **Case Study Table** (Table 3-5).

The AFFF application design is specific for each foam and use case and system design can vary significantly by location, manufacturer, foam product, and system objective. Changing between foam types or application objectives could require a complete system review and, potentially, redesign and modification of system components to meet the new objectives or material and performance requirements. When objectives or requirements are changed, each subject system should be evaluated and modified individually to ensure that operational objectives are met.

Procurement at U.S. airports is primarily driven by regulatory performance requirements, notably the DOD Mil-Spec, MIL-PRF-24385, as well as FAA requirements (**ACRP 2017**). DOD recommends complete replacement of the required AFFF concentrate supply and rinsing of the storage and discharge system prior to refilling with a different concentrate product (**USDOD 2017**). This not only prevents any unforeseen incompatibility issues, but also greatly reduces possible cross-contamination and the uncertainty of AFFF formulations (PFAS profile and content).

Applicable replacement products standards include NFPA Standards 11 (**NFPA 2016**) and 16 (**NFPA 2019**) for foam water sprinkler and foam water spray systems and NFPA Standards 1901 (**NFPA 2016**) and 412 (**NFPA 2020**) for equipment.

3.11.1 Replacement Products

Replacing foams and foam systems generally follows four steps:

1. Assess and understand the specific hazards and application objectives.
2. Ensure that foam product to be adopted is listed and approved for use on the specific assets that are being protected and the hazards that that are being mitigated.
3. Ensure that the foam product storage system and the foam/water application system meet product storage (for example, materials compatibility and storage temperature), proportioning, and application requirements.
4. Ensure that the selected foam product(s) meet applicable requirements (Requirements are based on where and how the foam is being used and rely on sector-specific standards such as Mil-Spec, Underwriters Laboratories (UL), or Factory Mutual compliance). These organizations audit manufacturers to ensure compliance with their standards.

Where two or more foam products meet applicable performance requirements, the foam with the best environmental performance may be considered for use. Alternatives currently available as replacement products for legacy AFFF include products discussed in the following sections.

3.11.1.1 Fluorine-Free Foams (F3)

Most foam manufacturers now produce Class B F3s. Performance of these foams should be evaluated carefully as future purchasing decisions are made. As of spring 2024, there are three military-specified F3s approved for use on Class B fires at federal- and FAA-regulated facilities that require Mil-Spec–compliant AFFF. For a list of the most recent military-specified foams, go to the Qualified Products Database hosted by the DoD at **https://qpldocs.dla.mil/**. For other F3s, the GreenScreen for Safer Chemicals website provides a list of PFAS-free firefighting foams that do not contain intentionally added PFAS. The website is **https://www.greenscreenchemicals.org/certified/fff-standard**.

3.11.1.2 Modern Fluorotelomer Foams

If it is determined that the performance of a fluorinated Class B foam is required for a specific hazard (for example, the federal regulation requiring AFFF use for military applications, at FAA-regulated airports, and/or other high hazard Class B fires and potential incidents), users should purchase modern fluorotelomer foams. Most foam manufacturers have transitioned to the production of only short-chain (C6) fluorosurfactants, so it is likely that any AFFF bought today meets that requirement. But foams made with only short-chain (C6) PFAS may still contain smaller quantities (parts per billion) of PFOA and PFOA precursors as byproducts of the manufacturing process. This should be confirmed with the supplier.

Although there are currently mandated specifications requiring the use of fluorinated foams at airports and military installations, users should be aware that some compounds in modern fluorotelomer foams are regulated by several states and are known to have probable effects on human health (**Section 7.1**). Use of these foams may be restricted to emergency situations only and not for use in firefighting training activities. Local and state regulations may require reporting of their release, including emergency use. **Section 3.12** discusses the current state of regulations on AFFF use.

3.11.1.3 Replacements, Certifications, and Alternatives Assessments

Several efforts are underway to evaluate F3 AFFF replacements for environmental and human health effects, as well as performance effectiveness. SERDP and ESTCP programs continue to "fund several research and development projects to evaluate performance, lifecycle impacts, and health and safety implications of commercially available, non-fluorinated alternatives." For example, **Jones et al. (2022)** examined the direct lethal effects of seven F3 and a PFAS-containing AFFF on 14 aquatic species using a series of lethal concentration (LC50) tests. Across all aquatic species tested, they discovered that exposure to at least one F3 was more or as toxic as exposure to the PFAS-containing AFFF. This illustrates that more research is needed to understand new F3 formulations to ensure they are not regrettable substitutions. Additional information regarding PFAS toxicity, data gaps, and research needs is presented in **Section 7.1**. The DOD SERDP program has invested heavily in these efforts; representative studies supporting these efforts are listed in **Section 3.13**.

In related efforts, some organizations have developed certification processes to help consumers understand which products are considered "PFAS-free" (see **Section 2.5.3**). For example, Clean Production Action developed the first-ever ecolabel for firefighting foam products via their GreenScreen certification process, which identifies products as eco-labeled but does not include a release of liability. They worked with a technical review team of scientists, firefighting foam researchers, and governments to ensure the PFAS-free standard is protective, achievable, and supports purchasers to choose foam products that are safer and better for the environment. Clean Production Action defines PFAS-free as zero PFAS intentionally added to the product and PFAS contamination in the product less than 0.0001

percent by weight of the product (1 part per million) total organic fluorine as measured by combustion ion chromatography. There are currently more than two dozen certified firefighting foam products available. Go to https://www.greenscreenchemicals.org/certified/fff-standard for more information.

Alternatives assessments have been another mechanism to further evaluate F3 alternatives in terms of regrettable substitution. The first-ever alternatives assessment for AFFF (**Wood Environment & Infrastructure, 2020**) was completed for the European Commission and European Chemicals Agency. This assessment included an evaluation of substances in formulation, a market analysis, emissions and hazards evaluation, remediation costs and technology, an analysis of alternatives and socioeconomic impacts, and regulatory management options. As a result, a Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) restriction proposal for AFFF was submitted in 2022. **Tickner (2022)**, funded by SERDP, completed an alternatives assessment for AFFF. The assessment focused on understanding alternatives assessments completed, supporting assessment and decisions about substitutes regarding "safer" and "sufficient performance," and supporting needs related to adoption. **Tickner (2022)** developed six guiding considerations, including:

1. "Determine the function of the chemical of concern for the specific application. Understand this function within the production chain.

2. Define the application-specific use scenario(s). Identify alternatives that are fit for that particular purpose.

3. Establish and/or use performance standards independent of the standards dependent on using chemicals/materials of concern. Adjust based on available alternatives or alternatives on the horizon.

4. Use a range of performance standard benchmarks, e.g., 'inadequate' to 'sufficient' to 'best in class.'

5. Consider technical performance separately from technical feasibility.

6. Consult stakeholders for determining acceptable tradeoffs between performance results and other elements such as environmental health and safety."

3.11.2 System Decontamination and Sampling During Foam Replacement

The replacement of Mil-Spec legacy foam with the modern foams requires review of system components, particularly the proportioning system, to ensure that appropriate system performance will be maintained. During foam replacement, a thorough clean-out of storage tanks and associated pipework is highly recommended prior to filling with replacement foam concentrate. There is potential for PFOS and PFOA contamination from legacy AFFF, as described in **Section 3.1**, and from PFOA and other PFAS from fluorotelomer foams. For nonmilitary applications, legacy AFFF and replacement modern foams may not be compatible. In these cases, the foam manufacturers should be consulted when a foam change is required and current best practices for foam replacement, system decontamination, and verification sampling should be considered. The degree of cleanliness required and the cost balance between cleaning and replacing system components should be considered during the planning phase of a foam concentrate change-out event.

Currently, there are no regulatory guidelines or requirements pertaining to the clean-out of AFFF firefighting systems when foam concentrates containing legacy foams are replaced with alternative foams; however, local and state governments and other organizations continue to develop policy and guidance on replacing foams. DOD (and other foam users) have performed triple water rinsing step after the legacy AFFF is removed (**USDOD 2018**). The rinse water is containerized and managed as a waste

material as presented in **Section 3.6.2**. Proprietary cleaning solutions and coagulants have also been used for AFFF clean-out (**CTDEEP 2022**). These methods have been compared to the triple water rinse. No single cleaning method has yet been proven to be 100% effective in eliminating residual PFAS concentrations (**CTDEEP 2022**). Use of proprietary methods is more costly than triple water rinse, but these methods are more effective at reducing PFAS concentrations (>99% compared to approximately 95% removal) (**CTDEEP 2022**). Organizations should check with local and state regulatory agencies regarding local policies and guidance for foam change-out and system clean-out requirements or recommendations. Sampling of rinsate to ensure that residual contamination has been removed may be considered before adding replacement foams, and sampling of replacement foams that have gone through the system may provide the best assurance that PFAS will not continue to be released when the systems are used.

3.11.3 AFFF Transition Planning

The Priority Topics for Firefighting Foams include updates to the information about transition planning of foam systems from AFFF to F3 (see **Section 1.2.3**). Protocols around transition planning and execution of foam change-out are becoming ever more important to understand. Several factors need to be carefully considered when F3 alternatives, including but not limited to:

- What will the foam be used for and max volume of fuel source handled?
    - Fuels fires and max volume (large atmospheric storage tanks or other)
    - Chemical fires and max volume (large atmospheric storage tanks or other)
    - Other
- What are the current performance specification requirements for the foam?
    - Mil-Spec
    - Other
- What application and application technique are anticipated?
    - Fire suppression system
    - Fire response vehicles
    - Industrial fire extinguisher
    - Other
- What water type is used for mixing?
    - Fresh water (compatible with most foam products)
    - Salt water (incompatible with some foam products)
- What other types of foam characteristics should be considered? (**NFPA 2020**)
    - Viscosity of the foam concentrate (Newtonian and thixotropic)
    - Suitability for use with existing proportioning hardware
    - Homogeneous mixing of concentrate with water
    - Compatibility with materials in the system (for example, plastic, rubber seals, metals)
    - Stability of foam concentrate or premix solution (separation, stratification, sedimentation)

- Suitability for use on the flammable liquids in question
- Suitability of application method (aspirated, non-aspirated, forceful, gentle)
- Extremes of ambient temperature that may be encountered in an incident
- Suitability of the expansion ratios produced by existing equipment for effective firefighting performance
- Suitability of the application rates produced by existing equipment for effective firefighting performance
- Suitability in specific climate (extreme ambient temperatures, both high and low)

Table 3-5 (provided as a separate Excel file) is presented to provide example case studies for transition planning and execution (see also **Section 1.2.3.5**). Case studies from the aviation industry and the oil and gas industry are provided. Case studies also vary by geography to illustrate potential variability by country. They are provided only as examples of how sites are implementing transition planning, but are not intended to represent guidance to be applied at other sites. The following items are included in the table:

- foam procurement, including selection criteria used to evaluate and select alternatives
- system decontamination and sampling, specifically how replacement versus clean-out was evaluated, how and whether sampling was conducted, and the definition of "clean"
- treatment and disposal, including type of cleaning reagent, waste streams generated, and how they were managed.

Because there are currently no federal or state standards on how much residual fluorine contamination in replacement foam is acceptable, each foam user is responsible for determining whether sampling and analysis of the replacement foam is necessary, and if sampled and analyzed, if the cross-contamination of replacement foam is considered acceptable for their use.

3.11.3.1 AFFF Replacement and System Clean-out

Both system replacement and system clean-out are options when transitioning to F3. There is currently no known standard practice for AFFF system clean-out procedure that is widely recommended by state or federal regulatory agencies. However, system clean-out using triple water rinse has been used by the U.S. Department of Defense, and hot water rinse (<100° F) is approved for use in some states (for example, Connecticut and New York) and is recommended in an article published by the International Fire Fighter website (**Preiss 2022**). U.S. vendors are developing clean-out methodologies that may be more effective than currently used methodologies—for example, rinsing with low- or high- temperature solvents or acids. Most methodologies are currently being performed as demonstration projects, are not widely used, and have not been proven on a wide scale as of the publication of this document.

When selecting a methodology for cleaning out a system, practitioners should aim to achieve the maximum level of clean-out to minimize potential for future PFAS release when the system is deployed, considering both objectives and costs. It's important to understand that more aggressive clean-out procedures will generally be more expensive and generate more waste that will require proper management and disposal. However, inadequate system clean-out may result in the presence of residual AFFF, which may contaminate new F3 with PFAS when the system is refilled.

For mobile systems, DOD recommends a single rinse using water (heated or unheated) that is employed after the old AFFF foam has been drained from the system and containerized (**USDOD 2024**). The State of Connecticut recommends a sitting time of 30 minutes with hot water or 1–2 hours with cold water for

municipal systems such as trailers and trucks (**State of Connecticut 2022**). Note that there are no established standard guidelines for cleaning procedures due to the immense variety of foam delivery systems for which the procedures can vary greatly even among the same manufacturer. All rinsing fluids and other waste generated during the system clean-out process should be containerized, labeled, and managed for proper future disposal. After the system has been cleaned out and rinse waters have been completely drained, new foam concentrate can be added. The practitioner should be aware that changing foam products may necessitate changes to system components, such as proportioners and discharge nozzles.

Foam change-out practitioners should also be aware of and take measures to mediate potential hydrogen sulfide generation in rinse waters that are improperly stored (**Sheinson and Williams 2007**). Hydrogen sulfide can be generated when foam contains sulfate (such as PFOS) or the water source itself contains sulfate. As a result, hydrogen sulfide may be in foam change-out rinse waters that are stored in sealed containers and that are allowed to transition into anoxic conditions. The hydrogen sulfide is generated through anaerobic microbial transformation of sulfate in the rinse water to sulfide followed by complexation of sulfide and hydrogen. Hydrogen sulfide generation can result in risk to site workers, particularly if starting sulfate concentrations in the rinse water are high. Regular inspection of stored rinse waters is necessary to detect any potential hydrogen sulfide generation, allowing for early implementation of mitigation steps.

3.12 Federal, State, and International Regulations and Guidance

The Priority Topics for Firefighting Foams include updates to the information in this section (see **Section 1.2.3**). The updates include information about state activities and guidance, federal agency guidance, and other guidance on foam transition.

3.12.1 Overview

This section summarizes representative information on the regulation of PFAS-containing firefighting foams (AFFF). Although federal law currently does not prohibit the use of existing stocks of legacy AFFF, any discharge of foam containing PFAS to public waters can be considered a release of a "pollutant or contaminant" under CERCLA, 42 U.S. Code § 9601, and therefore subject to remediation requirements. In February 2019, the USEPA announced in its PFAS Action Plan that the agency is beginning to evaluate designating PFOA and PFOS as "hazardous substances" through one of the available statutory mechanisms, including potentially CERCLA Section 102 (**USEPA 2019**). In October 2021, the EPA published the *PFAS Strategic Roadmap: EPA's Commitments to Action 2021-2024* (**USEPA 2021**). The USEPA's stated goals for addressing PFAS are focusing on research, restriction, and remediation. The strategic roadmap includes actions across the different divisions of USEPA. More information about USEPA's actions in 2021 to address PFAS are available on their website (**USEPA 2021**).

As of February 2021, 18 states have established restrictions on the use of AFFF, ranging from limitations on training, notification of PFAS content and/or release, storage, and firefighter personal protective equipment (PPE) (**Horst et al. 2021**). AFFF use is explicitly regulated by some states, such as the State of Washington and the State of New York (**Table 3-6**); however, other states regulate PFOA, PFOS or their salts, and other PFAS in AFFF as hazardous substances or hazardous waste. These regulations effectively limit the storage and/or environmental release of legacy AFFF (both legacy PFOS AFFF and legacy fluorotelomer AFFF), as well as potentially triggering cleanup actions. Similar bills, banning the use of AFFF for testing and training, have been passed in other states such as Arizona, Colorado, Georgia, Kentucky, and Minnesota.

Examples of hazardous substance and hazardous waste regulations, as well as other federal, state, and international guidance pertaining to AFFF, are presented below. For more information pertaining to the regulation of PFAS, see **Section 8**. This section addresses only regulations related to AFFF.

Table 3-6. Representative state AFFF regulatory and legislative activity.

State	Regulation or Bill	Initial Effective Date	What is Regulated?	Specific Requirement	Reference
New York	6NYCRR Part 597	March 2017	PFOS, PFOA, and Class B foams	PFOS and PFOA are hazardous substances. Storage and registration requirements for class B foams if those foams contain at least 1% by volume of PFOS and PFOA (acid and salt) and prohibit the release of 1 pound or more of each into the environment during use. If a release exceeds the 1-pound threshold, it is considered a hazardous waste spill and must be reported. Clean-up may be required under the state's superfund or brownfields program (NYDEC 2017). New York's Chemical and Bulk Storage regulations may also trigger further registration and storage requirements for foams that contain one of the four PFAS designated as hazardous substances (NY CRR Parts 596-599).	(**NY DEC 2017**)
Washington	WAC 296-24-33001	July 2020	Class B foams	Class B firefighting foams cannot be used or discharged for training purposes, and manufacturers of firefighting personal protective equipment must provide written notification to purchasers if the equipment contains PFAS. Beginning July 1, 2020, manufacturers of class B firefighting foams may no longer manufacture, sell, or distribute for sale PFAS-containing class B firefighting foams except for the following uses: applications where the use of a PFAS-containing firefighting foam is required by federal law, including but not limited to the requirements of 14 CFR 139.317 (such as military and FAA-certified airports). Other exceptions include: Petroleum Terminals (as defined in RCW 82.23A.010), Oil Refineries, Chemical Plants (WAC 296-24-33001)	(**Washington State Legislature 2018**)
Virginia	House Bill 2762ER	January 2020	PFAS-containing AFFF	Virginia Department of Fire Programs and the Virginia Fire Services Board begin assisting municipal fire departments to transition to F3, where possible. Effective the same date, the bill bans the discharge or use of PFAS-containing AFFF foams for testing or training unless the facility has implemented containment, treatment, and disposal measures to prevent release to the environment.	(**State of Virginia, 2019**)

3.12.2 Take-Back Programs

Several states have implemented “take-back” programs for AFFF. For example, in May 2018, the Massachusetts Department of Environmental Protection (MA DEP), in partnership with the Massachusetts Department of Fire Services, implemented a take-back program to assist fire departments in the proper disposal of legacy firefighting foams that could impact water resources (**MA DEP 2018**). MA DEP provided funding to assist local fire departments in identifying these foams in their stockpiles and for MA DEP to dispose of them. Any AFFF manufactured before 2003 is eligible under the take-back program. Vermont also announced a take-back program (**VT ANR 2022**). Users should contact their state regulatory agency for information on available take-back programs.

3.12.3 Federal Guidance

As of publication, F3s do not meet the performance requirements of the Mil-spec and therefore are not used at federal- and FAA-regulated facilities. A mandate within the FAA Reauthorization Act of 2018 (enacted October 5, 2018) directs the FAA to stop requiring the use of fluorinated foam no later than 3 years from the date of enactment (October 4, 2021), however, per Cert Alert 21-05, no fluorinated Mil-Spec existed as of that date. In January 2023, the FAA released a Cert Alert to all Title 14 CFR Part 139

Certificated Airport Operators and Aircraft Rescue and Firefighting Departments and Mutual Aid Providers (**FAA 2023**). The alert noted that FAA will accept the airport operator's use of the new F3 extinguishing agent at certificated Part 139 airports once the agent passes the military performance standards and qualification testing and is added to the Navy's Qualified Products' List/Qualified Products' Database. The alert further noted that currently, the FAA will not require certificated Part 139 airports to transition to the new F3, and airport operators are authorized to continue using AFFF, but should check with their state and local municipalities for any local requirements. The National Defense Authorization Act of fiscal Year 2020 (signed into law Dec 20, 2019) requires the DOD to phase out its use of AFFF at all military installations by Oct. 1, 2024, with limited exceptions, and immediately stop military training exercises with AFFF.

In January 2023, DOD released a new Mil-Spec (MIL-PRF-32725) to replace AFFF with F3s at military installations. The F3 Mil-Spec contains a product qualification step that requires a "non-detect" for PFAS as measured by Draft USEPA Method 1633, and also a specification limitation on PFAS content, prohibiting F3s from containing more than one part per billion PFAS (**USDOD 2023**).

3.12.4 International Guidance on AFFF

Internationally, there are many governmental agencies that have developed guidance or operational policy for AFFF. Some examples are briefly presented in **Table 3-7**. The international guidance and regulations are shaped by the unique regulatory structure and regional history of the areas in which they are implemented. As such, they may not necessarily provide informative insights to readers who are unfamiliar with those specific contexts.

Table 3-7. Representative international AFFF regulatory and guidance activity.

Country	Initial Effective Date	What is Regulated?	Specific Requirement	Reference
Canada	January 2018	PFOS, PFOA, long-chain PFCAs	Canada prohibits the manufacture, use, sale, or import of a number of PFAS-containing chemicals and products, such as AFFF, that have these chemicals. Canada allows certain exemptions, including the use of AFFF that contains residual levels of PFOS at a maximum concentration of 10 ppm; the use and import of AFFF contaminated with PFOS in military equipment returning from a foreign military operation; and the import, use, sale, and offer for sale of AFFF that contains PFOA and/or LC-PFCAs used in firefighting.	(**ECCC 2017**)
Canada	2022	PFOS, PFOA, long-chain PFCAs, polybrominated diphenyl ethers (PBDEs), and hexabromocyclododecane (HBCD)	The proposed prohibition would remove or provide time limits for exemptions for PFOS, its salts and precursors, PFOA, its salts and precursors, long chain PFCAs, PBDEs, and HBCD to further restrict the manufacture, use, sale, and import of these substances, and products that contain them. It would also prohibit the manufacture, import, use, sale, and offer for sale of Dechlorane Plus (DP) and decabromodiphenyl ethane (DBDPE), and products that contain them, with exemptions.	(**ECCC 2022**)
Germany	May 2013	AFFF	The German Federal Environment Agency released a Guide for the Environmentally Responsible Use of Fluorinated Fire-fighting Foams. The guidance discusses what AFFFs are, when it is necessary for use, why it endangers humans and the environment, and the consequences of use.	(**German Federal Environment Agency 2013**)
Australia	July 2016	Firefighting foam	The Queensland Department of Environment and Heritage Protection issued an Operational Policy on the Environmental Management of Firefighting Foam. The objective of the policy was to define the requirements and expectations for the handling, transport, storage, use, release, waste treatment, disposal, and environmental protection measures of AFFF.	(**Australia Government DOD 2007**)

Country	Initial Effective Date	What is Regulated?	Specific Requirement	Reference
Australia	July 2016	Firefighting foam	Australia's state of Queensland established restrictions on application and procurement of C8-AFFF (eight carbon-fluorine bonds or greater) and designated that C6-AFFF (six carbon-fluorine bonds or less) replacement foams contain less than 10 mg/kg PFOS and less than 50 mg/kg of PFOA, PFOA precursors, and their long-chain homologues.	**Queensland DES 2021** (replaced Queensland DES 2016)
Australia	January 2018	Firefighting foam	Australia's state of South Australia instituted a ban on fluorinated firefighting foams with a grace period of 2 years to complete foam transition.	**SA EPA May 2019**
European Union	July 2020	PFOA, its salts, and related substances	Prohibit the manufacture of PFOA and related substances on their own from 4 July 2020. Products manufactured after 4 July 2020 should not contain PFOA and its salts greater than 25 ppb or sum of PFOA-related substances (e.g., precursors) greater than 1,000 ppb.	**European Commission 2017**
European Union	December 2021	PFHxA, its salts, and related substances	Proposed a restriction on the manufacture of PFHxA and related substances on their own, as well as in products that contain concentrations equal to or above 25 ppb for the sum of PFHxA and its salts or 1,000 ppb for the sum of PFHxA-related substances.	**European Chemicals Agency (ECHA) 2021**
European Union	February 2023	C9–C14 PFCAs, their salts, and C9–C14 PFCA-related substances	Prohibit the manufacture of C9–C14 PFCAs and related substances on their own from 23 February 2023. Products manufactured after 25 February 2023 should contain less than 25 ppb for the sum of C9–C14 PFCAs and their salts or less than 260 ppb for the sum of C9–C14 PFCA-related substances.	**European Commission 2021**

3.13 Foam Research and Development

Current modern AFFF fluorosurfactant alternatives are largely short-chain C6 telomer-based fluorosurfactants. The fluorosurfactants do persist in the environment, and they have the potential to create breakdown products that are also persistent. Although numerous fluorine-free alternatives are already on the market, there is still a need to develop novel firefighting foams that provide the desired firefighting performance while not being harmful to human health and the environment. Research is currently being conducted to further evaluate modern fluorotelomer and fluorine-free alternatives. Research is discussed below.

3.13.1 Research on Current AFFF

Research is being conducted to provide a better understanding of AFFF in the environment and to develop novel technologies to clean up or remove AFFF at contaminated sites. Due to the ability of these legacy AFFF to spread quickly and prevent re-ignition of fuel fires, combined with the fact the USEPA did not require manufacturers to remove their long-chain inventory as part of the 2010/2015 PFOA Stewardship Program, some legacy stockpiles are still being used today (**Barclift 2013**).

Since 2017, the Strategic Environmental Research and Development Program (SERDP) has been funding research intended to identify and test F3s that meet the performance requirements defined in MIL-PRF-24385. New formulations must be compatible with existing AFFF and supporting equipment. Projects include evaluation of persistence and aquatic toxicity of the alternative materials and will provide human health and environmental impact assessments on the ingredients, formulations, and byproducts being studied. **Table 3-8** summarizes the current AFFF alternatives studies supported by SERDP-Environmental Security Technology Certification Program (ESTCP). The user is encouraged to view the results and full reports of these and future projects on the SERDP-ESTCP website (https://serdp-estcp.org/).

Table 3-8. Summary of the AFFF alternatives studies supported by SERDP-ESTCP.

Lead Investigator	Objectives	Expected Completion	Project Link
Dr. Joseph Tsang, Naval Air Warfare Center Weapons Division	Proof-of-concept for the development of the next generation of fluorine-free firefighting foam formulations as a replacement for existing aqueous film-forming foam (AFFF). The novel foam systems produced in this research are derived from polysaccharide copolymers and nanoparticles that are sustainable, nontoxic, and water-soluble (or water-dispersible), and will be applied using existing military firefighting equipment.	Aug-18	https://serdp-estcp.org/Program-Areas/Weapons-Systems-and-Platforms/Waste-Reduction-and-Treatment-in-DoD-Operations/WP-2737/WP-2737
Dr. John Payne, National Foam	Improve understanding of the physical and chemical processes that underlie firefighting foams, and how the components of a foam formulation can deliver the properties required for good fire-extinguishing performance while minimizing environmental burdens. Statistical method will be employed to develop a fluorine-free surfactant formulation that meets the performance requirements defined in MIL-F-24385. A life cycle assessment will compare the environmental impact of each foam type and identify routes to improving environmental performance.	Sept-19	https://serdp-estcp.org/Program-Areas/Weapons-Systems-and-Platforms/Waste-Reduction-and-Treatment-in-DoD-Operations/WP-2738/WP-2738
Dr. Ramagopal Ananth, U.S. Naval Research Laboratory	Develop a fluorine-free firefighting surfactant formulation that meets the performance requirements of MIL-F-24385F and is an environmentally friendly drop-in replacement for the current environmentally hazardous AFFF.	Dec-20	https://serdp-estcp.org/Program-Areas/Weapons-Systems-and-Platforms/Waste-Reduction-and-Treatment-in-DoD-Operations/WP-2739/WP-2739
Prabhat Krishnaswamy Engineering Mechanics Corporation of Columbus (Emc2)	WP22-7521. This project's technical objective is to develop a novel approach for fighting gasoline pool fires based on fire-retardant additive releasing smart beads.	Initiated 2022	https://www.serdp-estcp.org/projects/details/352aa6f8-fae0-4cf6-8080-0fc319700142/wp22-7521-project-overview
Dr. Girish Srinivas, TDA Research, Inc.	WP22-7456. TDA Research, Inc.'s objective is to collect baseline data for the PFAS-free foam under MIL-PRF-24385F to inform what specifications could be adjusted to fully evaluate PFAS-free foams for fire suppression and environmental impact.	Initiated 2022	https://www.serdp-estcp.org/projects/details/baa72637-e3c8-40ee-a007-f295311c72ad/wp22-7456-project-overview
Dr. Tirumalai Sudarshan, Materials Modification Inc.	WP22-3456. This project's technical objective is to develop a novel approach for fighting gasoline pool fires based on fire-retardant additive releasing smart beads.	Initiated 2022	https://www.serdp-estcp.org/projects/details/b4cada93-5acf-47ff-ab68-c115a9c6c6ab/wp22-3436-project-overview
Eric Sievert, Naval Air Warfare Center Weapons Division	WP21-3461. During this follow-on effort, the capabilities of the top fluorine-free products will be assessed and validated against the test configurations used to assess the capabilities of AFFF 30–40 years ago.	2021	https://www.serdp-estcp.org/projects/details/1bed98f7-dbe6-4bdd-98d2-1f9cfeb5f3d9/wp21-3465-project-overview
Dr. Satya Chauhan, Battelle Memorial Institute	WP20-5335. The objective of this project is to provide comparative and unbiased demonstration and validation of mature Fluorine-Free Fire Suppression Alternatives (FF_FSA) against military specifications (MIL-SPEC), specifically MIL-PRF-24385F, as amended, to permit transition to field use as a firefighting agent.	2020	https://www.serdp-estcp.org/projects/details/164cac28-0322-4d7a-8980-80a1146b5afa/wp20-5335-project-overview
Kevin Roth, ADA Technologies, Inc.	WP20-5381 Testing of New Fluorine-Free Green Surfactants Mixture to Replace AFFF	4/20/2022 Project Brief	https://serdp-estcp-storage.s3.us-gov-west-1.amazonaws.com/s3fs-public/project_documents/WP20-5381%2BProject%2BOutbrief.pdf?VersionId=5e69zE0HUHJoVs.NrGmWPp1ZiZM1wWjH
Dr. Bridgett Ashley, Air Force Civil Engineer Center	WP 20-5381. The goal of a water mist system in an aircraft hangar is to suppress and mitigate fire events and prevent damage to aircraft surfaces that are directly above and/or adjacent to the fuel spill fire.		https://www.serdp-estcp.org/projects/details/cb97638e-8d4e-4892-adce-343575ca862c/wp21-5212-project-overview

4 PHYSICAL AND CHEMICAL PROPERTIES

This section provides information about available physical and chemical properties of PFAS. Understanding of the physical and chemical properties of PFAS is important for the prediction of their fate and transport in the environment. The available information about physical and chemical properties varies between the different PFAS. Tabulated values are included in the Physical and Chemical Properties Table (Table 4-1) that is provided as a separate Excel file. The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about perfluoroalkyl acid (PFAA) precursor biotransformation (see **Section 1.3.3**). In addition, a new tab named Biotransformation was added to the Physical and Chemical Properties Table (Table 4-1). The biotransformation table includes a compilation of available precursor kinetics data (see **Section 1.3.3.2**).

Section Number	Topic
1.3	**Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization (2025)**
4.1	**Challenges and Limitations Related to PFAS Physical and Chemical Properties**
4.2	**Physical Properties**
4.3	**Chemical Properties**

4.1 Challenges and Limitations Related to PFAS Physical and Chemical Properties

Understanding the physical and chemical properties of PFAS is important for the prediction of their fate and transport in the environment. More specifically, reliable values are very important when attempting to explain the environmental behavior of PFAS through mathematical fate and transport modeling, where small variations in values can have large implications on predictions (see **Section 10.4** on data analysis and interpretation, which includes a discussion of fate and transport modeling). There is large variation in both the quantity and robustness of published data (a lot is known about some PFAS, but almost nothing about others) on chemical and physical properties of PFAS. Reliable physical and chemical properties of PFAS are scarce (for example, vapor pressure and Henry's Law constants), and some of the available values are estimated using predictive mathematical techniques, which predict properties of compounds from knowledge of their chemical structure. These are collectively referred to as quantitative structure-activity relationship (QSAR) models. Predicted, as opposed to directly measured, values are accompanied by additional uncertainty that may be significant in certain fate and transport modeling scenarios. In addition, many of the available properties are based on the acid form of the PFAAs, which is not present in the environment except at low pH. These uncertainties can result in wide ranges of reported values and thus limit confidence in the precision of current fate and transport models. The Physical and Chemical Properties Table (Table 4-1 provided as a separate Excel file) summarizes some of the physical and chemical properties that are available for PFAS. The object of this table is to serve as a starting point for the research and selection of relevant properties by the practitioner. Selection of appropriate physical and chemical parameters for a specific use is beyond the scope of this document.

4.2 Physical Properties

This section briefly describes some standard physical properties of PFAS. Additional references for more information are provided. In addition, the Physical and Chemical Properties Table (Table 4-1 provided as a separate Excel file) summarizes some of the physical and chemical properties that have been published for PFAS and are discussed in this section.

4.2.1 Physical State/Appearance

Most PFAS are solids, often crystalline or powdery in form, at room temperature; however, shorter chained compounds (the acid forms of PFCA and PFSA, FTS and FTOH with a 4- to 6-carbon tail) tend to take liquid form at room temperature (melting point is addressed in **Section 4.2.3**).

4.2.2 Density

Density (ρ) is the mass per unit volume of a substance. For an individual PFAS compound (or mixture of PFAS) that exists as a liquid at ambient temperatures, density can influence its behavior in the environment.

If the density of the liquid PFAS is greater than that of water, the liquid PFAS has the potential to migrate downward through the water column in groundwater or surface water as a dense nonaqueous phase liquid (DNAPL); see **ITRC (2003)** for discussion on density and solubility impacts on DNAPL behavior. For example, 4:2 FTOH, which is a liquid at 20ºC and has a density and aqueous solubility of 1.59 g/cm^3 and 974 mg/L (**Table 4-1**), respectively, would be predicted to behave similarly to carbon tetrachloride (with a density of 1.59 g/cm^3 and a solubility of 800 mg/L) if released into the environment as a pure product (also referred to as a neat liquid). However, if 4:2 FTOH dissolved in water, the change in density of the solution relative to water is unlikely to result in a separate layer. Floating separate-phase liquid layers have been observed on the surface of aqueous PFOA and PFOS solutions at high concentrations (**Costanza et al. 2019**). However, the formation of these layers appears to be driven by the tendency of PFAAs to accumulate and aggregate at air-water interfaces, and not by density. See Sections **4.2.8**, **5.2.2.2**, and **5.2.4.1** for additional information on the behavior of PFAS at air-water interfaces and in aqueous solutions.

4.2.3 Melting/Boiling Points

Melting and boiling point information refers to the temperature of phase transitions of pure compounds. These properties determine whether a specific pure PFAS compound will exist as a liquid, solid, or gas under typical environmental temperatures. These data can vary among references. Predicted melting and boiling point values are available for most PFAS, but empirically derived values are not available for many compounds. Predicted values are generally useful in understanding the various physical states of PFAS; however, the accuracy of these results is still unknown and warrants further investigation. Available data indicate that melting and boiling points of PFAS will tend to increase as the fluorinated chain increases in length. For example, the melting point of PFBA is -17.5°C while the melting point of perfluorotetradecanoic acid (PFTeDA) is 130–135°C. See **Table 4-1** for a list of melting and boiling points.

4.2.4 Solubility

Solubility (S) refers to the ability of a given substance, the solute, to dissolve in a solvent. It is measured in terms of the maximum amount of solute dissolved in a solvent at a specified temperature and pressure. Typical units are milligrams per liter (mg/L) or moles per liter (mol/L). Currently, experimentally measured data for the solubility of PFAS in water are available for many of the well-studied compounds, but values are still needed for less studied compounds. This limited availability of experimental data should be considered when relying on PFAS solubility data. Most cited values are based on predicted or modeled values and the input values to these calculations may themselves be estimates. Further, because some PFAS can form different types of supramolecular assemblies, as discussed in **Section 4.2.7**, the reported water solubilities may include microdispersions of micelles or hemi-micelles in addition to truly solubilized molecules.

Values of solubility for the acid forms of PFAAs and other PFAS are summarized in **Table 4-1**. Reported values for solubility of individual PFAS analytes may vary depending upon the method used to determine solubility, the form of the analyte (that is, acid or salt), pH, salinity, and whether the value is empirical or obtained through modeling. For example, laboratory studies of water solubilities for PFOS indicate that solubility decreases when the water salt content increases (**3M Company 2000**). Other factors may affect the reported value of solubility as well.

4.2.5 Vapor Pressures (V_p)

Vapor pressure is an indication of the tendency of a substance to partition into the gas phase. Vapor pressure is a measure of volatility in that the higher the vapor pressure of a compound, the more volatile it is. Compounds with higher vapor pressures, because they are in the gaseous phase or sorbed to aerosols in the atmosphere, have a higher potential for long-range transport. Compounds with lower vapor pressures, which are more likely to remain in solid or liquid form, are transported only via soil or surface/groundwater (**Barton, Botelho, and Kaiser 2008**), unless they are dissolved into airborne water droplets or sorbed on airborne particulates, as discussed in Sections **5.3.2** and **6.1**. **Section 1.1.3.3** includes information about volatile PFAS. See also the **PFAS and Vapor Intrusion Fact Sheet** developed in 2025.

Values for vapor pressure of PFAS are summarized in **Table 4-1**. Although there are multiple values for PFCAs, FASEs, and FTOHs, very little data exist for measured vapor pressure values for PFSAs, fluorotelomer acids, and perfluoroalkyl ether compounds, and much of the data are extrapolated or modeled. Caution must be taken when using the vapor pressures for PFAAs listed in **Table 4-1** with respect to the acid or **anion** form of the compound, which may have very different vapor pressures. Efforts were made to report the values for the acidic form in **Table 4-1**, but references are not always clear. These values also should not be used for their corresponding salt form for the same reason (for example, the vapor pressure of ammonium perfluorooctanoate has been measured experimentally to be three orders of magnitude lower than the vapor pressure of perfluorooctanoic acid at 25°C (**Barton, Botelho, and Kaiser 2009**)).

4.2.6 Henry's Law Constant (K_h)

The Henry's law constant (K_h), as well as the air-water partition coefficient (K_{aw}), indicate the relative concentrations of a compound between an aqueous solution and gas phase at equilibrium (air-water distribution ratio) and provide an indication of the propensity of a chemical to remain dissolved in water versus volatilizing into the gas phase. A chemical with lower solubility and higher volatility will have a higher Henry's law constant than a chemical with higher solubility and lower volatility. **Section 1.1.3.3** includes information about volatile PFAS. See also the **PFAS and Vapor Intrusion Fact Sheet** developed in 2025.

For most organic compounds of moderate to low solubility, K_h can be approximated by:

$$K_h = (V_p)(M)/S$$

where K_h is the Henry's law constant, V_p is vapor pressure, M is molecular weight, and S is solubility. This constant can be expressed in a variety of units or as the inverse (water-air distribution ratio); thus, the units of expression should always be confirmed prior to use of this constant. K_h also displays nonlinear temperature-dependence and is typically reported at 25°C, which is higher than most ambient environmental conditions.

Experimental and modeled Henry's law constants are available for many PFAS in several families, including FTOHs (for example, **Wu and Chang (2011)** and **Xie et al. (2013)**), PFSAs, PFCAs, FTCAs, FTSAs, FASEs, and FASAAs (for example, **Kwan (2001)** and **Zhang et al. (2010)**). For PFAS that can

dissociate into anions or cations, as discussed in **Section 4.3.2**, the Henry's law constant is pH-dependent and reported constants may not be applicable depending on the pH conditions within the solution (for example, **Rayne and Forest (2009)** and **Johansson et al. (2017)**). In a study of airborne PFOA release in industrial settings, monitoring above sumps found concentrations 40 times greater when the pH was 1.8 than at neutral pH, and PFOA release from aqueous solution was found to be several times greater at pH 4 than at pH 7 (**Kaiser et al. 2010**). Henry's law constant values, converted between a variety of units, are presented in **Table 4-1**. Corresponding K_{aw} values and, where available, the temperature and pH at which the value is relevant, are also presented.

4.2.7 Critical Micelle Concentration

Given the difference in behavior between the "head" and "tail," traditional surfactants (surfactants that contain a hydrocarbon chain), when in water, tend to aggregate into micelles (form a sphere with the hydrophobic portion of the molecules on the inside) when present above a certain concentration. Surfactants can also form other supramolecular assemblies, such as hemi-micelles or mixed micelles (micelles composed of a mixture of surfactant-type molecules), either independently in solution or at boundaries occurring between phases (**Krafft and Riess 2015**).

Early studies of PFAAs concluded that they behaved like traditional surfactants and aggregated in both micelles and mixed micelles (**Pedone et al. 1997**; **Downer et al. 1999**). The theoretical threshold concentrations for aggregation, generally referred to as critical micelle concentrations (CMCs), for PFAS are presented in **Table 4-1**. However, there remain some observed properties of PFAS that do not fit the traditional understanding of micelle formation. For example, it appears that some reported CMC concentrations are above the known corresponding solubilities of that compound. For example, **López-Fontán, Sarmiento, and Schulz (2005)** reported a PFOA CMC of more than 12,000 mg/L when the reported solubilities of PFOA are generally less than 10,000 mg/L (see **Table 4-1**). Several reported CMC concentrations for PFOS are also above the reported solubility values (**Yu et al. 2009**; **Sørli et al. 2020**; **Bhhatarai and Gramatica 2011**). In addition, **Costanza et al. (2019)** reported a separate-phase liquid at the surface of high-concentration solutions of PFOS and PFOA. These anomalous breaks with traditional micelle formation behavior have yet to be fully explained in the literature. Some researchers have also postulated that the nature of PFAA supramolecular aggregations is much more complicated in environmental settings than formation of micelles at concentrations exceeding the CMC value, which is derived from single compound systems. Some have hypothesized that PFAA supramolecular aggregations may occur at concentrations much lower than the CMC in groundwater, due to interactions with particles and/or co-contaminants, formation of hemi-micelles, or spatially variable concentrations within soil matrices (**Johnson et al. 2007**; **Yu et al. 2009**). Other researchers have been studying the variable nature of PFAS micelles in the presence of solvents (**Dong et al. 2021**). These hypothesized supramolecular aggregations, coupled with the interrelationship of adsorption to interfaces such as the air-water interface, present an extremely complex set of interactions that may be occurring in the environment. It is evident that there is much more research to be done on this topic, which can aid our understanding in what may be a key PFAA characteristic that influences fate and transport in the environment. This topic is further discussed in **Section 5.2**.

4.2.8 Partitioning to Fluid-Fluid Interfaces

The amphiphilic structure of PFAAs (hydrophobic tail with hydrophilic head) implies that they behave like traditional surfactants, accumulating to the fluid-fluid interfaces (for example, air-water or NAPL-water) by orienting themselves along the air-water boundary so that their hydrophobic tails are in the air while their hydrophilic head groups are in the water (**Krafft and Riess 2015**; **Figure 4-1**). Although there has been a good deal of research done that confirms surface aggregation, the actual structure of the molecular assemblies has not yet been elucidated. Work done by **Hasegawa et al. (2017)**, however, has provided some theories that the aggregational shape of PFAS may be more complex than that of

traditional surfactants and depend on the length of the fluorinated tail. See **Section 1.3.1.1** for information about air-water partitioning.

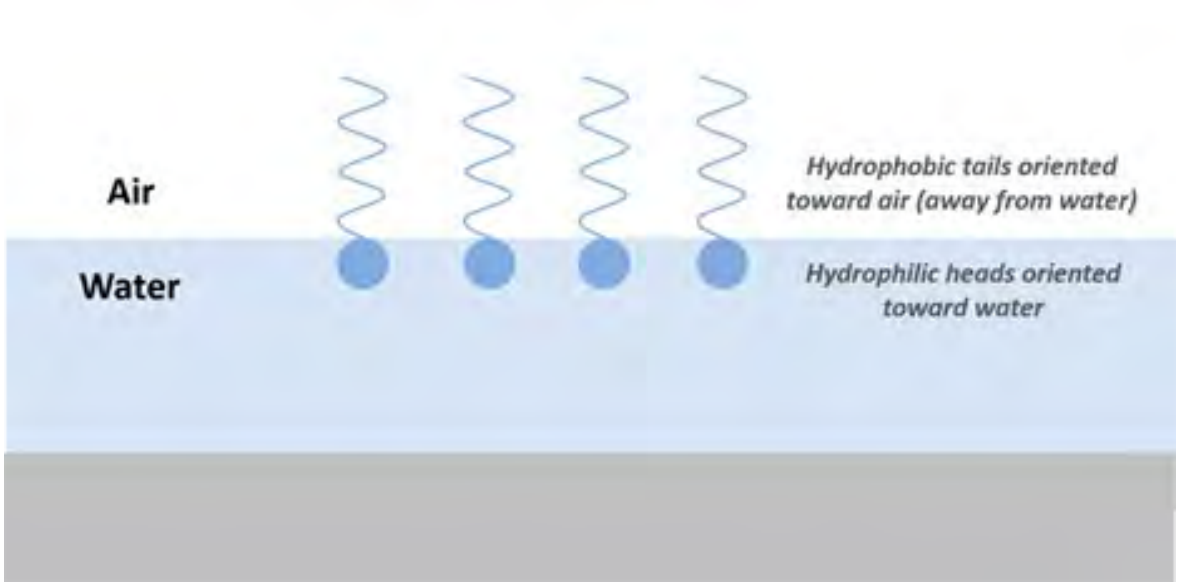

Figure 4-1. Example of expected orientation and accumulation of PFAS at air-water interface.

Source: D. Adamson, GSI. Used with permission.

Because of the low polarizability of the C-F bond relative to the C-H bond, PFAAs have a stronger affinity for interfaces than that of traditional hydrocarbon surfactants (**Brusseau 2018**). These strong surface-active properties and propensity toward self-assembly into films are what makes PFAAs extremely effective and widely used in a variety of applications such as water/grease repellent packaging and AFFF.

Studies have shown that PFAAs are enriched at the air-water interface up to eight times that of the bulk water concentration, with enrichment factors increasing with alkyl chain length (**Psillakis et al. 2009**; **Costanza et al. 2019**; **Silva et al. 2019**; **Schaefer et al. 2019**). A similar process is thought to occur for PFAAs at NAPL-water interfaces (**Brusseau 2018**; **Silva et al. 2019**; **Brusseau 2020**), however, the magnitude of accumulation at the NAPL-water interface appears to be far less than at the air-water interface at environmentally relevant concentrations. Recently, **Costanza, Abriola, and Pennell (2020)** reported that concentrations of PFOA, PFOS, and FOSA at the air-water interface were from 2 to 16 times greater than at the NAPL-water interface when the PFAS water concentrations were below 100 mg/L. This study also estimated that, in an unsaturated soil system with a dissolved water concentration below 1 mg/L, up to 87% of the PFOS mass accumulates at the air-water interface, while less than 4% of the mass occurs at the dodecane-water interface.

The degree of affinity that PFAAs exhibit for interfaces is related to the change in surface tension that occurs between the fluids when the compound is introduced to the system. Generally, the surface tension and affinity for the interface both go down as the amount of PFAA increases in the system, although the relationship is not linear. This means that the relationship is influenced by other factors that also effect the surface tension at interfaces (for example, the ionic strength and pH of the solution). For example, **Constanza et al. (2019)** found that the reduction in surface tension was more pronounced as the total dissolved solids increased (for TDS = 40, 400, and 1700 mg/L), which corresponded to greater accumulation of PFOA and PFOS at the air-water interface.

The adsorption coefficient for the fluid-fluid interfacial layer, termed the K_i (also called the K_{ai} or K_{ia} for the air-water interface or the K_{ni} for the air-NAPL interface) is one metric for the affinity of a compound for

fluid-fluid interfaces. However, calculation of the K_i is highly dependent on which assumed sorption model (Freundlich vs. Langmuir) is used, and values can vary by orders of magnitude at low concentrations (**Schaefer et al. 2019**). Because of this, it can be more useful to measure the affinity using the metric of surface excess (Γ, units of mg/m^2 or mol/m^2), which is the area-related concentration at the interface as compared to the bulk phase (**Costanza, Abriola, and Pennell 2020**). Because of the complicated nature of interfacial adsorption, adsorption coefficient values are not reported in **Table 4-1**.

4.2.9 Octanol/Water Partition Coefficient (K_{ow})

The K_{ow} is defined as "the ratio of a chemical's concentration in the octanol phase to its concentration in the aqueous phase of a two-phase system" (**USEPA 2015**). The Kow is a useful descriptor of the tendency of a compound to associate with hydrophobic or hydrophilic substances. Direct measurement of the K_{ow} of PFAAs has proven difficult because they tend to aggregate at the interface between octanol and water (**Kim et al. 2015**), although some researchers have employed nontraditional methods with some success (**Jing, Rodgers, and Amemiya 2009**). Alternatively, K_{ow} can be estimated using quantitative tools that predict physical and chemical properties. The K_{ow} values that are typically tabulated for the PFCAs and PFSAs are for the acid form and are therefore not directly relevant to the anionic forms of PFCAs and PFSAs that exist within the typical range of environmental pH, although the K_{ow} for the anionic form can potentially be estimated from the K_{ow} for the neutral species (**Escher et al. 2020**).

K_{ow} values are often used as surrogates for other properties, such as estimating K_{oc}, the soil organic carbon/water partition coefficient; bioaccumulation; uptake in biological systems; and ecotoxicity. However, in the case of PFAS, the use of their K_{ow} values as surrogates is generally not appropriate because PFAS do not behave like other well-researched nonionic polar chemicals. For example, the use of K_{ow} as a surrogate for bioconcentration assumes partitioning to lipids in fatty tissues, but ionic PFAS such as PFOA and PFOS generally bind to proteins. See **Section 5.5** for further discussion about PFAS uptake into aquatic organisms. For these reasons, K_{ow} values are not presented in **Table 4-1**.

4.2.10 Organic Carbon/Water Partition Coefficient (K_{oc})

K_{oc} is a metric commonly used to quantify the potential of a given dissolved compound to associate with, or sorb to, organic matter occurring in soil. Although short- and long-chain PFAAs both exhibit high potential mobility in water, long-chain PFAS are more likely to partition to sediment than short-chain PFAAs (**Dalahmeh et al. 2018**). Relative to commonly researched PFAS like PFOA and PFOS, studies have suggested K_{oc} can be appropriately defined as a distribution coefficient (K_d) normalized to organic carbon content, thus implying K_{oc} specifically represents the singular process of hydrophobic interaction (**Milinovic et al. 2015**). Broader reviews highlight the complexity and variability of processes that may contribute to the sorption of PFAS and significant differences between laboratory- and field-scale results (**Li, Oliver, and Kookana 2018**). These reviews, which cite the influence of pH, ionic composition, and other soil properties on sorption, suggest that simple hydrophobic interaction-based relationships may be unreliable for predicting partitioning for PFAS (see **Section 5.2** for more discussion on partitioning). As such, the current state-of-science supports K_{oc} being reported in relatively broad ranges on a compound-specific basis. The K_{oc} values included in **Table 4-1**, while not an exhaustive list, are an indicator of the number of values currently available for PFAS. Discussion of the use of K_{oc}, including site-specific K_{oc}, in the prediction of PFAS transport in remedial scenarios is included in **Section 10.4.2**.

4.2.11 Partitioning to Biota

The extent of accumulation of PFAAs in organisms is controlled by several mechanisms, including uptake from food and from water, depuration, growth dilution, and biotransformation. These processes are described in **Section 5**. Within organisms, PFAA accumulation differs among tissues, depending on transport factors (for example, the ability to cross the blood-brain barrier, as discussed in **Dassuncao et**

al. (2019) or active cellular transport (as discussed in **Section 17.2.3**) as well as partitioning. Partitioning is the subject of this section.

Similar to solids partitioning in the environment, the surfactant structure of PFAAs determines the types of interactions that occur within biota. Nonionic hydrophobic chemicals are known to partition into lipids within body compartments. PFAAs are amphiphilic, however, and thus are likely to interact with other organic molecules with both polar and nonpolar regions within living organisms. Many studies have found significantly different PFAA concentrations between body compartments, with the most accumulation occurring in the blood plasma, liver, and kidneys of many organisms (**Labadie and Chevreuil 2011**; **Goeritz et al. 2013**; **Murakami et al. 2011**). This marked difference in PFAA concentrations between bodily compartments has prompted some researchers to deem PFAAs "proteinophilic" to contrast with the description of other well-researched neutral hydrophobic environmental pollutants as "lipophilic" (**Kelly et al. 2009**; **Labadie and Chevreuil 2011**). Indeed, these differences in accumulation are likely, at least in part, due to interaction with/partitioning to proteins, which have binding pockets with varying charges that can interact with amphiphilic molecules like PFAAs. However, because the size, shape, and charge of binding pockets vary widely between proteins, there is an evident difference in PFAA binding between types of protein. Multiple studies have found strong interaction of PFAAs to serum albumin, fatty acid–binding proteins, and organic anion transporters (**Chen and Guo 2009**; **Zhang, Ren, and Guo 2013**). The magnitude of protein binding affinity differs with the type of PFAAs; **Zhang, Ren, and Guo (2013)** found that PFAA chain length and functional group determined the amount of binding affinity, but the relationship between binding and chain length was not linear. They also found that FTOHs (neutral charge molecules) did not bind to fatty acid–binding proteins, indicating that the charge of the functional group plays a large part in the protein interaction.

In addition to proteins, PFAAs likely interact with phospholipids (the basic building block of cell membranes). **Dassuncao et al. (2019)** found a positive correlation between PFAA and phospholipid content in several body compartments of pilot whales. It has been suggested that the interactions occur because of the amphiphilic nature of both phospholipids and PFAAs, which have the potential for binding at both their polar and nonpolar regions (**Armitage, Arnot, and Wania, 2012**). However, researchers have not found evidence that these interactions are the main determinant of tissue binding. **Dassuncao et al. (2019)** noted variability in the correlations between phospholipid content and tissue concentrations and concluded that the variability was likely due to the combined effect of protein and phospholipid partitioning.

For nonionic hydrophobic compounds, differences in lipid content can explain some of the variation in chemical concentration among organisms; under some conditions, individuals with higher lipid content have higher body burdens. In general, protein content differs to a much smaller extent among organisms than does lipid content, suggesting that differences in protein partitioning among individuals do not contribute strongly to differences in body burden among individuals. However, the sources of interindividual variation in PFAA body burdens is not well-understood and there is no current framework to incorporate our understanding of PFAS partitioning (for proteins and phospholipids, as well as lipids, which may still have a role) into reliable models for the prediction of bioaccumulation, biotransfer, or biomagnification.

4.3 Chemical Properties

This section briefly describes some standard chemical properties of PFAS. Additional references are provided for more information. In addition, the Physical and Chemical Properties Table (Table 4-1 provided as a separate Excel file) summarizes some of the physical and chemical properties that are available for PFAS.

4.3.1 Carbon-Fluorine (C-F) Bond Properties

The properties of PFAS are principally due to the unique properties of the carbon-fluorine bond. Some key chemical properties of this bond and the characteristics they impart to PFAS are provided in **Table 4-2**.

Table 4-2. Fluorine characteristics.

Fluorine Characteristic	Description	Effect	Resulting Property of PFAS
High electronegativity	Tendency to attract shared electrons in a bond	Strong C-F bond	Thermal stability
			Chemical stability (low reactivity)
		Polar bond with partial negative charge toward F	Strong acidity (low pKa)[1]
Low polarizability	Electron cloud density not easily impacted by the electric fields of other molecules	Weak intermolecular interactions	Hydrophobic and lipophobic surfactant properties[2]
		Low surface energy	
Small size[3]	Atomic radius of covalently bonded fluorine is 0.72 Å	Shields carbon	Chemical stability (low reactivity)

[1]When paired with an acid functional group such as a carboxylic or sulfonic acid
[2]When paired with a functional group that is hydrophilic (for example, a carboxylate)
[3]Smallest of the halogen atoms
Å = angstrom

Properties such as the high electronegativity and small size of fluorine lead to a strong C-F bond, the strongest covalent bond in organic chemistry (**Kissa 2001**). The low polarizability of fluorine further leads to weak intermolecular interactions, such as Van der Waals interactions and hydrogen bonding (**Kissa 2001**). These unique properties of fluorine give many PFAS their mutually hydro- and lipophobic (stain-resistant) and surfactant properties and make them thermally and chemically stable. But not all of these characteristics (for example, surface activity) are universal to all PFAS.

4.3.2 Functional Group Properties

PFAS functional groups include carboxylates, sulfonates, sulfates, phosphates, amines, and others, as introduced in **Section 2.2.2**. These functional groups, including dissociated and undissociated forms, govern many fate and transport properties of PFAS. The ionic state of a compound determines its electrical charge and its physical and chemical properties, which in turn control its fate and transport in the environment. For example, the state (anionic or undissociated acid) of a given PFAS may alter aspects such as volatility and bioaccumulative potential. As further described below, due to their low acid dissociation constants (K_a), PFAAs are found in the environment in the anionic (negatively charged) state, except in very rare situations (for example, pH <3).

Functional groups of some PFAS (ionic PFAS) can dissociate into anions or cations in aqueous solution under appropriate pH conditions. For example, as discussed in **Section 2.2.2**, PFOA dissociates into the perfluorooctanoate anion and the hydrogen ion when dissolved in water over a wide range of pH conditions. The ion associated with the fluoroalkyl portion of ionic PFAS can be a negatively charged anion, a positively charged cation, or a zwitterion. Therefore, PFAS can be divided into four classifications

based on functional groups (examples of the structures of many ionic PFAS can be found in **Barzen-Hanson et al. (2017)**:

- anionic–contains one or more acidic functional groups such as carboxylic acids, sulfonic acids, sulfates, and phosphates, and can release a hydrogen ion, thereby forming an anion (see **Figure 2-8** for PFBA dissociation)
- cationic–contains one or more basic functional groups such as amines, which can gain a hydrogen ion and form a cation, or have a permanent charge as in the case of a quaternary ammonium group
- zwitterionic–contains two or more functional groups, at least one of which can form an anion and one of which can form a cation
- nonionic–does not dissociate into ions; for example, alcohols.

Based on the behavior of other cationic and anionic surfactants, cationic PFAS are expected to have different environmental transport characteristics than anionic PFAS (**Place and Field 2012**). For example, sorption of organic anions such as PFAA anions is typically suppressed at higher pH due to electrostatic repulsion with the increasingly negative charge from deprotonated oxides and other functional groups present on the soil surface (**Lee and Mabury 2017**). Cations can be expected to sorb strongly to soils, which often possess a net negative charge over a range of environmentally relevant pHs. For example, cationic fluorotelomer-based PFAS in an AFFF product have been found to sorb strongly to soils and sediments (**Barzen-Hanson et al. 2017**). Zwitterionic PFAS can be expected to sorb to soils and sediment more strongly than anionic PFAS, but less strongly than cationic PFAS, owing to the mixed charges on the functional groups. The transport characteristics of specific PFAS are also highly dependent on matrix interactions, and detailed site-specific information is necessary to accurately predict PFAS transport (**Guelfo and Higgins 2013**). See **Section 5.2.3** for further discussion of partitioning onto solid matrices.

For acids such as PFAAs, the acid dissociation constant K_a is the equilibrium constant for the dissociation of the acid in aqueous solution into the anion and hydrogen ion, and at dilute to moderate concentrations, is defined by the equation:

$$K_a = [anion^-]*[H^+]/[acid]$$

where [acid] is the concentration of the undissociated acid form, $[anion^-]$ is the concentration of the anion, and $[H^+]$ is the concentration of the hydrogen ion at equilibrium.

The dissociation constant is also commonly expressed as its negative logarithm, pK_a, where:

$$pK_a = - \log_{10}(K_a)$$

Higher pKa values indicate that an acid will dissociate less in water at a given pH than will an acid with a lower pKa. When the pH of a solution equals the pKa for a particular constituent, then one half of the constituent molecules will exist as the undissociated acid and one half will exist as the dissociated anion. PFAS with pKa values of 4 or less will exist in aqueous solutions at neutral pH (7) almost entirely as the dissociated acid (see **Figure 4-2** for a representation of reported pKa values for PFOA in relation to environmental pHs). Because the undissociated acid and anionic forms of PFAAs may have very different physical and chemical properties, it is essential to distinguish between the undissociated acid form and the anionic form to select the appropriate physical and chemical parameters for fate and transport evaluations.

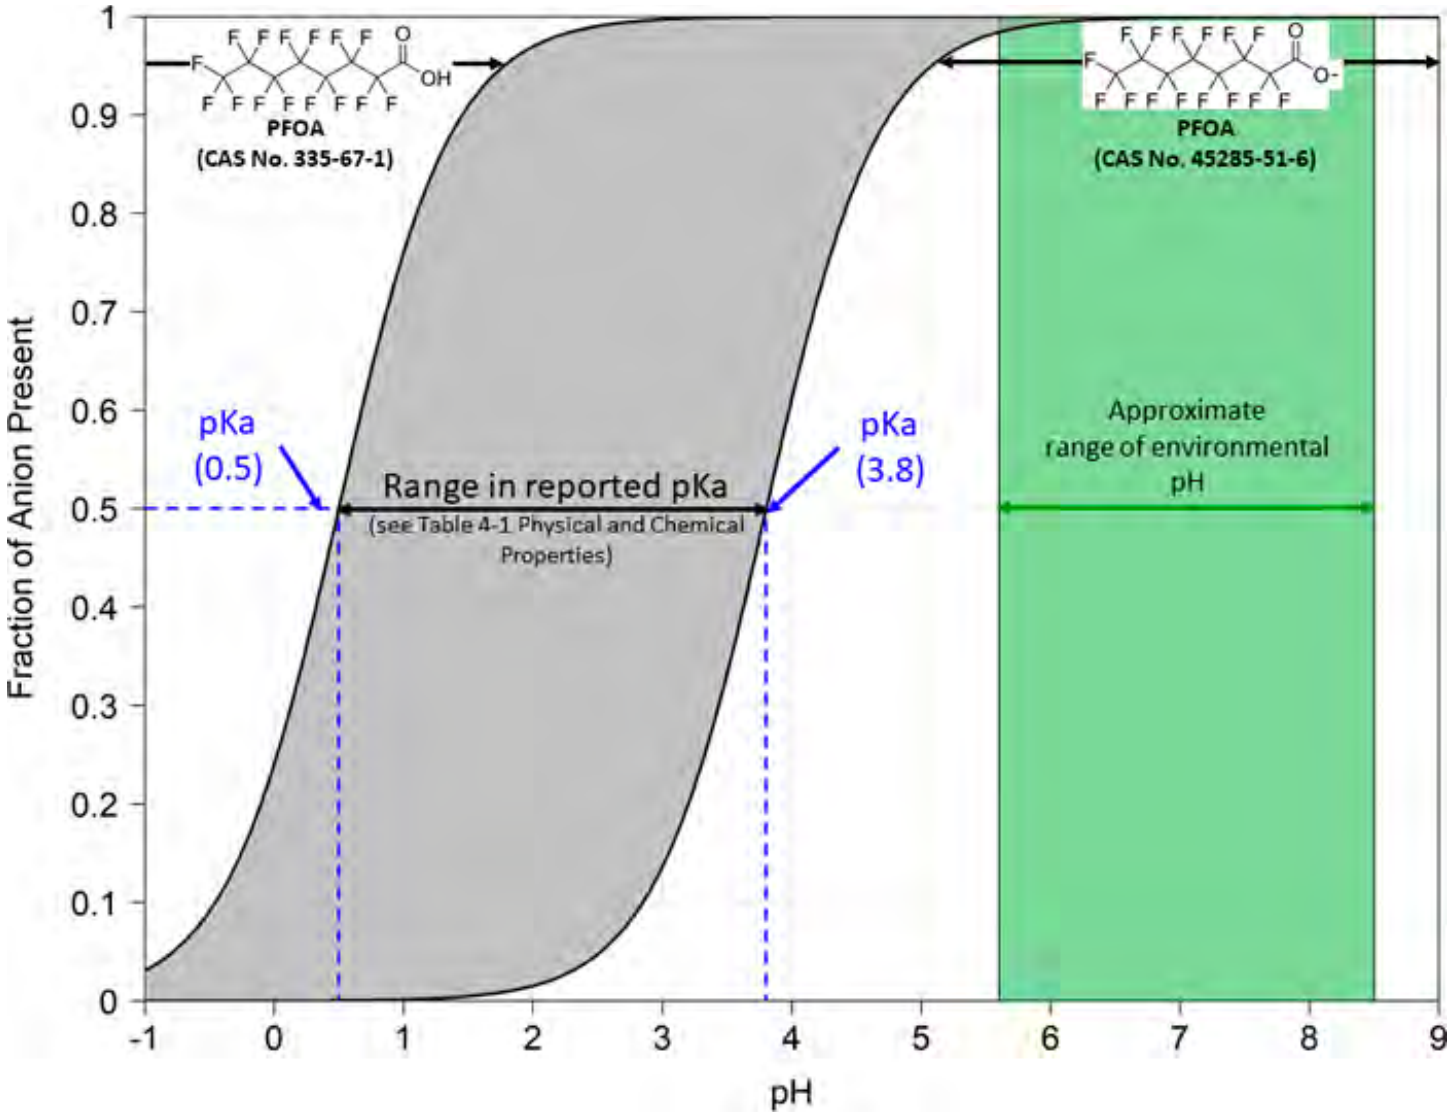

Figure 4-2. Titration curve for PFOA—relation of pKa to environmental pH.

Table 4-1 presents pK_a values for PFAS. Limited model-predicted and experimental values are available for most PFAAs.

4.3.3 Thermal Stability

Thermal stability, the degree to which a chemical remains intact under thermal stress, is an important property to predict how long a chemical will persist in the environment. PFAAs, such as PFOA and PFOS, are extremely stable, thermally and chemically, and resist degradation and oxidation. Thermal stability of PFAAs is primarily attributable to the strength of the C-F bond in the fluoroalkyl tail (**Kissa 2001**), but the relative stability is also determined by the specific functional group that is attached to the fluoroalkyl tail. PFCAs and PFSAs are the most thermally stable fluorinated surfactants. The temperatures at which PFAAs decompose and complete mineralization occurs is an area of active research (see **Section 12.4**). Reports on temperature needed to destroy PFAS vary, but it seems that to destroy PFAS in soil, temperatures upwards of 1,000°C may be required (**Colgan et al. 2018**; **Winchell et al. 2021**). It was

previously reported that limited PFOS, PFOA, and PFHxA mineralization (less than or equal to 72%) may occur at temperatures of 700ºC (**Watanabe et al. 2018**). In this same study, mineralization reportedly increased to 90% in the presence of granular activated carbon and sodium hydroxide. The thermal stability is lower for the salts of PFAA compounds and depends on which cation is the counterion. For example, the 20% decomposition temperature of sodium perfluorooctanoate is 298°C, but it is 341°C for lithium perfluorooctanoate (**Kissa 2001**). Additionally, salts of PFSAs are more thermally stable than the corresponding salts of PFCAs (**Kissa 2001**).

4.3.4 Chemical Stability

Like thermal stability, knowledge of the chemical stability of a molecule helps predict its persistence in the environment. PFCAs and PFSAs have been shown to be persistent in the environment. PFCAs are resistant to oxidation under environmental conditions; however, transformation has been demonstrated in the presence of oxidants under extreme pressure. In contrast, transformation of precursors can be associated with substantial changes in the physicochemical properties of those compounds (**CONCAWE 2016**). See **Section 1.3.3** for information about PFAA precursor biotransformation.

In the perfluorinated tail of the alkyl acids, the strength of the C-F bond, shielding of carbon by fluorine, and inductive effects (caused by fluorine electronegativity) also lead to chemical stability. For example, electron-rich chemical species called nucleophiles normally would be attracted to the partial positive charge of carbon. If these nucleophiles could get close enough to the carbon to bond, the subsequent reaction could replace a fluorine with the nucleophile and potentially make the molecule vulnerable to degradation. But the relatively large size of the fluorine atoms surrounding the carbon (when compared to hydrogen) prevents this from happening (**Schwarzenbach, Gschwend, and Imboden 2003**). This is why processes such as hydrolysis, which involve eliminating one or more fluorines, are ineffective at degrading the perfluorinated tails of PFAAs. Similarly, many PFAAs are resistant to degradation by oxidative processes that rely on a loss of electrons (**Kissa 2001**). PFAAs are also resistant to reductive processes, which involve gaining electrons. Despite having a high affinity for electrons, fluorine does not have vacant orbitals favorable for accepting additional electrons (**Park et al. 2009**). In contrast to the stability of perfluorinated tails, polar regions of PFAS (the functional groups), as well as polyfluorinated groups, can be vulnerable to a range of chemical transformations. See **Section 5.4** for further discussion of abiotic and biotic transformations.

5 ENVIRONMENTAL FATE AND TRANSPORT PROCESSES

This section provides current information about PFAS fate and transport in the environment. Understanding relevant fate and transport processes for PFAS is critical in evaluating the potential risk from a release, where to look for PFAS following a release, and what treatment alternatives may be effective. The available information about fate and transport processes varies between the different PFAS. PFAS fate and transport is a rapidly evolving field of science.

Section Number	Topic

5.1 Fate and Transport Introduction

5.1.1 Overview of PFAS Fate and Transport

PFAS fate and transport describes the behavior of these compounds following their release to the environment. This includes the physical, chemical, and biological processes that influence distribution of PFAS in various media, as well as the extent of migration within and between media (for example, plume development, groundwater discharge to surface water). Given the wide variety of PFAS, it is not surprising that they collectively exhibit a wide range of different physical and chemical characteristics that can affect their behavior in the environment. This adds to the complexity of fate and transport assessments and highlights the risk in making broad assumptions based on the behavior of a few well-studied PFAS.

Understanding relevant fate and transport processes for PFAS is critical in answering several key questions:

- ***What are the transport mechanisms for PFAS in the environment?*** PFAS fate and transport characteristics can assist understanding of the mechanisms through which PFAS discharge and migration may occur (for example, atmospheric/vapor transport, surface water runoff, infiltration into the subsurface, vadose zone sorption/leaching, groundwater migration).

- ***What is the potential risk from a PFAS release?*** An understanding of fate and transport processes provides the basis for defensible predictions about occurrence, migration, persistence, and potential for exposure.

- ***Where do I need to look for PFAS following a release?*** Knowledge of PFAS fate and transport characteristics strongly informs site characterization by providing insight on where efforts should be focused and developing an appropriate conceptual site model (CSM).

- ***How can I treat PFAS?*** Establishing how these compounds behave in the environment is important in developing and/or selecting PFAS treatment strategies.

5.1.2 Factors Affecting PFAS Fate and Transport

Factors that influence PFAS fate and transport can be broadly divided into two categories:

- ***PFAS characteristics:*** Critical factors include the chain length, the ionic state of the compound (for example, the charge(s) carried by the molecule at a typical environmental pH), the type of functional group(s), and the extent of fluorination (for example, perfluorinated versus polyfluorinated compounds). These properties strongly influence the type and extent of PFAS partitioning and transformation that can be expected to occur. A description of these physical-chemical properties is provided in **Section 4**.

- ***Site characteristics:*** Site characteristics generally define the nature of the source but also have an effect on PFAS-media interactions. Potentially relevant characteristics include soil type (including properties such as permeability, surface charge, organic carbon content, exchange capacity, mineralogy, water content), depth to groundwater, aquifer characteristics (for example, geology, presence of confining layers), oxidation-reduction conditions, precipitation/infiltration rates, groundwater velocities/flow directions, groundwater/surface water interactions, surface water flow rates, prevailing atmospheric conditions, and the presence of co-contaminants.

The characteristics of sites with releases of PFAS often share many similarities with sites having releases of other contaminants, although there are some source scenarios that are relatively unique to PFAS (see **Section 2.6** for description of source scenarios). In addition, relevant transport pathways for PFAS can be similar to those for other contaminants. For example, transport of PFAS in groundwater as the result of advection is a potential concern at many sites where PFAS-containing products have been released. Although many PFAS share similar characteristics, such as resistance to transformation, those same PFAS may have widely varying physical-chemical properties, such as those associated with partitioning. As a result, PFAS fate and transport in the environment can be quite different from other contaminants. Therefore, this section focuses on mechanisms where PFAS behavior is different from other contaminants.

5.1.3 Section Organization

This section includes a detailed description of several processes that are particularly relevant for PFAS fate and transport and are illustrated in **Figure 5-1**.

- ***Partitioning:*** Both hydrophobic partitioning to organic carbon and electrostatic interactions between charged surfaces and PFAS are discussed, along with the tendency of PFAS to aggregate at air-water interfaces. These processes can affect migration in the environment by promoting retention within sediments and unsaturated soils, as well as retardation within groundwater. Varying degrees of retention on solids can contribute to differential transport where certain PFAS (for example, short-chain, anionic) are more rapidly transported than others.

- ***Media-specific processes:*** The potential impact of processes such as diffusion into low-permeability matrices, atmospheric transport, and leaching from soil to groundwater are described. Unlike the broader processes of partitioning and transformation, most of these processes are unique to specific media or a specific cross-media transport pathway.

- ***Transformation:*** Although a number of individual PFAS, such as perfluoroalkyl acids and perfluoroalkyl ether carboxylic acids, are highly persistent due to the strength of the C-F bond, a

number of polyfluorinated substances can be partially degraded via several different biological and abiotic mechanisms. Transformation of these precursors to PFAAs has been shown to occur in a variety of environmental media and can result in unexpected temporal and spatial trends in PFAS occurrence. The susceptibility of individual PFAS to transformation processes can also influence how each will bioconcentrate and bioaccumulate within various biotic species.

- ***Uptake into biota and plants:*** Once released into the environment, PFAS will migrate to both terrestrial and aquatic systems. Uptake into plants can occur within affected areas and may transfer PFAS to wildlife and humans that consume those plants. Some compounds have a propensity to bioaccumulate and then biomagnify up the food chain, with relatively low levels in invertebrates and fish and higher levels observed in animals at the top of the food chain (for example, seals, seabirds, polar bears).

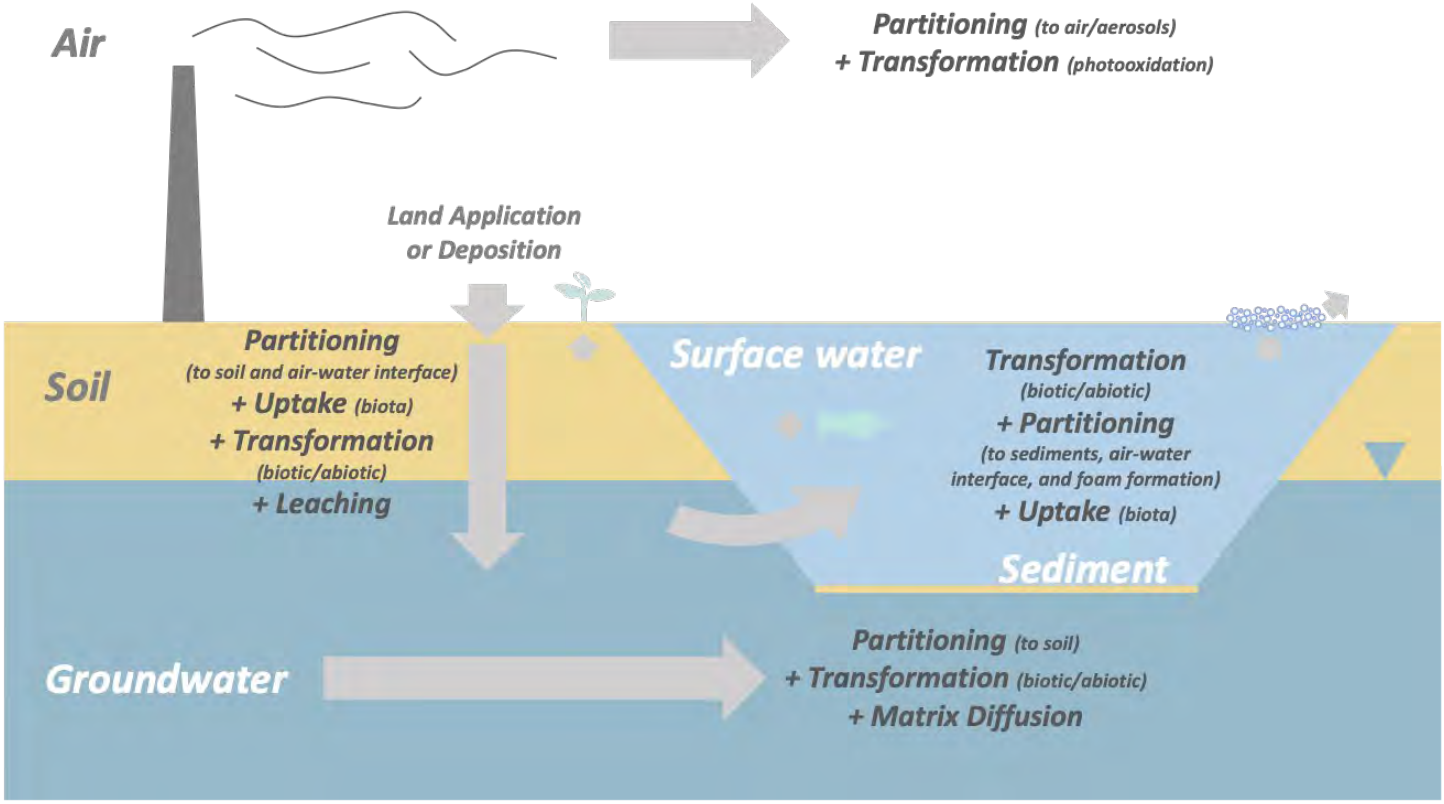

Figure 5-1. Fate and transport processes relevant for PFAS.

As noted previously, the physical-chemical properties of PFAS, and the influence of these properties on PFAS fate and transport within environmental media, are critical in determining how these compounds behave after they are released. To date, our understanding of PFAS fate and transport has relied largely on assumptions based on these physical-chemical characteristics, even though the specific parameter values have proven challenging to estimate; however, there is an increasing amount of lab- and field-derived data that has improved the empirical basis for understanding PFAS fate and transport. This section focuses on findings from peer-reviewed studies that directly evaluated PFAS fate and transport and provided key insight on the processes described above. The material in this section is also intended to provide a technical basis for subsequent sections on site characterization (**Section 10**) and treatment of PFAS (**Section 12**).

5.2 Phase Partitioning

5.2.1 Introduction

PFAS most commonly detected in the environment typically have a carbon-fluorine tail and a nonfluorinated head consisting of a polar functional group (see **Section 2.2** for more information about naming conventions and terminology). The tail is hydrophobic and generally lipophobic (attracted neither to water nor to nonpolar organic matter), while the head groups can be polar and hydrophilic (attracted to water) (**Buck et al. 2011**). The competing tendencies of the head and the tail can lead to a widespread yet uneven distribution in the environment. Given the heterogeneity of subsurface environments, soils with different surface charges, organic carbon, interfaces between air and water, and interfaces with water and hydrocarbon co-contaminants, multiple partitioning mechanisms should be considered when characterizing PFAS fate and transport. PFAS may also exhibit different behavior depending on concentration, such as the tendency to form micelles at high concentrations (**Section 5.2.2.2**). Although the structure of PFAS makes them generally oil- and water-resistant in many products (for example, dry surface coatings), in the aqueous phase, PFAS may not exhibit lipophobic tendencies, as shown by the ability of a variety of PFAS to partition to phospholipid bilayers (bacterial membranes) (**Jing, Rodgers, and Amemiya 2009**; **Fitzgerald et al. 2018**).

Important PFAS partitioning mechanisms include hydrophobic effects, electrostatic interactions, and interfacial behaviors. Electrostatic effects are a function of the charge of the polar functional group at the head of the molecule and are one of the processes that generally drive the association with organic carbon in soils. For instance, natural soils and aquifer materials often have a net negative surface charge that can repel the negatively charged heads of PFAAs, which are usually present as anions in environmental media, while attracting cationic or zwitterionic PFAS. As is the case for all surfactants, the competing nature of the head and tail groups result in accumulation along interfaces of environmental media such as soil/water, water/air, and water/nonaqueous phase liquid (NAPL) co-contaminants (**Guelfo and Higgins 2013**; **McKenzie et al. 2016**; **Brusseau 2018**).

5.2.2 Considerations for PFAS Partitioning

5.2.2.1 Pure Phase PFAS

Due to high aqueous solubility, PFAS occurrence as a separate phase in the environment (for example, solid PFAS, LNAPL PFAS, or DNAPL PFAS) is uncommon. Although PFAS may exist as solid salts, typical product applications involve miscible solutions that are frequently mixtures of many different compounds. Several of these compounds exhibit relatively high solubility in water (the Physical and Chemical Properties Table, Table 4-1 provided as a separate Excel file), defined by **Ney (1995)** as exceeding 1,000 mg/L water. For example, PFOA has a reported solubility of 9,500 mg/L at 25°C (**USEPA 2017**). Note that PFAS interactions with NAPL co-contaminants within the subsurface have been reported and can impact migration in the subsurface (**Section 5.2.5**).

5.2.2.2 PFAS Micelles and Foam Formation

A surfactant is a substance that tends to lower the surface tension of a liquid into which it is dissolved. As discussed in **Section 4.2.7**, the surfactant properties of some PFAS may result in the assembly of PFAS molecules into supramolecular aggregations (micelles, mixed micelles, hemi-micelles, or bilayer structures; see **Figure 5-2**). The surfactant properties of PFAS are also what cause collection at interfaces like the air-water interface (see **Section 4.2.8** and **Figure 4-1**). The surfactant properties, along with heat resistance, have been exploited for applications such as AFFF, which forms a thin film of water over the fuel source.

With respect to supramolecular aggregations, there is experimental evidence that PFAS can act like ionic hydrocarbon surfactants and form micelles at a critical micelle concentration (CMC) (**Pedone et al. 1997**; **Downer et al. 1999**), and many have theorized that, also like ionic hydrocarbon surfactants, hemi-micelle formation may begin at concentrations as low as 0.001 times the CMC (**Johnson et al. 2007**, **Yu et al. 2009**). The majority of these data are focused on PFAAs, but GenX has also recently been shown to form micelles (**Kancharla et al. 2022**). CMCs for various PFAS are discussed in **Section 4.2.7**. More research is needed on the tendency for PFAS to form traditional micelles (oil-in-water emulsions), since there is some data that suggest PFAS supramolecular aggregation may not be directly analogous to ionic hydrocarbon surfactant behavior (**Costanza et al. 2019** and discussed in **Section 4.2.7**). Additionally, the interrelated functions of several environmental variables (presence of co-contaminants, ionic concentration, pH, etc.) present additional complexities that research has only begun to address.

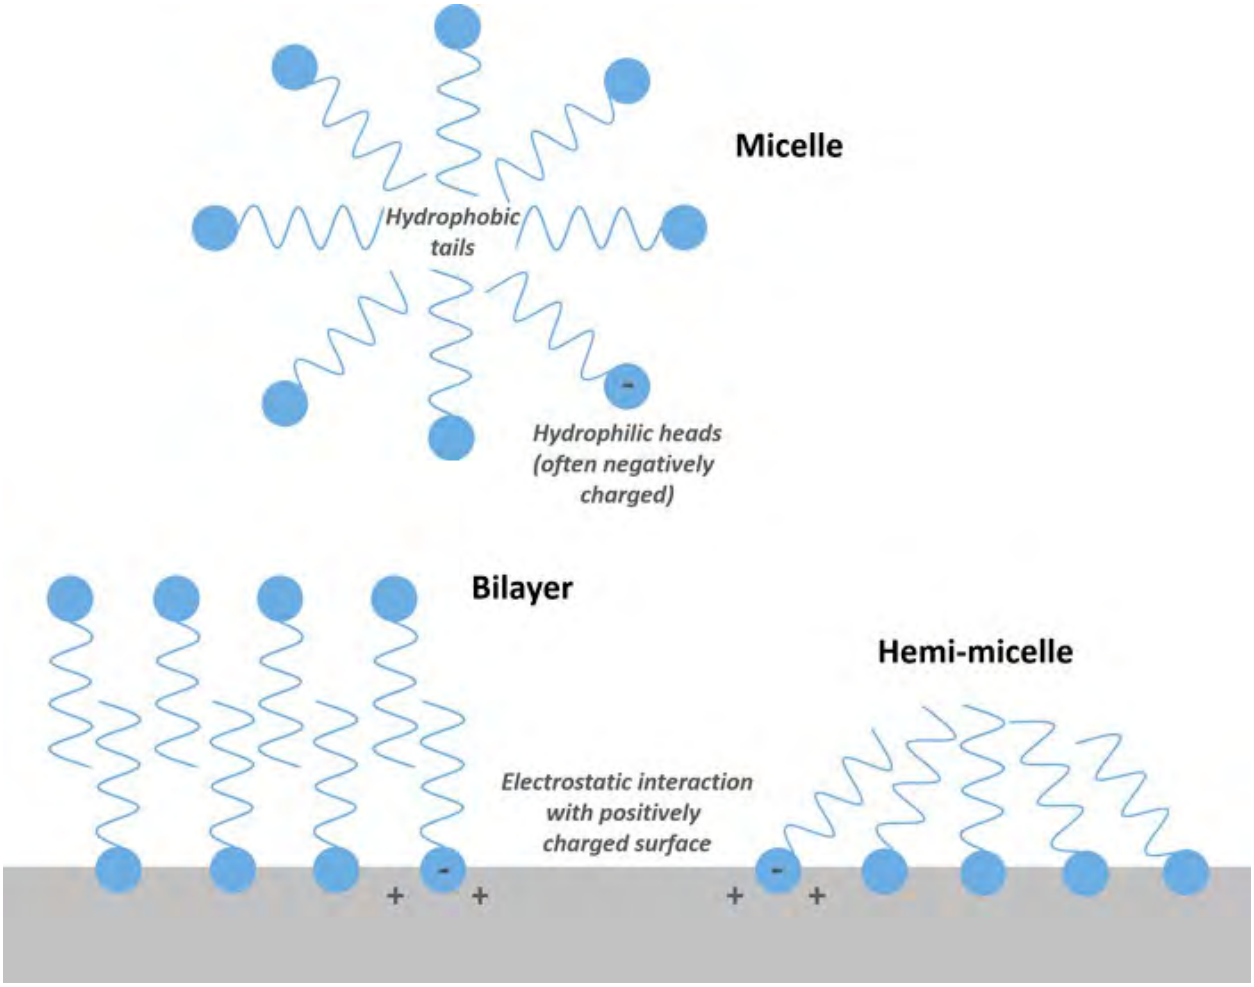

Figure 5-2. Illustration of the formation of PFAS micelles, hemi-micelles, and bilayers. Also shown is an example of aggregation at a positively charged surface. Note that the opposite effect (electrostatic repulsion of PFAS) can occur if the surface is negatively charged.

Source: D. Adamson, GSI. Used with permission.

Because the known CMCs of PFAAs are much greater than typical environmental concentrations (with the exception of possible AFFF source releases), some researchers have concluded that the behavior of PFAAs at the CMC likely has little practical relevance (**Horst et al. 2018**; **Brusseau et al. 2018**). However, like ionic hydrocarbon surfactants, hemi-micelle formation of PFAAs may begin at concentrations as low

as 0.001 times the CMC (**Johnson et al. 2007**; **Yu et al. 2009**), which is potentially relevant to the understanding of PFAA sorption for both the creation of potential treatment technologies and environmental fate and transport. The interaction of supramolecular aggregations of PFAAs with both charged and hydrophobic surfaces can affect the magnitude of sorption, but the extent and even the direction of influence is dependent on many factors (**Deng et al., 2012**; **Zhang, Zhang and Liang, 2019**; **Du et al. 2014**). For example, adsorption of the hydrophilic portions of PFAAs (that is, the "heads") onto positively charged absorbent surfaces can contribute to the formation and accumulation of hemi-micelles on surfaces. Simultaneously, it is possible that hemi-micelles and even micelles can block the intraparticle pores of porous surfaces, reducing the magnitude of sorption.

In surface water, PFAS may accumulate within the surface micro layer (SML) that is defined as the thin layer (50 µm) of water in contact with the ambient air (**Section 16.5.5**). This accumulation can also lead to foam formation above the surface water due to winds, waves, or other turbulent forces that introduce air into the water. In these cases, the presence of natural dissolved organic carbon within the water body can also enhance foam formation and contribute to enrichment of PFAS in these foams even at PFAS concentrations that are below reported CMCs (**Schwichtenberg et al. 2020**). This foam is different from AFFF because it is likely caused by the aggregation of dissolved-phase PFAS followed by agitation within a surface water body. As discussed in the Surface Water Foam Section (**Section 16.5**), the formation of this type of PFAS-containing foam above the surface of the water has been sampled and analyzed near or downgradient of areas where PFAS have been released (**MI EGLE 2021**).

5.2.3 Partitioning to Solid Phases

PFAS can partition to a number of different solid-phase materials, including soils and sediments (**Higgins and Luthy 2006**), biosolids (**Venkatesan and Halden 2013**), sewage solids (**Ebrahimi et al. 2021**), iron oxides in acidic environments (**Campos-Pereira et al. 2020**), and organic matter (**Fitzgerald et al. 2018**). Partitioning to solids results in retention of PFAS on the solids, thereby reducing or retarding leaching from vadose zone sources and retarding PFAS migration in the saturated zone. Conversely, PFAS may also partition to mobile colloids, resulting in facilitated transport rather than retardation (**Brusseau et al. 2019**), which may be particularly important in environments where colloidal transport is more likely to occur, such as sediment transport and deposition in moving water and environments undergoing wet-dry or freeze-thaw cycles (**Borthakur et al. 2021**). **Section 5.3.4.2** discusses surface water/sediment interactions.

In addition, published studies of migration of PFAS in bedrock aquifers are scarce, but many of the processes controlling sorption in soils will be limited in fractured crystalline bedrock aquifers, resulting in potential for migration of PFAS over longer distances once plumes migrate to the bedrock aquifer.

5.2.3.1 Partitioning Processes

As discussed in **Section 5.2.1**, partitioning of PFAS to solids and soils is widely studied and is thought to occur through two primary processes: 1) sorption through electrostatic interactions, and 2) sorption to organic matter via hydrophobic interactions (**Higgins and Luthy 2006**) (see **Sections 5.2.1** and **5.2.2** for a discussion of interfacial behavior, another subset of partitioning). The relative contribution of each process can vary depending on the PFAS, soil composition, surface chemistry, ion concentration, and other geochemical factors. Because the multitude of PFAS span a broad range of compositions and carbon chain lengths, PFAS partitioning to solids can be variable and uncertain, and dependent on site-specific factors.

5.2.3.2 Electrostatic Interactions

The contribution of electrostatic interactions to partitioning is highly dependent on soil type and soil chemistry (particularly pH and the presence of polyvalent cations). Most soils contain both fixed-charge

and variably charged surfaces, such that the net charge on the soil, as well as the charge of functional groups of individual PFAS, can be strongly influenced by pH. For example, the net negative charge on most clay minerals can result in electrostatic interactions with cationic functional groups that are present on some PFAS (**Barzen-Hanson et al. 2017**).

Changes in pH potentially impact these electrostatic processes by altering surface charges, or possibly the ionic nature of the PFAS (**Nguyen et al. 2020**). Lower pH values and higher calcium concentrations in soil solutions have been associated with increased sorption of anionic PFAS such as PFOS and other PFAAs (**Higgins and Luthy 2006**), although the buffering capacity of some soils (for example, carbonate minerals) may mitigate fluctuations in pH. Furthermore, increased concentrations of some polyvalent cations, such as Ca^{2+}, Mg^{2+} Fe^{2+}, which sorb strongly to permanent charge sites on clay minerals, can lead to increased partitioning to soil for some PFAS (**Higgins and Luthy 2006**; **McKenzie et al. 2015**), although the effect on cationic and zwitterionic PFAS can vary widely, which has been attributed to charge differences in the PFAS functional groups (**Mejia-Avendaño et al. 2020**). Although the literature has attributed anionic PFC sorption to iron-oxide materials, the dominant parameter influencing sorption in the **Higgins and Luthy (2006)** study was organic matter content.

5.2.3.3 Sorption to Organic Matter

In **Higgins and Luthy (2006)**, where organic carbon ranged from 0.56% to 9.66%, and other studies, organic carbon was found to be the dominant parameter driving the extent and kinetics of PFAS sorption (**Higgins and Luthy 2006**; **Li et al. 2018**; **Li et al. 2019**; **Sima and Jaffe 2021**; **Wei et al. 2017**). PFCAs and PFSAs tend to associate with the organic carbon fraction of soil or sediment (**Higgins and Luthy 2006**; **Guelfo and Higgins 2013**) in the saturated and unsaturated zones, although as anions at environmental pH values (see **Section 4.3.2**), they are relatively mobile in groundwater (**Xiao et al. 2015**).

Sorption to organic carbon generally increases with increasing perfluoroalkyl tail length, which is also associated with increased hydrophobicity (**Higgins and Luthy 2006**; **Guelfo and Higgins 2013**; **Sepulvado et al. 2011**; **Campos Pereira et al. 2018**; **Cai et al. 2022**), indicating that the short-chain PFSAs (for example, PFBS) and PFCAs (for example, PFBA) are less retarded than their long-chain counterparts (PFOS and PFOA, respectively). In addition, PFSAs tend to sorb more strongly than PFCAs of equal chain length (**Higgins and Luthy 2006**), and linear isomers are more sorptive than branched isomers (**Karrman et al. 2011**). Although simple correlations with organic carbon appear to be insufficient to predict PFAS partitioning coefficients, it is important to evaluate what PFAS are present and to quantify the fraction of organic carbon (f_{oc}) to model PFAS sorption as a potential predictive tool for estimating PFAS retention and retardation for certain PFAS.

5.2.3.4 Partitioning Coefficients

Table 4-1, provided as a separate Excel file, presents the range of available organic carbon partitioning coefficients (K_{oc}) for PFAS commonly observed in the environment. K_{oc} is a soil organic carbon-normalized adsorption coefficient and may serve as a useful parameter for evaluating potential retardation. However, this parameter does not directly capture any contributions from electrostatic interactions (**Higgins and Luthy 2006**), meaning that, depending on the PFAS being evaluated, estimating sorption by measuring the f_{oc} in soil in combination with a literature-derived K_{oc} value may underestimate (or in some cases, overestimate and the associated error could be significant) retardation. Additional site-specific information such as pH, presence of polyvalent cations, and electrostatic processes retardation coefficients, are mentioned in **Section 10.4.2**.

Li, Oliver, and Kookana (2018) compiled data from several literature studies and concluded that the bulk partitioning coefficients (Kd) estimated for various PFAS were best correlated with organic carbon content and pH. However, a study by **Barzen-Hanson et al. (2017)** showed a general lack of correlation between soil parameters (such as organic carbon) and partition coefficients derived for some PFAS, such

as anionic fluorotelomer sulfonates as well as several cationic and zwitterionic PFAS. **Anderson, Adamson, and Stroo (2019)** reviewed field data from a large number of AFFF release sites and deduced that organic carbon significantly influences PFAS soil-to-groundwater concentration ratios, and they used statistical modeling to derive apparent K_{oc} values for 18 different PFAS based on these data.

The use of partitioning coefficients to estimate sorption requires the assumption of steady state conditions, which rarely occur in natural systems. In idealized systems, PFAS sorption kinetics vary by functional group and carbon chain length, as well as soil composition, but equilibrium is generally achieved over several days to weeks (**Xiao et al. 2017**; **Schaefer et al 2021**). Lab-based and modeling studies have established that partitioning of PFAS cannot be easily modeled using equilibrium sorption parameters in some cases due to rate-limited sorption considerations (**Guelfo et al. 2020**;**Brusseau 2020**). Lab-based Kd values (derived using adsorption isotherms) could likely underestimate the impact of sorption during fate and transport modeling (for example, by underestimating the retardation factor or by overestimating the extent of desorption) (**Schaefer et al. 2021**). **Schaefer et al. (2021)** observed that the extent of desorption from soils exposed to PFAS decades ago generally was substantially less than predicted by published $K_{oc}f_{oc}$ relationships for the PFAS studied, suggesting that desorption from old PFAS releases may have a less pronounced impact on underlying groundwater, particularly for shorter chain PFAS. **Schaefer et al. (2022)** noted that much of the PFAS present in soils historically impacted with AFFF in their study was not readily leachable using the selected desorption procedure(s).

5.2.3.5 Nonlinear Sorption, Hysteresis, and Mass Transfer Limitations

Sorption processes of PFAS can be impacted by nonlinear sorption, hysteresis, and mass-transfer limitations. Nonlinear sorption typically implies that PFAS will sorb more strongly at low PFAS concentrations than high concentrations. Counter to typical nonlinear sorption tendencies, at least one field study observed greater sorption at higher concentrations (**Anderson et al. 2022**). There is also some evidence that desorption may occur more slowly than sorption for certain PFAS, which is hypothesized to be the result of entrapment and diffusion limitations (**Higgins and Luthy 2006**; **Chen et al. 2016**; **Zhi and Liu 2018**; **Xiao et al. 2019**). Several studies have observed that select PFAS can be subject to rate-limiting sorption (for example, diffusion limited), meaning that desorption of a portion of the sorbed PFAS will occur more slowly than other portions (**Xiao et al. 2019**; **Schaefer et al. 2021**). For example, **Brusseau et al. (2019)** showed that PFOS exhibited nonideal sorption/desorption behavior (tailing). Kinetic desorption modeling in the study indicated "that the rate of desorption was proportional to the PFAS aqueous diffusivity" (**Schaefer et al. 2021**), supporting the hypothesis that diffusion may also limit the rate of release from soil. Any portion of the released PFAS that is strongly retained within sediments or the soil matrix may be more persistent but likely less bioavailable and less subject to migration. This hysteresis effect on a portion of the sorbed PFAS in soils may also be a contributor to sorption included in the rationale for natural attenuation of some PFAS that was evaluated by **Newell et al. (2021)**.

PFAS partitioning due to electrostatic interactions has been shown to be nonlinear in some cases; **Xiao et al. (2019)** demonstrated that the variation in the coefficient of sorption for several zwitterionic PFAS to soils (for example, loams, clay loams) implies an increase in sorption as the PFAS concentrations decreased. The significant nonlinearity of zwitterionic PFAS observed by **Xiao et al. (2019)** also exhibited a high degree of hysteresis that was not related to soil organic matter or surface complexation and was postulated to be due to entrapment. For PFAS such as PFOA and PFOS that are anionic at environmentally relevant pH, measuring the anion exchange capacity in representative soils may serve as an indicator of the importance of electrostatic interactions with minerals. However, because soil pH can range considerably, pH can also serve as a useful measure of potential PFAS mobility. Measurements of **cation** concentrations or the ionic strength of an aqueous solution may also provide useful information on the potential contribution of electrostatic attraction to enhanced partitioning.

The findings discussed within this subsection are particularly relevant for strongly sorbing long chain PFAS such as PFOS (**Chen et al. 2016**) and sorbed PFAS that exhibit a high degree of hysteresis, such as

zwitterionic PFAS, and have important implications for PFAS fate and transport such as leaching from soil to groundwater (see **Section 5.3.3**), migration and retardation in the saturated zone, and whether sorption can function as a form of natural attenuation (**Newell et al. 2021**, **Newell et al. 2021**) (see **Sections 10.4.7** and **10.4.8**, **Table 10-1**, and **12.6.8** for further discussion). Additional research is needed to further evaluate if any of these bulk parameters can be used predictively for fate and transport studies (**Barzen-Hanson et al. 2017**) and to understand the parameters' role in irreversible sorption of PFAS that have been adsorbed for decades. Current research supports the conclusion that simple correlations of sorption with organic carbon or pH are insufficient to reliably predict PFAS partitioning coefficients for many PFAS. Thus, in the absence of a reliable model that predicts the role of different mechanisms on the extent of sorption (and hysteresis), site-specific data may be more appropriate for understanding PFAS transport (**Knight et al. 2019**; **Anderson et al. 2016**; **Li, Oliver, and Kookana 2018**) and considerations for pump-and-treat systems. Other considerations, such as air-water interface interactions, are discussed in **Section 5.2.4.1**.

5.2.4 Partitioning to Air

As discussed in greater detail in **Section 4.2**, reliable data on physical properties that relate to PFAS volatilization, such as vapor pressure and Henry's law constants (K_{aw}), are currently limited but the data set is growing. Additionally, volatilization from water to air of acidic PFAS, such as PFAAs, is affected by pH-dependent, aqueous phase dissociation from more-volatile acidic species to less-volatile anionic species (**Kaiser et al. 2010**). Measured vapor pressures are available for some select PFAAs, including the acidic forms of PFOA, perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA), perfluoroundecanoic acid (PFUnA), and perfluorododecanoic acid (PFDoDA) (**Barton, Botelho, and Kaiser 2008**; **Kaiser et al. 2005**), as well as FTOHs (**Krusic et al. 2005**). Henry's law constants (K_{aw}) for several PFAS are reported in **Section 4.2.6**. As noted by the values provided in **Table 4-1**, Kaw can vary over multiple orders of magnitude for a given PFAS; underlying causes for the large range in reported values are not clear, but may relate to variability in measurement conditions. For some PFAS that are acidic at environmentally relevant pH, such as PFOS and PFOA, the reported vapor pressures are low and reported water solubilities are high, limiting volatilization from water to air (**USEPA 2000**). Other PFAS, such as FTOHs, have specific functional groups that tend to impart greater volatility. In one study performed by **Roth et al. (2020)**, agitation of AFFF was demonstrated to release gas-phase PFAS, reportedly including PFOA. These experiments were performed in a controlled lab setting and resulted in detectable concentrations of five FTOHs and 10 PFCAs above background laboratory air concentrations. The potential for this type of partitioning to occur in field settings was not evaluated, and the veracity of the PFOA detections has been debated (**Titaley, De la Cruz, and Field 2020**; **Roth et al. 2020**). **Section 1.1.3.3** includes information about volatile PFAS. See also the **PFAS and Vapor Intrusion Fact Sheet** developed in 2025.

Under certain conditions, particularly within industrial stack emissions, or during fire suppression, incineration, or combustion, PFAS can be emitted and transported through the atmosphere. This can include volatiles like FTOHs that may be present in the gas phase (**Thackray, Selin, and Young 2020**) and anionic PFAS that may be sorbed to particulates (**Ahrens et al. 2012**). In the latter case, transport occurs through the association of anionic PFAS with airborne aerosols and other small particulates rather than direct partitioning to the gas phase. For example, PFOA and PFOS have been detected in airborne particulate matter in both urban and semirural areas, with PFOA dominant in the smaller, ultrafine particles and PFOS dominant in the larger, coarser fractions (**Dreyer et al. 2015**; **Ge et al. 2017**). These studies show that some PFAS can be adsorbed to particulates, likely reflecting the influence of local diffuse sources. As discussed in **Section 5.3**, removal of airborne PFAS can occur via wet and dry deposition processes that scavenge particle-bound PFAS or gaseous PFAS that has partitioned into water droplets (**Barton, Kaiser, and Russell 2007**; **Dreyer et al. 2010**). Wet deposition refers to the wash out of PFAS by rain droplets, where PFAS drops to the ground with no transfer of PFAS to the air (**Barton, Kaiser, and Russell 2007**). This has been shown to be a relevant mechanism for influencing airborne transport within a few kilometers downgradient of a major manufacturing source (**Barton, Kaiser, and Russell**

2007; **Davis et al. 2007**). Dry deposition is a naturally occurring process that depends on prevailing environmental conditions and particle characteristics. Since these deposition processes remove PFAS from the atmosphere, they can influence the location and magnitude of PFAS deposition to terrestrial and aquatic environments.

Kaiser et al. (2010) demonstrated the partitioning of PFOA to workplace air from water and dry surfaces. Partitioning to air from these substrates appears to depend on conditions within the substrate, with lower pH environments contributing more PFOA mass to air. The protonated acid form of PFOA has an elevated vapor pressure, which may explain these observations (**Kaiser et al. 2005**). Interestingly, these authors showed that more PFOA partitions from dry surfaces than from water and may contribute significantly to workplace exposures.

5.2.4.1 Partitioning to Air/Water Interfaces

As described above, PFAS often exhibit surfactant behavior because many display hydrophobic and hydrophilic properties. The impacts of these properties on transport are complex and are being actively investigated. By design, many PFAS will lower the interfacial tension and preferentially form films at the air-water interface (if present at elevated concentrations), with the hydrophobic carbon-fluorine (C-F) tail oriented toward the air and the hydrophilic head group dissolved in the water (**Krafft and Riess 2015**) (**Figure 4-1**). This behavior influences aerosol-based transport and deposition, and suggests that accumulation of PFAS at water surfaces will occur (**Prevedouros et al. 2006**).

This preference for the air-water interface has important implications for PFAS transport in the vadose zone, where unsaturated conditions provide significant air-water interfacial area (**Brusseau 2018**; **Brusseau et al. 2019**; **Brusseau and Guo 2022**). This includes the potential for enhanced retention in the vadose zone and the capillary fringe, which are the subject of significant ongoing research. For example, **Brusseau (2018)** showed that adsorption of PFOS and PFOA at the air-water interface can increase the retardation factor for aqueous-phase transport, accounting for approximately 50% of the total retention in a model system (well-sorted sand) with 20% air saturation. **Section 1.3.1** includes information about vadose zone characterization and transport, including air-water partitioning and vadose zone modeling.

As a result, air-water partitioning may contribute to retardation of PFAS in unsaturated soils. Using field data, **Anderson, Adamson, and Stroo (2019)** reported that soils with higher clay contents were associated with lower soil-to-water concentration ratios for multiple PFAS. The authors surmised that perhaps the more likely explanation was that the higher water content within these clay-rich zones (relative to other depth-discrete zones with more coarse-grained material) decreased the air/water interfacial area available for PFAS partitioning and thus decreased overall soil retention. This pattern is also consistent with the potential for negatively charged clay surfaces to reduce anionic PFAS adsorption through electrostatic repulsion. **Guo, Zeng, and Brusseau (2020)** highlighted the influence of soil type on air-water interfacial accumulation as a retention mechanism in a modeling study that demonstrated retardation factors for PFOS under their experimental conditions as between 233 and 1,355 in sands and 146 and 792 for finer-grained soils. This was attributed to weaker capillary forces in the sands that resulted in lower water contents and thus more air-filled pore space to promote PFAS partitioning. Note that the simulations performed by **Guo, Zeng, and Brusseau (2020)** examined only PFOS and did not use field-derived input parameters, so caution should be exercised when generalizing these results to the broader family of PFAS. In addition to the influence of soil type described above, ionic strength has been shown to affect air-water interfacial partitioning whereby PFAS retardation within unsaturated soils appears to be enhanced with increasing salinity (**Lyu and Brusseau 2020**; **Costanza, Abriola, and Pennell 2020**; **Le et al. 2021**).

The tendency for PFAS to accumulate at air-water interfaces has the potential to significantly influence mass retention and soil-to-groundwater leaching, as discussed further in **Section 5.3.3**.

This has stimulated interest in incorporating these processes into CSMs, as well as predictive fate and transport models. Estimates of the air-water interfacial area and the constituent-specific air-water adsorption coefficients, as well as direct measurements of mass discharge to groundwater, can help provide a quantitative basis for these types of models (**Brusseau 2019**; **Guo, Zeng, and Brusseau 2020**). In general, air-water adsorption coefficients for an individual PFAS decrease as the concentration increases, and the process appears to be nonlinear (for example, Freundlich-type partitioning) (**Schaefer et al. 2019**). Air-water adsorption coefficients also tend to increase as the number of perfluorinated carbons increases (**Brusseau 2019**; **Schaefer et al. 2019**) (see **Section 4.2**). This means that when PFAS are released as a multicomponent mixture, these processes will influence each compound to a different extent, with less retention of shorter chained PFAS (for example, PFBS, PFPeA) than longer chained PFAS (for example, PFOS, PFDA, PFNA) (**Silva, Martin, and McCray 2021**). **Silva, Martin, and McCray (2021)** also showed that preferential adsorption of the more surface-active PFAS within a mixed release is expected to reduce the adsorption of the other, less surface-active PFAS in the mixture. This type of competitive adsorption would influence the relative breakthrough times for different PFAS within a mixed release.

The potential retention of PFAS in the vadose zone due to adsorption at the air-water interface is an important component that should be addressed in the CSM, but the retention of PFAS is based on site-specific factors. At sites with shallow groundwater tables, or sites where the water content within the vadose zone soils is typically low, air-water interfacial partitioning may not be particularly relevant. As such, detailed site investigations are critical to understanding how these processes influence PFAS migration through the vadose zone of a specific site. For example, an extensive study of PFAS concentrations in soil at contaminated sites indicated significant retention of PFAS in the vadose zone over long periods of time, but vertical migration of PFAS to the water table was also evident, resulting in detectable PFAS in groundwater at a majority of the investigated sites (**Brusseau 2020**).

5.2.5 Partitioning into NAPL Co-Contaminants

PFAS and petroleum hydrocarbon fuels in the form of NAPLs may commingle at fire training areas, fire response sites, and other locations where fuels were used or disposed concurrently with PFAS-containing materials. In these settings, the released petroleum hydrocarbon fuel forms a NAPL into which the PFAS may partition and accumulate along the NAPL/water interface (**Brusseau 2018**). These processes may result in increased PFAS mass retained in NAPL source zones, increased PFAS sorption onto the NAPL/water interface and resulting retardation, and greater persistence of PFAS (**Guelfo and Higgins 2013**; **McKenzie et al. 2016**; **Brusseau 2018**). The contribution of this process relative to other PFAS partitioning mechanisms (for example, solid phase, air-water interface) will vary based on site-specific conditions. However, several studies have suggested that the PFAS mass accumulating at the NAPL-water interface is likely to be less than that at the air-water interface in systems where all these phases are present (**Brusseau 2019**; **Silva et al. 2019**; **Costanza, Abriola, and Pennell 2020**). The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about co-contaminant effects on PFAS fate and transport (see **Section 1.3.4.1**).

The presence of NAPL may have other effects on PFAS. The presence of biodegradable NAPL, such as petroleum light nonaqueous phase liquids (LNAPLs), may significantly alter the biogeochemistry and oxidation-reduction conditions in the subsurface. For example, subsurface petroleum LNAPLs remaining from a petroleum-based fire tend to locally deplete the concentration of oxygen and other electron acceptors and elevate the concentration of methane. The LNAPL creates a localized zone of anoxic reducing conditions where PFAS aerobic transformation processes are inhibited, and anaerobic transformation processes may occur. These transformation processes are discussed in more detail in **Section 5.4**.

5.3 Media-Specific Migration Processes

The potential impacts of processes such as diffusion into low-permeability matrices, atmospheric transport, and leaching from soil to groundwater are described. Unlike partitioning processes, which involve the exchange of chemicals between media, the following describes processes that occur within specific media that may be important considerations for PFAS migration.

5.3.1 Diffusion In and Out of Lower Permeability Materials

Diffusion is the movement of molecules in response to a concentration gradient. Diffusion in groundwater is often ignored because diffusion rates are slow relative to advection. In low permeability materials, migration of contaminants is mainly driven by molecular diffusion, and advective effects may be less dominant depending on the magnitude of hydraulic gradient. In the vicinity of groundwater pumping wells, analysis might need to be conducted by taking into account both the effects of molecular diffusion and advection simultaneously (**Al-Niami and Rushton 1977**). However, contaminant mass in groundwater can diffuse into the pore space of lower permeability soils or bedrock. Back-diffusion out of these low permeability materials may result in the long-term persistence of PFAS in groundwater even after source removal and remediation. Due to the lack of degradation of PFCAs and PFSAs, back-diffusion of these PFAS is also likely to be a more significant process than for conventional contaminants such as chlorinated solvents. **Adamson et al. (2020)** reported that approximately 82% of the total mass of PFAS measured at an AFFF site was found within soils that were classified as lower permeability. This included 91% of the polyfluorinated precursor mass, most of which was encountered in the vicinity of the presumed source area. The mass distribution at this site confirmed that diffusion into lower permeability soils had occurred and demonstrated that this process can contribute to long-term retention of PFAS. The relative impact of PFAS accumulation at the air-water interface was not fully investigated in this study, as the water table was very shallow, and the unsaturated/saturated transition zone was likely disturbed during excavation. PFAS may also diffuse into site materials such as concrete. For example, **Baduel, Paxman, and Mueller (2015)** reported that PFAS had penetrated 12 cm into a concrete pad at a fire training area, and diffusion was identified as a contributing process.

The potential impacts of diffusion on PFAS persistence in natural soils are a topic of ongoing research. Determining appropriate diffusion coefficients for the range of PFAS that may be present following a release is a key element in understanding how this process impacts PFAS persistence. **Schaefer et al. (2019)** reported experimentally derived diffusion coefficients for 9 different PFAAs and showed that aqueous diffusivity values decreased as the PFAS molar volume increased. However, this relationship was nonlinear due to the complex molecular interactions of fluorinated compounds, and the values showed reasonable agreement with some but not all comparable methods of deriving diffusion coefficients. In addition, the relative rates of diffusion of PFAS with differing charges (for example, anionic vs. zwitterionic/cationic) is a potential concern given that porous media particles may also be charged. In the study by **Adamson et al. (2020)** described above, 93% of the polyfluorinated mass that had diffused into the lower permeability zones was zwitterionic and/or cationic; a smaller percentage of the anionic polyfluorinated mass was found in these zones. Higher organic carbon and favorable electrostatic interactions likely contributed to further retention of PFAS. The results of this study suggest that matrix diffusion may enhance long-term retention and reduce PFAS mass discharge rates by transferring PFAS mass to less-transmissive zones.

5.3.2 PFAS Transport via Air

Many PFAS have been measured in air (**Section 6.1**) and are known to be released to air from a variety of sources (**Section 2.6**). Air serves as an important transport medium for PFAS, allowing PFAS to disperse in all wind directions, contributing to global dispersion, and leading to localized PFAS deposition to soils and surface water in the vicinity of emission sources (for example, (**Shin et al. 2012**)) which is of

potential concern to site investigations. **Section 1.1.3.3** includes information about volatile PFAS. See also the **PFAS and Vapor Intrusion Fact Sheet** developed in 2025.

The role of atmospheric transport depends on PFAS-specific properties such as vapor-particle partitioning, and mechanisms can be complex. Aerosols, representing a suspension of solid particles and liquid droplets in the air, provide a variety of environmental media and surfaces within or upon which a range of PFAS partitioning behavior can be observed. For example, **McMurdo et al. (2008)** described the release of concentrated PFAS aerosols from a water surface (where PFAS are often located). Airborne transport of PFAS is a potentially relevant migration pathway due to the common types of industrial release (for example, stack emissions). The specific means of PFAS releases from industrial sources have not been extensively studied, but could involve processes such as droplet mobilization from drying and agitation of liquid surfaces.

PFAS and other harmful air pollutants, including fluorinated products of incomplete combustion (PICs), can be released into the air from facilities that treat PFAS in air and solid media, such as incinerators, cement and lightweight aggregate kilns, sewage sludge incinerators, municipal waste combustors, soil desorbers, pyrolyzers, and spent carbon reactivation facilities (**Krug et al. 2022**; **Riedel et al. 2021**; **Stoiber, Evans and Naidenko 2020**). Few comprehensive waste characterization or full-scale demonstration studies have been conducted to document the performance of these treatment facilities in removing and destroying PFAS. In one recent study conducted under typical operations at a full-scale spent carbon reactivation facility, researchers reported full removal of PFAS compounds from the spent carbon and >99.99% destruction of PFAS compounds through the reactivation facility furnace and air pollution control systems (**DiStefano et al. 2022**). The importance of other sources, such as combustion emissions or windblown foam from fire training and fire response sites, may need to be assessed. **Section 12.4** includes additional information about incineration.

Once airborne, PFAS can occur in a gaseous state or be incorporated within particulate matter or other aerosols suspended within the air. The composition of the gas phase will be dependent on the industrial process(es) contributing to emissions. Neutral volatile precursor compounds, such as FTOHs, are often the dominant PFAS present in the gas phase (see **Section 17.1**) and can account for at least 80% of the total PFAS mass in ambient air in an urban area (**Ahrens et al. 2012**).

Over the open oceans and in remote regions, FTOHs also dominate neutral PFAS and almost all are present in the gas phase (**Bossi, Vorkamp, and Skov 2016**; **Lai et al. 2016**; **Wang et al. 2015**; **Dreyer et al. 2009**). In contrast, ionic PFAS, such as PFOA and PFOS, characterized by low vapor pressure and high water solubility, tend to be the dominant species found in airborne particulate matter. PFOA is associated with smaller, ultrafine particles, while PFOS is associated with larger, coarser fractions in both urban and semirural areas (**Ge et al. 2017**; **Dreyer et al. 2015**). Wet and dry deposition are the major mechanisms of removal of PFAS from the atmosphere and can occur from the scavenging of particle-bound PFAS or partitioning of gaseous PFAS to water droplets (**Dreyer et al. 2010**; **Barton, Kaiser, and Russell 2007**; **Hurley et al. 2004**). PFAS are commonly found in precipitation (rain and snow), with wet and dry deposition estimated to occur on a time scale of a few days (**Chen et al. 2016**; **Lin et al. 2014**; **Taniyasu et al. 2013**; **Zhao et al. 2013**; **Dreyer et al. 2010**; **Kwok et al. 2010**; **Liu et al. 2009**; **Barton, Kaiser, and Russell 2007**; **Kim and Kannan 2007**; **Hurley et al. 2004**). Certain PFAS, such as PFOS, have been found to persist in fine particulate matter (PM2.5) in the United States nearly 20 years after production was phased out, which confirms the presence of continuing sources (**Zhou et al. 2021**).

Atmospheric deposition can occur as dry or wet deposition, both of which are relevant for PFAS (**Barton, Kaiser, and Russell 2007**, **2010**; **Dreyer et al. 2010**; **Taniyasu et al. 2013**). During dry deposition, PFAS that are preferentially associated with liquid or particle phases in air (aerosols) can be naturally deposited onto surfaces via settling, diffusion, or other processes. When precipitation contributes to washout of these PFAS-containing aerosols, the process is known as wet deposition. Wet and dry deposition are the major mechanisms for removal of PFAS from the atmosphere and can occur from the scavenging of

particle-bound PFAS or partitioning of gaseous PFAS from water droplets (**Dreyer et al. 2010**; **Barton, Kaiser, and Russell 2007**; **Hurley et al. 2004**). Deposition is considered a sink term for the atmosphere because mass is removed and the potential for longer range atmospheric transport is reduced. However, this same process thus represents a potential source of PFAS to terrestrial and aquatic environments. Once settled, PFAS adsorbed onto soils or other surfaces (including indoor surfaces) can be resuspended when particulate matter is disturbed by wind or other physical means. See **Section 6.1** for further discussion of atmospheric deposition of PFAS.

Short-range atmospheric transport and deposition can result in PFAS contamination in terrestrial and aquatic systems near points of significant emissions, impacting soil, groundwater, and other media of concern (**Davis et al. 2007**). PFAS can migrate downward from surficial soils into the groundwater table via leaching processes described in **Section 5.3.3**. Evidence of releases has been observed in areas where hydrologic transport could not plausibly explain the presence of PFAS in groundwater, with the extent of contamination reaching several miles from sources and in distribution patterns independent of regional hydrology (**Frisbee et al. 2009**; **Post 2013**; **Post, Cohn, and Cooper 2012**; **NYS DOH 2016**; **NH DES 2017**; **VT DEC 2016**). Air emissions from industrial sources can cause contamination of drinking water sources and pose a potential increased risk to human health in communities over wide areas surrounding the emissions source (**Schroeder, Bond, and Foley 2021**). Releases of ionic PFAS from factories are likely tied to particulate matter (**Barton et al. 2006**), which settles to the ground in dry weather and is are also wet-scavenged by precipitation (**Slinn 1984**; **Sehmel 1984**). Key variables that should be used to predict impacts to groundwater wells include the rate of PFAS air emissions and distance from upwind sources, prevailing wind direction, soil characteristics, and well depth (**Roostaei et al. 2021**). In a study using a statewide data set to model PFAS in private wells (n~2300), researchers found that proximity to point sources, including plastics, rubber, and textile industries, was the most important predictor of impacts, with groundwater recharge, precipitation, soil sand and clay content, and hydraulic conductivity as secondary predictors (**Hu et al. 2021**).

Predictive models have been applied to estimate PFAS deposition (**D'Ambro et al. 2021**; **Shin et al. 2012**). The American Meteorological Society/USEPA regulatory model AERMOD system contains modules to estimate both wet and dry deposition of both aerosols and gases (**USEPA 2016**). The Community Multiscale Air Quality (CMAQ) model has also been applied to investigate the atmospheric fate and transport of PFAS emissions (including GenX) from a fluoropolymer manufacturing facility in North Carolina (**D'Ambro et al. 2021**). In this study, researchers predicted that 5% by mass of total emitted PFAS and 2.5% of total GenX are deposited within ~150 km of the source, with the majority of emissions being transported beyond 150 km (**D'Ambro et al. 2021**). Model validation is important and where uncertainty exists, model predictions should be interpreted with caution. Nevertheless, the model may be useful in understanding the pattern of PFAS found in soil and groundwater in the vicinity of PFAS emission sources (**Shin et al. 2012**). Key input parameters for emissions from a smokestack or vent include the height of the release point and adjacent structures, source emission rates and particle size distributions, stack effluent properties (temperature and volumetric flow rate), meteorological data, local topography, and land use characteristics. A number of states are actively engaged in the application and review of air models for evaluating the impact of PFAS emissions from industrial sources and can provide valuable information on their use and the interpretation of findings.

Long-range transport processes are responsible for the wide distribution of neutral and ionic PFAS across the earth as evidenced by their occurrence in biota, surface snow, ice cores, seawater, and other environmental media in remote regions as far as the Arctic and Antarctic (**Szabo et al. 2022**; **Langberg et al. 2022**; **Joerss et al. 2020**; **Yeung et al. 2017**; **Bossi, Vorkamp, and Skov 2016**; **Kirchgeorg et al. 2016**; **Rankin et al. 2016**; **Wang et al. 2015**; **Codling et al. 2014**; **Wang et al. 2014**; **Kirchgeorg et al. 2013**; **Kwok et al. 2013**; Benskin, **et al. 2012**; **Cai et al. 2012**, **2012**, **2012**; **Ahrens, Xie, and Ebinghaus 2010**; **Dreyer et al. 2009**; **Young et al. 2007**). Geochemical modeling of the contributions of atmospheric and oceanic inputs in the Arctic suggests that atmospheric inputs may account for as much as 34%–59% of measured PFOA concentrations in the polar mixed layer (PML) (**Yeung et al. 2017**). Declining trends in

the concentration of PFSAs in higher trophic arctic mammals has been largely attributed to reductions in long-range atmospheric transport as a result of industrial phaseout of certain PFAS (**Routti et al. 2017**). Distribution of PFAS to remote regions far removed from direct industrial input is believed to occur from both (1) long-range atmospheric transport and subsequent degradation of volatile precursors and (2) transport via ocean currents and release into the air as marine aerosols (sea spray) (**Lin et al. 2021**; **Casas et al. 2020**; **Joerss et al. 2020**; DeSilva, **Muir, and Mabury 2009**; **Armitage et al. 2009**; **Wania 2007**; **Ellis et al. 2004**).

5.3.3 Leaching

PFAS present in unsaturated soils are subject to downward leaching during precipitation, flooding, or irrigation events that promote dissolution and migration of contaminant mass (**Sepulvado et al. 2011; Ahrens and Bundshuh 2014**; **Sharifan et al. 2021**). This process can result in PFAS transport from surface soils to groundwater and surface water because PFAS releases often involve surface applications (for example, AFFF and biosolids) or atmospheric deposition (**Borthakur et al. 2022**; **Gellrich, Stahl, and Knepper 2012**; **Anderson, Adamson, and Stroo 2019**; **Galloway et al. 2020**). **Section 1.3.1** includes information about vadose zone characterization and transport, including air-water partitioning and vadose zone modeling. **Section 10.4.1** and **Section 1.5.1** include information about approaches, methods, and tools available to evaluate PFAS leachability.

PFAS migration from shallow soils to groundwater is influenced by several interacting processes, which may enhance or limit PFAS leaching rates. The leaching potential will be enhanced in areas with high water infiltration rates, which may include natural water sources such as precipitation or human-made sources such as irrigation. The thickness of the unsaturated zone (depth to water table) will also affect leaching potential. These factors are consistent with other (non-PFAS) contaminants in shallow soils. Conversely, several PFAS-specific processes, as described in **Section 5.2**, potentially limit the extent of PFAS leaching from shallow soil to groundwater. These include partitioning of PFAS to solid phases (for example, soil particles), adsorption at the air-water interface, and partitioning to NAPL. As a result, any soil properties that enhance the potential relevance of PFAS-sorptive processes may limit soil-to-groundwater leaching. This includes elevated levels of organic carbon, surface area and surface charge, increasing air content, and higher ionic strength within the vadose zone (**Guelfo and Higgins 2013**). The structural properties of the individual PFAS will also influence their transport, including the tendency for longer chain PFAAs to be less soluble and exhibit larger partitioning coefficients than shorter-chain PFAAs. In addition, several of these partitioning processes within the vadose zone have been shown to be nonlinear, which means that their relative contribution to leaching may change over time as concentrations change as a result of dilution and transformation (**Zeng and Guo 2021**). Finally, site conditions that influence the degree of flushing (for example, precipitation rates and depth to groundwater) should be considered when evaluating the potential for PFAS to leach from soil to groundwater.

While our understanding of these vadose zone processes continues to evolve, there are several possible implications that may be relevant for managing sites where PFAS have been released:

- These processes can affect the rate at which some PFAS migrate through the vadose zone to groundwater (breakthrough). As with hydrophobic partitioning, the relative importance of air-water interfacial partitioning is highly dependent on hydrogeologic and geochemical properties (for example, water content, salinity) of the formation (**Anderson, Adamson, and Stroo 2019**), as well as the air-water interfacial affinity of individual PFAS (**Brusseau 2019**). In general, air-water interfacial partitioning can contribute to the bulk soil retention of PFAS in a manner that is unique among organic contaminants. Time scales required for PFOS (and other PFAS that exhibit strong interfacial adsorption characteristics) to reach the underlying groundwater have been simulated to be from 1 or 2 years to several decades or longer. The extent of this retardation factor will likely vary due to climate conditions and PFOS concentrations (**Guo, Zeng, and Brusseau 2020**;

Brusseau 2020). This potential retardation could influence the selection and implementation of remedies, or even the duration of long-term management programs.

- Similar to the impact described above, retention within the vadose zone can occur because of the PFAS tendency to be associated with the air-filled pore space and (to a lesser extent) the solid phase, such that a limited portion of PFAS mass may be in the aqueous phase and subject to deeper infiltration (**Guo, Zeng, and Brusseau 2020**). Importantly, the interaction between solid phase sorption (hydrophobic partitioning and electrostatic interactions) and air-water interfacial partitioning could be important given that mass transfer limitations can create hysteretic desorption from soils with relatively high organic matter content (**Schaefer et al. 2021**).

Although some experimental and field-scale studies have reported PFAS transport by leaching (**Lindstrom et al. 2011**; **Filipovic et al. 2015**; **Hellsing et al. 2016**; **Bräunig et al. 2017**), others have observed long-term retention of longer chain PFAS on shallow soils after extended percolation (**Sepulvado et al. 2011**; **Stahl et al. 2013**; **Anderson et al. 2016**; **Anderson 2021**; **Anderson et al. 2022**). In a long-term lysimeter study using a silty soil with some clay and natural rainfall, PFOA and shorter chained PFCAs and PFSAs traveled more rapidly through the soil column than did PFOS (**Stahl et al. 2013**). However, even after 5 years, 96.88% and 99.98% of the mass of PFOA and PFOS, respectively, remained in the soil. This retention of PFOA and PFOS may increase the long-term persistence of the (soil-bound) source (**Baduel, Paxman, and Mueller 2015**). Due to the low (part per trillion) concentrations that are a concern in groundwater, slow leaching of PFAS from shallow soils may contribute to a persistent groundwater plume.

5.3.4 Transfer of PFAS between groundwater, surface water, porewater, and sediment

The interplay between PFAS and groundwater, porewater, surface water, and sediments is complex, and identifying the nature and implications of these interactions for PFAS fate and transport is very likely site-specific. The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about colloidal transport of PFAS in groundwater (see **Section 1.3.4.2**) and groundwater-surface water interactions (see **Section 1.3.4.3**).

For example, studies within the Little Neshaminy watershed in southeastern Pennsylvania indicate instances where PFAS-containing groundwater impacts surface water and other instances where surface water PFAS concentrations may be diluted by groundwater discharge (**Leidos 2019**; **Tetra Tech 2022**). Field investigations have also demonstrated the migration of PFAS from groundwater to surface water via infiltration of groundwater to stormwater utilities (**Leidos 2019**; **Wood 2020**). Other investigations have indicated transport of PFAS from groundwater to surface water features such as marshland (**Aerostar SES 2021**). Investigations involving larger tributaries also indicate that migration of PFAS from groundwater to surface water may be impacted by seasonal and local variations in stream flow that may affect groundwater flow direction and gradients (**Weston-ER Federal Services 2022**).

A complete understanding of fate and transport implications of transfer of PFAS between surface water and groundwater requires an understanding of the differing conditions between surface water, groundwater, and the hyporheic zone.

Development of surface water quality standards for PFAS is discussed in **Section 16**. Information about PFAS occurrence in surface water and groundwater is included in **Section 6.4** and **Section 6.3**, respectively and in **Section 17.1**. Additional case studies of PFAS transport between surface water and groundwater are discussed in **Section 15.5**.

5.3.4.1 Groundwater/Surface Water Interactions

Surface water and groundwater often have distinct chemistry or geochemistry, including differences in pH, ionic concentrations, dissolved oxygen, and sources and concentration of PFAS or other contaminants. Sediment porewater represents the boundary layer between groundwater and surface water where geochemical and redox transition zones may have significant fate implications for PFAS.

To date, there are very limited studies of PFAS at the surface water/groundwater boundary. One of the few published studies, **Tokranov et al. (2021)**, looked at the PFAS concentrations, dissolved oxygen, and nutrients in downwelling of lake surface water. They found that precursor concentrations decreased from surface water to groundwater across the porewater boundary and attributed this decrease to biotransformation and sorption.

Redox gradients at the sediment porewater zone are expected to impact the fate of PFAA precursors (for example, from anoxic groundwater flow into surface waters). Reaeration of anoxic groundwater during exfiltration to surface water will lead to shifts in microbial populations, which in turn may alter transformation of PFAA precursors. An analogous process occurred when increased PFAAs were detected after biosparging in the field (**McGuire et al. 2014**) and in column studies (**Nickerson et al. 2021**; also see **Section 5.4.4.2** and the case study in **Section 15.1.1**). This suggests groundwater/surface water redox transition zones have potential as hotspots for biotransformation. Additional abiotic transformations may also occur in anoxic groundwater to aerobic surface water boundaries.

There is limited information on how redox gradients impact PFAS sorption. However, aerobic transformation of PFAA precursors yields more mobile products (**Weber et al. 2017**), which in turn might be less likely to be adsorbed to solid phases. In addition to the impacts on precursor transformation, the perfluorocarbon chain length "head group, and a variety of environmental properties (for example, sediment organic carbon content, mineral and grain coating composition, pH, aqueous calcium and humic acid concentration) have all been shown to influence PFAS partitioning in laboratory experiments" (**Tokranov et al. 2021**). For example, **Steffens et al. (2021)** found that measured PFOS concentrations decreased significantly in ionic solutions due to an apparent "salting out" effect. The decrease in bulk solution PFOS concentrations with higher salinity was attributed to increased uptake of PFOS on the water-container interface, as well as increased aggregation at the air-water interface. The authors suggest that such an effect has implications on transport of PFAS in high-salinity environments or in areas where changes in salinity occur spatially or temporally, as increased salinity may lead to aggregation of PFAS on particulates, sediment, or other solids, as well as increased concentrations of PFAS in surface microlayers.

It is difficult to estimate the extent of PFAS introduction to surface waters from groundwater, especially when there are other surface point discharge sources, or transformation and sorption processes might significantly impact PFAS transport. However, **Pétré et al. (2021)** studied a site without direct outfalls of PFAS onto surface water and based on groundwater and surface water field measurements estimated up to 32 kg/yr for perfluoroether carboxylic acids (PFECAs) released from hyporheic exchange. Because of the high mobility and low retardation factor of PFECAs, the authors assumed low sorption and not enough time for transformation (days to months) assuming no transformation or sorption due to the low retardation factor of PFECAs. They indicated that adsorption would overestimate PFAS flux to surface water, and desorption would underestimate it.

5.3.4.2 Surface Water/Sediment Interactions

PFAS, particularly short chain PFAS, are mobile in the aquatic environment due to their high solubility in water (**Ahrens 2011**). This property further increases the difficulty of finding a correlation between concentrations in water, especially flowing water, and other media, such as sediments, fish, or invertebrates (**Campo et al. 2016**). A number of studies have sought to establish PFAS partitioning

between surface water and sediments in lakes or other stationary water bodies, such as wetlands and estuaries (**White et al. 2015**; **Mussabek et al. 2019**; **Bai and Son 2021**; **da Silva et al. 2022**).

Occurrence of PFAS in sediments can be the result of transfer (partitioning) from the surface water column or deposition of PFAS sorbed to suspended solids. The relative contribution of each process in PFAS transport to sediments remains unclear as partition coefficients measured in the field are consistently higher than those measured in the laboratory (**Zhang et al. 2015**; **Li, Oliver, and Kookana 2018**; **Rovero et al. 2021**). Suspended solids originating from erosion of PFAS-impacted soil may contain much higher levels of PFAS compared to suspended solids with PFAS due to equilibrium deposition (**Borthakur et al. 2021**; **Xiao et al. 2019**). These suspended solids, eroded from PFAS-impacted soils, may mix with particulates present in rivers and streams through turbulent mixing and may lead to higher PFAS concentrations in sediment when the suspended solids settle.

Dated sediment core analysis allows estimation of deposition rates and fluxes of PFAS to surface water bodies. Studies in the Great Lakes suggest it may be effective for long-chain PFAS that exhibit greater sorption to sediment, with concentration at a given depth interval representing deposition during that time period. Short-chain PFAAs showed less sorption and were apparently more mobile in the sediment column, and therefore were not effective indicators of PFAS deposition rates. The authors (**Codling et al. 2018**) also noted that as more short-chain PFAS are used as replacements for PFAS applications, sediment cores may have less utility for evaluating trends in deposition rates. Age-dated sediment cores in a Swedish study (**Mussabek et al. 2019**) allowed estimation of deposition rates and fluxes of PFAS to ponds impacted by AFFF releases. The study identified peak deposition rates occurring between 2003 and 2009, which correlated with reported activity near the water bodies. The study noted that interpretation of fluxes must consider seasonal variations in water chemistry, sedimentation, and partitioning (**Mussabek et al. 2019**). Heavy precipitation or storm events can also contribute to episodic or enhanced transport of sediment and resuspension or redistribution of contamination in some environmental settings. Resampling of marine sediment locations in Florida following the passage of a hurricane found sediment concentrations of total PFAS decreased 47% averaged across nine sites (**Ahmadireskety et al. 2021**). Sediments can also influence surface water concentrations. Tributary sediments with a mix of potential sources were shown to be potential secondary sources of PFAAs once those sediments were transported to a receiving water body (**Balgooyen and Remucal 2022**).

Because PFAS concentrations in sediment may be the result of average deposition conditions of discharges that may be episodic, passive porewater samplers may be useful to characterize the surface water concentrations and correlate them with the sediment PFAS concentrations. Passive sampling provides an accumulation of contaminants and so generates a time-weighted mean concentration instead of a snapshot of concentration at a discrete time point. However, careful consideration must be given to the type of sampler, as equilibrium devices may not be appropriate for episodic discharges and accumulation devices could potentially represent the average concentrations in sediments. See **Section 11.1.7** for more information about sampling environmental media.

In a recent study, PFBS, PFHxS, and PFOS in sediments collected from lake Sänksjön near Ronneby, Sweden, was found to be correlated to the sediment mineral content (Fe, Pb, Rb, and As) but not with the fraction of organic carbon (f_{oc}) based on principal component analysis (**Mussabek et al. 2020**). Other PFAS measured at the site (PFHxA, PFOA, and 6:2 FTS) had weaker associations with the mineral content. The sorption behavior of PFAS to sediments depends on both hydrophobicity and electrostatic interactions given the unique structure of PFAS with both polar and nonpolar moieties (**Ahmadireskety et al. 2021**; **Lampert 2018**). Sorption of PFAS to sediments is expected to be driven by similar variables as partitioning in soils. See **Section 5.3.2** for additional discussion of factors driving partitioning and sorption. In aquatic environments and the hyporheic zone, sorption and desorption are likely to have direct effects on the mechanisms of PFAS transport (for example, transport in dissolved phase, retention due to sorption, or particulate transport due to sorption).

5.4 Transformations

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about perfluoroalkyl acid precursor biotransformation (see **Section 1.3.3**). In addition, a new tab named Biotransformation was added to the Physical and Chemical Properties Table (**Table 4-1**). The biotransformation table includes a compilation of available precursor kinetics data (see **Section 1.3.3.2**).

5.4.1 Introduction

Numerous studies have reported both biotic and abiotic transformations of some polyfluorinated PFAS. Polyfluorinated PFAS shown to transform are referred to as *precursors* and typically form PFAAs. However, PFAAs have not been shown to degrade or otherwise transform under ambient environmental conditions. The fundamental differences between polyfluorinated precursors and perfluorinated chemicals that affect transformation potential are the presence, location, and number of carbon-hydrogen (C-H) bonds and *potentially* carbon-oxygen (C-O) bonds throughout the alkyl carbon chain. Specifically, PFAS with C-H bonds are subject to a variety of biotic and abiotic reactions that ultimately result in the formation of shorter chain PFAAs. Although available studies on both biotic and abiotic transformation of polyfluorinated PFAS primarily consist of controlled laboratory experiments (discussed below), an increasing number of field studies have also been published that demonstrate the relevance of precursors at a variety of sites with different source scenarios (for example, **Weber et al. 2017**; **Dassuncao et al. 2017**).

5.4.2 PFAA Precursors

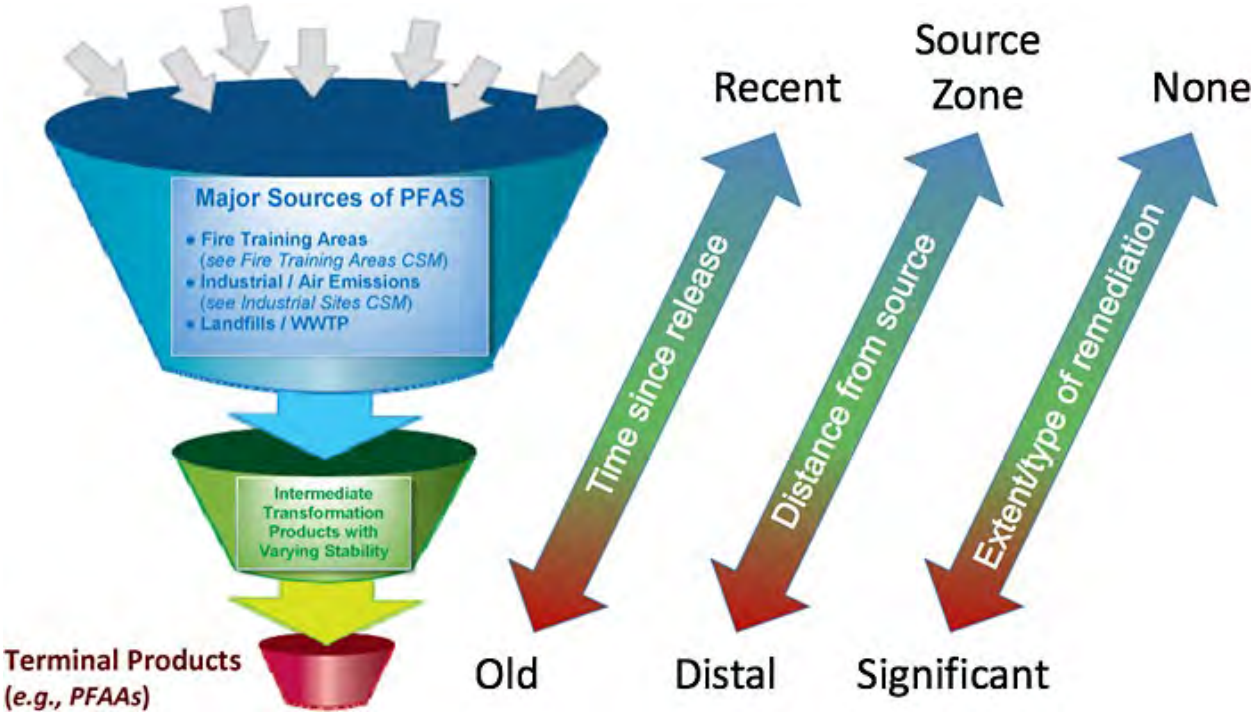

Figure 5-3. Illustration of precursor transformation resulting in the formation of PFAAs.

Although PFAAs are limited to a fairly small number of homologous compounds that differ only with respect to carbon chain length and the terminal functional group, the number and diversity of polyfluorinated chemicals is vast. Thousands of PFAS are currently thought to exist (or have existed) on the global market, and the vast majority are polyfluorinated (**Wang et al. 2017**) (**Section 2**). However, transformation studies published to date are available for only of a small subsample of these PFAS, and therefore, much uncertainty exists regarding 1) the extent to which precursor transformation occurs on a global scale, 2) which environmental compartments represent the majority of transformation, 3) relevant environmental conditions that affect transformation processes, and 4) transformation rates and pathways. Nevertheless, the fraction of total PFAS that consists of PFAAs, both globally and (in particular) at contaminated sites, should be expected to increase due to transformation over time, over distance, and due to remediation, as depicted in **Figure 5-3**.

5.4.3 Atmospheric Transformations

Although direct emission of PFCAs has declined globally, atmospheric emission of PFCA precursors has been increasing (**Thackray and Selin 2017**; **Wang et al. 2014**). Similarly, emission rates for PFSA precursors are increasing globally (**Löfstedt Gilljam et al. 2016**). Atmospheric transport is an important distribution mechanism for PFAS on both regional and global scales, which has led to documented PFAS occurrence (including PFAAs and PFAA precursors) in remote locations, including arctic regions (**Young et al. 2007**). Ocean currents also transports PFAS to arctic regions, although the relative contribution of each mechanism is not well understood (**Yeung et al. 2017**). Regardless of the relative contributions of atmospheric and oceanic transport, atmospheric transport and subsequent transformation of precursors has been documented as an important source of PFAAs in the environment (**Young et al. 2007**).

Widely measured PFCA precursors in the atmosphere include primarily FTOHs (**Thackray and Selin 2017**; **Young and Mabury 2010**; **Martin et al. 2002**). **Wang et al. (2015)** collected marine atmospheric samples during an expedition research cruise that spanned the Southern Ocean, Atlantic Ocean, and Arctic Ocean; samples were analyzed for several precursors, including FTOHs, FTAs, FOSAs, and FOSEs. The researchers found that FTOHs were the predominant species.

Atmospheric transformation of precursors, including FTOHs, may be an important source of PFCAs in the environment, such as those identified in the Arctic (**Schenker et al. 2008**). Although direct photolysis of PFAS has not been observed, indirect photolysis of some precursors does occur in the atmosphere and can be a significant contributor to PFCA deposition (**Armitage, MacLeod, and Cousins 2009**; **Yarwood et al. 2007**). For example, hydroxyl and chlorine radicals degrade 8:2 FTOH to PFOA in the atmosphere through reactions with hydroxyl and chlorine radicals, with similar reactions for 6:2 and 4:2 FTOHs (**Ellis et al. 2004**) and perfluoroalkyl sulfonamides, which may degrade to PFCAs and PFSAs (atmosphere) (**Martin et al. 2006**) and PFSAs (terrestrial environment) (**Mejia Avendaño and Liu 2015**). In addition to FTOH, other semivolatile precursors may also undergo atmospheric transformation to PFCAs (**Young and Mabury 2010**).

Atmospheric transformation of precursors to PFCAs is a multistep process, and the PFCA product yield is a function of several factors, including ratio of nitrous oxides (NO_x) and peroxy radicals (RO_2) species. High NO_x levels result in lower long-chain PFCA yields, thus long-chain PFCA yields are typically higher in remote regions (**Young and Mabury 2010**). **Thackray and Selin (2017)** calculated theoretical maximum yields for formation of PFOA and PFNA from 8:2 FTOH that were highly variable, ranging from far less than 1% to 40% (PFOA) or 80% (PFNA), depending on local photochemical conditions.

5.4.4 In Situ Transformations

5.4.4.1 Abiotic Pathways

Abiotic processes shown to cause transformations of precursors in soil and water under ambient environmental conditions include hydrolysis, photolysis, and oxidation. Hydrolysis of some precursors, followed by subsequent biotransformation, can produce PFSAs. An important example is the production of PFOS from perfluorooctane sulfonyl fluoride (POSF) (**Martin et al. 2010**). Other hydrolysis reactions produce PFCAs. In particular, **Washington and Jenkins (2015)** showed that the hydrolysis of fluorotelomer-derived polymeric precursors forms monomeric precursors of PFOA and other PFCAs with half-lives of 50–90 years at neutral pH. Also, oxidation of precursors by hydroxyl radicals can occur in natural waters, with the fluorotelomer-derived precursors being oxidized more rapidly than electrochemical fluorination (ECF)-derived precursors (**Gauthier and Mabury 2005**; **Plumlee, McNeill, and Reinhard 2009**). Shorter chain PFCAs as well as PFSAs such as perfluorobutane sulfonate (PFBS) also can be produced by oxidation reactions between hydroxyl radicals and sulfonamido derivatives (**D'Eon et al. 2006**). Finally, in some cases, abiotic precursor transformations may not initially produce any PFAA (for example, the formation of various polyfluorinated sulfonamido intermediate compounds from ECF-derived precursors), though eventual formation of PFAAs may still be possible.

5.4.4.2 Aerobic Biological Pathways

Evidence of aerobic biotransformation is provided from studies of PFAS composition throughout the continuum of wastewater treatment (see **Arvaniti and Stasinakis (2015)** for a comprehensive review), field studies at AFFF-impacted sites (for example, **Houtz et al. 2013**; **McGuire et al. 2014; Anderson et al. 2016**; **Weber et al. 2017**), and most authoritatively from microcosm experiments.

The literature on aerobic biotransformation collectively demonstrates, or indirectly supports, conclusions such as the following:

- Numerous aerobic biotransformation pathways exist with relatively rapid kinetics.
- All polyfluorinated precursors studied to date have the potential to aerobically biotransform to PFAAs.
- Aerobic biotransformation of various fluorotelomer-derived precursors *exclusively* results in the formation of PFCAs, including PFOA.
- Aerobic biotransformation of various ECF-derived precursors *primarily* results in the formation of PFSAs, including PFOS.

In detail, most commonly studied in microcosm experiments have been the 6:2 and 8:2 FTOHs in soil, sludge, or aqueous matrices. Although observed degradation rates and intermediates are variable among these studies, ≤ C8 PFCAs have been consistently observed as terminal transformation products (**Dinglasan et al. 2004**; **Wang et al. 2005**, **2005**; **Liu et al. 2007**; **Saez, de Voogt, and Parsons 2008**; **Wang et al. 2009**). However, a pure culture experiment with *P. chrysosporium* (a white-rot fungus) reported much lower PFCA yields with alternate pathways (**Tseng et al. 2014**). Other telomer-derived polyfluorinated PFAS investigated include the 6:2 fluorotelomer mercapto alkylamido sulfonate (**Weiner et al. 2013**), the 6:2 fluorotelomer sulfonate (**Wang et al. 2011**), the 4:2, 6:2, and 8:2 fluorotelomer thioether amido sulfonates (**Harding-Marjanovic et al. 2015**), the perfluorooctane amido quaternary ammonium salt (**Mejia-Avendaño et al. 2016**), the 6:2 fluorotelomer sulfonamide alkylamine, and the 6:2 fluorotelomer sulfonamide alkylbetaine (**D'Agostino and Mabury 2017**). All demonstrate the formation of PFCAs with variable rates and inferred pathways. Aerobic biotransformation of various ECF-derived polyfluorinated PFAS has also been demonstrated in several studies. Studied PFSA precursors include N-

ethyl perfluorooctane sulfonamido ethanol (**Rhoads et al. 2008**; **Zhao et al. 2016**; **Zhang et al. 2017**), N-ethyl perfluorooctane sulfonamide (**Mejia Avendaño and Liu 2015**), and perfluorooctane sulfonamide quaternary ammonium salt (**Mejia-Avendaño et al. 2016**). All demonstrate formation of PFSAs with variable rates and inferred pathways.

5.4.4.3 Anaerobic Biological Pathways

Few studies have been published to date conclusively demonstrating biotransformation of per- and polyfluorinated PFAS under anaerobic conditions. Different end-products of PFAA precursors have been observed between aerobic and anaerobic conditions (**Choi et al. 2022**). Aerobic, and to some extent, denitrifying conditions lead to PFAAs (**Yi et al. 2022**), but more reducing anaerobic conditions, such as iron- and sulfate-reducing, lead to other transformation products (**Yi et al. 2018**; **Yan et al. 2022**). FTOHs were studied in two instances, demonstrating the production of stable polyfluorinated acids under methanogenic conditions with much slower kinetics relative to aerobic biotransformation (**Zhang et al. 2013**; **Allred et al. 2015**). In a recent study, PFOA and PFOS were demonstrated to be defluorinated by a specific microbial strain (*Acidimicrobium sp*. Strain A6) under conditions where ammonium is oxidized while iron is reduced, a condition known as Feammox (**Huang and Jaffé 2019**). The environmental significance of anaerobic biotransformations of polyfluorinated PFAS as sources of PFAAs is uncertain.

5.4.5 Polymer Transformation

Polymeric substances in the PFAS family include fluoropolymers, polymeric perfluoropolyethers, and side-chain fluorinated polymers (**Buck et al. 2011**). Detailed descriptions of these polymers appear in **Section 2.2.2.1**. Briefly,

- fluoropolymers are high–molecular weight solid plastics (> 100,000 Daltons, or Da according to **Henry et al. (2018)**) containing a carbon polymer backbone with fluorine directly attached to backbone carbon atoms.
- polymeric perfluoropolyethers contain an ether polymer backbone with F directly attached to carbon atoms. These polymeric PFAS are complex and mainly used as surfactants and surface protectants.
- side-chain fluorinated polymers contain a nonfluorinated polymeric backbone with fluorinated side chains; these are synthesized from telomer-derived precursors.

Polymer transformation research has indicated the following.

- Given the wide range of estimated half-lives, modeling assumptions for estimating the half-lives, different levels of residuals present in the polymer studied, highly variable molecular weights of the polymers studied with different surface area and size and with different extraction protocols, the polymer degradation studies are inconsistent.
- Other environmental conditions that need to be considered are redox, pH, temperature, percent moisture, and microbial activity in the soil microcosms for these long-term studies.
- Additional research is needed primarily on the biotransformation of side-chain fluorinated polymers, which are potential precursors to PFAAs.

Side-chain fluorinated polymers are widely used for many commercial and industrial applications as surfactant and surface-protecting products (**Buck et al. 2011**). Therefore, understanding the biotransformation potential of these polyfluorinated polymers is essential. However, few studies have reported on the potential biotransformation of side-chain polymers—for example, the fluorotelomer-based

urethane polymer (**Russell et al. 2010**). Given the complexity of side-chain fluorinated polymers, there are many discrepancies among these studies. Primarily, the inability to monitor polymer concentrations is problematic. Because analytical methods for direct quantitation of polymers are not available, all the studies except **Rankin et al. (2014)** monitored suspected FTOH degradation products rather than the disappearance of the polymer (**Wang et al. 2005**; **Liu et al. 2007**; **Wang et al. 2009**; **Dasu, Liu, and Lee 2012**; **Dasu and Lee 2016**). **Rankin et al. (2014)** qualitatively monitored the disappearance of the polymer using matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry, in addition to monitoring known degradation products. Also, the presence of impurities or nonpolymerized residuals (monomers, oligomers, PFCAs, FTOHs, etc.) complicates data interpretation and potentially confounds conclusions on polymer biodegradation. Finally, the time frame for the biodegradability studies (max = 2 years) is much shorter than the extrapolated half-lives (decades to thousands of years) of these side-chain fluorinated polymers. Hence, modeling assumptions are also critical sources of variability.

Russell et al. (2008); **Russell et al. (2010)** investigated the biodegradation potential of two types of side-chain fluoropolymers, fluorotelomer-based acrylate polymer and urethane polymer in soils for 2 years. Based on the experimental data for PFOA, the estimated half-life of acrylate polymer was 1,200–1,700 years and of urethane polymer was 28–241 years (geometric mean of 102 years). However, the polymer used in this study contained high residuals. Later, **Washington et al. (2009)** studied the biodegradation potential of fluorotelomer-based polyacrylate, which contained low residuals, and based on the experimental data for PFOA, the acrylate polymer half-life was estimated at 870–1,400 years. Further, based on the assumption that degradation is surface-mediated, the authors also modeled and estimated the half-life for finely grained polymers, which are typical of commercial products. They did this by normalizing to the estimated surface area of the polymer and derived a half-life of 10-17 years, which suggests fine-grained, side-chain fluoropolymer products may be a potentially significant source of PFCAs to the environment. **Washington et al. (2015)** studied the biodegradability of commercial acrylate polymer for 376 days in soils using exhaustive extractions (**Washington et al. 2014**) and estimated half-lives ranging from 33 to 112 years. In this study, it was also observed that the acrylate polymer can undergo OH-mediated hydrolysis in pH 10 water and it degrades 10-fold faster than in the neutral treatment. This is the only abiotic transformation of side-chain fluorinated polymer reported in the literature, so the mechanism of abiotic degradation needs further investigation. Another research group, **Rankin et al. (2014)** studied the biodegradation of laboratory-synthesized fluorotelomer-based acrylate polymer in soil, plant, and biosolids for 5.5 months. Degradation rates were faster in plants and biosolids than in soils. Even in this study, a broad range of estimated half-lives of 8–111 years was reported. The modeling assumptions used in different studies lead to variability in reported half-lives (**Russell et al. 2008**; **Russell et al. 2010**; **Washington et al. 2009**, **2010**, **2015**, **2018**).

5.4.6 Practical Implications

Precursor transformation can complicate CSMs (and risk assessments) and should be considered during comprehensive site investigations. For example, atmospheric emissions of volatile precursors can result in long-range transport where subsequent transformation and deposition can result in detectable levels of PFAAs in environmental media independent of obvious point sources (**Vedagiri et al. 2018**). Moreover, downgradient PFOA and PFOS groundwater concentrations, or downstream concentrations within treatment systems, can oftentimes be higher than near the source area/influent due to precursor transformation reactions such as oxidation. Also, PFOA and PFOS concentrations can exhibit an increasing trend over time as precursors transform with time and distance (**Figure 5-3**), which can influence the Remedial Investigation/Feasibility Study (RI/FS) scope and data evaluation.

With respect to site-related precursors, transformation of otherwise unmeasured PFAS into detectable PFAAs is obviously relevant to site investigations to the extent transformation occurs after initial site characterization efforts. Additionally, differential transport rates between precursor PFAS and the

corresponding terminal PFAA could also confound CSMs if transformation rates are slower than transport rates, as has been suggested (**Weber et al. 2017**).

To account for otherwise unmeasurable precursors, several surrogate analytical methods have been developed, including the total oxidizable precursor (TOP) assay (**Houtz and Sedlak 2012**), particle-induced gamma-ray emission spectroscopy (PIGE) (**Schaider et al. 2017**), and adsorbable organic fluorine (AOF) followed by combustion ion chromatography (**Wagner et al. 2013**). For more information on these surrogate analytical methods to measure precursor concentrations, see **Section 11.2**.

5.5 PFAS Uptake into Aquatic Organisms

Some PFAS have a propensity to bioaccumulate. That is, they are taken up and accumulate in organisms from environmental media. Moreover, some PFAS may biomagnify up the food chain; for these compounds, lower levels of PFAS are observed in tissue from organisms at the base of the food chain and in lower trophic-level invertebrates and fish and higher tissue PFAS levels are observed in predatory fish and in air-breathing animals at the top of the food chain (for example, seagulls, polar bears) (**Houde et al. 2011**; **Gobas, Kelly, and Kim 2020**; **Burkhard 2021**). Trophic transfer of PFAS and biomagnification appear to be higher in air-breathing organisms (aquatic-dependent birds and mammals) than in gill-breathing species (for example, higher trophic-level fish species), presumably because the respiratory elimination of PFAS via gills to water is much greater than elimination from lungs to air (**De Silva et al. 2021**). It should be noted that not all PFAS biomagnify, and for some (for example, PFOS), the evidence regarding biomagnification is mixed (**Franklin 2016**). **Section 1.3.5.4** includes information about bioaccumulation of PFAS in marine biota.

The major mechanisms controlling aquatic bioaccumulation of PFAS are uptake (from water and food), depuration (which includes elimination across the gill surface, urine, and in feces) (**Chen, Gong, and Kelly 2016**; **Zhong et al. 2019**), growth dilution, and biotransformation. Within organisms, the extent of accumulation differs among types of tissues (for example, whole body, muscles, liver).

An understanding of bioaccumulation in field populations rests on evaluation of the following factors, which are common to PFAS, as well as to other contaminants:

- Exposure concentrations (concentrations of PFAS in sediments and water)
- Exposure to precursors
- Trophic level (higher trophic levels often exhibit higher concentrations)
- Movement and migration patterns, which determine the extent of exposure to contaminated areas that lie within the home range of an organism
- Bioenergetics (respiration rate, growth rate)
- Toxicokinetics (gut uptake efficiency, gill transfer efficiency, fecal elimination, biotransformation rate, differential protein binding)

Unlike nonionic polar organic compounds, which accumulate in fatty tissues, the bioaccumulation of ionic PFAS in aquatic biota is generally characterized as associated with proteins. Several studies (**Jones et al. 2003**; **Han et al. 2003**) reported that PFOS and PFOA are generally bound to serum albumin, as well as proteins in the liver and kidney, and differences among tissues in type of protein explain much of the PFAS variation among tissues (**Ng and Hungerbuhler 2014**, **2015**). Binding to phospholipids is another mechanism for PFAS accumulation (**Dassuncao et al. 2019**). Thus, methods and models that characterize the bioaccumulation of nonionic polar compounds by assuming partitioning to lipids (using lipid normalization) are likely to be inappropriate for PFAS (see discussion of partitioning in **Section 4.2.10**).

Bioaccumulation of PFAS is generally characterized using three parameters:

- Bioconcentration factor (BCF)—the direct uptake of PFAS by an organism from the water column (for example, through the gills). This is measured in the laboratory. It is defined as the ratio of the concentration in an organism to that in the exposure water (typically in units of ng/kg wet weight / ng/L, or L/kg wet weight).

- Bioaccumulation factor (BAF)—the amount of PFAS taken up from water plus the contribution of PFAS in the diet of the organism. Both the organism and its diet are simultaneously exposed to the same exposure sources. This is generally measured in the field. The units are the same as for the BCF.

- Biomagnification factor (BMF)—the increase in tissue PFAS concentration moving up the food chain, based on a specific predator/prey relationship. The BMF is measured in the field and is typically reported in units of ng/kg wet weight in predator / ng/g wet weight in prey. The trophic magnification factor (TMF) similarly describes the increase in tissue PFAS concentration with trophic level, but it is estimated using data for multiple trophic levels. It is typically calculated as a regression of log(PFAS concentration) vs. trophic level, which is usually determined using the stable isotope 15N method (**Franklin 2016**).

BCFs, BAFs, and BMFs are used to understand the nature of bioaccumulation; for example, they are used in the European Union REACH designation of compounds as "bioaccumulative" in the Persistent, Bioaccumulative, and Toxic (PBT) and Very Persistent and Very Bioaccumulative (vPvB) assessments. They are also used to support risk assessments and in development of surface water quality criteria (see **Section 16**). Publications addressing PFAS BCFs, BAFs, BMFs/TMFs are too many and too broad to cover in this document. Several publications have reviewed PFAS bioaccumulation, including but not limited to **Burkhard (2021)**; **Houde et al. (2006)**; **Houde et al. (2011)**; **Martin et al. (2013)**; **Conder et al. (2020)**; **Gobas, Kelly, and Kim (2020)**; and **De Silva et al. (2021)**.

To support better understanding of PFAS bioaccumulation in aquatic species, available BCF and BAF data are provided in **Table 5-1** (as a separate Excel file). BCF and BAF values for both invertebrates and fish are included. PFOS is the compound for which BCFs and BAFs are most commonly reported. This is expected because it is generally the most abundant PFAS in the tissues of aquatic organisms. The **Table 5-1** Excel file consists of two sheets, the Database that reports values found in relevant literature and a Log sheet that lists each reference that was reviewed.

Table 5-1 includes BCF or BAF values reported in published studies that were compiled as of September 2021. All of the BCF studies were performed in the laboratory under controlled conditions, while the BAF studies were performed in the field. All studies were subject to quality review, which was performed in a qualitative manner. First, the table includes only BCF and BAF values that were reported in the publications. In some studies, PFAS concentrations were measured in water and biota, but BCF or BAF values were not reported. In such studies, BCF or BAF values may not have been reported due to several potential factors—for example, proper spatial and temporal matching of the data. In light of such uncertainties, BCF or BAF values were not calculated for the table. These studies are noted in the Log sheet, for the user's consideration.

In addition, a number of studies were reviewed but not included in the Database sheet for various reasons; these studies are also indicated in the Log sheet (column "BAFs or BCFs presented in **Table 5-1**?"), and notes on each study are provided in the column "Comment." A quantitative ranking was not conducted, along the lines of **Burkhard (2021)**, who developed a parallel and largely overlapping database of BAF values and classified each study into one of three data quality categories based on several factors (number of fish and water samples, temporal and spatial coordination between the water and fish sampling, and general experimental design). **Burkhard (2021)** concluded that "The distributions suggest

that there are not big differences across the three measurement quality rankings." This suggests that the lack of a quantitative quality review of each study in Table 5-1, along the lines provided by **Burkhard (2021)**, is not likely to be a significant limitation to the usefulness of the information. Additional information is provided in the README sheet of the Table 5-1 Excel file.

Information on best practices for conducting laboratory bioaccumulation tests is provided by **OECD (2012)**, **USEPA (2016)**, and **ASTM (2013)**. Information is also available concerning the design and interpretation of field and laboratory BAF studies (for example, **Burkhard 2003**; **Gobas et al. 2020**). These resources may be useful in guiding the interpretation of the studies included in the database.

The following sections provide overviews of the available PFAS bioaccumulation data.

5.5.1 Bioconcentration

Table 5-1 presents available BCFs for several PFAS. Variation in the reported values is observed in the BCFs and is related to the specific PFAS, exposed species, tissue type, and other factors.

Studies have indicated that chemical structure, particularly the length of perfluoroalkyl chain and the presence of functional groups (carboxylate vs. sulfonate), influence their bioaccumulation potential. **Martin et al. (2003)** exposed rainbow trout to individual PFAS for 12 days. The PFAS with shorter perfluoroalkyl carbon chain lengths (< 7 for carboxylates and < 6 for sulfonates) had negligible BCFs. At 8–12 carbon chain length, uptake of PFAS compounds was proportional to the carbon chain length and inversely proportional to the critical micelle concentration (CMC; the concentration at which one half of the molecules are associated as micelles). Others have also shown that shorter chain PFCAs and PFSAs (less than eight and six carbons, respectively) are not readily bioconcentrated or accumulated (**Conder et al. 2008**; **Martin et al. 2013**; **Houde et al. 2011**).

Martin et al. (2003) also showed that PFSAs had greater BCFs and half-lives than the corresponding PFCAs of equal chain length, indicating that hydrophobicity, as predicted by the CMC, is not the only determinant of PFAS bioaccumulation potential and that the functional group must be considered.

With respect to tissue types, **Martin et al. (2003)** showed that PFAS accumulated to the greatest extent in the blood, followed by the kidney, liver, and gall bladder. Lower levels accumulated in the gonads, followed by adipose tissue and muscle tissue. This tissue-dependent distribution has been shown in many other studies and is apparently due to PFAS having a high affinity for serum albumin and fatty acid–binding proteins (**Ng and Hungerbuhler 2014**, as well as to binding to phospholipids (**Dassuncao et al. 2019**).

5.5.2 Bioaccumulation

Table 5-1 presents available BAF data for several PFAS. As shown, BAFs may be reported using concentrations measured in whole bodies or specific tissues. BAFs reported for fish muscle or fillet are useful for human health risk assessments (for fish consumption) and for developing corresponding water quality criteria (see **Section 16**). Whole-body BAFs can be used in ecological risk assessments for higher trophic organisms (for example, predatory fish, piscivorous birds and mammals) and developing corresponding water quality criteria. However, **Conder et al. (2020)** proposed using lab-derived BCFs instead of field-based BAFs in ecological risk assessments, primarily because lab-based BCFs are less variable and generally more reliable than field-based BAFs. Furthermore, PFAS associated with freshly spiked laboratory media may be more bioavailable than in the field, potentially leading to conservative BCFs (higher than what would occur under field conditions). Field-based BAFs may be affected by the presence of precursors (**Langberg et al. 2020**), making risk assessments and water quality criteria based on these BAF estimates unreliable. However, site specificity of field-based BAFs may be important to

consider in specific situations, such as in the refinement of site-specific risk assessments and development of site-specific water quality criteria.

When comparing BAFs among organisms, or when developing statistical summaries of BAF values, differences among tissues in the extent of accumulation must be considered. The approach that is simplest, and which probably provides the most robust approach to comparisons of BAFs among organisms, is to report BAF values on a whole-body basis, since tissue-specific BAFs may vary among species due to differences in toxicokinetics. Such data may be collected using either whole-body samples or tissue-specific measurements that can be mathematically combined to yield equivalent whole-body concentrations. In aquatic organisms, PFAS concentrations in muscle are generally within a factor of two of whole-body concentrations (**Goeritz et al. 2013**; **Shi et al. 2015**).

Bioaccumulation of some PFAS has been observed in a variety of wildlife, generally fish-eating species, across the globe as demonstrated by the large number of studies reporting wildlife PFAS residues. Bioaccumulation data are now available for a wide range of environments, including water bodies directly adjacent to or downstream of manufacturers of PFAS, industries that use PFAS in manufacturing processes, firefighting, and wastewater treatment plants, as well as urban areas and areas distant from specific sources (**De Silva et al. 2021**). The majority of sampling has been conducted to support risk assessments and fish consumption advisories, as well as hypotheses concerning long-range fate and transport, temporal trends, and the identification of sources. Most of the work has been performed in the Northern Hemisphere, and some authors have found that levels are lower in the Southern Hemisphere (**Armitage et al. 2009**; **Ahrens et al. 2009**; **Ahrens 2011**; **Benskin et al. 2012**). One study in Australia, however, found among the highest PFOS concentrations reported worldwide in the livers of dolphins in heavily industrialized regions of South Australia (**Gaylard 2017**).

Some insights regarding PFAS bioaccumulation of PFCAs, PFSAs, and precursors are as follows:

- Similar to bioconcentration, bioaccumulation of PFAAs depends on carbon chain length (**Brendel et al. 2018**]). **USEPA (2017)** considers PFCAs with less than seven perfluorinated carbons (PFCAs shorter than PFOA) and PFSAs with less than six (such as PFBS) to less bioaccumulative. PFSAs are more bioaccumulative than PFCAs of the same carbon chain length.

- Bioaccumulation and biomagnification factors measured in the field vary widely (**Franklin 2016**; **Gobas, Kelly, and Kim 2020**; **Burkhard 2021**). Some PFAAs exhibit BAFs that overlap the range often used as criteria for bioaccumulation, for example by USEPA, Canada, and the European Union (1,000–5,000 L/kg).

Available BAFs in **Table 5-1** validate some of the above insights. For example, in comparing BAFs for PFOA with PFOS across all species, it is clear that the BAFs for PFOA are much lower than PFOS. Moreover, comprehensive reviews (**Ahrens and Bundshuh 2014**; **Houde et al. 2008**) indicate that PFOS (8-carbon chain PFSA) is typically the most common PFAS observed in fish, as well as air-breathing animals, although in invertebrates, PFOA and PFOS can exhibit similar concentrations (~1–10 ug/kg). **Ahrens and Bundshuh (2014)** attributed the lower bioaccumulation of PFOA than PFOS to shorter chain (7 perfluorinated carbons in PFOA vs. 8 perfluorinated carbons in PFOS). Overall, the data in **Table 5-1** indicate that for perfluorocarboxylates, BAFs increase until 11 or 12 perfluorinated carbons and decline for larger compounds.

Finally, it is important to note that PFAS precursors may contribute to the PFAS body burden. **Asher et al. (2012)** and **Langberg et al. (2020)** provided field data indicating an important contribution from precursors to PFOS concentrations in organisms via internal transformation. In addition, atmospheric measurements have shown the widespread occurrence of PFAS precursors like FTOHs and perfluorinated sulfonamide alcohols. Once absorbed by an organism, the precursor(s) may be metabolized to PFOA (for example, from 8:2 fluorotelomer alcohol) or to PFOS (for example, from N-ethyl

perfluorooctane sulfonamidoethanol) (**Gebbink, Berger, and Cousins 2015**; **Galatius et al. 2013**). Additional research on how PFAS precursors may contribute their bioaccumulation in fish and wildlife is needed.

5.5.3 Biomagnification

Biomagnification factors may be used in the regulatory determination of whether contaminants biomagnify up the food chain and in food web modeling in risk assessments. Key conclusions from published literature are summarized in this section.

Studies of PFAS in the Great Lakes and marine/arctic ecosystems have generally shown that there can be trophic-level biomagnification within a food web, particularly for PFOS and some long-chain PFCAs (**Martin et al. 2004**; **Houde et al. 2006**; **Houde et al. 2011**; **Butt et al. 2010**; **Tomy et al. 2004**, **2009**).

Martin et al. (2010) estimated BMFs for a pelagic food web in Lake Ontario, with the lake trout as the top predator. They were able to show, after adjusting for benthic versus pelagic organisms, that some PFAS compounds biomagnify, with TMFs ranging from 0.51 for FOSA to 5.88 for PFOS.

A study by **Houde et al. (2006)** looked at PFOS and C8–C14 perfluorinated carboxylates in the bottlenose dolphin at two marine sites (Sarasota Bay, FL, and Charleston, SC). Based on estimated TMFs, those authors concluded that PFOS and C8–C11 PFCAs biomagnified in this marine food web (**Table 5-1**, also cited by (**Franklin 2016**)). Interestingly, for PFCAs, PFOA had the highest TMF, with values progressively decreasing as chain length increased. **Conder et al. (2008)** reported similar results for perfluorinated acids, with BMF values ranging from 0.1 to 20 (geometric mean of 2). They concluded and **Lescord et al. (2015)** affirmed that PFCAs with less than seven carbons, and PFSAs with less than six carbons, do not biomagnify and that the bioaccumulation of PFCAs can be directly related to fluorinated carbon chain length (just as the bioaccumulation of persistent lipophilic compounds can be related to hydrophobicity). **Conder et al. (2008)** also noted that the biomagnification of PFCAs in aquatic food webs is lower than that of most persistent lipophilic compounds, with PFOS being the only perfluorinated acid consistently exhibiting the potential for biomagnification. Finally, **Butt et al. (2008)** observed biomagnification factors for PFAS in "ringed seal–polar bear" food webs of the Canadian Arctic. Biomagnification factors were greater than one for C8–C14 PFCAs, as well as for PFOS and PFOSA. Like **Houde et al. (2006)**, they observed a decrease in BMF as the carbon chain number increased.

Contrary to other freshwater studies, **Lescord et al. (2015)** did not find evidence for biomagnification in total PFAS, total PFCA, total PFSA, and PFOS. These authors observed negative relationships between trophic level, as measured using stable nitrogen isotope ratios (δ15N), and concentrations of the studied PFAS compounds (PFOS, total PFCA, total PFSA, and total PFAS) in several of the six lakes, suggesting no biomagnification in these freshwater arctic food webs. Overall, their results suggested that a taxon's horizontal but not vertical position in the food web affects its PFAS concentrations.

Because the BMF or TMF is the concentration in a predator divided by the concentration in its prey, calculated BMFs can be highly variable depending on what types of tissues were analyzed and what assumptions the researcher made in defining biomagnification relative to the animals' prey diet (often determined through analysis of stomach contents). **Franklin (2016**) analyzed the results of 24 peer-reviewed studies reporting field-derived BMFs or TMFs for 14 PFAS. BMF values ranged over several orders of magnitude, from 0.01 to 373 (including only nonzero values). TMFs varied from 0.1 to 20 (including only nonzero values). **Franklin (2016)** attributed this variability to several factors, including differing ways in which the metrics are expressed (for example, individual tissue analyses versus whole body), nonachievement of the assumed steady-state conditions, uncertainties in feeding ecology, and the metabolism of precursor compounds.

5.5.4 Characterization of Bioaccumulation in Criteria Development and Risk Assessments

In regulatory contexts, BMFs may be used to determine whether or not contaminants are considered bioaccumulative: a BMF greater than 1 indicates that a contaminant is bioaccumulative. The relationship between the BAF and BCF also provides relevant evidence.

Because consensus has not been reached regarding the extent of bioaccumulation and/or biomagnification of some PFAS, most importantly PFOS, the best approach to determining bioaccumulative status of PFAS and to conducting risk assessments is an active subject of discussion (**Franklin 2016**; **Conder et al. 2020**). **Franklin (2016)** made the case that "in practice, the study-to-study (and even within-study) variability of the results is so great that [field-measured BMFs and TMFs] are of very restricted usefulness for assessing bioaccumulation potential status." **Franklin (2016)** proposed basing the bioaccumulative status of a compound only on laboratory BCFs and on measurements of BMFs conducted under strictly monitored conditions, rather than relying on field-measured BMFs or TMFs. For fish, studies can make use of the OECD 305 protocol (**OECD 2012**). For terrestrial and avian species, dietary BMF determinations can be performed using laboratory rodents or cows or pigs fed with naturally contaminated feed, as well as avian species.

Similarly, **Conder et al. (2020)** proposed using laboratory-derived BCFs instead of field-based BAFs in ecological risk assessments, because lab-based BCFs may be less variable and generally more reliable than field-based BAFs. Moreover, lab-based BCFs are expected to provide conservative estimates of bioaccumulation, as PFAS may be more available in freshly spiked environmental media compared to aged PFAS in field samples. Furthermore, **Conder et al. (2020)** argued that laboratory BCFs avoid complications with the presence of PFAS precursors, which may transform into stable PFAS in field samples.

However, laboratory BCFs (studies in which organisms are exposed to contaminant in the water only) are subject to methodological limitations—for example, for substances that are highly sorptive. Furthermore, laboratory BCFs do not account for biomagnification, and for this reason will tend to provide low estimates of true BAFs. An approach similar to that proposed by **Franklin (2016)**, namely, combining laboratory-measured BCFs with BMFs measured under controlled conditions, may be reasonable.

Furthermore, while avoiding the complications of precursors, laboratory BCFs also do not account for the contributions of precursors to tissue concentrations of PFOS. PFOS BAFs measured by **Langberg et al. (2020)** were the highest in **Table 5-1**, ranging up to about 250,000 L/kg wet weight muscle for PFOS in yellow perch. This value far exceeds values that have been measured in other sites, generally in the range of 1,000–10,000 (**Table 5-1**). This high value was attributed to the primary role of precursors in determining organisms' tissue concentrations of PFOS at this site. In an ecological risk assessment for such a site, a tissue concentration determined using measured water column PFOS concentrations and a laboratory-derived BCF (on average, on the order of approximately 1,000 L/kg wet weight whole body for PFOS) would significantly underestimate the true tissue concentration. Thus, if tissue concentrations are primarily determined by precursor levels in the system, then measurement of the substance in water is not appropriate in the first place. Rather, the organism exposure to the precursor(s) itself needs to be measured.

Gobas, Kelly, and Kim (2020) proposed that the bioaccumulative nature of compounds can best be evaluated by focusing on the BMF as measured using dietary-based OECD 305 studies (**OECD 2012**) , interpreted using a two-compartment bioaccumulation model to estimate the BCF and the BAF. The domain of applicability of the model developed by **Gobas, Kelly, and Kim (2020)** was limited to nonionic organic chemicals, and so would have to be modified for application to PFAS.

Bioaccumulation rates may differ between linear and branched isomers of PFAS (**Conder et al. 2020**), and it is hypothesized that linear PFAS are more bioaccumulative than branched PFAS (**Houde et al. 2008**, **2011**). The use of more bioaccumulative isomers in laboratory BCF studies would result in a conservative, but potentially unrealistic, risk assessment for a field population exposed to a mixture of isomers. A full evaluation of the impact of isomer composition will require evaluation of the extent to which differences in bioaccumulation are significant, as well as the relative abundances of isomers in the environment.

Thus, in determining bioaccumulative status and in conducting risk assessments, the variability of field-measured BAFs and BMFs must be balanced against the biases and limitations associated with laboratory BCFs and BMFs. Such evaluations must be performed on a compound-specific basis, taking into account the confounding role of precursors. It is likely that a weight of evidence approach will be called for, given the uncertainties associated with PFAS bioaccumulation.

5.6 PFAS Uptake into Plants

Because PFAS contain a hydrophilic functional group, plants can be expected to take some of these compounds up through their root systems, after which they would be translocated to stems, shoots, leaves, and fruiting bodies. Plants growing closer to contaminated sources or irrigated with PFAS-containing water would be expected to accumulate higher concentrations of PFAS compared to plants more distant from the PFAS source (**Gobelius, Lewis, and Ahrens 2017**), subject to site-specific conditions such as soil properties. It has already been documented that the land application of biosolids may contaminate soil with PFAS and that animals fed silage from land-applied fields can have elevated concentrations of PFAS in their tissues (**Lindstrom et al. 2011**; **Skutlarek, Exner, and Farber 2006**). The Priority Topics for Biosolids Land Application include information about plant uptake (see **Section 1.7.4**) and uptake by animals (see **Section 1.7.5**).

This also raises concerns about contamination of wildlife consuming plants from agricultural areas. Airborne PFAS emissions from industrial sites in China were found to impact the concentration of PFAS in bark and tree leaves, with the theory that bioconcentration in the latter may occur through the stomata (**Shan et al. 2014**).

Understanding uptake of PFAS into plants is critical in evaluating the fate of PFAS among various environmental compartments, particularly along the food chains with implications for human and ecological exposures to PFAS. Human exposure may occur via consumption of PFAS-impacted produce and dairy and meat products from animals fed with PFAS-impacted plant-based feed. Potential wildlife exposure to PFAS may occur via PFAS taken up in plants at impacted sites and releases.

The following sections provide an overview of PFAS uptake pathways and mechanisms in plants and bioconcentration/bioaccumulation.

5.6.1 Uptake Pathways

Wang et al. (2020) provides an extensive review of uptake and accumulation of PFAS in plants. That study forms the basis of the overview provided in this section. As described in **Wang et al. (2020)**, uptake of PFAS has been well documented in different native and planted species to varying degrees. The majority of these studies have focused on PFOA and/or PFOS uptake by agricultural crops, although there are many other PFAS that have been shown to be subject to plant uptake. **Wang et al. (2020)** also reported that while most published studies were conducted under controlled lab conditions, at least 16 field studies were identified. These field studies typically have focused on point sources of PFAS, including manufacturing sites, fire training areas, wastewater treatment plants, or landfills.

PFAS may be introduced to plants from soil, water, or air by:

- irrigation with impacted water
- land application of biosolids
- leachates from landfills
- impacts or releases at PFAS sites
- emissions and atmospheric deposition

Plant uptake is both PFAS- and soil-specific. PFAS with higher aqueous solubilities/diffusivities with less soil/air-water interface (AWI) retention affinity are often observed with greater uptake potential (bioavailability). For example, **Wang et al. (2020)** compiled bioconcentration factors (BCFs) for different PFAS that had been reported in literature studies; the bioconcentration factor is the ratio of the PFAS concentration in the plant tissue to the concentration in the soil. This compilation showed the median BCF values for PFBA and other short-chain PFAS were generally more than an order of magnitude greater than the values for long-chain PFAS like PFOA and PFOS. These patterns confirm that the physical-chemical properties of PFAS influence the extent of plant uptake. Likewise, physical-chemical soil properties (for example, organic matter content and composition, pH, salinity, temperature) affect plant uptake of PFAS, although this has not been comprehensively studied. Also, plant species and physiology (for example, transpiration rate and protein content) are important factors as discussed below.

PFAS accumulation in plants occurs primarily via root uptake from soil and water (**Stahl et al. 2009**; **Lee et al. 2014**; **Wen et al. 2013**; **Zhang et al. 2019**). Aerial uptake of PFAS from the ambient environment (vapor-phase and particle-bound) have also been reported, such as into leaves and bark (**Stahl et al. 2014**; **Jin et al. 2018**; **Tian et al. 2018**; **Liu et al. 2019**). However, aerial uptake contributes minimally to overall PFAS accumulation in plants (**Wang et al. 2020**).

As noted above, availability of PFAS in soil porewater for root uptake is largely dependent on the aqueous solubility of specific PFAS (see **Section 4**) and controlled by interactions with the soil phases and the AWI (see **Section 5.2.3**). PFAS in soil porewater migrates toward plant roots by transpiration and diffusion resulting from a local concentration gradient (**Lechner and Knapp 2011**). Recent studies by **Zhang et al. (2019)** and **Wen et al. (2013)** indicate a concentration-dependent process in root uptake that is mediated by transport proteins in cell membranes such as aquaporins and anion channels. PFAS enter the vascular tissue after passing through the root epidermis, cortex, and endodermis via apoplastic and symplastic pathways (**Blaine et al. 2013**).

Once in the root xylem, PFAS are translocated to different parts of a plant, such as stem, shoots, leaves, fruits, and grains. The degree of PFAS translocation in these tissues appears to depend on the transpiration stream, with more PFAS accumulation occurring in parts with greater capacity for sorption or incorporation and receiving greater amounts of water (**Krippner et al. 2015**; **Lechner and Knapp 2011**; **Gobelius, Lewis, and Ahrens 2017**; **Stahl et al. 2009**). For example, in carrots, cucumbers, and potatoes grown in soil mixed with PFAS-contaminated sewage sludge, **Lechner and Knapp (2011)** found less PFOA and PFOS accumulation in peeled edible parts than in foliage, leaves and stalks., **Stahl et al. (2009)** found much higher PFOA and PFOS in grains than in straw of spring wheat, oat, and maize. In trees, **Gobelius, Lewis, and Ahrens (2017)** evaluated the distribution of PFAS at an AFFF release site and reported that total PFAS accumulation followed leaves > twigs > trunk/core or roots in birch and spruce.

5.6.2 Bioconcentration/Bioaccumulation

Table 5-2 (provided as a separate Excel file) contains BCF and BAF values for 14 different PFAS for a variety of plant species. In the cited plant uptake studies, BCF and BAF are defined as PFAS concentration in plant (mass/mass) divided by PFAS concentration in soil (mass/mass) and are used interchangeably. This differs from the definition of BCF and BAF for animals in **Section 5.5**. A number of BAF values were obtained from studies in which PFAS was introduced to crops through irrigation water or

biosolids-amended soils (**Blaine et al. 2013**, **2014**, **2014**). The materials harvested for analysis included both inedible (for example, plant leaves) and edible portions of crops (fruit, lettuce leaves, and roots). Other BCFs and BAFs were obtained from investigations of plants exposed to PFAS from soil, groundwater, surface water, or air in close proximity to PFAS release sites (**Mudumbi et al. 2014**; **Zhang et al. 2015**; **Gobelius, Lewis, and Ahrens 2017**). In general, it can be observed that 1) the shorter chain (more water soluble) PFAS are taken up more readily than the longer chain homologues, and 2) the majority of the plant BCFs and BAFs fall between a range of 0.1 and 10. A BCF or BAF of 1.0 indicates no net accumulation of PFAS from soil to plant. Such a BCF or BAF indicates that the soils and the plant of interest have the same concentration of PFAS per unit weight. This, however, does not indicate that an equilibrium condition exists between soils and plants. Some plants, like lettuce, contain a large percentage of water, which may help to explain the relatively high BAF of 56.8 observed by **Blaine et al. (2013)**. In the controlled studies of edible crops, short-chain PFCAs and PFSAs exhibited greater BAFs compared to long-chain compounds.

Blaine et al. (2013) studied the uptake of PFAAs by greenhouse lettuce and tomato grown in soils prepared to mimic an industrially impacted biosolids-amended soil, a municipal biosolids-amended soil, and a control soil (but incorporated contaminated biosolids equivalent to 10 times higher than the agronomic rates allowed for Class B biosolids), a municipal biosolids-amended soil, and a control soil. BCFs for many PFAAs were well above unity, with PFBA having the highest BCF in lettuce (56.8) and PFPeA the highest in tomato (17.1) in the industrially impacted biosolids-amended soil. BAFs for PFCAs and PFSAs were, in general, slightly higher in the industrially impacted soil than in the municipal soil (~0.3–0.8 log units). The BCFs for PFAAs in greenhouse lettuce decreased approximately 0.3 log units per -CF_2 group (one carbon, two fluorine groups in a molecule). They also conducted a limited field study, in which they measured PFAA levels in lettuce and tomato grown in field soil amended with only a single application of biosolids (at the agronomic rate for nitrogen). The PFAA levels were predominantly below the limit of quantitation (LOQ). In addition, corn stover, corn grains, and soil were collected from several full-scale biosolids-amended farm fields. At these fields, all PFAAs were below the LOQ in the corn grains and only trace amounts of PFBA and PFPeA were detected in the corn stover. The **Blaine et al. (2013)** study confirms that the bioconcentration of PFAAs from biosolids-amended soils depends strongly on PFAA concentrations, soil properties, type of crop, and analyte. BCFs developed in **Blaine et al. (2013)** can be seen in **Table 5-2**.

Ghisi, Vamerali, and Manzetti (2019) provided a review of PFAS uptake in agricultural plants, including the potential for uptake from groundwater, soil, and air. Factors contributing to plant uptake include PFAS chain length, functional group, plant species, growth media, soil organic matter, and other soil properties. In general, higher PFAS concentrations in soil are correlated with higher PFAS concentrations in plants; however, the increase in concentrations may not be directly proportional. Short-chain compounds tend to accumulate at higher concentrations in leafy vegetables and fruits, whereas long-chain compounds tend to accumulate more in roots. Several studies have found that PFCAs accumulate at higher rates than PFSAs. Soil organic matter has been found to sequester PFAS and limit plant uptake in some studies reviewed. Another review of bioaccumulation factors for agricultural plants is **Lesmeister et al. (2021)**.

Gobelius, Lewis, and Ahrens (2017) studied the uptake of 26 PFAS in plants (trees) at an AFFF (fire training) site with contaminated soil and groundwater. Samples from groundwater and different plant species (birch, spruce, cherry, ash, elder, beechfern, and wild strawberry) and tissues (that is, roots, trunk/cores, twigs, leaves/needles) were collected. Foliage had the highest BCFs of all tissues, ranging from 0 to 14,000 and accumulated the highest number ofPFAS (8 out of 26), with birch sap showing BCF values up to 41 for 6:2 FTSA. The highest mean BCFs were found for 6:2 FTSA (472; n = 52), PFOS (28; n = 36), PFHxS (10; n = 42), and PFOA (5; n = 24), which might correspond to the AFFF composition used at the site. For PFOA, the mean BCFs (±s.d.) were 18 ± 15 for spruce, followed by birch (1.2 ± 1.5) and cherry (0.25 ± 0.043). The authors concluded that PFAS were detected in all plant species, and the distribution followed the order of "shoots to roots"—that is, leaves > twigs/stems > trunk > roots. They cited other

authors who have shown that “this order has proven applicable to all samples and species.” Hence, PFAS tend to accumulate in the vegetative portions rather than in the plant storage tissues.

6 MEDIA-SPECIFIC OCCURRENCE

The long period of time during which PFAS have been produced and the many sources of PFAS release to the environment have resulted in low-level contamination of most environmental media worldwide. The concentrations of these human-caused ambient or "anthropogenic background" concentrations may vary widely, based on proximity to industrial areas, patterns of air and water dispersion, and many other factors. As a result, any claims regarding "universal" values for anthropogenic background levels of PFAS should be viewed skeptically.

This section provides a relative understanding of PFAS concentrations in various environmental media but does not represent an exhaustive literature review. These figures and summaries are intended to provide context to the reader and a starting point for further study. Media-specific occurrences of PFAS are constantly being added in the literature and on state, federal, and other countries' PFAS websites. USEPA has developed an online database called the PFAS Analytic Tools that provides access to different sources of information about potential PFAS sources, drinking water sampling data, occurrence in environmental media, and other types of information (**USEPA 2023**).

Section Number	Topic
1.4.4	**Health Effects of Ultra-short-chain PFAS (2025)**
1.7	**Priority Topics for Biosolids Land Application (2025)**
6.1	**Air**
6.2	**Soil, Sediment, and Biosolids**
6.3	**Groundwater**
6.4	**Surface Water**
6.5	**Biota**

The following sections include figures summarizing the observed concentrations of PFAS that have been reported in the recent literature (approximately 2017–2022) and new information to date on the occurrence of PFAS in media that were not included in the previous version of this guidance document for outdoor air, indoor air, precipitation, dust, soil, sediment and biosolids. The figures for ground water and surface water were updated with the new format, but the data are from the previous summary. The previous version of this section (June 2022) is archived as a PDF under **Archived External Tables and Sections** on the home page of this site. **Figure 6-5**, Observed PFAS concentrations in fish, has not been updated.

Tables (linked as PDFs) that include important details concerning the studies used in developing the figures below and interactive versions of the figures (linked as a web page) are in **Section 17.1**. The figures were developed using **R software** and the static figures were developed using ggplot2 (**Wickham 2016**). Media-specific occurrence information that was included in the previous version of this guidance document (June 2022) is archived as a Section 17.1 PDF, found under **Archived External Tables and Sections** on the home page of this site.

As discussed in **Section 2.6**, the presence of some PFAS in environmental media and ecological receptors has been traced to the migration of PFAS in air emissions and through the direct discharges to soil, groundwater, and surface water. Sections on Phase Partitioning (**Section 5.2**) and Media-Specific Migration Processes (**Section 5.3**) illustrate that PFAS occurrence in the air, aqueous, and solid phases is highly interrelated. Sections on Human Health Effects (**Section 7.1**) and Ecological Toxicology (**Section 7.2**) suggest that PFAS risks to human health may result from exposure via drinking water, groundwater, soils, food, and other media types. Further, ecological impacts are widely observed. This suggests that a complete assessment of PFAS sources and exposure risks, including fate and transport processes that

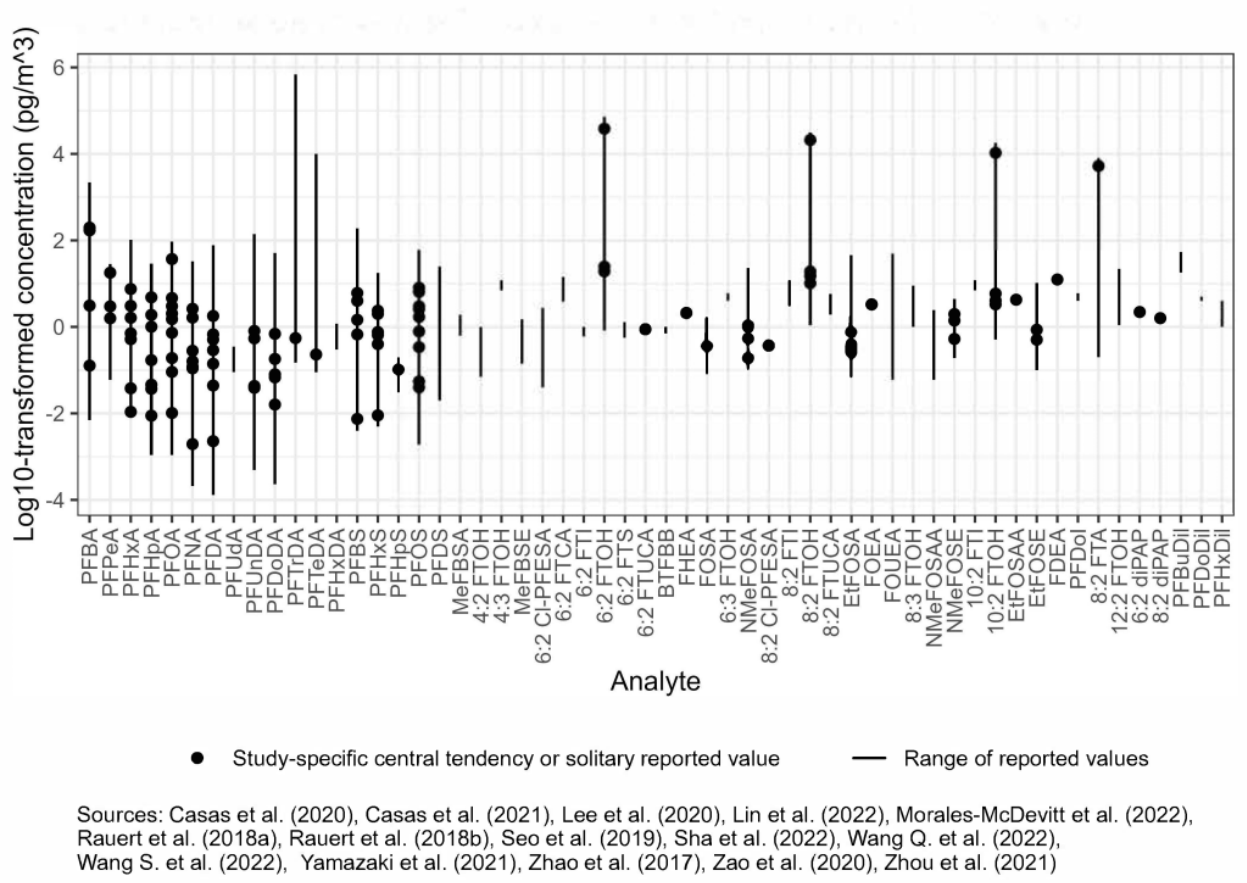
may drive future exposure concerns, requires understanding of PFAS occurrence across multiple phases. The processes that influence media-specific PFAS concentrations are illustrated in CSMs shown in **Figure 2-20**, **Figure 2-21**, and **Figure 2-22**. This section focuses on occurrence in air; soil, sediment, and biosolids; groundwater; surface water; and biota. **Section 1.4.4** focuses on available information for health effects of ultra-short-chain (ultrashort) PFAS. Summaries of available environmental occurrence data for ultrashort PFAS are included with the health effects information, but the summaries are not intended to be comprehensive.

Environmental PFAS occurrence is an area of active research. As discussed in **Section 11**, sampling and analytical methods are still being optimized and standardized, and vary between studies. Data-reporting formats also vary, often including the observed minimum, maximum, or percentiles to represent the range, and arithmetic mean, geometric mean, or median values to represent central tendency. In some cases, only the average or maximum values are reported. Studies also vary in terms of research objectives and site characteristics, focusing on relatively pristine (for example, rural) or impacted (for example, industrial) sites. Some studies focus on certain PFAS, Finally, variable method detection limits between studies introduces the potential for non-detect data to impose artificial patterns. Due to these data limitations, the ranges and averages of detected PFAS concentrations presented in the following figures should be considered as a general frame of reference, rather than precise, dispositive thresholds.

6.1 Air

Certain PFAS are found in ambient air, with elevated concentrations observed or expected in urban areas nearest to major emission sources described in **Section 2.6**. These include industrial facilities that produce PFAS or use PFAS chemicals or products in manufacturing; areas where Class B firefighting foams containing fluorine are used or released; waste management facilities, including landfills and wastewater treatment plants; and areas of biosolids production and application (**Borthakur et al. 2022**; **Barton et al. 2006**; **Ahrens et al. 2011**; **Liu et al. 2015**).

As discussed in **Section 5.3.2**, short-range atmospheric transport and deposition may result in PFAS contamination in terrestrial and aquatic systems near points of significant emissions, contaminating soil, groundwater, and other media of concern (**Davis et al. 2007**), as well as several miles from industrial emission sources (**Shin et al. 2011**; **Post, Cohn, and Cooper 2012**) (**NYS DOH 2016**; **NH DES 2017**; **VT DEC 2016**). Releases of ionic PFAS from factories are likely tied to particulate matter (Barton et al. 2006[241]), which settle to the ground in dry weather and are also wet-scavenged by precipitation as discussed in **Section 5.3.2**. Models indicate that deposition depends on amount of PFAS emissions, local topography, particle size, weather patterns, and release characteristics such as smokestack height, effluent flow rate, and effluent temperature. In addition to short-range transport and deposition, long-range transport processes are responsible for a wide distribution of PFAS across the earth, as evidenced by their occurrence in biota and environmental media in remote regions as far as the Arctic and Antarctic. Long-range transport processes and effects are similar to atmospheric transport of other recalcitrant contaminants.



The **PFAS and Vapor Intrusion Fact Sheet** developed in 2025 includes information about PFAS in Soil Vapor, Indoor Air, and Outdoor Air. The Priority Topics for History, Use, and Naming Conventions include information about less-studied PFAS (see **Section 1.1.3**), including ultrashort PFAS, volatile PFAS, and fluorinated gases.

6.1.1 Outdoor Air

Concentrations of perfluoroalkyl acids such as PFOA and PFOS reported in outdoor air in the recent scientific literature (2017–2022) typically fall within a range of about 1–30 pg/m^3 (picograms/cubic meter) (**Figure 6-1A**). However, near major industrial sources, including fluorochemical manufacturing

complexes in China (**Zhao et al. 2020**) and South Korea (**Lee et al. 2020**; **Lin et al. 2020**; **Seo et al. 2019**), maximum PFOA concentrations in the range of about 50–200 pg/m^3 have been reported. In the United States, concentrations of PFOA as high as 900,000 pg/m^3 have been observed near a large manufacturing facility in Parkersburg, West Virginia (**Barton et al. 2006**). PFOS concentrations greater than 2,000 pg/m^3 have also been observed in outdoor air near major fluorochemical manufacturing complexes in South Korea (**Seo et al. 2019**). Concentrations of PFBA have been observed in the hundreds of pg/m^3 at a number of global monitoring sites and at concentrations greater than 1,000–2,000 pg/m^3 at sites in Canada (**Rauert et al. 2018**).

The literature range of concentrations of volatile PFAS such as FTOHs is in the hundreds of pg/m^3 in outdoor air (**Figure 6-1A**). Atmospheric transport and deposition of PFAS occur on regional and global scales, suggesting that low-level concentrations detected in soil or other media are not necessarily indicative of a local source (**Section 5.3.2**). More information is included in **Section 17-1**, Media-Specific Occurrence Tables.

(2022), Wang Q. et al. (2022), Wang S. et al. (2022), Yamazaki et al. (2021), Zhao et al. (2017), Zao et al. (2020), Zhou et al. (2021)

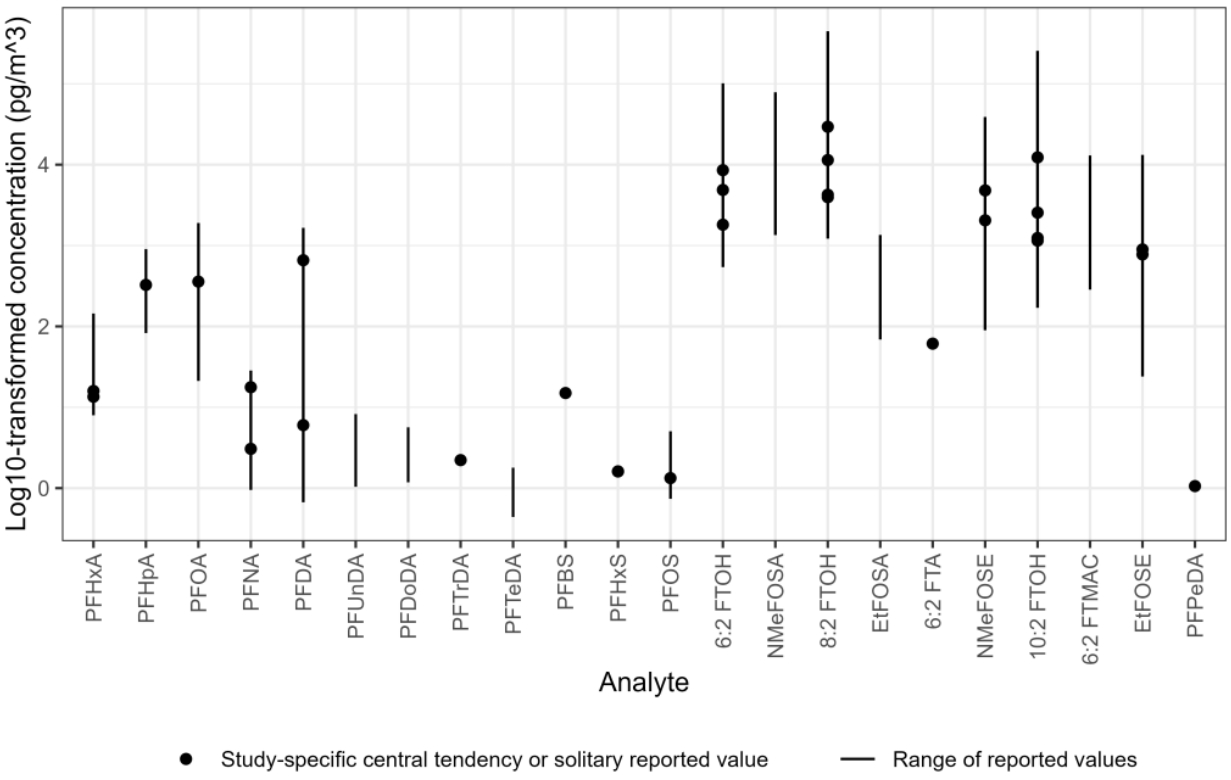


Figure 6-1A. Observed PFAS concentrations in outdoor air.

*Source: Figure developed using ggplot2 (**Wickham 2016**).*

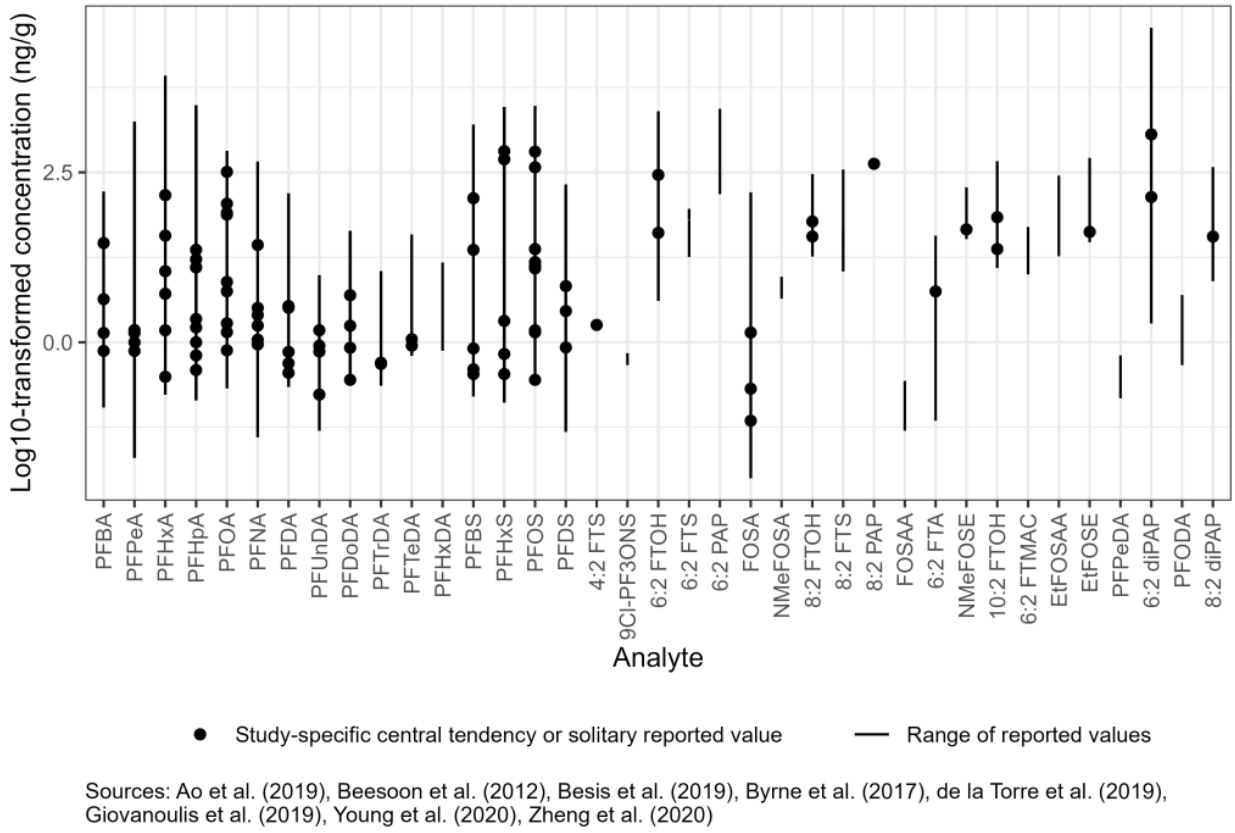
6.1.2 Indoor Air

PFAS have also been observed in indoor air and dust in homes, offices, and other indoor environments (**Figure 6-1B**). Indoor air concentrations of certain PFAS can be higher than outdoor air concentrations due to the presence of indoor sources (**Fromme et al. 2015**; **Fraser et al. 2012**; **Goosey and Harrad 2012**; **Shoeib et al. 2011**; **Kaiser et al. 2010**; **Langer, Dreyer, and Ebinghaus 2010**; **Strynar and Lindstrom 2008**; **Shoeib et al. 2004**). Examples of indoor sources of potential PFAS exposure include stain- and water-

resistant coatings used on a number of consumer products, such as carpets, upholstery, clothing, grease-resistant paper, food packaging, and nonstick cookware and ingredients in cleaning products, personal care products, cosmetics, paints, varnishes, and sealants (**ATSDR 2019**; **Liu et al. 2015**; **Liu et al. 2014**) (**Gewurtz et al. 2009**; **Guo et al. 2009**). In the recent literature (2017–2022), PFOA concentrations in PM2.5 collected from indoor air across 17 kindergartens in Hong Kong ranged from about 200–1,900 pg/m^3 (**Li et al. 2021**). In a study of 57 households in eastern Finland, concentrations of PFOA and PFOS ranged from nondetect to about 100 pg/m^3 and 7 pg/m^3, respectively (**Winkens et al. 2017**).

Sources: Beesoon et al. (2012), Li et al. (2021), Padilla-Sanchez et al. (2017), Wilkens et al. (2017)

Figure 6-1B. Observed PFAS concentrations in indoor air.



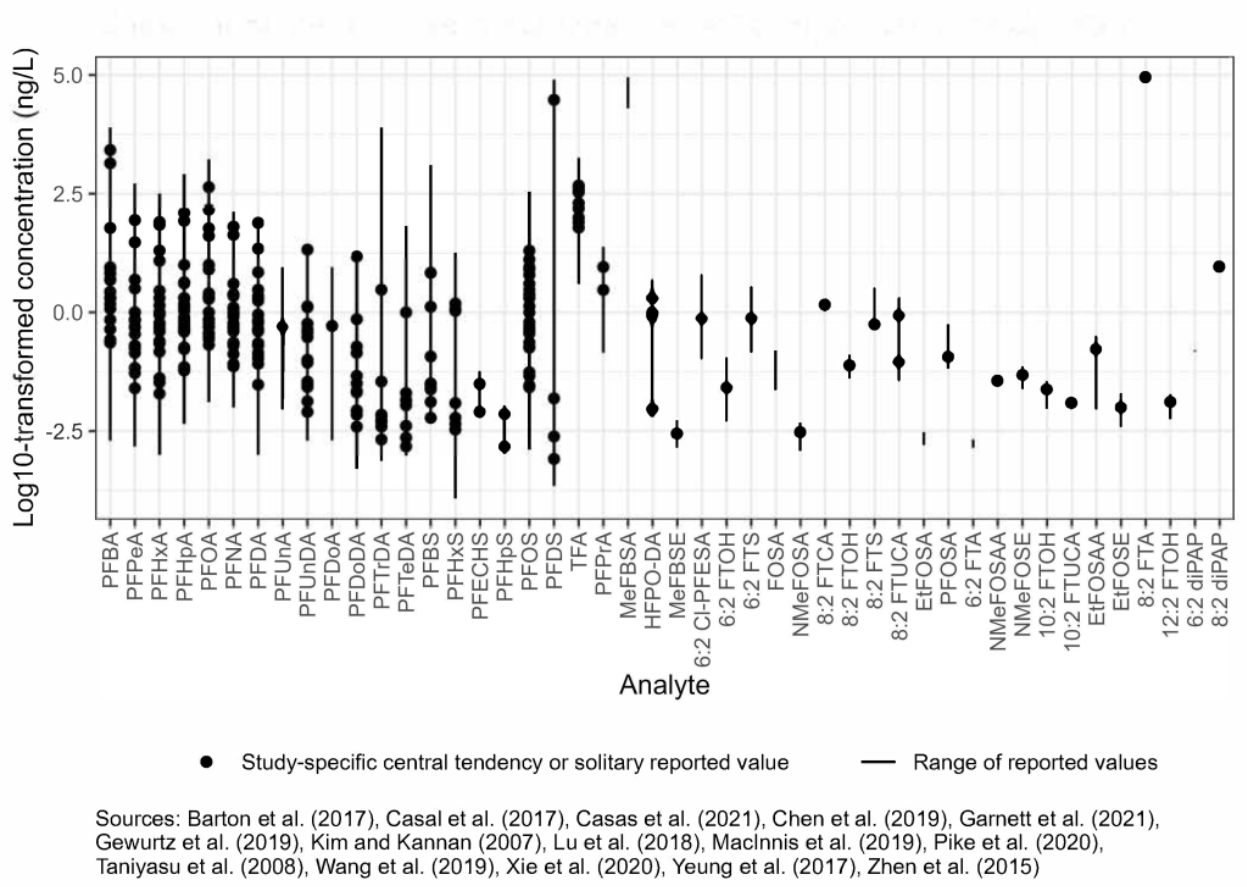
*Source: Figure developed using ggplot2 (**Wickham 2016**).*

Concentrations of volatile PFAS such as FTOHs have been reported on the order of 10,000–50,000 pg/m^3 in schools, homes, and offices. Concentrations of FTOHs have been observed in excess of 300,000 pg/m^3 inside commercial buildings (**Fromme et al. 2010**) and as high as 255,000 pg/m^3 in residences in the area of Oslo, Norway (**Padilla-Sanchez et al. 2017**). More information is included in **Section 17-1**, Media-Specific Occurrence Tables.

6.1.3 Settled Dust

PFAS have been measured in settled dust from floors and other surfaces and from samples collected from air conditioner filters, vacuum cleaner bags, and carpets from a variety of indoor environments, including schools and universities, preschools and childcare facilities, homes, and workplaces (**Young et al. 2020**; **Zheng et al. 2019**; **Ao et al. 2019**; **Besis et al. 2019**; **de la Torre et al. 2019**; **Giovanoulis et al. 2019**; **Byrne et al. 2017**; **Beesoon et al. 2012**). The literature range of concentrations of PFAS in dust in indoor environments vary over many orders of magnitude (**Figure 6-1C**). Concentrations of PFOA and PFOS range from nondetect to about 650 ng/g and 3,000 ng/g, respectively. Fluorotelomers have also

been observed in indoor dust, ranging from nondetect to about 2,500 ng/g for FTOHs. Fluorotelomer phosphate diesters (diPAPs) were reported in a study of preschools in the area of Stockholm, Sweden, and ranged from nondetect to greater than 42,000 ng/g (**Giovanoulis et al. 2019**). More information is included in **Section 17-1**, Media-Specific Occurrence Tables.



Sources: Ao et al. (2019), Beesoon et al. (2012), Besis et al. (2019), Byrne et al. (2017), de la Torre et al. (2019), Giovanoulis et al. (2019), Young et al. (2020), Zheng et al. (2020)

Figure 6-1C. Observed PFAS concentrations in settled dust.

*Source: Figure developed using ggplot2 (**Wickham 2016**).*

6.1.4 Precipitation

PFAS have also been observed in precipitation and other samples impacted by precipitation, including rainwater, surface and subsurface snow, sea ice, and meltwater. The literature range of concentrations of PFAS in precipitation vary over many orders of magnitude (**Figure 6-1D**) (**Casas et al. 2021**; **Pike et al. 2020**; **Xie et al. 2020**; **Chen et al. 2019**; **MacInnis et al. 2019**; **Wang et al. 2019**; **Lu et al. 2018**; **Casal et al. 2017**; **Yeung et al. 2017**; **Zhen et al. 2015**; **Taniyasu et al. 2008**; **Barton, Kaiser, and Russell 2007**; **Kim and Kannan 2007**). Lower levels of PFAS have been observed in precipitation from remote locations such as the Arctic and Antarctic as compared to more populated and urbanized, continental regions. Concentrations of perfluoroalkyl acids in precipitation, such as PFOA and PFOS, were typically <1 ng/L in remote regions, while concentrations greater than 1,600 ng/L and 50 ng/L were observed, respectively, in continental regions. Fluorotelomers, including FTOHs, fluorotelomer sulfonic acid (FTSA), and fluorotelomer unsaturated carboxylic acids (FTUCAs), have been observed in precipitation with concentrations of FTOHs and FTSA exceeding 100 ng/L (**Chen et al. 2019**; **Zhen et al. 2015**) and FTUCAs ranging from nondetect to about 2 ng/L (**Chen et al. 2019**; **Taniyasu et al. 2008**). Heptafluoropropoxy propanoic acid (HFPO-DA), or GenX, has also been found in precipitation as high as 5 ng/L (**Pike et al. 2020**). More information is included in **Section 17-1**, Media-Specific Occurrence Tables.

6.2 Soil, Sediment, and Biosolids

PFAS occurrence in soil and sediment can result from direct inputs (for example, AFFF releases or industrial discharge) or indirectly through exposure to impacted media (for example, atmospheric deposition, landfill leachate, or wastewater effluent). Another focus of current research is agricultural application of biosolids, compost, or pesticides, all of which are potential PFAS sources (**Table 2-6**). As a result of these inputs, soil and sediment may act as secondary sources of PFAS via leaching to groundwater and runoff to surface water through leaching and percolation processes, respectively. The concentration and distribution of PFAS observed in soils, sediments, and biosolids is complex and can be a function of source (direct versus indirect), site-specific considerations (for example, TOC, particle surface charges, and phase interfaces, see **Section 5.2.3**) and PFAS-specific chemistry (for example, alkyl chain length and ionic functional group). PFOS, PFOA, and other long-chain PFAAs are typically the predominant PFAS reported in surface soils and sediments (**Cai et al. 2022**; **Rankin et al. 2016**; **Strynar et al. 2012**; **Zhu et al. 2019**). Based on the increasing interest in biosolids, data related to that topic have been compiled separately from other sources.

6.2.1 Soil

Surface and subsurface soil are a significant reservoir for PFAS released to the environment. Numerous studies show individual PFAS concentrations in soil vary across multiple orders of magnitude, found at

low concentrations (<1 ug/kg) globally even in remote areas, and at concentrations exceeding 1,000 µg/kg at industrial and AFFF release sites (**Rankin et al. 2016**; **Brusseau et al. 2020**) (**Figure 6-2A**).

Sources: Brusseau et al. (2020), Groffen et al. (2019), Sanborn Head & Associates (2022), Sorengard et al. (2022), USGS (2022), Wang et al. (2018)

Figure 6-2A. Observed PFAS concentrations in site and anthropogenic background soil.

*Source: Figure developed using ggplot2 (**Wickham 2016**).*

Improving the understanding of anthropogenic background PFAS concentrations for comparison to site data has been a focus of recent work. A survey of anthropogenic background concentrations of PFAS in soil found PFOS ranging from 0.003 to 162 ug/kg and PFOA from 0.01 to 124 ug/kg (**Brusseau et al. 2020**). Although not focused on contaminated sites, many of the surveys were in or near populated regions and included agricultural fields. Recent studies in Maine and New Hampshire also focused on anthropogenic background soil levels without identified sources and in those studies PFOS ranged from nondetect to 5.4 and PFOA from nondetect to 5.3 ug/kg for the combined data. Median data for detected PFOS were 0.37 and 0.94 ug/kg, and for PFOA, 0.17 and 0.76 ug/kg for Maine and New Hampshire, respectively (**MEDEP 2022**; **Santangelo et al. 2022**). In contrast, data at known PFAS release sites such as fire training areas and biosolids application sites showed maximum concentrations of PFAS that may exceed anthropogenic background by several order of magnitude. PFOS and PFOA in fire training areas and other source zones may be as high as 373,000 and 50,000 ug/kg respectively, though the median values for AFFF source zones were much lower—18 and 1.4 ug/kg for PFOS and PFOA (**Brusseau et al. 2020**).

Published data on soil PFAS concentrations in industrial settings are limited, and can be highly variable, depending on the nature of PFAS release and proximity to the source. More information is included in **Section 17-1**, Media-Specific Occurrence Tables. Additional detail on AFFF is found in **Section 3**.

6.2.2 Sediment

Direct discharge of AFFF, leachate, wastewater effluent, and runoff to surface waters and subsurface discharge of contaminated groundwater to surface water has resulted in PFAS impacts to freshwater and marine sediments. Detected concentrations for surface sediments in lakes and rivers reported in the literature generally range from below detection limit to approximately 100 µg/kg, and concentrations and relative distributions of PFAS are variable depending upon types of sources and distance from point sources (**Figure 6-2B**).

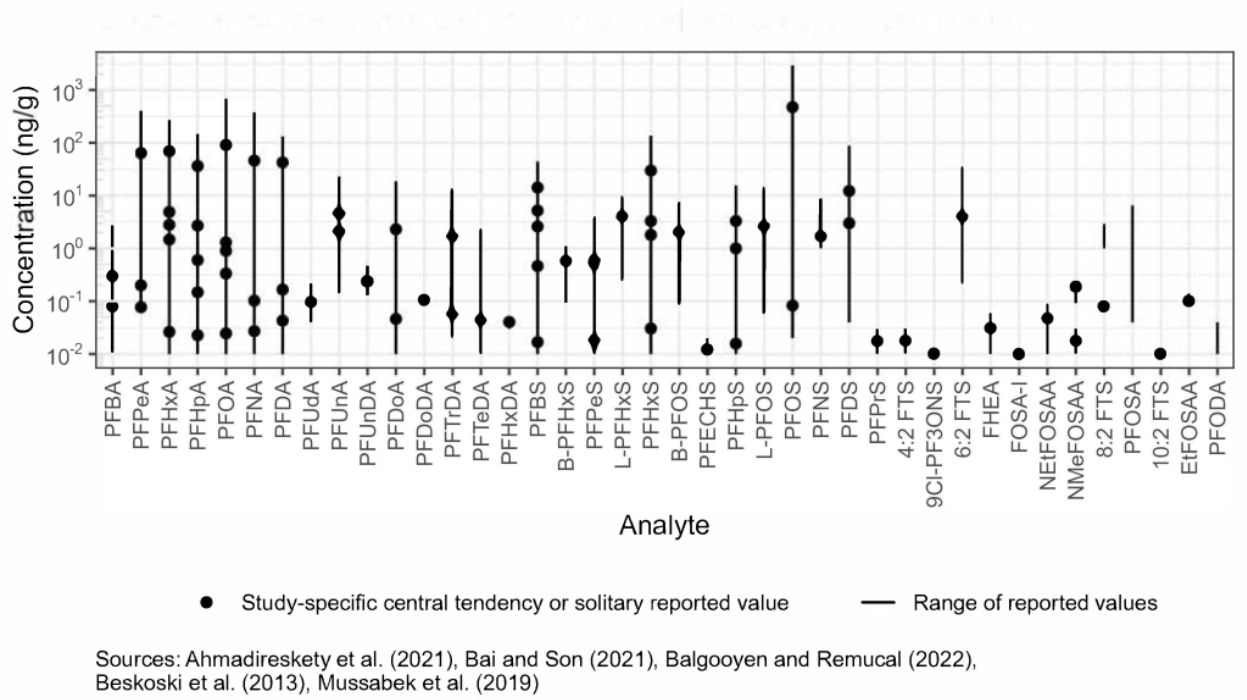

Figure 6-2B. Observed PFAS concentrations in sediment.

*Source: Figure developed using ggplot2 (**Wickham 2016**).*

A study of 48 lakes and two reservoirs with different limnological and geographic settings across China found surface sediment concentrations for a sum of detected PFCAs + PFOS ranged from 0.086 to 5.79 ng/g with a detection frequency of 100%. These samples collected in 2010–2013 showed that PFAS concentrations correlate to parameters such as TOC, nitrogen, and phosphorus in sediment (**Qi et al. 2016**).

A study from the Great Lakes (**Codling et al. 2018**) evaluated the use of dated sediment cores to assess PFAS deposition trends and analyzed for 22 PFAS. Reported values for the sum of PFAS in cores ranged from nondetect to 68.3 ug/kg dry weight, with the max value attributed to a detection of PFHpA of 46.6 µg/kg at that location. Concentrations typically increased with time in the cores. Grab samples were also collected, and PFOS ranged from 0.1 to 2.5 ug/kg, PFOA from nondetect to 3.0 ug/kg, and PFHpA from nondetect to 8.5 ug/kg. Concentrations in grab samples for the sum of PFAS ranged from nondetect to 26.0 ug/kg. Sediment core analysis may be effective for estimating deposition rates and fluxes for a subset of PFAS that exhibit strong sorption to sediment, with concentration at a given depth interval representing deposition during that time period (**Codling et al. 2018**).

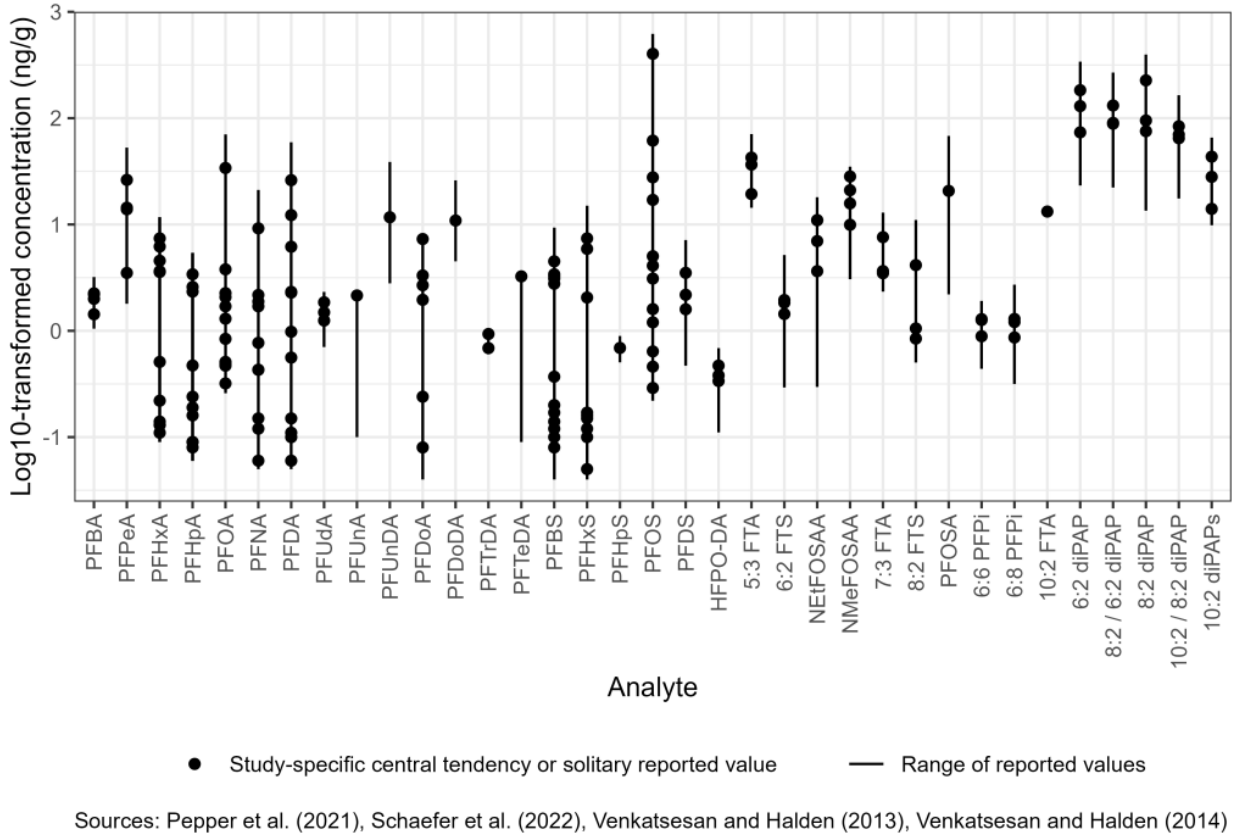
A Swedish study of sediment cores in a lake and pond impacted by AFFF showed that PFOS and PFHxS were the dominant PFAS in sediment. Concentrations of PFOS and PFHxS ranged as high as 64 and 13

ng/g, respectively, and the study identified peak deposition rates occurring between 2003 and 2009, which correlated with reported activity near the water bodies (**Mussabek et al. 2019**).

Large precipitation or storm events can also contribute to episodic or enhanced transport of sediment and resuspension or redistribution of contamination in some environmental settings. Resampling of marine sediment locations in Florida following the passage of a hurricane found sediment concentrations of total PFAS decreased 47% averaged across nine sites. Highest concentrations of PFAS were spatially correlated to potential sources such as military installations and manufacturing facilities, and across all locations short-chain PFCAs dominated the total PFAS at 68% of locations, while long-chain PFAAs dominated the other 32% of sites (**Ahmadireskety et al. 2021**). Sediment in two urban watersheds showed concentrations of individual PFSAs as high as 88 ng/g, and found seasonal variability in sediment concentrations, potentially related to higher/lower water flows, or variation in organic matter and uptake during algal blooms (**Bai and Son 2021**). Once deposited, sediments can directly impact biota and can influence surface water concentrations. Tributary sediments with a mix of potential sources were shown to be potential secondary sources of PFAAs once those sediments were transported to a receiving water body (**Balgooyen and Remucal 2022**). **Figure 6-2B** illustrates the concentration distribution in sediment across multiple environmental settings from these recent studies. More information is included in **Section 17-1**, Media-Specific Occurrence Tables.

6.2.3 Biosolids

PFAS occurrence in biosolids is reported to be prevalent across the United States at a wide range of concentrations, and may be from municipal, residential, or industrial sources, or a combination of any of those sources. Biosolid designations may include “land applied,” Class A, Class B, Class C, unclassified, and mixed land-applied organic waste products. New information about PFAS occurrence at land application sites has been compiled in the Priority Topics for Biosolids Land Application, see **Section 1.7.2.2** and **Section 1.7.2.3**.



A 2013 study of archived samples of biosolids from 2001 in the United States, which targeted 12 PFAAs and PFOSA, reported mean concentrations of PFOS (403 ng/g) and PFOA (34 ng/g) with the mean values of other PFAAs ranging from 2 to 21 ng/g. With the exception of PFBA, PFBS, and PFHpA, the target PFAAs and PFOSA were detected in all samples (**Venkatesan and Halden 2013**). A 2021 review of reported values for biosolids, compost, and related biowastes highlighted the wide concentration range of reported PFAS (primarily PFAAs) and the relationship of biowaste source to resulting concentrations (**Bolan et al. 2021**). **Figure 6-2C** illustrates concentration ranges in biosolids for a selection of PFAS from a subset of recent data. Early studies reported that the most abundant PFAAs (see **Section 2.2.3.1**) found in biosolids (PFOS and PFOA) are similar to those found in wastewater effluent, although biosolids may also contain other PFAS, including long-chain PFAS (**Hamid and Li 2016**; **Washington et al. 2010**). Although multiple studies have reported data showing transformation of polyfluorinated substances to PFAAs in land-applied biosolids (**Yoo et al. 2010**; **Sepulvado et al. 2011**; **Washington et al. 2010**), other evidence indicates that some polyfluorinated substances remain in biosolids-amended soils for many years to decades (**Yoo et al. 2010**; **Rich et al. 2015**; **Washington et al. 2018**).

PFOS is the most frequently reported PFAS and typically at the highest concentration of the PFAAs most frequently reported (**Clarke and Smith 2011**; **Gallen et al. 2018**; **Moodie et al. 2021**; **Munoz et al. 2021**; **Pepper et al. 2021**). Target and nontarget precursor compounds are also commonly detected in biosolids, including 6:2 diPAP and 6:2 FTS (**Kim Lazcano et al. 2020**; **Schaefer et al. 2022**; **Moodie et al. 2021**), EtFOSAA, and cationic and zwitterionic electrochemical fluorination precursors to PFOS (**Munoz et al. 2021**). Biosolids tend to be enriched in long-chain PFAAs containing more than six carbon atoms (**Kim Lazcano et al. 2019**).

Repeated application of biosolids to agricultural soil can result in PFAS accumulation in shallow soil depths, and eventual leaching to groundwater, as well as uptake by agriculturally sourced products (**Ghisi**

et al. 2019). "Shallow soil" in this context will be variable depending on the crop or farm practices. For example, Maine considers 0–2 feet to be the "plow layer" (**ME DEP 2023**), whereas USEPA refers to shallow soil "extending to site-specific depths that can be sampled easily by manual methods," generally 0–12 inches (**USEPA 2023**). Based on the biosolid application rates in the United States and the mean total PFAS concentrations observed for archived biosolids from 2001, it is estimated that 1,375–2,070 kg of PFAS may have been added to agricultural land annually across the United States during that time (**Venkatesan and Halden 2013**). Data for more recent testing of biosolids and compost typically show lower concentrations of PFAAs and lower annual application rates (**Bolan et al. 2021**).

PFAS concentrations in soils at sites with applied biosolids or sludge will vary depending upon application rates, frequency, duration, geochemical and hydrogeologic factors, and concentration of PFAS in the applied material. Perfluorocarboxylic acids (PFCAs) and perfluoroalkylsulfonic acids (PFSAs) have been observed in surface soils treated with biosolids at 1 and 2 orders of magnitude higher than global anthropogenic background soils, respectively (**Johnson 2022**). In contrast, another study observed that even after decades of land application, the concentration and accumulation of PFAS in soils where biosolids were applied was comparatively low. In addition, the study observed that there was ~73% attenuation of measured PFAS from the shallow soil sample at 30.5 cm to the deepest interval of 183 cm (**Pepper et al. 2021**). This variability of reported data illustrates the importance of site-specific history and conditions to resulting concentrations in soil at land application sites.

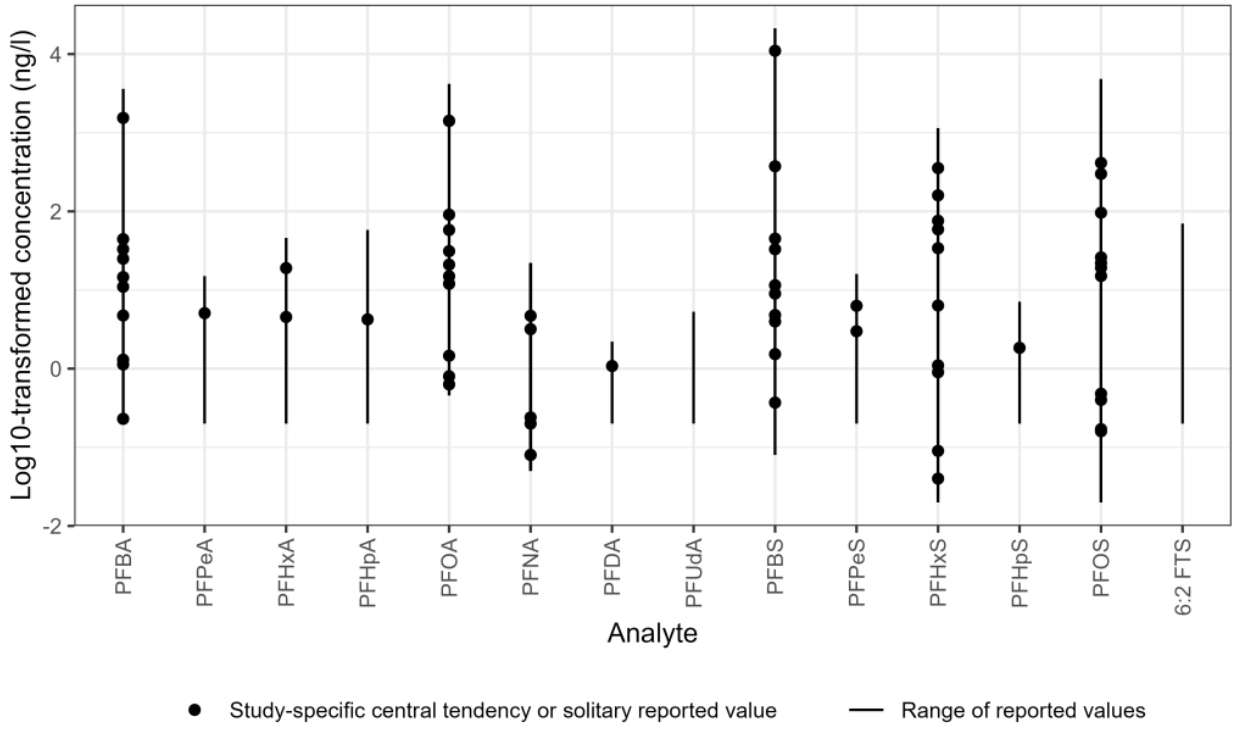

Figure 6-2C. Observed PFAS concentrations in biosolids and land-applied soil.

*Source: Figure developed using ggplot2 (**Wickham 2016**).*

Ultra-short-chain PFAS, certain precursors to PFAS, and new generation PFAS potentially account for a significant fraction of the total fluorine present in biosolids, but are largely unquantifiable by current standard methods (**Kim Lazcano et al. 2020**; **Munoz et al. 2021**; **Schaefer et al. 2022**). The highest

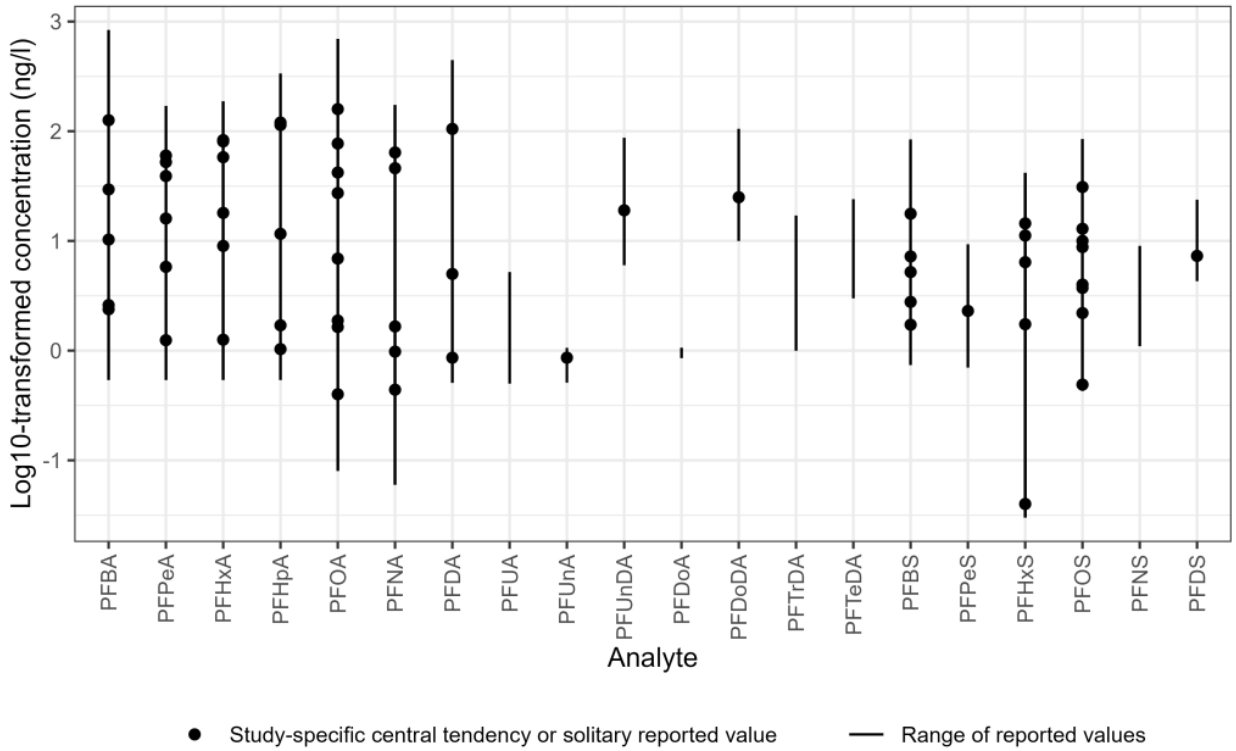
average minimum and maximum concentrations observed in recent publications were n:2 polyfluoroalkyl phosphoric acid esters, polyfluoroalkyl phosphates, and fluorotelomer phosphates (diPAPs). In addition to diPAPs, perfluoroalkane sulfonamido acetic acids (FASAAs), perfluorooctane sulfonamides, and fluorotelomer sulfonic acids (FTS) were abundant (**Munoz et al. 2021**; **Schaefer et al. 2022**). This suggests that limiting PFAS analysis of biosolids to the standard suite of analytes may not account for a substantial fraction of the overall fluorine mass (**Schaefer et al. 2023**; **Thompson et al. 2023**). Of the perfluoroalkyl acids (PFAAs), long-chain perfluoroalkyl sulfonic acids (PFSAs) were present at the highest concentrations, likely due to their hydrophobicity and greater tendency to remain sorbed to soils within the vadose zone (**Figure 6-2C**). More information is included in **Section 17-1**, Media-Specific Occurrence Tables.

6.3 Groundwater

Sources: Cao et al. (2019), Chen et al. (2016), Hepbern et al. (2019), Bao et al. (2019a), Liu et al. (2019), McMahon et al. (2022), MDE (2021), Sammut et al. (2019), Schaefer et al. (2018), Sharma et al. (2016), Wang et al. (2016a)

Figure 6-3. Observed PFAS concentrations in groundwater.

*Source: Figure developed using ggplot2 (**Wickham 2016**).*



USEPA has assembled an extensive data set of the occurrence of six PFAAs in public drinking water. This data set is the result of required monitoring of approximately 4,900 public water systems (all large systems serving more than 10,000 people, plus a subset of smaller systems) for six PFAAs in finished drinking water at points of entry to the drinking water distribution system. The study was conducted between 2013 and 2015 under the third Unregulated Contaminant Monitoring Rule (UCMR3) and included the results from treated water that originated from groundwater wells (n = 22,494), groundwater under the direct influence of surface water (n = 436), surface water sources (n = 13,228), and mixed sources (n = 814) (**USEPA 2017**). A summary of the UCMR3 occurrence data, including analytical reports, is included in **Section 8.2.2.4**. An analysis conducted on the nonfinalized UCMR3 data set found that one or more

PFAAs were detected in 4% of the reporting public water systems (**USEPA 2017**); however, groundwater sources had approximately double the detection rate of surface water sources (**Hu et al. 2016**).

As of June 2022, USEPA issued interim health advisories for PFOA and PFOS in drinking water (**USEPA 2022**). These replace the former values USEPA issued in 2016 of 70 ng/L (**USEPA 2016**, **2016**). The interim values of 0.004 ng/L for PFOA and 0.02 ng/L for PFOS are lower than the minimum detection limit of 0.52 ng/L for drinking water methods (ITRC Table 11-3, PFAS Analytical Methods Excel file). Therefore, all detected concentrations would be above the interim health advisories. Detections were geographically widespread but showed quantifiable associations with suspected sources, including industrial sites, military fire training areas, AFFF-certified airports, and wastewater treatment facilities (**Hu et al. 2016**). Individual states are collecting information on PFAS occurrence in smaller public water supplies such as schools and mobile home parks that do not meet the threshold to comply with the Unregulated Contaminant Monitoring Rule, so were not sampled during UCMR3, and for which data are often publicly available, for example, in New Hampshire at **NH DES (2020)**. UCMR5 will include a larger list of PFAS analytes, public water systems (PWSs) serving 3,300 or more persons, and up to 800 smaller PWSs (**USEPA 2021**).

Groundwater occurrence data collected as part of domestic and international studies have also characterized the range of PFAS concentrations associated with AFFF release sites, industrial facilities, and landfills; examples of these study results are provided in **Figure 6-3**. More information is archived as a Section 17.1 PDF, found under **Archived External Tables and Sections** on the home page of this site.

6.4 Surface Water

Sources: Bai et al. (2020), Cao et al. (2019), Chen et al. (2016), Garnett et al. (2021), Gewurtz et al. (2019), Sharma et al. (2016)

Figure 6-4. Observed PFAS concentrations in surface water.

*Source: Figure developed using ggplot2 (**Wickham 2016**).*

Freshwater, marine water, and stormwater PFAS concentrations usually depend on proximity to the point of release and source concentrations. In addition to releases associated with identified sources, stormwater runoff from nonpoint sources may contribute significant loads of PFAS to surface water (**Wilkinson et al. 2017**; **Zushi and Masunaga 2009**). The sorption of PFAS to suspended solids may affect surface water PFAS concentrations. Suspended microplastics may also influence PFAS in surface water (**Llorca et al. 2018**). **Figure 6-4** presents examples of observed PFOS and PFOA surface water concentrations, organized by source type. In addition to PFOS and PFOA, many other PFAS have been observed in surface waters, including compounds other than PFAAs. For example, a recent study found perfluoro-2-propoxypropanoic acid (PFPrOPrA also known as the GenX chemical HFPO-DA) in untreated water drawn from the Cape Fear River in North Carolina at concentrations up to 560 ng/L, and GenX was just one of many non-alkyl acid PFAS identified (**Sun et al. 2016**). Surface water occurrence is also an important source of drinking water supply impacts (**USEPA 2018**; **Post et al. 2013**). More information is archived as a Section 17.1 PDF, found under **Archived External Tables and Sections** on the home page of this site.

6.5 Biota

Because PFAS are distributed globally and have a propensity to bioconcentrate, they have been found in fish, wildlife, and humans. PFAAs, particularly PFOS, are typically the dominant PFAS detected in biota (**Houde et al. 2011**). PFAA concentrations in biota are influenced by uptake and elimination of both PFAAs and their precursors, as well as biotransformation rates of PFAA precursors (**Asher et al. 2012**; **Gebbink, Bignert, and Berger 2016**). Therefore, concentrations of PFAAs observed in biota at one location may not reflect concentrations in other environmental media.

6.5.1 Plants

Studies show evidence of uptake and accumulation of PFAAs by plants in several settings and applications, including both controlled experiments and field investigations. Concerns about introducing PFAAs into livestock or crops have led to investigations of uptake and accumulation in plants (**Section 5.6**). Uptake mechanisms and the extent to which native plant species remove and accumulate PFAS have not been as well studied.PFAS may be introduced to plants from soil, water, or air by:

- irrigation water
- the application of biosolids or sludge-amended soils
- the application of pesticides
- soil and groundwater at PFAS sites or near releases of PFAS
- exposure through contact with rainwater and atmospheric deposition

Studies demonstrating plant uptake of PFAAs have focused on irrigated crops (**Stahl et al. 2009**; **Scher et al. 2018**; **Bolan et al. 2021**), crops in biosolids-amended soil (**Yoo et al. 2011**; **Blaine et al. 2013**; **Blaine et al. 2014**; **Felizeter et al. 2021**; **Costello and Lee 2020**; **Knight et al. 2021**), and aquatic plants in constructed wetlands (**Chen, Lo, and Lee 2012**). PFAS have also been found in pesticides (**Zabaleta et al. 2018**; **Lasee et al. 2022**). USEPA's Analytical Chemistry Branch repeated the analyses conducted by **Lasee et al. (2022)** for PFAS and conducted additional analyses. In USEPA's results no PFAS were detected above the method detection limits (**USEPA 2023**).Other investigations have focused on flora exposed to PFAAs in the natural environment (**Zhang et al. 2015**) or near known PFAS sources (**Shan et al. 2014**). Based on bioconcentration factors discussed in **Section 5.6**, concentrations in plants will generally reflect the same concentrations in soil and, for trees with deep roots, groundwater (**Gobelius, Lewis, and Ahrens 2017**).

6.5.2 Invertebrates

Invertebrates act as the main component of the food web base and play a key role in the dynamics of biomagnification. Aquatic invertebrates can reside in the water column, as well as on (or in) the sediment substrate. In higher trophic level organisms, PFOS has been documented as the dominant PFAS, with concentrations increasing up the food chain, while PFOA has a lower bioaccumulation potential with similar concentrations among species of different trophic level animals (**Houde et al. 2011**; **Conder et al. 2008**). In invertebrates, both PFOS and PFOA have maximum values within similar ranges (**Ahrens and Bundshuh 2014**). A recent review of PFAS occurrence in marine and estuary invertebrates (i.e., mollusks and crustaceans) found that patterns of PFAS bioaccumulation can vary slightly between these taxa, but historical differences in sampling and analytical methods complicate comparisons to more recent investigations (**Giffard et al. 2022**). Studies present a PFAS range of approximately 0.1–10 mg/kg in invertebrate tissue, although their sources predominantly address marine organisms (**Houde et al. 2011**). Similar levels of PFOS have been found in freshwater invertebrates (< 2–4.3 mg/kg) with a BCF (biota/water) estimated at 1,000 L/kg (**Kannan et al. 2005**). Concentrations of PFOS, PFCAs, and heptadecafluorooctane sulfonamide (PFOSA) have been observed in Lake Ontario invertebrates, ranging from < 0.5 to 280 mg/kg (**Martin et al. 2004**). The PFAS concentrations in invertebrates were greater than in fish from this lake.

In soil invertebrates, current research indicates that bioaccumulation potential of PFOS is low, as is biomagnification (increasing concentrations in predators over their prey) from lower to higher trophic level organisms (**CEPA 2017**). In biosolids-amended soils, the mean PFAS BAFs in earthworms have been found to range from 2.2 (PFOA) to 198 (PFDoA) g dry weight (dw) soil/g dw worm (**Navarro et al. 2016**). Maximum BAFs in earthworms for all PFAS types have been observed at <45 g dw soil/g dw worm for biosolids-amended soils and <140 g dw soil/g dw worm for soils contaminated with AFFF (**Rich et al. 2015**).

6.5.3 Fish

Accumulation of PFAS in fish is well documented, particularly for PFOS, longer chained PFCAs (with eight or more carbons), and perfluorodecane sulfonate (PFDS) (**Houde et al. 2011**; **Martin et al. 2013**; **Conder et al. 2008**). PFOS generally has the highest concentrations in fish due to the historically high use of this chemical and its bioaccumulation potential (**Houde et al. 2011**). PFDS, long-chain PFCAs, and other PFAS have also been measured in fish (**Houde et al. 2011**; **Fakouri Baygi et al. 2016**).

In fish, PFOS tends to partition to tissues of high protein density, including the liver, blood serum, and kidney (**Falk et al. 2015**; **Ng and Hungerbühler 2013**). This distribution pattern is contrary to other persistent chemicals, which tend to partition to adipose tissue. Concentrations of PFOS and other PFAAs tend to be higher in whole fish samples compared with fillets given that a major fraction of PFAAs is found in the carcasses of fish rather than fillets (**Fliedner et al. 2018**). PFAA concentrations sometimes increase with fish size; however, the relationship with fish size is not consistent as observed for other contaminants such as mercury (**Babut et al. 2017**; **Gewurtz et al. 2014**).

Fish data for PFOS collected near known sources (for example, AFFF sites) from some key studies are summarized in **Figure 6-5**. More information is archived as a Section 17.1 PDF, found under **Archived External Tables and Sections** on the home page of this site.

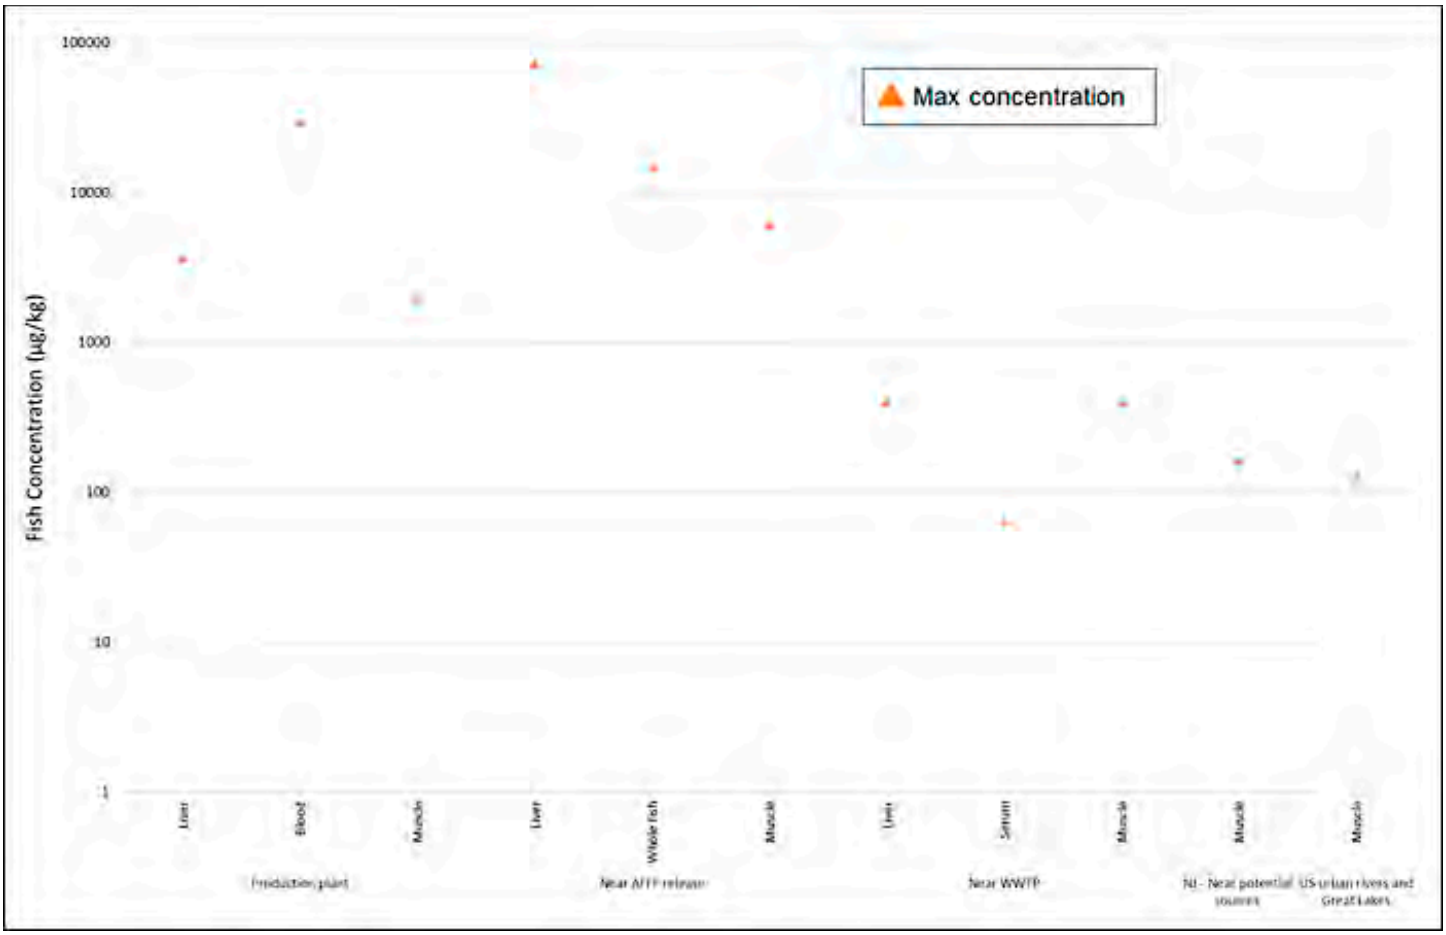


Figure 6-5. Observed PFAS concentrations in fish.

6.5.4 Vertebrates

Most research addressing PFAS concentrations in vertebrates focuses on temporal trends in animals at the top of the food chain, such as piscivorous birds (for example, osprey) and mammals (for example, dolphins, seals). The concentrations are often reported in protein-rich organs known to concentrate PFAS. For example, to evaluate temporal trends between 2002 and 2014, levels of PFAS were measured in liver samples of Indo-Pacific humpback dolphins and finless porpoises (136–15,300 and 30.5–2,720 ng/g dw, respectively) (**Gui et al. 2019**). Livers of Beluga whales in the Artic were the only organ sampled to better understand the relative bioaccumulation of persistent organic compounds (**Reiner et al. 2011**). These data using top marine predators as "sentinels" of PFAS are important in terms of assessing whether concentration trends are increasing or decreasing in the global environment.

PFAS bioaccumulation in terrestrial human food sources (livestock, livestock products, and game) is a critical area of occurrence discussions, and few research or review articles currently exist. Animals raised for food and wildlife species may come into contact with PFAS through contaminated air, water, soil, substrate, or feed. However, the extent to which these exposures contribute to PFAS concentrations in food products is not extensively researched (**Death et al. 2021**). A study focused on livestock drinking water and grazing found that sites with mean livestock drinking water concentrations as low as 0.003 µg PFOS/L may exceed action levels or advisory levels for PFOS in cattle meat (**Mikkonen et al. 2023**). Current understanding is that most PFAS accumulates in muscle tissue and milk (**Brake et al. 2023**). Some state agencies are conducting sampling surveys of game animals and issuing "Do Not Eat" advisories (**ME DIFW 2023**; **MPART 2023**).

7 HUMAN AND ECOLOGICAL HEALTH EFFECTS OF SELECT PFAS

This section discusses both the information related to assessing health effects of PFAS in humans (**Section 7.1**) and the adverse effects on ecological (nonhuman) species (**Section 7.2**). This is an active area of scientific research. **Section 7.1** provides information on human biomonitoring and exposure, toxicokinetics, toxicology in mammalian species, and human epidemiology for long-chain and short-chain PFAAs and the per- and polyfluorinated ether carboxylates (PFECAs) commonly known as the GenX chemicals and ADONA. The section is supplemented by additional material on each of these topics, which is included as **Section 17.2**. **Section 7.2** is organized to include ecological toxicology information on invertebrates (aquatic, benthic, terrestrial), vertebrates (fish, birds, reptiles, amphibians, mammals), and plants.

In December 2023, **ITRC (2023)** published their Contaminants of Emerging Concern (CEC) framework document that includes a discussion of sources of key variables to consider when evaluating human health risk and ecological risks. Links and references in the framework may be useful for understanding PFAS.

For further information on the scientific names and carbon chain length of PFAAs addressed in these sections, see **Section 2.2** of this document. Use of the human health effects information in guidance values is discussed in **Section 8.3** and in site risk assessment in **Section 9.1**.

Section Number	Topic
1.4	**Priority Topics for Human and Ecological Health Effects (2025)**
7.1	**Human Health Effects**
7.2	**Ecological Toxicology**
17.2	**Additional Information for Human Health Effects**

7.1 Human Health Effects

The PFAS discussed in this section and in **Section 17.2** include perfluorocarboxylic acids (PFCAs) with 4–14 carbons and perfluorosulfonic acids (PFSAs) with four or more carbons. Also covered are several PFECAs that are used as replacements for PFOA as processing aids in production of certain fluoropolymers, including the GenX chemicals, hexafluoropropylene oxide dimer acid (HFPO-DA) and its ammonium salt, (also known as perfluoro-2-propoxypropanoic acid [PFPrOPrA] and ammonium 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoate, respectively) and 4,8-dioxa-3H-perfluorononanoate, commonly known as ADONA. In addition, **Section 17.2.6** reviews other ether and polyether PFAS, fluorotelomer alcohols, and fluorotelomer sulfonic acids. They are included because they are of current interest and health effects data are available. There is little or no publicly available health effects information for most of the many other PFAS used in commerce (**Section 2.5**), including precursors that may be converted to PFAAs in the environment and in the human body. Several groups have developed systematic evidence maps that seek to collate available human and animal data for certain PFAS chemicals including a group of 29 PFAS (PFAS-Tox Database) (**Pelch et al. 2019**, **Pelch et al. 2022**) and the US EPA's Office of Research and Development Systematic evidence maps for several hundred PFAS chemicals (**Carlson et al. 2022**, **Radke et al. 2022**, **Carlson et al. 2024**, **Shirke et al. 2023**). These evidence maps are large data repositories, with interactive visualizations and downloadable datasets that are a resource for PFAS researchers to compare what data are available for different PFAS across this diverse chemical class.

The best studied PFAAs are PFOS and PFOA, although considerable information is available for some other PFAS, including PFNA, PFHxS, PFBA, PFBS, and the GenX chemical HFPO-DA. Laboratory animal toxicology studies and human epidemiological studies suggest health effects that may occur as a result of long-term exposure to PFOA and PFOS at environmentally relevant levels. **Figure 7-1** summarizes current health effects information, the references for which are discussed in this section. The other PFAS mentioned above cause generally similar effects in animal studies, with toxicity generally occurring at higher doses for the short-chain PFAAs than for long-chain PFAAs. These health effects, discussed in more detail in Sections **7.1.3**, and **7.1.4** are the basis for current guidance values and regulations for PFOA, PFOS, and several other PFAS. These are available in the **Environmental Media Values Table** Excel file.

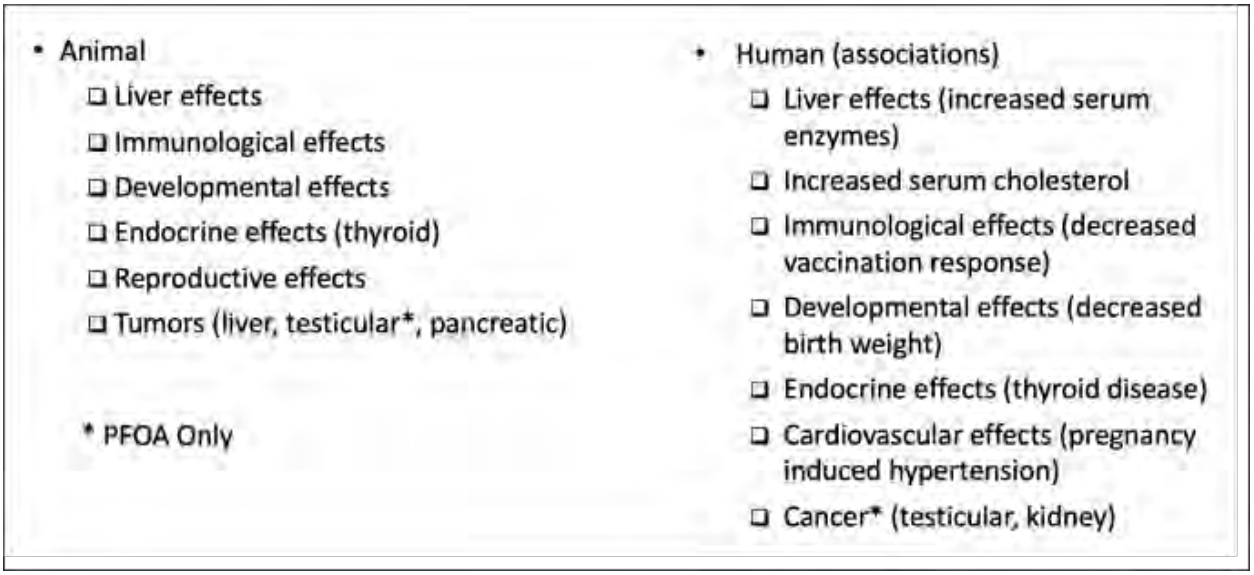

Figure 7-1. Some health effects of PFOA and/or PFOS identified from published studies (not exhaustive).

USEPA has finalized its toxicity assessments for the following PFAS:

- the GenX chemicals (**USEPA 2021**)
- PFBS (**USEPA 2021**)
- PFBA (**USEPA 2022**)
- Perfluoropropanoic acid (PFPrA)(**USEPA 2023**)
- Lithium bis[(trifluoromethyl)sulfonyl]azanide (HQ-115)(**USEPA 2023**)
- PFHxA (**USEPA 2023**)
- PFDA (**USEPA 2024**)
- 6:2 Fluorotelomer Sulfonic Acid (**USEPA 2024**)
- PFHxS (**USEPA 2025**)

As of April 2025, a draft IRIS assessment was available for PFNA (**USEPA 2024**).

USEPA (**USEPA 2021**; **2021**) developed draft updated toxicity assessment for PFOA and PFOS which were used as the basis for the updated PFOA and PFOS interim drinking water Health Advisories (**USEPA 2022**; **2022**). The **USEPA (2021)** also made a final regulatory determination to establish drinking water standards (maximum contaminant levels, MCLs) for PFOA and PFOS, proposed these standards in 2023 (**USEPA 2023**), and finalized them in 2024 (**USEPA 2024**). After consideration of public comments on the proposed **USEPA (2023)** MCLs, the USEPA finalized MCLs for PFOA and PFOS at 4.0 ng/L in 2024 (**USEPA 2024**). The USEPA toxicity evaluations of PFOA (**USEPA 2024**) and PFOS (**USEPA 2024**) that

support these MCLs reflect input from the USEPA Science Advisory Board (SAB) (**USEPA Science Advisory Board 2022**) and from public comments on the basis of the proposed MCLs. In the same National Primary Drinking Water Regulation, the USEPA finalized MCLs for three additional PFAS; PFNA, PFHxS, and GenX Chemicals (10 ng/L each) and an MCL of a Hazard Index of 1 for mixtures of any two or more of the following four PFAS: PFNA, PFHxS, PFBS, and GenX Chemicals (**USEPA 2024**).

Much of the information presented here is recent, and new studies continue to become available. Additionally, it should be noted that it was not possible to include all relevant citations, particularly for those compounds with large health effects data sets. Further information on the topics in this section can be found in databases such as the National Library of Medicine's PubMed (a database containing citations to relevant peer-reviewed publications), and in reviews such as **Kirk et al. (2018)** and **Lau (2012)**, and in several chapters of the Agency for Toxic Substances and Disease Registry (ATSDR) toxicological profile (**ATDSR 2021**); **DeWitt (2015)**, and **NICNAS (2018)** for PFAS in general. Some references for specific PFAS are included in this list:

- PFOA: **Australia Government DOH (2018)**; **USEPA (2016)**; **USEPA (2016)**; **NJDWQI (2017) NJDWQI (2017)**; **USEPA (2023)**
- PFOS: **USEPA (2016)**; **USEPA (2016)**; **MDH (2019)**; **NJDWQI (2018)**; **USEPA (2023)**
- PFNA: **NJDWQI (2015)**
- PFBS: **MDH (2022)**; **USEPA (2021)**
- PFBA: **USEPA (2021)**; **MDH (2018)**
- PFHxS: **MDH (2020)**
- PFHxA: **MDH(2021)** and **USEPA (2022)**
- GenX chemicals: **RIVM (2016)**, Chemours (posted online by **NC DEQ (2018)**); and **USEPA (2021)**
- Short-chain PFAAs: **Buck (2015)** and **Danish EPA (2015)**
- PFECAs: **Buck (2015)**; **NJDEP (2021)**

Human biomonitoring and sources of exposure are addressed in **Section 7.1.1**. Information on serum levels of long-chain PFAAs from communities with contaminated drinking water is presented in **Table 17-6**. The unique toxicokinetic properties of PFAS are discussed in **Section 7.1.2**. Table 17-7 summarizes available data on PFAS elimination half-lives in humans and experimental animals. The numerous reviews of potential epidemiological associations of health endpoints with PFAAs are discussed in **Section 7.1.3**. Toxicology studies in mammalian species are summarized in **Section 7.1.4**, and more detailed toxicology information is presented in **Section 17.2.5** and Table 17-8 Toxicological Effects Excel file (last updated November 2021). **Section 7.1.5** discusses PFAS mixtures. **Section 7.1.6** includes information about using new approach methodologies for evaluating PFAS. **Section 7.1.7** provides information about regulating PFAS as a class. **Section 7.1.8** includes information about PFAS inhalation toxicity, and **Section 7.1.9** includes data gaps and research needs. **Section 1.4.4** includes information about health effects of ultra-short-chain (ultrashort) PFAS.

7.1.1 Human Biomonitoring and Sources of Exposure

Numerous human biomonitoring studies (**CDC 2022**; **Olsen et al. 2017**) have demonstrated that certain PFAS, particularly long-chain PFAAs, are present in the blood serum of most U.S. residents. Long-chain PFAAs, with half-lives of one to several years, are slowly excreted in humans. Therefore, serum levels are indicators of long-term exposure to long-chain PFAAs and do not fluctuate greatly with short-term variations in exposure. Serum PFAA concentrations originate from direct exposure to the compounds and from metabolism of precursor compounds to PFAAs within the body (reviewed in **Kudo (2015)**). The largest U.S. general population biomonitoring studies are from the National Health and Nutrition Examination Survey (NHANES), a nationally representative survey conducted by the Centers for Disease Control and Prevention (CDC), which began monitoring for PFAS in 1999–2000 (**Figure 7-2**). As can be seen in **Figure 7-2**, serum PFAS levels in the general population have declined over time, most notably for PFOS. The most recent NHANES monitoring data (2017–2018) includes eight PFAAs (PFOA, PFOS, PFNA,

PFHxS, PFHxA, PFDA, PFUnDA, PFHpS) and four other PFAS (GenX, ADONA, 9-Chlorohexadecafluoro-3-oxanonane-1-sulfonic acid, MeFOSAA); five additional PFAS (PFBS, PFHpA, PFDoDA, PFOSA, EtFOSAA) that were infrequently detected in earlier rounds of NHANES were not monitored in 2017–2018 (**CDC 2022**). Other adult U.S. general population biomonitoring data come from four studies of blood donors in 2000–2015 (**Olsen et al. 2017**) and the California Environmental Contaminant Biomonitoring Program (**CA OEHHA 2011**).

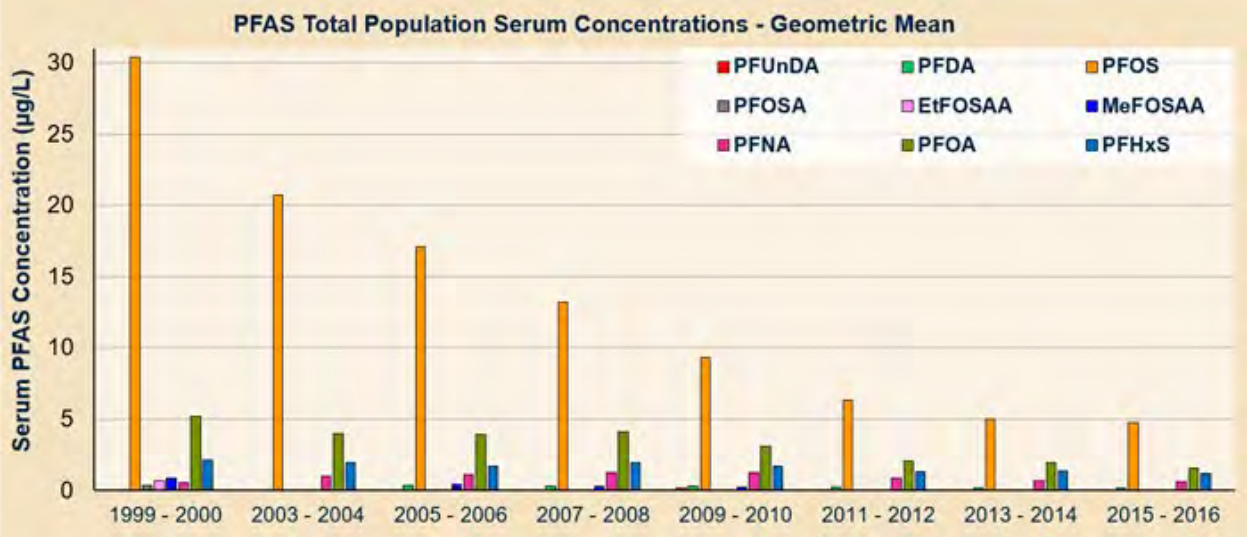

Figure 7-2. Geometric mean serum concentrations (ng/ml) of selected PFAAs (NHANES, 1999-2016).

In the general population, where this is no specific source of PFAS contamination and PFAA concentrations in drinking water and serum are in the typical "background" range, the primary sources of exposure to PFAAs and their precursors appear to be food and food packaging, and consumer products (particularly nonpolymer aftermarket treatments and coatings; **Section 2.5**), and house dust formed from such consumer products (**Trudel et al. 2008**; **Fromme et al. 2009**; **Vestergren and Cousins 2009**; **Beesoon et al. 2012**; **Gebbink, Berger, and Cousins 2015**). The Priority Topics for Human and Ecological Health Effects include information about potential PFAS exposures from consumer products (see **Section 1.4.2**).

PFAS have been detected in air (**ATSDR 2021**), and inhalation is therefore an additional potential exposure pathway. Serum levels of PFOS and PFOA documented by NHANES data appear to indicate that the phaseout of production and use of these chemicals in most products has resulted in decreased PFOS and PFOA exposures for the general population from these sources. As this occurs, the relative contribution from drinking water to these PFAAs will increase (where they are present in the drinking water).

In communities near sources of PFAS contamination, exposures that are higher than those in the general population can result from ingestion of contaminated drinking water or consumption of fish from contaminated waters. **Section 1.4.1** includes information about potential human health effects from PFAS exposure arising from AFFF in drinking water. As PFAS concentrations in drinking water increase, the contribution of drinking water to the total body burden increases and typically dominates an individual's exposure. Information on serum levels of long-chain PFAAs from communities with contaminated drinking water in several U.S. states and other nations is found in **Table 17-6**. Finally, occupational exposures to workers (for example, in fluoropolymer manufacturing facilities) can be higher than exposures from environmental media. **Section 1.4.6** includes information about potential PFAS exposures in occupational settings.

Specific considerations and exposure routes relevant to PFAS exposures in the fetus, breast-fed and formula-fed infants, and young children are discussed in **Section 17.2**. Also see **Section 17.2.2** for additional discussion of human biomonitoring and sources of human exposure.

7.1.2 Toxicokinetics

Toxicokinetics refers to the absorption, distribution, metabolism, and excretion of toxic substances. PFAAs and some other types of PFAS discussed herein have unique toxicokinetic properties as compared to other types of persistent organic pollutants (POPs). Unlike most other bioaccumulative organic compounds (for example, dioxins, PCBs), PFAAs do not have a high affinity for adipose tissue (fat). In contrast, PFAAs are water soluble, have an affinity for proteins, and generally distribute primarily to the liver and blood serum (**Bischel et al. 2011**; **Lau 2012**, **2015**; **Kato, Ye, and Calafat 2015**). Some PFAAs have also been found in kidney, bone, lung, brain, and other organs in laboratory animals and/or limited human studies (**Bogdanska et al. 2011**; **Perez et al. 2013**; **reviewed in USEPA 2023**). PFAAs, GenX chemicals, and ADONA are not metabolized (meaning they do not break down to other PFAS). However, some PFAS that are PFAA precursors (for example, fluorotelomer alcohols, **Section 17.2.5.2**) can be metabolized to PFAAs within the body.

Table 17-7 summarizes available data on PFAS elimination half-lives (the half-life is the length of time it takes for half of the chemical to be eliminated from the body) in humans and experimental animals. In general, short-chain PFAS are excreted more rapidly than longer chain PFAS in humans and other mammalian species. As discussed in more detail in **Section 17.2.3**, the excretion rates (for example, elimination half-lives) for specific PFAS can vary substantially between species, and in some cases between males and females of the same species. Half-lives in laboratory animals (rodents and nonhuman primates) generally range from hours to several months for long-chain PFAS, and hours to several days for short-chain PFAS. Human half-lives for PFAS are longer than in other mammalian species, with estimates of several years for long-chain PFAAs and several days to one month for shorter chain PFAAs such as PFBA, PFHxA, and PFBS. Because of the much longer human half-lives, animal-to-human comparisons must account for the much higher internal dose (for example, blood serum level) in humans than in animals from the same administered dose.

Toxicokinetics relevant to developmental exposures to PFAAs are important because developmental effects are considered to be sensitive endpoints for toxicity of long-chain PFAAs, and some human studies have found associations of long-chain PFAAs with decreased fetal growth. PFAAs cross the placenta (reviewed in **Lau (2012)** and **Kudo (2015)**) and are present in breast milk (**Luebker et al. 2005**; **White et al. 2009**; **Kato, Ye, and Calafat 2015**), and long-chain PFAAs have been found in cord blood, for example, (**Wang et al. 2019**), and amniotic fluid (**Stein et al. 2012**; **Zhang et al. 2013**). In human infants, exposures from breast milk result in substantial increases in long-chain PFAA serum levels during the first months after birth (**Fromme et al. 2010**; **Mogensen et al. 2015**). Due to the higher rate of fluid consumption by infants versus older individuals (**USEPA 2019**), exposures to infants from formula prepared with PFAS-contaminated water are also higher.

Toxicokinetic factors called clearance factors represent the volume of blood from which a substance is removed per unit time (L/kg/day). Clearance factors have been used to relate external doses (ng/kg/day) of PFOA and PFOS to steady-state serum levels (ng/L). When combined with average water ingestion rates (**USEPA 2023**), these clearance factors have been used to predict that the expected average increases in the levels of PFAS in blood serum from long-term drinking water exposure are at least 100-fold higher than the concentration in the drinking water (**Bartell 2017**; **NJDWQI 2017**; **Post, Gleason, and Cooper 2017**). See **Section 17.2.3.2** for more detail. Bartell (**2017**), **Lu and Bartell (2020)**, and **ATSDR (2022)** have developed online calculators that provide estimates of an individual's serum concentrations of PFOA, PFOS, PFNA, and PFHxS from the information that is entered, including drinking water levels of these PFAS and other relevant factors. It should be noted that these estimates are based on long-term exposure to a constant drinking water concentration and that serum PFAS concentrations are impacted

by interindividual variability in both toxicokinetic factors (for example, PFAS half-lives) and the daily drinking water ingestion rate.

Finally, toxicokinetics in rodents (**Loveless et al. 2006**; **De Silva et al. 2009**) and humans (**Zhang et al. 2013**; **Gao et al. 2015**; **Beesoon et al. 2011**) may differ among isomers of the same PFAA.

See **Section 17.2.3** for additional discussion of PFAS excretion and excretion rates, toxicokinetics relative to developmental exposure, the relationship of human exposure to serum levels, and isomer-specific toxicokinetics.

7.1.3 Human Epidemiology Studies

The epidemiological database for long-chain PFAAs, particularly PFOA and PFOS, is more extensive than for many other environmental contaminants. Many of the studies are recent, and the number of available studies is continually increasing. **USEPA (2023)** identified over 400 human epidemiology studies of PFOA and/or PFOS from searches of the following databases through February, 2022: Pub Med (National Library of Medicine); Web of Science (Thomson Reuters); ToxLine (incorporated into PubMed post 2019); and TSCATS (Toxic Substances Control Act Test Submissions). Many of these studies also evaluated other long-chain PFAAs and/or other PFAS. Some effects, such as changes in serum lipids, liver biomarkers, uric acid levels, thyroid endpoints, vaccine response, and fetal growth, have been evaluated in multiple studies and populations, while only one or a few studies were located for some other effects

These studies can be categorized based on the type of population evaluated: general population, communities with contaminated drinking water, or occupationally exposed workers. Almost all of these studies were published after 2009, with the exception of a small number of occupational studies from a few years prior to that time.

Although discussion of individual epidemiological studies is beyond the scope of this section and the corresponding appendix section, evidence for associations and/or causality for some PFAAs and certain health effects (for example, increased cholesterol, increased liver enzymes, decreased vaccine response, thyroid disease, and for PFOA, some types of cancer) has been evaluated by various academic researchers and government agencies. USEPA (**2023**; **2023**) has concluded that the noncancer human health effects with the strongest evidence for association with PFOA and PFOS are increased serum cholesterol, increased serum alanine aminotransferase (ALT; a marker of liver damage), decreased vaccine response, and decreased birth weight. **USEPA (2023)** has also concluded that PFOA is linked to testicular and kidney cancer in humans. The conclusions of some of these evaluations are discussed briefly below, with additional detail provided in **Section 17.2.4**.

For some health endpoints, including increased serum cholesterol, there is general consensus for consistent evidence for association with one or more long-chain PFAAs. Conclusions differ among evaluations by different groups of scientists for other endpoints, noting that the earlier evaluations considered fewer studies than the more recent evaluations. For additional endpoints, data are too limited to make a conclusion, results are inconsistent, or there is no evidence for an association. The general reviews cited in **Section 17.2.4** include detailed discussions of epidemiological data for PFOA, PFOS, and PFNA.

As shown in **Figure 7-1**, associations in human epidemiological studies of PFAAs (primarily PFOA and PFOS) for some endpoints (for example, increased liver enzymes, decreased fetal growth, decreased vaccine response) are consistent with animal toxicology studies (**Section 7.1.4**). For serum lipids (for example, cholesterol), observations of decreased cholesterol in rodents in some studies, while cholesterol is increased in humans, may result from the higher fat content in the diets of humans as compared to the diet used in most laboratory animal studies and/or large differences in the exposure

levels in human versus animal studies (**Tan et al. 2013**; **Rebholz et al. 2016** ; **NJDWQI 2017**; **USEPA 2023**).

Associations of some health endpoints with certain PFAAs are generally, although not totally, consistent, and some evaluations have concluded that the data for certain effects support multiple criteria for causality. Historically, risk-based toxicity factors (reference doses for noncancer effects and slope factors for cancer risk) developed by most government agencies are based on dose-response relationships from animal data, with the human data used to support the hazard identification component of toxicity factor development. One factor that has precluded the use of human data in the dose-response component of toxicity factor development is the concurrent exposure to multiple PFAAs in most or all study populations. Because serum levels of co-occurring PFAAs tend to correlate with each other, special modeling approaches must be used to determine the dose-response relationship for individual PFAAs, and the use of these approaches is currently increasing. That fact notwithstanding, **Hölzer, Lilienthal, and Schümann (2021)** and **Schümann, Lilienthal, and Hölzer (2021)** developed Human Biomonitoring Values (serum levels below which adverse effects are not expected) and the European Food Safety Authority (**EFSA 2020**) developed a Tolerable Weekly Intakes (TWI) of 4.4 ng/kg body weight for the sum of four PFAS (PFOA, PFOS, PFNA, and PFHxS) in food based on human data for decreased vaccine response from the general population. These values are lower than many of the values that are based on toxicity data from animals. More recently, California EPA and USEPA have developed reference doses for PFOA and PFOS (**CA OEHHA 2024**; **USEPA 2024; 2024**); cancer slope factors for PFOA (**USEPA 2024**; **CA OEHAA 2024**); and reference doses for PFHxS (**USEPA 2025**), PFDA (**USEPA 2024**), and draft reference doses for PFNA (**USEPA 2024)** based on human general population data that are far below current values for long-chain PFAS based on animal data.

The National Academies of Science, Engineering, and Medicine (**NASEM 2022**), at the request of ATSDR and the National Institute of Environmental Health Sciences (NIEHS), developed recommendations for testing for PFAS exposure and clinical monitoring for exposed individuals. ATSDR will consider these recommendations in updating its guidance to clinicians regarding PFAS. As part of its work, **NASEM (2022)** developed "strength of evidence" determinations based on human data for a variety of health effects that are collectively applicable to the total serum concentration of the seven PFAS (PFOA, PFOS, PFHxS, PFNA, PFDA, PFUnDA, and methyl-perfluorooctane sulfonamide [MeFOSA]) currently included in the CDC's National Report on Human Exposure to Environmental Chemicals (**CDC 2022**). The NASEM relied on risk-based assessments conducted by **EFSA (2020)** and the German Human Biomonitoring Commission (**2016**), (**2018**) to identify PFAS levels in serum or plasma to inform clinical care. The NASEM determined that: (1) adverse health effects related to PFAS exposure are not expected at PFAS serum levels less than 2 ng/mL; (2) there is a potential for adverse effects, especially in sensitive populations, for PFAS serum levels between 2 and 20 ng/mL; and (3) there is an increased risk of adverse effects for PFAS serum levels above 20 ng/ml. The NASEM recommended PFAS exposure reduction—if a source has been identified—for the two highest categories of PFAS serum concentrations. **NASEM (2022)** further recommended that clinicians should "offer PFAS [blood] testing to patients likely to have a history of elevated exposure," including those with potential occupational exposure and those who have lived in communities with known or potential PFAS contamination. The NASEM also recommended that clinicians conduct health screening for several health conditions when the sum of the seven PFAS in serum exceeds the recommended benchmarks. Also see the discussion of the NASEM document in **Section 7.1.8**, Regulation of PFAS as a Class.

See **Section 17.2.4** for additional discussion of epidemiologic studies that have been conducted on PFAS.

7.1.4 Animal Toxicology Studies

This section focuses on the most notable toxicological effects in mammalian studies of certain PFCAs, PFSAs, and PFECAs. All PFAS covered in this section for which data are available cause increased liver

weight; additional effects common to some of these PFAS include immune system, hematological (blood cell), and developmental toxicity, as well as more severe types of liver toxicity. Of the four PFAS that have been tested for carcinogenicity in rodents, PFOA, PFOS, and the GenX chemical HFPO-DA caused tumors while PFHxA did not.

In general, toxicity is dependent on both intrinsic potency of the compound (**Gomis et al. 2018**) and its toxicokinetics. Longer chain PFAAs are generally toxic at lower administered doses than shorter chain compounds because their slower excretion results in a higher internal dose from the same administered dose. Similarly, for those PFAS that are excreted much more rapidly in female rats than in males (**Section 7.1.2** and **Table 17-7**), higher doses in females than in males are needed to achieve the same internal dose.

Toxicological data from animal studies are used as the basis for many human health toxicity factors (for example, reference doses, cancer slope factors) for PFAS. However, as noted above, both California and the USEPA have based recent draft reference doses and/or cancer slope factors for on human data. Certain European toxicity factors are also based on human data (**Section 7.1.3**) (also see **Sections 8.3** and **9.1**). Unlike most other environmental contaminants, PFAS have been associated with health effects in humans at much lower exposure levels than the doses used in animal toxicology studies.

Table 17-8 Toxicological Effects Excel file provides information on toxicological effects in mammalian species (hazard identification information) for the following PFAS:

- PFCAs including PFBA, PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnA, and PFDoA
- PFSAs including PFBS, PFPeS, PFHxS, PFHpS, and PFOS
- PFECAs including ADONA and the GenX chemical HFPO-DA.

Section 17.2.5.1 also summarizes information on systemic effects; reproductive and developmental effects, and chronic toxicity and tumorigenicity of these PFAS.

- Largest publicly available toxicological data sets for: PFOA and PFOS
- Considerable data for: PFBA, PFHxA, PFNA, PFDA, PFBS, and the GenX chemicals HFPO-DA and its ammonium salt
- One or a few studies for: PFHpA, PFUnA, PFDoA, PFHxS, and ADONA
- No toxicological data were located for PFPeA, PFTrDA, PFTeDA, PFPeS, PFHpS, PFNS, or PFDS.

Most toxicological studies of PFAS have been conducted in rats and mice, with a few studies in nonhuman primates (monkeys) and other species such as rabbits.

The National Toxicology Program (**NTP 2019**; **NTP 2019**) has conducted 28-day studies of seven PFAS (PFHxA, PFOA, PFNA, PFDA, PFBS, PFHxS, PFOS) in male and female rats that evaluated numerous toxicological endpoints and provided serum PFAA data for each dosed group; results of these studies are included in **Table 17-8 Toxicological Effects** Excel file. Although the doses at which effects occurred are not provided in this section or in the supporting appendix material, it is emphasized that No Observed Adverse Effect Level (NOAELs) and Lowest Observed Adverse Effect Level (LOAELs) vary widely between compounds for a given endpoint, between different endpoints for the same compound, and between species (and sexes in some cases) for the same compound and endpoint. Furthermore, the effects noted may not have been observed in all studies in which they were evaluated.

NTP (2020) has also conducted a chronic carcinogenicity study of PFOA administered in feed to rats that assessed the contribution of combined gestational and lactational (perinatal) exposure as compared to exposure beginning after weaning. It was concluded that there was clear evidence of carcinogenic activity in male rats based on the increased incidence of liver tumors and pancreatic acinar cell tumors, and some evidence of carcinogenic activity in female rats based on increased incidence of pancreatic acinar cell tumors. Non-neoplastic lesions were increased in the liver and pancreas in males and in the liver, kidney, forestomach and thyroid in females. There were very few significant differences in effects when exposure began in the perinatal period compared to when it began after weaning.

See **Section 17.2.5.1** for additional discussion of studies in animals that have evaluated the effects of these PFAS on noncancer and cancer endpoints.

There is increasing awareness and interest in potential human exposure to PFAS other than the PFAAs and the PFECAs, GenX and ADONA, that are discussed in **Section 17.2.5.1**. These include ether and polyether PFAS, dicarboxylic acid polyether PFAS, fluorotelomer alcohols, and fluorotelomer sulfonic acids. Information relevant to health effects of these additional PFAS is discussed in **Section 17.2.6.1**.

7.1.5 PFAS Mixtures

This section provides a summary of current toxicity-based approaches for addressing mixtures of PFAS and currently available information on toxicity of PFAS mixtures. This is an active area of research. Additional information is presented in **Section 17.2**.

Although humans are generally exposed to mixtures of PFAS, relatively few studies of the toxicity of PFAS mixtures, including defined mixtures (i.e., mixtures for which the identities and concentrations of the components are known) or complex mixtures (i.e., mixtures for which the identities and concentrations of the components are not fully characterized) such as AFFF, were located; they are summarized in **Section 17.2.7.2**. These include in vitro studies of nuclear receptor activation in cultured cells transfected with the receptor of interest, and toxicity in cultured cells; in vivo studies in zebrafish (a model species for human toxicity) and mammalian species; and epidemiologic studies of a population exposed to AFFF in drinking water.

7.1.5.1 Approaches for Assessing Toxicity of PFAS Mixtures

Multiple PFAS are present in the blood serum of almost all U.S. residents (**Section 7.1.1**), and PFAS often occur as mixtures of individual chemicals in the environment (for example, drinking water, fish, soil, and air). Therefore, approaches to assess the toxicity of PFAS mixtures are needed. Development of approaches for consideration of the health effects of mixtures of PFAS is a priority for USEPA, ATSDR, and other U.S. federal agencies, as discussed at a recent National Academy of Sciences (NAS) workshop on federal research on human health effects of PFAS (**NAS 2021**), and **USEPA (2023)** developed a draft framework for evaluation of non-cancer risk of PFAS mixtures that was reviewed by the **USEPA Science Advisory Board (2022)**. Approaches to assessing the toxicity of PFAS mixtures have also been the subject of several peer-reviewed publications (discussed below), including **Peters and Gonzalez (2011)**, **Bil et al. (2021)**, **Cousins et al. (2020)**, and **Goodrum et al. (2021)**. However, as discussed at the NAS workshop, relevant data on several aspects of this topic are limited. For example, there is a lack of information on in vivo and in vitro toxicity of PFAS mixtures, as well as on health effects in human populations when exposure to multiple PFAS has occurred (**NAS 2021**).

As is the case for mixtures of environmental contaminants in general, the toxicity of PFAS mixtures can be evaluated through studies of defined or undefined mixtures (mixtures of known concentrations of individual PFAS or complex mixtures that may include both known and unidentified PFAS, respectively). The small database of currently available toxicity studies of PFAS mixtures is summarized in **Section 17.2**. These include a few studies of the undefined PFAS mixtures found in AFFF and a limited number of

studies of defined PFAS mixtures, including in vitro studies of nuclear receptor activation in transfected cultured cells, and toxicity studies in cultured cells and zebrafish. Notably, no rodent or primate studies of defined mixtures of PFAS were located. When evaluating exposure and health effects for PFAS mixtures in drinking water or other media, it must be emphasized that identification of the PFAS that are present is dependent both on the composition of the mixture and the suite of PFAS detected by the analytical method that was used (**McDonough et al. 2019**). Methods currently used for routine analysis are described in **Section 11.2**. Additional analytical methods (for example, nontarget analysis) that are primarily used in research studies can identify numerous additional PFAS not currently included in standard methods.

As discussed in USEPA and ATSDR guidance for risk assessment of mixtures (**USEPA 1986**; **USEPA 2000**; **ATSDR 2018**), toxicological interactions among components of a mixture may include dose additivity, response additivity, synergism, and antagonism. Dose additivity is based on the assumption that the chemicals in the mixture have the same mode of action (MOA) and cause the same effects, and differ only in potency. The components are assumed to have similarly shaped dose-response curves, and the effect caused by the mixture is assumed to be the sum of the effects caused by each of the individual chemicals present. Because MOA information for PFAS is incomplete, the final **USEPA (2024)** framework for evaluation of risks of PFAS mixtures assumes dose additivity based on similarity of toxicological endpoint/health effects without requiring a common MOA. Response additivity is based on the assumption that the toxic effect of a mixture can be predicted by summing the doses of each chemical in the mixture (relative to each chemical's critical effect dose) such that the contribution from each chemical to the overall effect of the mixture is not influenced by the other chemicals. For example, when assuming additivity, the sum of the incremental cancer risks of multiple individual co-occurring carcinogens can be used to estimate the total cancer risk of the mixture. Toxicological interactions of components of mixtures may also be synergistic (greater than additive) or antagonistic (less than additive), resulting in larger or smaller effects than would occur with dose additivity or response additivity.

As discussed in this section, currently available toxicological information for PFAS does not clearly support a specific approach for conducting risk assessments of PFAS mixtures. While the toxicological effects of many PFAS are generally similar, the most sensitive toxicological endpoints may vary among PFAS. Additionally, multiple MOAs for PFAS toxicity are likely; these MOAs appear to be complex, and currently are not well understood. Furthermore, the MOA for a specific PFAS may not be the same for all effects (for example, hepatic toxicity, developmental toxicity), and a specific effect may not occur through the same MOA for all PFAS (for example, different MOAs for liver toxicity of PFOA and PFOS; **Peters and Gonzalez 2011**; **NAS 2021**). In the limited number of studies of PFAS mixtures, additive, synergistic, and antagonistic interactions among PFAS have been observed. As noted by **Wolf et al. (2014)**, toxicological interactions of PFAS are dependent on the identities and concentrations of the PFAS in the mixture, the biological model, and the endpoint being evaluated (see **Section 17.2**).

Some regulatory agencies consider the cumulative toxicity of PFAS that co-occur in environmental media, while other agencies consider PFAS individually as required by their regulatory process and/or the scientific uncertainty as to whether co-occurring PFAS are sufficiently similar to consider them as a group. Several approaches that have been proposed to address the toxicity of PFAS mixtures are discussed in **Section 17.2.7.1**. The goal of these approaches is to facilitate the risk assessment of PFAS mixtures detected at contaminated sites and to develop health-protective guidelines that potentially account for the combined effects of multiple PFAS. Some general approaches for assessing the cumulative effects of exposure to PFAS, as related to site risk assessment, are discussed in **Section 9.1.3.1**. Examples of the application of such approaches to PFAS are reviewed by **Cousins et al. (2020)**, who also provided a "summary of existing or proposed grouping approaches based on the sum of various PFAS in drinking water." Most of the approaches that have been proposed assume dose additivity, although scientific uncertainties are associated with this assumption, as discussed above and in **Section 17.2.7.1**.

7.1.5.2 Toxicology Studies of PFAS Mixtures

The relatively few studies of the toxicity of defined mixtures of PFAS that were located are summarized in **Section 17.2.7.2**. These include in vitro studies of nuclear receptor activation in cultured cells transfected with the receptor of interest, toxicity in cultured cells and zebrafish (a model species for human toxicity), and a few mammalian studies.

7.1.6 Evaluating PFAS using New Approach Methodologies

Traditional toxicity testing methods using in vivo mammalian models are time-, cost-, and labor-intensive. As noted in **Section 17.2.8**, including **Table 17-8 Toxicological Effects** Excel file, mammalian (most commonly rodent) toxicity information is available for only a relatively small group of PFAS, including a number of long- and short-chain PFCAs and PFSAs, certain fluorotelomer alcohols and fluorotelomer sulfonates, and several of the per- and polyfluoroether replacements, with PFOS and PFOA having the most extensive data sets. Under current USEPA risk assessment guidelines used by most states, in vivo mammalian laboratory animal or human data are required for development of chemical-specific toxicity factors (for example, reference doses) used as the basis for standards and guidance values for PFAS in drinking water and other environmental media. It is therefore important that in vivo mammalian data continue to be made available for those PFAS with a high level of public health concern, such as those detected at elevated concentrations in drinking water. However, in vivo mammalian studies are not feasible for all of the individual PFAS, of which there are thousands (**USEPA 2020**). Additionally, USEPA aims to refine and reduce the use of mammalian species in toxicology testing and to use non-animal testing methods when appropriate. With the goal of rapidly generating toxicity, MOA, toxicokinetic, and exposure information on PFAS and reducing the use of mammalian species in testing, the USEPA is collaborating with the National Toxicology Program (NTP) of the National Institutes of Environmental Health Sciences through the REACT (Responsive Evaluation and Assessment of Chemical Toxicity) Program. New Approach Methodologies, such as rapid toxicity assays in cultured cells and zebrafish, in silico (computational) approaches, and high throughput exposure modeling are being developed and used with the goal of generating data that will inform toxicology and risk assessment of PFAS (**Patlewicz et al. 2019**; **USEPA 2019**, **2019**). More information on this effort is provided in **Section 17.2.8**.

7.1.7 Regulation of PFAS as a Class

Recent estimates could have the total number of individual PFAS at more than 12,000 (see **Section 2** and **USEPA 2020**). Although not all of these PFAS are commercially important, more than 3,000 individual PFAS have been found in European commerce (**OECD 2018**), and approximately 4,700 PFAS are in the current global marketplace (**Cousins et al. 2020**). Of these, **Buck et al. (2021)** reported that 256 PFAS are commercially relevant on a global basis. Fewer than 20 PFAS are well-studied toxicologically (all of which are nonpolymer PFAS), and all of those that have been studied have been found to be capable of causing adverse effects in animals and/or humans (Sections **7.1**, **7.2**, and **17.2**). The Priority Topics for Human and Ecological Health Effects include additional considerations for addressing PFAS as a class (see **Section 1.4.5**).

Because substantial time and resources are required to adequately characterize the chemical and physical properties and potential adverse effects of an individual chemical (for example, **NTP, 2022**), the conclusion that it is neither feasible nor health-protective to follow the “chemical-by-chemical” regulatory paradigm for PFAS has gained increasing acceptance. Beginning with the Helsingør Statement (**Scheringer et al. 2014**) and continuing with the Madrid Statement (**Blum et al. 2015**) and Zurich Statement (**Ritscher et al. 2018**), groups of scientists and others have called for the coordinated regulation of all PFAS, citing their persistence, widespread use, and frequent lack of toxicity data, among other concerns. The FluoroCouncil (**Bowman 2015**) took issue with the Madrid Statement (**Blum et al. 2015**) for failing to acknowledge the fact that “fluorotechnology is essential technology,” and for ignoring

scientific information that indicates differences in persistence and toxicity between long- and short-chain PFAAs and the efforts of industry to limit environmental impacts of PFAS.

One of the various regulatory strategies proposed by **Blum et al. (2015)**, **Ritscher et al. (2018)**, and subsequently by **Cousins et al. (2019)**, is to limit ongoing uses of PFAS to those PFAS deemed to be "essential." **Cousins et al. (2019)** proposed that essential uses of PFAS are those "uses considered essential because they are necessary for health and safety or other highly important purposes and for which alternatives have not been established." Examples of essential uses are certain medical devices and occupational protective clothing (**Cousins et al. 2019**). **The European Commission (2020)** developed a strategy to phase out the use of PFAS in the European Union "unless it is proven essential for society." Similarly, while noting that "a ban on all PFAS as a group is neither practical, necessary, nor achievable," the **Royal Society of Chemistry (2021)** supported the concept of essential use for those PFAS defined as "vital or highly desirable by wider society." Other publications have also supported the concept of "essential use" as a regulatory strategy for PFAS (**Kwiatkowski et al. 2020**; **Dean et al. 2020**), with **Gluge et al. (2022)** describing the information requirements and analyses necessary to regulate PFAS under the concept of essential use.

Kwiatkowski et al. (2020) also emphasized the importance of eliminating nonessential uses of PFAS as an example of a class-based approach to PFAS regulation. Other class-based regulatory strategies cited by **Kwiatkowski et al. (2020)** include banning PFAS in certain product categories; prioritizing research and development funding for treatment and disposal/destruction methods that are targeted to (and effective for) PFAS as a class; and development of class-based cleanup standards so that all PFAS—not just a few—are remediated.

7.1.7.1 Grouping Strategies

The Zurich Statement (**Ritscher et al. 2018**) and others (**Cousins et al. 2020**; **Anderson et al. 2022**) have considered the utility of and strategies for grouping PFAS for more effective regulation, as distinct from treating all PFAS as a single class. **Cousins et al. (2020)** offered a number of potential bases for grouping PFAS, with the selected method depending on whether the intended action is to regulate based on intrinsic properties or to inform risk assessment. Each of the proposed grouping methods has different data requirements, advantages, and disadvantages (see **Cousins et al. 2020**). Examples of the grouping methods proposed by **Cousins et al. (2020)** are summarized in **Table 7-1**.

As described in its National PFAS Testing Strategy, the **USEPA (2021)** is working to understand the impacts of different categories of PFAS, in part to identify which PFAS will require testing under the Toxic Substances Control Act authority. The PFAS categorization will also support the prioritization of individual PFAS or "classes" of PFAS for additional research on human exposure or toxicity. The USEPA's categorization of PFAS is based on similarities in structure, physical-chemical properties, and toxicological properties. The USEPA plans to use these categories for hazard assessment and to support risk-based decision making and will also develop categories of PFAS based on removal technologies. The USEPA will draw on information from both of these approaches to prioritize research.

Anderson et al. (2022) considered several options for grouping of PFAS for the purpose of protecting human health from drinking water exposure and assessing risks of PFAS mixtures. No single grouping strategy was identified that was "sufficient" for all regulatory or public health risk assessment purposes. However, the study authors generally supported the conclusions that: "Not all PFAS should be grouped together, persistence alone is not sufficient for the purposes of assessing health risk, and that the nature and definition of the subgroups can only be defined on a situation-dependent and case-by-case manner" (**Anderson et al. 2022**).

A recent review of the properties of fluoroplastics and fluoroelastomer—two types of fluoropolymer—concluded that based on their high molecular weight, lack of biological availability, and other physical and

chemical properties, these PFAS are a distinct group of PFAS that "should not be grouped with other PFAS for hazard assessment or regulatory purposes" (**Korzeniowski et al. 2022**).

Table 7-1. Grouping approaches for PFAS (excerpted and adapted from Cousins et al. 2020, CC BY-NC 3.0).

	Individual approaches	PFAS grouped	Data requirements
Approaches based on intrinsic properties	P-sufficient approach[1]	All PFAS	None
	According to PBT/vPvB[2]	PFAS that are bioaccumulative	Bioaccumulation potential
	According to PMT/vPvM[2]	PFAS that are mobile in water	Water solubility
	Polymers of low concern (PLC)	Some fluoropolymers	Polymer composition, molecular weight, other properties
Approaches that inform risk assessment	Arrowhead[3]	Specific PFAAs and precursors	Degradation schemes
	Total organofluorine	Extractable or adsorbable PFAS	None
	Simple additive toxicity	2-20 PFAS, currently primarily PFAAs	Toxicity
	Relative potency factor	Multiple PFAAs	Toxicity, potency, toxicokinetics
	Grouping PFAS with similar adverse effects, mode of action, toxicokinetic	Limited PFAAs	Toxicity, mode of action, toxicokinetics

[1] P-sufficient = grouping based on the persistence of perfluoroalkyls and on the formation of perfluoroalkyls as stable end products of precursor polyfluoroalkyls.
[2] PBT = persistent, bioaccumulative, toxic; vPvB = very persistent and very bioaccumulative; PMT = persistent, mobile, and toxic; vPvM = very persistent and very mobile.
[3] Arrowhead = "when a representative PFAS, usually a PFAA, is managed together with its salts and precursors."

California's Department of Toxic Substances (DTSC) regulates PFAS as a class by prohibiting the sale of select consumer products if the product contains any PFAS and an Alternatives Analysis has determined that there are viable replacements. Supported by specific California laws that define environmental persistence and toxicity as hazard traits warranting regulation, the DTSC considers that (1) all PFAS or their degradation, reaction, or metabolic products are environmentally persistent, and (2) "nearly all" PFAS exhibit other hazard traits as defined by California law, including toxicity (**Balan et al. 2021**). PFAS-containing product categories that DTSC has identified for regulation include (1) carpets and rugs with perfluoroalkyl or polyfluoroalkyl substances, (2) treatments containing perfluoroalkyl or polyfluoroalkyl substances for use on converted textiles or leathers, such as carpets, upholstery, clothing, and shoes, and (3) plant fiber–based food packaging containing perfluoroalkyl or polyfluoroalkyl substances (**https://dtsc.ca.gov/scp/**). In August 2022, California's legislature banned the use of any PFAS "intentionally added" to a cosmetic product manufactured, sold, or delivered into the state of California. The text of the legislation cites the "highly toxic" and "highly persistent" "class of chemicals known as PFAS" (**California Assembly 2022**).

The National Academies of Science, Engineering, and Medicine (**NASEM 2022**) developed "strength of evidence" determinations collectively applicable to the seven PFAS currently included in the CDC's National Report on Human Exposure to Environmental Chemicals (**CDC 2022**) for each health effect that they considered, while recognizing that differences exist among these PFAS. Specifically, the **NASEM (2022)** stated: "Most people are exposed to mixtures of PFAS such that specific effects are difficult to disentangle. Considering these issues, and recognizing that some PFAS are infrequently measured, the committee provided one strength-of-evidence determination for all PFAS for each health effect, recognizing that providing one conclusion across PFAS may not account for the distinct physical, chemical, and toxicological properties of each type of PFAS."

The European Chemicals Agency (ECHA) proposed to restrict all per- and polyfluoroalkyl substances with a single regulation (**ECHA 2023**). The proposed regulation cites concerns that "all PFAS" are "very

persistent" in the environment and may adversely affect the health of humans and the environment. **ECHA (2023)** observed that if the proposal is put into effect, it would prevent the release of around 4.4 million tons of PFAS over a 30-year period.

In February 2023, Health Canada proposed to regulate all PFAS in drinking water that can be quantified with U.S. EPA Method 533, Method 537.1, or both. The sum of total detectable PFAS will be required to be no more than 30 ng/L, based on potential health effects from exposure to this group of PFAS in drinking water (**Health Canada 2023**).

7.1.8 PFAS Inhalation Toxicity

This section provides an overview of available information on inhalation exposure and toxicity of PFAS. While exposure to PFAS via inhalation can potentially occur both outdoors and indoors, most of the exposure studies that were identified focused on residential and nonresidential indoor environments. A review by **Savvaides et al. (2021)** reported that, in the available studies, the profile of PFAS detected in indoor air varied in different indoor environments and in different seasons of the year in the same location. The Priority Topics for History, Use, and Naming Conventions include information about less-studied PFAS (see **Section 1.1.3**) including ultrashort PFAS, volatile PFAS, and fluorinated gases. **Section 1.4.4** includes information about health effects of ultrashort PFAS. See also the **PFAS and Vapor Intrusion Fact Sheet** developed in 2025.

In general, inhalation exposure considerations differ for ionized (negatively charged) PFAS [(for example, PFAAs such as PFOA and PFOS, and perfluoroether carboxylates such as HPFO-DA, which have low volatility and occur primarily in indoor (for example, house) dust], as compared to neutral PFAS [(for example, FTOHs, FOSAs, and FOSEs), which are much more volatile and tend to occur in the vapor phase] (**Table 4-1**; **De Silva et al. 2021**). For this reason, the negatively charged and neutral PFAS are discussed in separate sections below. For example, **Shoeib et al. (2011)** and **Ericson Jogsten et al. (2012)** reported that PFAAs and neutral PFAS were both found in residential environments. However, the concentration of neutral PFAS was higher than PFAAs in residential indoor air while the concentration of PFAAs in house dust was higher than neutral PFAS. Furthermore, **Gustafsson et al. (2022)** reported that the total concentration of PFAS and the distribution of specific PFAS varied in different size fractions of house dust. The highest total PFAS concentration was found in the smallest particles, which represent the respirable fraction, while PFCAs were highest in the largest and smallest particles, with lower concentrations in the intermediate-size particles. Information about media-specific occurrence studies is included in **Section 6**.

Some neutral PFAS are "precursors" (i.e., PFAS that can be metabolized or otherwise degraded to form terminally stable PFAAs), so that inhalation exposure to PFAAs may occur both through "direct" and "indirect" pathways. For example, **Gomis et al. (2016)** characterized the contribution of "direct" exposure to PFOA and "indirect" exposure to 8:2 FTOH to the total serum PFOA concentrations in ski waxers exposed to PFAS via inhalation, and **Chang et al. (2017)** reported the metabolism of EtFOSE to PFOS in rats exposed via inhalation.

Although this section does not focus on development of reference concentrations and unit risk factors for inhalation exposure, it is noted that **ECOS (2024)** provides information on inhalation toxicity factors for PFAS that have been developed by some states. In general, inhalation toxicity studies that can be used to develop toxicity factors are not available for PFAS, and these inhalation toxicity factors are based on oral toxicity data and route-to-route (oral-to-inhalation) extrapolation; a recent publication (**Monnot et al. 2022**) supports this approach.

7.1.8.1 Negatively Charged PFAS

As mentioned above, negatively charged PFAS such as PFAAs and perfluoroether carboxylates (for example, HPFO-DA) are not highly volatile. The primary route of occupational exposure to PFAAs is "likely [to be] inhalation of aerosols complexed with airborne dusts," and elevated serum PFAA levels in occupationally exposed individuals indicates that absorption occurs via inhalation (**ATSDR 2021**). A major contributor to inhalation exposure to negatively charged PFAS in the general population is indoor dust containing PFAS that originates from consumer products (for example, treated carpets and furniture) and other potential sources; such dust can also contain neutral PFAS (**Savvaides et al. 2021**). Although exposure to dust can occur through direct ingestion, dust can also be inhaled and then swallowed after being trapped in mucous in the respiratory tract (**USEPA 2017**). Floor-stripping and waxing were also reported as sources of PFAAs in airborne particulate matter ($PM_{2.0}$; **Zhou et al. 2022**).

Depending on the individual chemical, there are limited or no laboratory animal data on the inhalation toxicity of negatively charged PFAS, including those with a large number of oral toxicology studies in laboratory animals. For example, ATSDR and/or USEPA toxicity evaluations cite two acute, one short-term, and one developmental rat inhalation study of PFOA (**ATSDR 2021**; **USEPA, 2016**), and a single acute rat inhalation study for each of three additional PFAS: PFNA **(ATSDR 2021**); PFOS (**USEPA 2016**); and GenX (**USEPA 2021**). In these inhalation studies, exposure was via aerosols or dust. No additional inhalation studies for PFOA or PFOS were identified in more recent draft USEPA evaluations (**USEPA 2023; 2023**), and no inhalation toxicity studies were identified by **ATSDR (2021)** for PFBA, PFHxA, PFHpA, PFDA, PFUnDA, PFDoDA, PFBS, PFHxS, or PFOS, or by USEPA for PFBS (**USEPA 2021**), PFBA (**USEPA 2022**), or PFHxA (**USEPA 2023**).

In toxicokinetic studies, PFOA was detected in the blood serum of rats after inhalation exposure via aerosols (**Hinderliter 2003**; **Hinderliter, DeLorme, and Kennedy 2006**). However, little data are available on extent of absorption for inhalation vs. oral exposure, and an analysis by the Michigan Department of Environmental Quality (**MI DEQ 2018**) of PFOA data from Hinderliter, DeLorme, and Kennedy (**2006**) demonstrated that the relative extent of absorption from inhalation versus oral exposure was not constant over the concentration range in the study. Inhalation exposure to PFOA, PFOS, and PFNA caused systemic effects similar to oral exposure, including hepatic toxicity (**PFOA–Kennedy et al. 1986**; **Staples et al. 1984**; **PFNA–Kinney, Chromey, and Kennedy 1989**; **PFOS–Rusch, Rinehart, and Bozak 1979**) and decreased neonatal body weight after gestational exposure (**Staples et al. 1984**). Nasal and/or eye irritation, and/or respiratory effects, were also reported from acute exposure to relatively high concentrations of PFOA (**Rusch 1979**; **Griffith and Long 1980**; **Kennedy et al. 1986**), PFNA (**Kinney, Chromey, and Kennedy 1989**), PFOS (**Rusch, Rinehart, and Bozak 1979**), and GenX (**DuPont 2009**).

7.1.8.2 Neutral PFAS

Neutral PFAS such as FTOHs, FOSA, and FOSE are more volatile than negatively charged PFAS. They have been found in the vapor phase in indoor environments, including residences, classrooms and offices, outdoor gear/apparel and carpet stores, and ski waxing facilities (**Shoeib et al. 2011**; **Morales-McDevitt 2021**; **Gomis et al. 2016**), and inhalation can be a primary human exposure route (**De Silva et al. 2021**). Furthermore, **Titaley et al. (2022)** reported high concentrations of neutral PFAS in AFFF and predicted that vapor intrusion of these PFAS will occur from AFFF-contaminated groundwater.

The toxicokinetics of 6:2 FTOH and 8:2 FTOH in rats were reported to be similar after inhalation and oral exposure, including systemic absorption and the profile of metabolites formed (**Himmelstein et al. 2012**). As discussed in **Section 17.2.6.2**, metabolites of FTOHs include terminal PFCAs (for example, formation of PFHpA, PFOA, and PFNA from 8:2 FTOH), as well as persistent toxic metabolites in some cases (for example, 5:3 FTA from 6:2 FTOH) (**Kabadi et al. 2020**). Although no inhalation toxicology studies of FTOHs in laboratory animals were identified, the similarity in inhalation and oral toxicokinetics, including metabolite profiles, suggests that systemic toxicity is likely similar from both exposure routes. Similarly,

although no inhalation toxicity studies of FOSA or EtFOSE were identified, FOSA was reported to be metabolized to PFOS in humans believed to be exposed through inhalation (**Olsen et al. 2005**) and EtFOSE was metabolized to PFOS in rats (**Chang et al. 2017**).

7.1.9 Data Gaps and Research Needs

Although many studies relevant to health effects of PFAAs have become available in the last few years, important data gaps remain for most of the PFAAs and PFECAs discussed here and in **Section 17.2**, as well as for many additional PFAS used in commerce or found in AFFF. The data gaps (discussed in more detail in **Section 17.2.9**) include:

- Human half-lives and other toxicokinetic data are not available for some PFAS found in drinking water and other environmental media.
- Currently available data indicate that reactive intermediates may form in the body from the metabolism of PFAA precursors to PFAAs. More studies are needed to understand the toxicologic significance of these intermediates.
- Data on absorption and toxicity of PFAS via dermal contact and inhalation are very limited, and more studies to characterize these exposure routes are needed.
- There are relatively few epidemiological studies of communities exposed to AFFF, PFOS, and/or other PFAS in drinking water. Although a number of studies of associations of PFAS with a variety of health effects have recently been reported for populations exposed to AFFF-contaminated drinking water in Sweden (**Section 17.2.4**), more such studies from other locations are needed.
- Additional toxicology data are needed for some PFAAs found in environmental media, including drinking water. In particular, very little toxicologic data are available for PFHpA, and no information was located for PFPeA.
- There is also a need for additional toxicological studies on the effects of PFAS mixtures in that although humans are exposed to multiple PFAS, information on toxicological interactions of PFAS is limited.
- Multigenerational studies of the reproductive and developmental effects of additional PFAS are needed.
- Chronic toxicity and carcinogenicity studies are currently available for only four PFAS (PFHxA, PFOA, PFOS, GenX), and are needed for PFHxS, PFNA, ADONA, and other PFAS to which humans may be exposed.
- The majority of the many thousands of PFAS, including those in commercial use, have very limited or no toxicity data. This is a critical data gap in health effects information for PFAS.
- Similarly, current NHANES biomonitoring in blood serum includes only 11 PFAS, primarily PFAAs, and breast milk biomonitoring data for these PFAS are limited. There is limited or no biomonitoring data in blood serum or breast milk for many other PFAS produced or used in the United States, some of which are known to be bioaccumulative in humans.
- Information on PFAS in powdered and prepared infant formula are extremely limited. Monitoring data for formula are needed to understand this potentially important source of exposure to infants.

- Little is known about how racial or socioeconomic differences may affect susceptibility to the adverse effects of PFAS exposure. Studies are needed to address this.

7.2 Ecological Toxicology

This section is organized around currently available toxicity information for invertebrates (aquatic/benthic/terrestrial), vertebrates (fish, birds, reptiles/amphibians, mammals), and plants. Toxicological data can be obtained from a general literature review as well as by querying of the USEPA Ecotox Database (**USEPA 2023**). As discussed below, this is an active area of research, and interested readers are encouraged to query the literature for updated research and reviews, such as the Environmental Toxicology and Chemistry Special Issue on Understanding Environmental Risk from Exposure to Per- and Polyfluoroalkyl Substances (PFAS; Vol 40, Issue 3, March 2021 https://setac.onlinelibrary.wiley.com/toc/15528618/2021/40/3); **Argonne 2021**; **Zodrow et al. 2021**; and **Divine et al. 2020**. There are also much data available for PFOS and PFOA toxicity that were used to derive the USEPA's draft Aquatic Life Ambient Water Quality Criteria (**US EPA 2022**).

It is important to note that this section is not intended to represent an exhaustive review of PFAS ecological toxicology (referred to herein as "ecotoxicity") studies. Ecotoxicity of PFAS is an area of active research, with new information emerging regularly. Toxicological effects of apical endpoints presented and discussed herein are generally those considered most relevant to ecological communities—mainly survival, growth, and reproduction. Both acute and chronic exposure studies are discussed in this section. Although data have been generated for other toxicological endpoints, these studies are not the focus of this section, but may occasionally be referenced. Application of these data in ecological risk assessment is discussed in **Section 9.2**. The Priority Topics for Human and Ecological Health Effects include information for evaluating risk to livestock from PFAS exposure (see **Section 1.4.7**). The Priority Topics for Firefighting Foams include information about fluorine-free firefighting foam ecotoxicity (see **Section 1.2.2**).

7.2.1 Introduction

Biomonitoring studies across a variety of organisms, habitats, and geographies show that certain PFAS can accumulate in wildlife and that exposures are occurring on a global scale (**Reiner and Place 2015**; **Giesy and Kannan 2001**[]). Therefore, it is important to understand how PFAS exposure and bioaccumulation may manifest in adverse effects, particularly as these effects relate to ecological communities. Information on bioaccumulation of PFAS is addressed in **Section 6.5**. This section provides an overview of resources available and some published toxicological data relating exposure of PFAS to toxic effects on aquatic, benthic, and terrestrial organisms, with the goal of broadening the reader's understanding of known or potential effects in ecological systems, as well as highlighting areas where more data are needed. This information can also be applied for use in ecological risk assessments (ERAs), particularly because the ecological risk of PFAS is currently neither well understood nor uniformly assessed or regulated. However, the reader is encouraged to review the primary source literature from which cited ecotoxicity values have been derived to confirm and understand the basis and assumptions of the cited literature before using information obtained from this section in an ERA.

This review shows that ecotoxicity data are available for certain PFAS, particularly for PFOA and PFOS, with most studies focused to date on aquatic invertebrates. Although there are numerous studies on PFAS exposure in terrestrial vertebrates (for example, mammals, reptiles, birds), and ample toxicological studies in laboratory animals, there is, overall, relatively little to no ecologically relevant toxicity data for terrestrial vertebrates in the wild (though this is currently being investigated for avian receptors; see SERDP ER22-3202, https://serdp-estcp.org). Although some mechanistic studies have been conducted with aquatic organisms, little has been done with other organisms and even less has been done with different classes of PFAS in aquatic and terrestrial wildlife. However, see research funded under SERDP's

Statement of Need (SON): Improved Understanding of the Ecotoxicity of Mixtures of Per- and Polyfluoroalkyl Substances (ERSON-22-C1) for projects investigating mechanisms of PFAS toxicity and accumulation in aquatic and terrestrial receptors.

The focus of most ecotoxicity studies to date has been primarily on PFOS and PFOA. Therefore, most of the data discussed and summarized in this section are for those two compounds. However, data for other PFAS, including short-chain PFAS and precursors (**Section 2.2**), are also presented where available. Given the historical differences among older analytical methods and more recent advances in analyzing PFAS, the focus of the ecotoxicity studies covered in this review is generally on those published from approximately the year 2000 and later.

In general, single-chemical PFAS exposure studies indicate that the sensitivity of invertebrates to PFAS exposure can be chemical-specific and vary by organism and environmental factors (for example, see **Lewis et al. 2022**). Published studies of the toxicity of PFAS mixtures are available (**Section 17.2.7.2**), but the understanding of PFAS mixtures toxicity remains uncertain at this time. Risk assessment implications of exposure to mixtures are discussed further in **Section 9.2.1.3**. There is a paucity of field studies for avian and mammalian wildlife species, and confounding factors such as the co-occurrence of other stressors (other pollutants, physical stressors, etc.) makes it difficult to definitively associate PFAS exposure with adverse outcomes (**Custer 2021**). There are a handful of avian studies on multiple species that investigate egg hatching outcomes and potential correlations to PFAS exposures (**Custer et al. 2014**; **Groffen et al. 2019**; **Tartu et al. 2014**), and field-based effects studies on mammals are difficult to find (**ECCC 2018**). However, laboratory animal studies (see **Section 7.1**) suggest potential relationships between PFAS tissue concentrations and immunological, hematological, liver, kidney, and reproductive effects (**DeWitt 2015**; **ECCC 2018**).

Data from biomonitoring studies (see **Section 5.5**) indicate that PFAS exposure is occurring in wildlife; however, the lack of toxicity data for this group of organisms represents a significant data gap. This highlights the need for additional study of this class of compounds in general, as well as the need for expansion of toxicity studies to a larger group of PFAS and to a greater variety of taxa, and for field studies that may assess population-level effects.

Relative aquatic toxicity for PFAS is discussed in the following sections using descriptive criteria developed by the USEPA within their Design for the Environment Program for the Alternatives Assessments and the Safer Choice Program (**USEPA 2011**; **USEPA 2015**). These criteria are expressed as relative toxicity based on effects concentrations ranging from less than 0.1 mg/L (very high toxicity) to greater than 100 mg/L (low toxicity); criteria are provided in **Table 7-2**.

Table 7-2. Aquatic toxicity classification criteria (USEPA 2011) (in mg constituent/L water).

Toxicity	Very High	High	Moderate	Low	Very Low
USEPA: Aquatic Toxicity (Acute, LC_{50})	<1.0	1–10	>10–100	>100	NA
USEPA: Aquatic Toxicity (Chronic, LOEC)	<0.1	0.1–1	>1–10	>10	NA

7.2.2 Invertebrates

7.2.2.1 Aquatic

Aquatic invertebrates may be exposed to PFAS by direct contact with PFAS in the water column, as well as via the diet, including trophic transfer and particle ingestion. There are more toxicity data available for PFOS than for other PFAS. PFAS have a very wide range of toxicities to aquatic organisms under acute exposure scenarios following the USEPA Hazard Criteria (**Table 7-2**), but overall, they would be classified as having moderate to low toxicity to invertebrates. One exception with this generalization is that of

mussel exposures to PFOS and PFOA in the marine environment, where no effect was seen at 0.00001 mg/L but a LOEC was reported at 0.0001 mg/L (**Fabbri et al. 2014**); this would result in classification as a very high hazard using the USEPA Hazard Criteria. With the current body of literature, the sensitivity of marine invertebrates to PFOS and PFOA appears equivocal.

Given that PFAS are persistent pollutants, chronic exposure scenarios are most relevant for aquatic receptors. Importantly, compared to acute studies, there are relatively few chronic studies in aquatic invertebrates. Most chronic effects data are for PFOS and PFOA. Life cycle tests with multiple taxa have been conducted to evaluate the chronic toxicity of PFOS to freshwater aquatic invertebrates. The chironomid (*Chironomus tentans*) is currently reported as having the greatest sensitivity to chronic exposure, with reduced total emergence reported at 0.0023 mg PFOS/L (**MacDonald et al. 2004**). More recent studies, including **McCarthy et al. (2021)**, show impairment on survival in the chironomid (*C. dilutus*) at even lower concentrations, with EC10 and EC20 values in 20-day tests for PFOS at 1.4 and 1.7 ug/L, respectively. Studies by **Bots et al. (2010)** and **Van Gossum et al. (2009)** indicated that damselflies (*Enallagma cyathigerum*) may also be similarly sensitive to PFOS, with NOEC and LOEC values of 0.01 and 0.1 mg/L, respectively. In the marine environment, a life cycle toxicity test with the saltwater mysid (Mysidopsis bahia) yielded a NOEC of 0.24 mg PFOS/L based on growth and number of young produced (**Drottar and Krueger 2000**).

Some PFAS may potentially cause adverse effects in aquatic invertebrates that span across multiple generations. **Marziali et al. (2019)** evaluated generational effects in chironomids (*C. riparius*); each generation was exposed to a nominal concentration of 0.01 mg/L of PFOA, PFOS, and PFBS; all treatments showed reduced growth in at least several generations, with no observed induced tolerance to the studied PFAS. However, potential effects at the population level were not demonstrated in this study based on similar population growth rates between treatments and controls, suggesting that toxicity risk to an ecosystem is unlikely (**Marziali et al. 2019**).

Benthic Organisms and Sediment Toxicity

Toxicity to benthic (sediment-dwelling) organisms is generally the result of exposure to the chemical in overlying water, sediment, and porewater, including trophic transfer and sediment particle ingestion (**Zareitalabad et al. 2013**). There are relatively few published sediment toxicity studies on PFAS exposure to benthic invertebrates compared to those for aquatic invertebrates. The **UK Environment Agency (2004)** provided a freshwater sediment screening value of 0.0067 mg/kg (wet weight), based upon a predicted no-effect concentration (PNEC) of 2.5 µg/L and a river sediment K_d of 8.7 L/kg. Note, however, that sediment screening values based on K_d may not be applicable across all sites. **Section 9.2** (Ecological Risk Assessment) discusses application of K_d in deriving sediment screening values.

Additionally, **Bakke et al. (2010)** provided PFOS concentration ranges for marine sediment quality classified as background, good, moderate, bad, and very bad. The PFOS threshold for “good” sediment, for which no toxic effects are expected, was reported as 0.22 mg/kg. This value, however, is based on an aquatic PNEC of 72 µg/L derived from a limited data set and an unspecified Kd value, and thus is not a reliable concentration with which to predict toxic effects. More recently, **Simpson et al. (2021)** conducted a multimedia acute and chronic study on a variety of marine/estuarine invertebrates (including an amphipod, a copepod, a crab, and two species of bivalve) that included PFOS-spiked sediment toxicity tests. **Simpson et al. (2021)** found that PFOS significantly decreased survival and/or reproduction for the amphipod (Melita plumulosa) at sediment concentrations of 29 mg/kg or greater. Although they did not identify a relationship between toxicity and PFOS concentrations in sediment, they observed a strong relationship among toxicity, organic carbon content of sediments, and dissolved PFOS concentrations in the overlying water of the test vessel. These results suggested that the dissolved fraction of PFOS in water is likely a key contributor to sediment toxicity. Based on sediment concentrations normalized to 1% organic carbon (1%OC), the authors derived an LC10 of 132 mg/kg (1%OC) and LC50 of 150 mg/kg (1%OC) for PFOS, and EC10, EC20, and EC50 of 21, 35, and 89 mg/kg (1%OC), respectively, for

reproductive effects (**Simpson et al. 2021**). The focus of **Simpson et al. (2021)** was on the amphipod, but this publication also provided data for additional marine species. The authors also developed sediment thresholds using Kd and species sensitivity distributions from water exposures.

Laboratory-controlled freshwater and marine sediment toxicity tests for PFAS are sparse. With so few studies available and with variability in test organisms and testing methods, it is difficult to define PFAS toxicity thresholds for benthic organisms or to determine if benthic organisms are similarly sensitive to PFAS compared to other aquatic invertebrates. However, benthic organism toxicity thresholds do not need to be limited to just invertebrates, as shown by **Simpson et al. (2021)**, who developed PFOS thresholds from a species sensitivity distribution (SSD) generated from published data on other types of species using a K_d approach.

7.2.2.2 Terrestrial Invertebrates

Compared to aquatic invertebrates, there are fewer studies on the effects of PFAS on terrestrial invertebrates (i.e., invertebrates living in terrestrial habitats). **Brignole et al. (2003)**, whose study was summarized in **Beach et al. (2006)**, summarized results of acute oral and dermal studies of PFOS conducted on the honeybee (*Apis melifera*), although the dose was reported in terms of mass of PFOS per bee, which may not be relevant for evaluating ecological risks. However, these studies, when converted to a dose per kilogram of food (2 mg PFOS per kg sugar solution), suggested that PFOS was "highly toxic" to honeybees, as defined by the International Commission for Bee Botany. **Mommaerts et al. (2011)** identified in a chronic oral dosing study on the bumblebee (*Bombus terrestris*) an LC50 of 1.01 mg PFOS/L sugar water and noted that PFOS exposure caused detrimental reproductive effects (decreased ovarian size).

Effects on fecundity from exposure to various PFAS have been shown to carry down through multiple generations in the roundworm (*Caenorhabditis elegans)*. **Tominaga et al. (2004)** conducted a multigenerational study in *C. elegans* exposed to PFOA, PFOS, and PFNA, finding that concentrations orders of magnitude lower than those causing lethality decreased worm abundance, and that effects were observed even in the fourth generation. Other studies have evaluated the mechanisms of PFAS toxicity. **Xu et al. (2013)** indicated that exposure to PFOS induced oxidative stress and DNA damage in the earthworm, *Eisenia fetida*. **Stylianou et al. (2019)** evaluated food chain transfer of PFOS-treated *Escherichia coli* to *C. elegans* and noted distinct gene expression profiles associated with development, innate immunity, and stress response.

With regard to soil invertebrate toxicity testing, studies (while few in number) suggest a low to moderate toxicity of PFOS and PFOA, with toxicity generally occurring on a parts per million scale. These studies have mainly focused on the earthworm *Eisenia fetida*. **Sindermann et al. (2002)** conducted a 14-day chronic soil study on *E. fetida* with PFOS and identified a NOEC of 77 mg PFOS/kg soil, a LOEC of 141 mg/kg, and an LD50 of 373 mg/kg. Other chronic earthworm studies indicated toxic concentrations of a similar magnitude, with LC50s ranging from 84 mg/kg–447 mg/kg (**Mayilswami et al. 2014**; **Zareitalabad et al. 2013**). The Norwegian Pollution Control Authority **NPCA (2006)**, as reported in **Danish Ministry of the Environment (2015)**, conducted acute soil toxicity tests in *E. fetida*, looking at reproductive endpoints for PFOA, PFOS, and the short-chain 6:2 fluorotelomer sulfonate (6:2 FTS). Results of this study indicated that, overall, the evaluated PFAS exhibited a moderate-high toxicity. Reproductive effects (decreased number of cocoons, decreased hatchability, and decreased number and weight of juveniles) for PFOS and PFOA were noted. 6:2 FTS toxicity was found to be less than that for either PFOS or PFOA in the same study. **Karnjanapiboonwong et al. (2018)** conducted a 21-day soil study with *E. fetida* on bioaccumulation, mortality, and weight loss with PFBS, PFHxS, PFNA, and PFHpA and generally observed no effects at soil concentrations below 100 mg/kg in comparison with the controls. Importantly, the authors report tissue concentrations following exposures to PFBS, PFHxS, PFNA and PFHpA thus indicating potential for trophic transfer from soil to higher level organisms (**Karnjanapiboonwong et al. 2018**).

The limited amount of terrestrial invertebrate data presents a data gap; additional toxicity studies are needed to better characterize ecotoxicological effects in this group of organisms. Additionally, it will be important to understand how field/soil conditions (for example, organic carbon content, pH, etc.) may influence toxicity. For example, **Princz et al. (2018)** found that PFOS toxicity for two different species of soil invertebrates was approximately two to four times greater when organisms were tested on sandy loam versus clay loam soils.

7.2.3 Vertebrates

The following sections describe available toxicity data for vertebrate species, including fish, amphibians/reptiles, birds, and mammalian wildlife.

7.2.3.1 Fish

Acute freshwater LC50 values based on survival for PFOS range from 7.8 to 22 mg/L for Rainbow trout (*Oncorhynchus mykiss*), to 9.1 mg/L for fathead minnow (*Pimephales promelas*) (**Robertson 1986**; **Palmer, Van Hoven and Krueger 2002**).

There are relatively few chronic PFOS studies in fish, but (**Drottar and Krueger (2000)**) calculated a chronic NOAEL based on early life stage mortality in Pimephales promelas to be 0.29 mg/L. **Palmer, Van Hoven and Krueger (2002)** also calculated an acute NOAEL of 6.3 mg/L for *Oncorhynchus mykiss*. Saltwater acute values based on survival for *Oncorhynchus mykiss* were calculated to be 13.7 mg/L.

Other than PFOS, there are limited aquatic ecotoxicity data for other PFAS. Within the summary data presented here, acute exposure durations were for 6 days. One study was noted that investigated the chronic toxicity of PFNA following a 180-day exposure; the LOEC ranged from 0.01-1 mg/L depending on the endpoint (**Zheng et al. 2011**).

7.2.3.2 Amphibians/Reptiles

There are relatively limited toxicity data available for PFAS effects on amphibians, including several studies on various species of frogs; no studies on reptiles were found in the literature search. The data available for PFOS and PFOA show a wide range of effects-based concentrations. The Priority Topics for Human and Ecological Health Effects include information about reptiles toxicity data (see **Section 1.4.8**).

More amphibian data are available for PFOS in comparison to other PFAS, and indicate mortality generally tends to occur at levels of 10 mg/L or higher, whereas nonlethal effects (for example, growth; EC10) may occur at approximately 1–2 mg/L (that is, moderate to high toxicity) or lower (**Ankley et al. 2004**; **Yang et al. 2014**; **Fort et al. 2019**). However, more recent studies suggest chronic toxicity may occur at levels lower than 1 mg/L. Flynn et al. (**2019**), for example, found a 72-day LOEC in the American bullfrog (*Lithobates catesbeiana*) of 0.29 mg/L based on developmental effects (reduction in snout vent length).

Ankley et al. (2004) conducted a 5-week study on PFOS toxicity in the northern leopard frog (*Rana pipiens*) and observed that LC50s decreased with increasing test duration time; LC50s ranged from 12.5 mg/L at 1 week to 6.2 mg/L at 5 weeks. This study also anecdotally noted the presence of kinked tails, as well as a delayed time to initial metamorphosis and differences in limb bud and foot paddle emergence in the 1, 3, and 10 mg/L groups. A PFOS study, based on a 3M study reported in **OECD (2002)** on another frog species, African clawed frog (*Xenopus laevis*), suggested toxicity at concentrations of similar magnitude to those observed in the Ankley study, and identified inhibition of growth and malformation during development.

PFAS exposure has also been shown to affect the thyroid, and hence development, in amphibians (for example, **Cheng et al. 2011**; **Flynn et al. 2022**). A study by **Cheng et al. (2011)** that exposed African clawed frog (*X. laevis*) tadpoles to PFOS at concentrations ranging from 0.1 to 100 ug/L in water found up-regulation of several thyroid hormone–regulated genes, suggesting possible thyroid disruption. **Flynn et al. (2022)** conducted a chronic study that evaluated sublethal developmental effects on *R. pipiens*, the American toad (*Anaxyrus americanus*), and the eastern tiger salamander (*Ambystoma tigrinum*), following exposure up to 30 days to 10, 100, and 1,000 ug/L of PFOS, PFOA, PFHxS, and 6:2 FTS). They found a LOEC of 10 ug/L based on reduced body mass for all four PFAS in anurans, and PFOA, PFHxS, and 6:2 FTS in the salamander.

Amphibian studies suggest that PFOS may be less toxic than certain other PFAS (**Yang et al. 2014** and **Abercrombie et al. 2021**) **Brown, Flynn, and Hoverman (2021)** found increased trematode infection in the northern leopard frog resulting from exposure to 0.01 mg/L PFHxS, whereas no effect was observed for PFOS (however, no such effect was noted in the higher PFHxS treatment dose of 0.1 mg/L; the authors postulated that this could potentially be due to adverse effects of PFHxS to the trematode itself). **Pandelides et al. (2023)** recommended a chronic NOEC and LOEC for PFOA of 0.1 mg/L and 1.4 mg/L, respectively based on growth (body mass) for the northern leopard frog, and a chronic NOEC and LOEC for PFOS of 0.6 mg/L and 1.1 mg/L, respectively, based on the median time to complete metamorphosis in the western clawed frog.

Many of the older amphibian studies focused on early life aquatic exposures. More recent studies suggest that amphibians may be even more sensitive to PFAS if one looks at later life stages; nonlethal effects other than survival; growth and reproduction; terrestrial exposure routes; or multiple exposure media. **Abercrombie et al. (2021)** indicated LOECs ranging from 0.05-0.12 mg/L for a toad, frog, and salamander exposed to PFOS, PFOA, or PFHxS in a soil substrate. **Flynn et al. (2021)** found enhanced PFOS and PFOA toxicity in a spiked sediment outdoor mesocosm study, suggesting that evaluating only aquatic exposures may underestimate toxicity from exposure to PFAS in multiple media, which is more representative of actual field conditions.

7.2.3.3 Birds

There are currently a limited number of published laboratory studies available that address PFAS toxicity in avian wildlife species (**Newsted et al. 2006**; **Newsted et al. 2005**; **Newsted et al. 2007**; **Newsted et al. 2008**; **Dennis et al. 2020**; **Bursian et al. 2021**). The northern bobwhite quail (*Colinus virginianus*) and the mallard duck (*Anas platyrhynchos*) were exposed to PFOS (**Newsted et al. 2005**; **Newsted et al. 2006**; **Newsted et al. 2007**) or PFBS (**Newsted et al. 2008**) via the diet. The LD50s reported following acute exposure to PFOS are 61 mg/kg-bw/d and 150 mg/kg-bw/d for the northern bobwhite quail and the mallard, respectively (**Newsted et al. 2006**). In a separate chronic dietary study, **Newsted et al. (2007)** found that a feed concentration of 10 mg PFOS/kg resulted in an average daily intake (ADI) LOAEL of 0.77 mg/kg-bw/d based on increased liver weight in female quail. A feed concentration rate of 50 mg/kg resulted in an ADI LOAEL of 6.4 mg/kg-bw/d based on lethality in mallards (**Newsted et al. 2007**).

More recent avian studies on the northern bobwhite (**Dennis et al. 2020**) and Japanese quail (*Coturnix japonica*) (**Bursian et al. 2021**) evaluated dietary effects of PFOS, PFOA, PFHxS, and the AFFF formulations from 3M and Ansul. **Bursian et al. (2021)** estimated average daily doses causing 50% mortality (ADD50) at 5 days' exposure ranging from 38 mg/kg-d for PFOS (≥98% chemical grade) to 130 mg/kg-d for PFOS in feed spiked with 3M AFFF, which is a product formulation that is a mixture of fluorinated and other compounds (LC50 of 351–467 mg/kg of feed, respectively). More information about AFFF is included in **Section 3**. This subacute study also evaluated effects resulting from a mixture of PFOS and PFOA; the authors suggested that these results showed potential additive effects, and a relative potency of PFOA approximately half that of PFOS (**Bursian et al. 2021**). **Dennis et al. (2020)** evaluated chronic toxicity associated with PFOS and a mixture of PFOS and PFHxS in drinking water on the northern bobwhite quail. Reduced body weight in females and impaired hatching success were

observed at doses lower than those used in the Newsted study (**Newsted et al. 2007**), deriving a chronic toxic dose of 0.0031 mg PFOS+ PFHxS/kg-bw/d and 0.00245 mg PFOS/kg-bw/d, respective to the previously mentioned endpoints.

Some egg injection studies suggest exposure to PFOS may adversely affect chick development during incubation. For example, **Molina et al. (2006)** found that eggs injected with varying doses of PFOS had a lower rate of hatching success and had noted pathological changes in the liver in the leghorn chicken. However, there is some concern regarding the use of these data in risk assessments due to issues related to the method of exposure and other methodological issues that can influence the outcomes of the studies. Although these studies are useful for evaluating mechanisms and creating structure-activity relationships, they may not be appropriate for direct application in risk assessments.

Quail and mallard appear less sensitive to PFBS relative to PFOS. Acute dietary exposure to PFBS resulted in NOAELs of 3,160 and 5,620 mg PFBS/kg-feed for the northern bobwhite quail and mallard, respectively, for the lethal endpoint; these feed concentrations are equivalent to an ADI of 774 mg/kg-bw/d in quail and 2,190 mg/kg-bw/d in mallards (**Newsted et al. 2008**). A NOAEC for northern bobwhite quail reproduction following chronic dietary exposure to PFBS was reported at 900 mg/kg-feed, equivalent to an ADI of 87.8 mg/kg-bw/d (**Newsted et al. 2008**).

Although there are few PFAS laboratory toxicity studies for birds, there are even fewer effect-based field studies. **Custer et al. (2012)** and **Custer et al. (2014)** evaluated PFOS exposure in tree swallows (*Tachycineta bicolor*), identifying a negative association between PFOS concentration in eggs (~150 ng/g-ww) and hatching success. One issue with the findings as suggested by the authors is that the greatest observed effects on hatching were typically found in areas that likely have co-contamination issues (PCBs, PAHs, mercury); however, the influence of these other contaminants is still not clear. This issue of effects from co-contaminants came to light when **Custer et al. (2019)** conducted a field study evaluating the effects of PFAS on tree swallows in a more isolated area with known PFAS impacts (Clark's Marsh near the former Wurtsmith Air Force Base, MI); other potential contaminants were at or below regional anthropogenic background levels. This study resulted in mean PFOS egg concentrations of 662 ng/g-ww, and overall hatching success was not impacted. **Groffen et al. (2019)** conducted a field study in great tits (*Parus major*) near a former fluorochemical plant. They reported median egg concentrations of 48,056 ng/g-ww for PFOS, 18 ng/g-ww for PFOA, and 315 ng/g-ww for PFDS. The authors concluded that reduced hatching success in the birds was associated with a mixture of PFAS (PFOS, PFDS, PFDoDA, PFTrDA, and PFTeDA) (**Groffen et al. 2019**). Taken together, a linear relationship between PFAS exposure and potential effects in avian species remains uncertain; this highlights the importance of considering co-exposure of common environmental contaminants and PFAS mixtures when reviewing field studies.

Lastly, indirect effects, such as reduction in a local food source resulting from a PFAS release, may potentially affect bird populations. **de Vries et al. (2017)**, for example, found a decline in abundance of flamingos following a release of fire-fighting foams containing PFOS and other PFAS to a salt lake; the authors postulated that this decline was potentially related to a reduction in prey item abundance due to PFOS toxicity.

7.2.3.4 Mammalian Wildlife

PFAS exposure to wildlife is occurring on a global scale and across a variety of habitats (**Reiner and Place 2015**; **Giesy and Kannan, 2001**). Wildlife may accumulate PFAS from direct exposure to air, dust, water, soil, and sediments, as well as through diet. Maternal transfer of PFAS is also a relevant exposure route, as these compounds have been shown to cross the placenta (**Gronnestad et al. 2017**; **Houde et al. 2006**). PFAS have also been shown to biomagnify, so higher trophic level predators have higher PFAS levels in tissues compared with prey items (**Reiner and Place 2015**). Of the PFAS analyzed in wildlife exposure studies, PFOS is the one most frequently detected, and at the highest concentrations, in tissue

samples (**Reiner and Place 2015**). Concentrations in tissue have also been observed to vary with age, sex, and species (**DeSilva et al. 2021**).

Given the widespread occurrence of PFAS in wildlife, it is important to understand if such exposure manifests in adverse effects and ultimately how exposure may impact wildlife populations. Laboratory animal models show that, in general, PFAS are readily absorbed and distributed among protein-rich tissues (liver, serum, kidney) in mammals, and that certain PFAS (particularly long-chain compounds) have a relatively long half-life in the body. Toxicity tests on laboratory mammals (mice, etc.) have shown that exposure to PFAS may result in adverse effects on the hepatic, endocrine, and immune systems; development; and certain types of cancers, as discussed in **Section 7.1.4**.

Based on the findings from mammalian toxicity studies in laboratory animals, one might expect to find similar effects in mammalian wildlife (at similar exposure levels). Laboratory studies focusing on growth, reproduction, and survival effects on laboratory mammals provide data to support the development of toxicity reference values for use in ERA of wildlife species. NOAELs and LOAELs can be derived from these studies for use in ERA (as further discussed in **Section 9.2**, Ecological Risk Assessment), but these values should be used with caution and understanding of their associated uncertainty. Many of these studies may have also included other endpoints, such as systemic or metabolic endpoints, that are not typically used for ERA and may demonstrate effects at lower doses than the growth, reproduction, and survival effects.

Although there are numerous studies evaluating toxicity of PFAS in laboratory animals (as discussed in **Section 7.1.4**), and there are numerous exposure studies in mammalian wildlife, very few studies have evaluated PFAS toxicity with respect to wildlife exposures. The studies that have been conducted typically evaluated relationships between the concentrations of a small number of PFAS in various protein-rich biological media (for example, blood serum, liver) and expression of select biomarkers. One study on sea otters related concentrations of PFOA and PFOS in liver tissue to health condition and possible immune effects (**Kannan, Perotta and Thomas 2006**). **Table 7-3** summarizes these studies.

Table 7-3. Summary of PFAS toxicity studies in mammalian wildlife.

Species	Summary of Findings	Reference
Sea otter *Enhydra lutris*	Higher PFOS/PFOA concentrations in liver samples found in diseased otters versus nondiseased group	**Kannan, Perrotta and Thomas 2006**
Bottlenose dolphin *Tursiops truncatus*	Significant positive associations between serum total PFAS concentrations and multiple immunological, hematopoietic, renal, and hepatic function endpoints	**Fair et al. 2013**
Wood mouse *Apodemus sylvaticus*	Significant positive relationship between liver PFOS concentration and hepatic endpoints (relative liver weight, microsomal lipid peroxidation level); significant negative association with serum alanine aminotransferase (ALT) activity	**Hoff et al. 2004**
Wild pig *Sus scrofa*	No significant correlation between PFAS liver concentrations and multiple blood, hepatic, and immunological endpoints, whereas significant correlations were observed for other pollutants (for example, dioxin-like compounds, PCBs, organohaline pesticides)	**Watanabe et al. 2010**

It is important to note that while certain associations have been observed between PFAS concentrations and various immunological, hematopoietic, renal, and hepatic function biomarkers, these associations are not necessarily indicative of actual impairment to an individual organism or within a larger population.

Perhaps one of the biggest challenges with wildlife toxicity studies is that wildlife are exposed to multiple chemical, biological, and physical stressors, making it difficult to determine whether noted effects are directly related to PFAS, to other stressors, or to a combination of stressors. The accumulation of other types of POPs, such as PCBs, dioxins, and pesticides, and metals such as mercury, in wildlife has been well established and, in some studies, correlated body burden to adverse effects. Arctic mammal studies have reported relationships between organohalogen exposure and endocrine disruption, reduced immune function, and adverse effects on the liver and other organs (**Letcher et al. 2010**). Numerous nonchemical environmental factors such as climate change, habitat loss, and seasonal availability of food may also confound toxicity studies, making it difficult for field studies to discriminate those effects related solely to PFAS. As an example, **Watanabe et al. (2010)** found no association between PFAS levels and a variety of biomarkers in wild pigs, whereas the study found significant positive associations between these parameters and other types of contaminants (for example, PCBs) that were also detected in liver tissue samples.

Currently, there are few data points available for mammalian wildlife, and the current literature focuses on bioaccumulation and specific endpoints that may not be ecologically relevant, as discussed above. Additionally, bioaccumulation studies have traditionally focused on protein-rich tissues such as liver or blood serum because PFAS preferentially bind to proteins; because PFAS could also be present in other tissues, focus on only a subset of tissues can potentially underestimate the total body burden of PFAS. Thus, exposure cannot be fully characterized from these studies, and pinpointing correlations between target organ or whole-body effects and PFAS exposure is not possible at this point in time. A better understanding of mammalian exposures to the broad spectrum of PFAS, precursor compounds, and mixtures of PFAS, as well as other environmental contaminants, is critical in advancing this field of study. Given the challenges with conducting field studies, this information could be obtained in part through more robust dosing studies in mammals that are representative of various wildlife taxa, and on toxicological endpoints that are directly relevant to population-based effects; however, more field studies are also needed to confirm laboratory models. Groups such as the U.S. Department of Defense's Strategic Environmental Research and Development Program (SERDP) and the Environmental Security Technology Certification Program (ESTCP) have recently identified such critical data needs (**SERDP-ESTCP 2017**).

7.2.4 Plants

The following sections describe available toxicity data for aquatic and terrestrial plants.

7.2.4.1 Aquatic Plants

Data on the toxic effects of PFAS on aquatic plants are limited, with available studies focusing on PFOS included in USEPA Ecotox Database (**USEPA 2023**). The acute toxicity (EC50s) of PFOS to aquatic plants (such as *Selanastrum* and *Lemna* species) generally ranges from roughly 31 to 108 parts per million (mg/L), with NOEC values from the same studies being approximately 7–30 mg/L; (**Boudreau et al. 2003**; **Sutherland and Krueger 2001**; **Drottar and Krueger 2000**). Chronic effects (EC50s) were found to be similar to acute values, but varied over a wide range, depending on species and endpoint (2–305 mg/L), with NOECs from the same studies ranging from 0.3 to 11.4 mg/L (**Hanson et al. 2005**; **Boudreau et al. 2003**; **Desjardins et al. 2001**, **Desjardins et al. 2001**; **Desjardins et al. 2001**).

7.2.4.2 Terrestrial Plants

There are limited PFAS toxicity data for terrestrial plants; a review of the literature yielded only a few soil phytotoxicity studies. **Brignole et al. (2003)** evaluated PFOS exposure (21 days) on a variety of crop plants (alfalfa, onion, ryegrass, soybean, tomato, flax, and lettuce) using emergence, survival, and shoot height and weight as endpoints, and demonstrated effects occurring at concentrations ranging from 57 mg/kg to over 1,000 mg/kg. Other studies (**Li 2009**; **Zhao et al. (2011)**) conducted on both PFOS and

PFOA on multiple crop plants found a wide range of toxicity among species and also observed a range of toxicity within species (specifically, *Brassica rapa chinensis*). The most sensitive species may be *Triticum aestivum* where the 30-day NOEC reported was 1 mg/kg (**Zhao et al. 2014**). Toxicity may also be moderated by soil characteristics; for example, **Zhao et al. (2011)** showed that the amount of organic matter in soil significantly influenced toxicity, where higher organic carbon content decreased both accumulation of PFOA and PFOS and phytotoxicity. Additionally, PFAS chain length may affect uptake of PFAS into plant tissue; see **Section 5.6** for further discussion.

7.2.5 Uncertainties and Conclusions

This section presented ecotoxicological information with the intent of providing the reader with an overview of the types of organisms and ecotoxicity studies available for PFAS in the current literature (as of 2023). This section also presented available information about the ranges of concentrations of PFAS (notably, PFOS) in soil, sediment, and water that have been associated with adverse effects. In summary, ecotoxicity studies demonstrate a wide range of effects concentrations across the various terrestrial and aquatic biota. In general, aquatic invertebrates appear to be more sensitive to PFOS and other PFAS than their terrestrial counterparts. Differences in species sensitivities, analytical methods, environmental substrate, test conditions, and reproducibility of results make it difficult to generalize overall effects, and some species may be more or less sensitive than others.

Although there are numerous studies on the toxicity of select PFAS to aquatic invertebrates, these studies are generally limited to a very small number of PFAS (typically PFOS, and to a lesser extent, PFOA). Because PFAS represent a broad spectrum of compounds, it is important to expand ecotoxicity studies to evaluate additional PFAS, including short-chain and precursor compounds, as well as "next generation" replacement compounds. Recently, **Jones et al. (2022)** published a compilation of acute aquatic toxicity following exposures to "next-generation" foams and one reference foam (short-chain PFAS AFFF). Of the 14 species tested, the short-chain PFAS AFFF was least toxic in comparison to the next-generation foams in 11 taxa following acute exposure. In cross-species comparison for the short-chain PFAS AFFF lethality data, the mud snail (*T. obsoleta*) and the freshwater amphipod (*H. azteca*) were the most sensitive, and a variety of amphibian species were the least sensitive (**Jones et al. 2022**). More data are anticipated from these authors on chronic exposures to a subset of these species with projects funded under the SERDP Statement of Need ERSON-20-A1, which is aimed at quantifying the potential ecotoxicity of fluorine-free surfactant foam formulations (www.serdp-estcp.org). Other studies show that some of the short-chain replacements, such as GenX, are more toxic than PFOS-based foam formulations (**Conley et al. 2022**).

Importantly, the available studies on foam formulations and individual PFAS exposures indicate a wide range of effects levels for PFAS in aquatic invertebrates, suggesting a level of complexity that has not yet been adequately assessed.

Significantly fewer toxicity studies are available for other groups of aquatic or benthic organisms, and few to no studies are available for avian or mammalian wildlife or plants, presenting a significant gap in our understanding of how the widespread presence of PFAS in the environment may be affecting ecological communities. Additional (or any) data on toxicological endpoints most relevant to community-level effects, such as survival, growth, and reproduction, will be extremely beneficial in understanding potential ecological impacts.

8 BASIS OF REGULATIONS

This section describes various federal and state regulatory programs that apply to PFAS. Because state regulations for PFAS in environmental media are changing rapidly, only a few state regulations are summarized in this section, as examples. A **PFAS Regulatory Programs Summary** Excel file has been developed and is available as an Excel file. ITRC also maintains updated the PFAS **Environmental Media Values Table** Excel file that includes information on state, federal, and some international countries. This section includes a brief explanation of examples of various health effects and how they are used in the development of regulations and advisories.

Section Number	Topic
8.1	**Introduction**
8.2	**Regulatory Programs**
8.3	**Differences in the Available Regulations, Advisories, and Guidance**

8.1 Introduction

PFAS became contaminants of emerging concern in the early 2000s. In recent years federal, state, and international authorities have established a number of health-based regulatory values and evaluation criteria. As with the case for most emerging contaminants, the regulatory process dealing with PFAS is in various stages of development, and the values and criteria being established vary between individual states, the U.S. government, and international agencies. This section describes examples of various federal and state regulatory programs and includes links to tables that provide established PFAS health-based criteria.

The terms “regulatory” or “regulation” are used in this document to refer to requirements that have gone through a formal process to be promulgated and legally enforceable as identified under local, state, federal, or international programs. The terms “guidance” and “advisory” apply to all other policies and numerical values.

8.2 Regulatory Programs

8.2.1 Background to Regulation of PFAS

The scientific community is rapidly recognizing and evolving its understanding of PFAS in the environment, causing an increased pace of development of guidance values and regulations. the PFAS **Environmental Media Values Table** Excel file has been developed and is available as an Excel file. Human health protection is the primary focus of the PFAS regulations, guidance, and advisories developed to date. Regulations and guidance have focused on the PFAAs, precursor compounds, and FECAs. Like many other emerging contaminants, the regulatory and guidance values for PFAS can vary across programs, with differences due to the selection and interpretation of different key toxicity studies, choice of uncertainty factors, and approaches used for animal-to-human extrapolation. The choice of exposure assumptions, including the life stage and the percentage of exposure assumed to come from non-drinking water sources, may also differ. Thus, both differences in scientific conclusions and public health policy choices affect the myriad of regulatory and guidance initiatives for PFAS. More information is included in **Section 8.3**.

In addition to values that specify health-based concentration limits, agencies have used various strategies to limit the use and release of PFAS. For example, the USEPA worked with the eight primary U.S. PFAS manufacturers and processors to eliminate PFOA and many PFOA precursors and higher

homologues by 2015 (**USEPA 2017**). Additionally, the Organisation for Economic Co-operation and Development **OECD (2015)** has described various international policies, voluntary initiatives, biomonitoring, and environmental monitoring programs to control PFAS. More information regarding the history of these developments is in **Section 2.4**.

Authority for regulating PFAS in the United States is derived from a number of federal and state statutes, regulations, and policy initiatives. This section provides a brief overview of the major federal statutes and regulatory programs that govern PFAS.

8.2.2 Federal PFAS Regulations

Within the United States, currently both the USEPA and the FDA have regulatory or guidance initiatives for PFAS. The USEPA has the authority to regulate PFAS under several different statutes as outlined below. To date, USEPA has not yet finalized listing PFAS as hazardous wastes or substances under its available statutory authorities, including the Resource Conservation and Recovery Act (RCRA), Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), Emergency Planning and Community Right-to-Know Act, or the Clean Air Act. USEPA has also not yet finalized regulations for any PFAS under the Safe Drinking Water Act. However, USEPA has now proposed listing PFOS and PFOA as CERCLA hazardous substances (**Section 8.2.2.6**) and has proposed draft primary drinking water regulations for a number of PFAS (**Section 8.2.2.4**). The Key Actions to Address PFAS website includes more detailed information about the actions of some of these programs (**USEPA 2023**). Key Actions to Address PFAS website includes more detailed information about the actions of some of these programs.

Through the Office of Regulatory Affairs, the Office of Management and Budget maintains a list of regulatory actions which have been initiated by the USEPA and certain other federal agencies. That list is updated periodically to give the status of the regulations and is available at **https://www.reginfo.gov/public/Forward?SearchTarget=RegReview&textfield=PFAS**.

8.2.2.1 National Defense Authorization Act (NDAA)

Through the NDAA, which is enacted early each year, Congress mandates many actions that the Department of Defense (DOD) must comply with, some of them concerning PFAS. At times, separate PFAS-related requirements for the USEPA or other federal entities are also made. Although these activities are not regulatory or guidance in nature, they are important in advancing human health exposure studies of PFAS, remediation of PFAS-contaminated water, development of new technologies to reduce PFAS exposure, interagency collaboration on PFAS, and other PFAS-related actions at the federal level.

The **Regulatory Programs Summary** Excel file lists by responsible agency the PFAS actions enacted through each NDAA. The NDAA for 2018 was the first one to have a PFAS requirement mandating the Centers for Disease Control and Prevention (CDC) and the Agency for Toxic Substances and Disease Registry (ATSDR) to study PFAS exposure and health implications in communities near current or former military bases and known to have had PFAS in their drinking water, groundwater, or other sources of water. Subsequent NDAAs have had increasing numbers of PFAS-related requirements, as listed on the **PFAS Regulatory Programs Summary** Excel file.

8.2.2.2 USEPA PFAS Action Plan

USEPA issued a PFAS Action Plan (**USEPA 2019**) in February 2019 and an update a year later (**USEPA 2020**). The plan included a discussion about the process for moving forward to establish PFOA and PFOS MCLs for drinking water, and it included a number of main actions that encompassed more than just safe drinking water issues. More information about USEPA's previous actions to address PFAS is available on their website (**USEPA 2021**). The USEPA (2021) document was superseded by the strategic roadmap described below.

8.2.2.3 USEPA Strategic Roadmap

In October 2021, the USEPA published the *PFAS Strategic Roadmap: EPA's Commitments to Action 2021–2024* (**USEPA 2021**). The USEPA's stated goals for addressing PFAS are focusing on research, restriction, and remediation. The strategic roadmap includes actions across the different divisions of USEPA. More information about USEPA's actions to address PFAS under this roadmap is available on their website (**https://www.epa.gov/pfas**), and in a November 2022 progress report (**USEPA 2022**).

8.2.2.4 Safe Drinking Water Act (SDWA)

The SDWA is the federal law that protects public drinking water supplies throughout the nation (**USEPA 1974**). Under the SDWA, the USEPA has authority to set enforceable National Primary Drinking Water Regulations, such as MCLs, for specific chemicals and to require testing of public water supplies. The SDWA applies to all public water systems (PWSs) in the United States but does not apply to private domestic drinking water wells or to water not being used for drinking.

Much of the current occurrence data available regarding PFAS in public drinking water was generated by USEPA under the SDWA Unregulated Contaminant Monitoring Rule (UCMR) program (**USEPA 2017**). USEPA uses the UCMR to collect data for chemicals that are suspected to be present in drinking water but that do not have standards set under the SDWA. The third round of this monitoring effort, or UCMR3, included six PFAAs:

- perfluorooctanesulfonic acid (PFOS)
- perfluorooctanoic acid (PFOA)
- perfluorononanoic acid (PFNA)
- perfluorohexanesulfonic acid (PFHxS)
- perfluoroheptanoic acid (PFHpA)
- perfluorobutanesulfonic acid (PFBS).

Samples were collected during a consecutive 12-month monitoring period between 2013 and 2015 from large PWSs serving more than 10,000 people, and a limited number of smaller systems determined by USEPA to be nationally representative. Based on USEPA's UCMR3 reported limits of between 10 and 90 ng/L, depending on the specific PFAAs, at least one of the six PFAAs listed above was detected in 194 out of 4,920 PWSs tested (~4%), which serve about 16.5 million people in 36 states and territories (**Hu et al. 2016**).

Table 8-1. UCMR3 occurrence data for PFOA and PFOS.

Chemical	Analytical reporting limit (ppt)	Number of PWSs[1]	PWS (%)[1]
PFOS	40	46	0.9
PFOA	20	13	0.3
∑ PFOA + PFOS		63	1.3
[1] Number and percent of public water systems (PWS) that exceeded the 2016 health advisory by chemical.			

The USEPA and some states use occurrence data produced by the UCMR program, not only for PFOA and PFOS, but also for other PFAS as well (**Table 8-1** and **Table 17-3**), to help determine which substances to

consider for future regulatory action. All of the data from the UCMR program are published in the National Contaminant Occurrence Database (NCOD) and available for download from USEPA's website (**USEPA 2017**).

The Fifth Unregulated Contaminant Monitoring Rule (UCMR 5) was published in December 2021. UCMR5 requires sample collection for 30 chemical contaminants between 2023 and 2025. This includes a list of 29 PFAS with minimum reporting limits ranging from 2 to 20 ppt (**USEPA 2021**). Individual PWS data has been reported online (**USEPA 2024**). UCMR5 will include all US public water systems serving 3,300 or more people, which is a change from previous UCMRs that included systems serving 10,000 or more people.

The USEPA has established final regulations for PFAS under the SDWA. USEPA published a rule on April 26, 2024 that includes National Primary Drinking Water Regulations (NPDWRs) for six PFAS (**USEPA 2024**). In May 2025, the USEPA published a news release indicating their intention to review the current regulation (**https://www.epa.gov/newsreleases/epa-announces-it-will-keep-maximum-contaminant-levels-pfoa-pfos**). This includes the extension of the compliance deadlines for PFOA and PFOS, and the reconsideration of the regulatory determinations for PFHxS, PFNA, HFPO-DA (GenX), and the Hazard Index mixture of these three plus PFBS. USEPA plans to issue a proposed rule in the fall of 2025 and finalize this rule in the Spring of 2026. In the current rulemaking, USEPA has classified PFOA and PFOS as likely human carcinogens and proposes health-based MCLGs for PFOA and PFOS of zero, consistent with USEPA's approach for likely human carcinogens in general. The individual MCLs for PFOA and PFOS are at 4 ng/L, which is the analytical reporting level and practical quantitation level. This rulemaking includes MCLGs and MCLs for PFNA, PFHxS, and GenX individually at 10 ng/L provided they are not in a mixture as well as mixtures of PFHxS, Gen-X, PFNA, and PFBS at a total hazard index of 1 (unitless). All six of these PFAS are included in the UCMR5 analyte list.

For PFAS and other unregulated drinking water contaminants with limited occurrence data, the USEPA begins the process of making regulatory decisions under the SDWA by evaluating the nationwide extent of drinking water contamination and potential health effects that may result from exposure to contaminants via drinking water. This evaluation begins with considering contaminants for inclusion on the Contaminant Candidate List (CCL), which is a list of contaminants that are currently not subject to any proposed or promulgated national primary drinking water regulations but are known or anticipated to occur in public water systems. USEPA uses the CCL to identify priority contaminants for regulatory decision-making and information collection, including occurrence data collection under UCMR. On November 14, 2022, USEPA published the final CCL5, which includes PFAS as a chemical class (**USEPA 2022**).

In addition, when the USEPA determines there may be an "imminent and substantial endangerment" from a contaminant that is present in or likely to enter a PWS, under Section 1431 of the SDWA, it may issue emergency administrative orders (EAOs) to take any action necessary to protect human health if state and local authorities have not acted (42 U.S.C. §300i). USEPA has issued several such EAOs to protect public and private water supply wells contaminated with PFOA or PFOS (**USEPA 2009**, **2014**, **2015**, **2022**).

8.2.2.5 Toxic Substances Control Act (TSCA)

TSCA authorizes the USEPA to require reporting, record keeping, testing, and restrictions of chemicals and chemical mixtures that may pose a risk to human health or the environment. Section 5 of TSCA authorizes the USEPA to issue Significant New Use Rules (SNURs) to limit the use of a chemical when it is newly identified, or when a significant new use of an existing chemical is identified, before it is allowed into the marketplace (**USEPA 2017**). From 2002 to 2013, USEPA issued four final SNURs covering 271 PFAS, including PFOS and PFOA. The first three SNURs covered PFAS included in the 3M Corporation's voluntary phaseout of PFOS. The 2013 SNUR required notification to USEPA prior to manufacture or import of seven PFAS that had been reviewed by USEPA under the TSCA New Chemicals Program but

had yet to be commercially manufactured or imported into the United States. This SNUR also included long-chain perfluoroalkyl carboxylic acids (PFCAs) and their salts and precursors that were used in carpets or to treat carpets (**USEPA 2015**). Collectively, these SNURs placed notification requirements on the manufacture (including import) of specific PFAS for new use. The SNURs allowed for continued, low-volume use of some PFAS in photographic/imaging, semiconductor, etching, metal plating, and aviation industries (**USEPA 2017**). In January 2015, USEPA proposed another SNUR to require notification to USEPA before any future manufacture (including import) of PFOA and PFOA-related chemicals, including as part of articles, and processing of these chemicals. As a result of changes made to section 5(a) of TSCA when TSCA was amended in June 2016, USEPA undertook developing a supplemental SNUR for the import of certain long-chain PFCA and PFSAs as part of categories of certain articles (**USEPA 2018**).

As required by the NDAA, the USEPA finalized the supplemental SNUR in June 2020 and published the final notice in the Federal Register in July 2020 (**https://www.govinfo.gov/content/pkg/FR-2020-07-27/pdf/2020-13738.pdf**). The 2020 SNUR designates as a significant new use the manufacture, import, or processing of a specific subset of long-chain perfluoroalkyl carboxylate (LCPFAC) substances for any use that was not ongoing as of December 15, 2015, and for all other LCPFAC chemical substances for which there were no ongoing uses as of January 21, 2015. The SNUR also prohibits the import of certain LCPFAC as part of a surface coating on articles, and the import of carpet containing perfluoroalkyl sulfonate chemical substances, without USEPA review.

Finally, USEPA recently proposed a new SNUR for those PFAS that have not been manufactured (including imported) or processed for many years and are consequently designated as inactive on the TSCA Chemical Substance Inventory (**USEPA 2023**). Persons or companies subject to the SNUR would be required to notify USEPA at least 90 days before commencing any manufacture (including import) or processing of the chemical substance for a significant new use.

The USEPA continues to review new PFAS through USEPA's New Chemicals Program before approving commercialization. In October 2021, USEPA published the National PFAS Testing Strategy to "help EPA identify and select PFAS for which the Agency will require testing using TSCA authorities" (**USEPA 2021**). In 2023, USEPA released a new framework for addressing new PFAS and new uses of PFAS which is intended to require more extensive toxicity and fate data for PFAS with potential exposures or releases (**USEPA 2023**).

8.2.2.6 Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)—"Superfund"

PFAS, other than PFOA and PFOS, are not currently listed as CERCLA hazardous substances but may be addressed as CERCLA pollutants or contaminants as defined by section 101 (33) of CERCLA (40 CFR 300.5). USEPA finalized a rule in April 2024 to designate PFOA and PFOS as hazardous substances (**USEPA 2024**). This rulemaking requires entities to immediately report releases of PFOA and PFOS that meet or exceed the reportable quantity to the National Response Center, state or Tribal emergency response commission, and the local or Tribal emergency planning committee (local emergency responders). Entities would not be required to report past releases of PFOA or PFOS as they were not yet listed as hazardous substances. In addition to the final rule, EPA is issuing a separate **CERCLA enforcement discretion policy** (**USEPA 2024**) that makes clear that EPA will focus enforcement on parties who significantly contributed to the release of PFAS chemicals into the environment, including parties that have manufactured PFAS or used PFAS in the manufacturing process, federal facilities, and other industrial parties.

CERCLA Protection of Human Health. CERCLA requires, among other things, that Superfund response actions ensure protectiveness of human health and the environment, and compliance with laws and regulations that constitute "applicable or relevant and appropriate requirements" (ARARs); the statute also provides possible ARAR waivers in limited circumstances. The lead agency (as defined in 40 CFR

300.5) identifies potential ARARs and to-be-considered values (TBCs), based in part on the timely identification of potential ARARs by states. Risk-based cleanup goals may be calculated and used to determine cleanup levels when chemical-specific ARARs are not available or are determined not to be sufficiently protective (**USEPA 1997**). The ARAR process can be complex and can result in impacts on scope, budget, and public acceptance components of a project (**USEPA 2019**).

The **Environmental Media Values Table** Excel file includes information from state, federal, and some international agencies. These values are not necessarily automatically recognized as ARARs and must be evaluated by the lead agency to determine their ARAR status. In the Superfund program, USEPA regions evaluate potential ARARs, including state standards, on a site-specific basis to determine whether a specific standard or requirement is an ARAR for response decision and implementation purposes. Determining if a state requirement is promulgated, substantive, and enforceable are some of the factors in evaluating whether a specific standard may constitute an ARAR or TBC (**40 CFR 300.5 2001**; **40 CFR 300.400 2019, (g)**; **USEPA 1988**, **1991**).

As mentioned above, risk-based cleanup goals may be calculated when chemical-specific ARARs are not available or are determined not to be protective (**USEPA 1997**). The USEPA's Regional Screening Levels (RSLs) Generic Tables (**USEPA 2023**) and the RSL online calculator (**USEPA 2017**) are used by risk assessors to identify screening levels and preliminary remedial goals for contaminants of potential concern at a site. These goals are typically based on toxicity values that have been selected in accordance with the USEPA's published hierarchy (**USEPA 2003**). In May 2022, USEPA added five PFAS (PFOA, PFOS, PFNA, PFHxS, and GenX) to the RSL table (**USEPA 2023**). PFBS had previously been listed in the RSL generic tables. For these six PFAS, the generic tables provide noncancer reference doses (RfDs), screening levels for soil and tap water, and soil screening levels for the protection of groundwater. USEPA issued a final toxicity value for PFBS in April 2021 (**USEPA 2021**). In October 2021, USEPA issued a final toxicity assessment for GenX chemicals (**USEPA 2021**). The online RSL calculator currently supports site-specific calculations for the same six PFAS. The USEPA also provides tables and a calculator for removal management levels (RMLs). In general, RMLs are not final cleanup levels, but can provide a reference when considering the need for a removal action (for example, drinking water treatment or replacement) (**USEPA 2016**).

Because RSLs and RMLs are periodically updated, they should be reviewed for revisions and additions before using them. RSLs and RMLs are not ARARs, but they may be evaluated as TBCs. The USEPA has emphasized that RSLs and RMLs are not cleanup standards (**USEPA 2023**) and suggests that final remedial goals be informed by a baseline risk assessment so that site-specific information can be incorporated. **Section 9** provides more information on site-specific risk assessment for PFAS.

CERCLA Protection of the Environment. CERCLA requires that remedies also be protective of the environment. Risk-based cleanup goals that are protective of the environment are site-specific and depend in part on the identification of the ecological receptors to be protected. Another example of a risk-based cleanup goal is a cleanup standard for a chemical in soil that is protective of groundwater quality and is developed on a site-specific basis. Given the challenge associated with deriving accurate physical and chemical properties for PFAS (Sections **4.1**and **5.1**), site-specific values will need to be derived.

8.2.2.7 Resource Conservation and Recovery Act (RCRA)

RCRA provides USEPA with the authority to regulate hazardous waste management, nonhazardous solid waste facilities and practices, and underground storage tanks holding petroleum or certain hazardous substances. No PFAS have been formally listed as RCRA hazardous waste for regulation under this program. However, there are at least a couple of examples where action on PFAS was taken under the auspices of RCRA. For example, in 2004 USEPA pursued violations of RCRA and TSCA at an E.I. DuPont de Nemours and Company (DuPont) facility in West Virginia due to environmental release of the hazardous constituent PFOA (**USEPA 2015**). In the case of DuPont, the facility already had a RCRA permit

for hazardous waste disposal and was under a Corrective Action Permit. Some states, Texas, for example, are regulating certain PFAS under their RCRA permits and requiring investigation and cleanup.

In February 2017, a U.S. District Court denied motions to dismiss RCRA "imminent and substantial endangerment" claims relating to PFAS (*Tennessee Riverkeeper, Inc. v. 3M Co.*, No. 5:16-cv-01029-AKK, 2017 WL 784991 (N.D. Ala. Feb. 10, 2017)). This case involved the alleged continuing contamination of the Tennessee River and associated public drinking water supplies with PFAS that the plaintiff claims originated from a local manufacturing facility and two local landfills. There were several arguments that the claims should be dismissed. One argument by the landfill owners was that the claims were an attack on existing, valid permits that included a solid waste permit authorizing disposal in the landfill of PFAS-bearing materials. The court denied the motion to dismiss, stating that the permits only authorize disposal of nonhazardous waste, and there is a dispute over whether the PFAS-containing material is a hazardous waste. Additionally, there are a continually growing number of citizen lawsuits filed under RCRA in state courts throughout the United States. Thus, the applicability of RCRA regulations and statutes to PFAS does not appear to be settled and can be complicated.

On June 23, 2021, New Mexico Governor Michelle Lujan Grisham petitioned USEPA Administrator Michael Regan to designate PFAS as "hazardous waste" under the Resource Conservation and Recovery Act, citing imminent and substantial endangerment. On October 26, 2021, EPA administrator Regan responded to the governor's petition (**USEPA 2021**). In February of 2024 USEPA proposed to add nine PFAS (PFOA, PFOS, PFBS, GenX, PFNA, PFHxS, PFDA, PFHxA, and PFBA) as RCRA Hazardous Constituents in Title 40 of the Code of Federal Regulations Part 261 Appendix VIII (**USEPA 2024**). In addition, USEPA has proposed a rulemaking to clarify that RCRA has the authority to require the cleanup of solid wastes that meet the statutory definition of hazardous waste. This will mean that "emerging contaminants such as PFAS can be cleaned up through the RCRA corrective action process." (**USEPA 2024**).

8.2.2.8 Clean Air Act (CAA)

Under the CAA, USEPA is required to regulate emissions of hazardous air pollutants from industrial facilities. USEPA may develop standards for controlling certain hazardous air emissions from sources in a specific industry group. Within 8 years of establishing emission standards, USEPA must determine whether the standards are sufficiently protective of human health and protect against adverse environmental effects. This determination also considers improvements in air pollution controls and evaluates effective and feasible alternatives. There are no air emission standards for PFAS at this time. There is no indication how far along USEPA is in this process for regulating PFAS under the CAA.

8.2.2.9 Clean Water Act (CWA)

Since 1972, the CWA has given the USEPA authority to control water pollution by regulating discharges into the nation's surface water by setting wastewater standards for industry. There are no nationally recommended water quality criteria for any PFAS at this time. However, USEPA published draft aquatic life criteria for PFOA and PFOS in summer 2022 (**USEPA 2022**, **2022**). USEPA released the Final 2016 Effluent Guidelines Program Plan in May 2018, which listed PFAS as a topic for future investigation (**USEPA 2018**). More recently, USEPA finalized Effluent Guidelines Plan 15 in January 2023 (**USEPA 2023**) (see **Section 16.6**).

In December 2022, USEPA released a memorandum relating to NPDES permitting for PFAS discharges which supersedes the April 2022 USEPA memo (**USEPA 2022**, **2022**). More information about these USEPA documents can be found in **Section 16.1**. The regulation of PFAS in discharge effluents by states is discussed below in **Section 8.2.3**, and in **Section 16.6**.

8.2.2.10 Toxics Release Inventory (TRI) Program

The Toxics Release Inventory (TRI) program requires the annual reporting of environmental releases of approximately 800 chemicals which the USEPA has concluded cause:

- Cancer or other chronic human health effects
- Significant adverse acute human health effects
- Significant adverse environmental effects

For chemicals regulated under the TRI, facilities that manufacture, process or use these chemicals in amounts above established levels must submit annual reporting forms for each chemical.

As stipulated by the NDAA, the USEPA finalized a rule requiring 180 PFAS be added to the list of chemicals that must be reported under the TRI program for Reporting Year 2022 (**USEPA 2023**). An additional nine PFAS were added to the list for Reporting Year 2023 (**USEPA 2023**) and an additional seven PFAS were added for Reporting Year 2024 (**USEPA 2024**). The PFAS subject to TRI reporting requirements under the original NDAA included all PFAS listed as an active chemical substances under TSCA's Section 8(b)(1) inventory. Each of these PFAS will have a 100-pound reporting threshold. In the 2022 changes to reporting requirements (**USEPA 2022**), these PFAS were added to the List of Lower Thresholds for Chemicals of Special Concern (chemicals of special concern), which eliminates the use of the *de minimis* exemption, which is expected to increase the reporting of PFAS found in mixtures or products in low concentrations (**USEPA 2023**). Reporting for each calendar year is due in July of the following calendar year; these data–as with all TRI data–will be publicly-available approximately 1 year after they were reported (**USEPA 2020**).

8.2.2.11 U.S. Food and Drug Administration (FDA)

One of the responsibilities of the FDA is regulation of "food contact substances" (FCSs), chemicals added to or components of "food contact materials" (FCMs), such as food wrappers and packaging. The FDA currently regulates certain PFAS used as grease-proofing agents for food packaging via a Food Contact Notification Program within the Center for Food Safety and Applied Nutrition's Office of Food Additive Safety. The PFAS used in FCMs and their known degradants and impurities have all undergone review for human health and environmental safety concerns through the food contact notification process and food additive petition process, which requires submission of chemical, toxicological, and environmental information on the FCS itself and on any potential impurities. Perfluorinated ion exchange membranes are also regulated under these processes.

In 2016 the FDA banned three perfluoroalkyl ethyl compounds from use in food packaging material (81 FRN 5, Jan. 4, 2016, Indirect Food Additives: Paper and Paperboard Components): diethanolamine salts of mono- and bis (1 H, 1H, 2H, 2H perfluoroalkyl) phosphates with even-numbered alkyl groups in the range of C8–C18; pentanoic acid, 4,4-bis [(*gamma*–*omega*-perfluoro-C8-20-alkyl)thio]; and perfluoroalkyl substituted phosphate ester acids, ammonium salts formed by the reaction of 2,2-bis[([gamma],[omega]-perfluoro C4–C20 alkylthio) methyl]-1,3-propanediol, polyphosphoric acid, and ammonium hydroxide.

In July 2020, the FDA announced that three manufacturers had agreed to a voluntary phase out of FCS that contain 6:2 fluorotelomer alcohol (6:2 FTOH). A fourth manufacturer had previously stopped sales of 6:2-FTOH-containing products in the US. The phase-out began in January 2021; the FDA predicted that it may take up to 18 months after that time to exhaust existing supplies of food contact papers that contain 6:2 FTOH (**USFDA 2020**).

As of February 2022, there were some FCS with PFAS listed on FDA's inventory of effective FCS notifications. The FDA (**2023**) inventory of FCS notifications is an online database. PFAS that are authorized for use in contact with food generally fall into four application categories:

- Nonstick cookware: PFAS may be used as a coating to make cookware non-stick.
- Gaskets, O-rings, and other parts used in food-processing equipment: PFAS may be used as a resin in forming certain parts used in food-processing equipment that require chemical and physical durability.
- Processing aids: PFAS may be used as processing aids for manufacturing other food contact polymers to reduce build-up on manufacturing equipment.
- Paper/paperboard food packaging: PFAS may be used as grease-proofing agents in fast-food wrappers, microwave popcorn bags, take-out paperboard containers, and pet food bags to prevent oil and grease from foods from leaking through the packaging (**FDA 2019**). However, the side-chain PFAS polymers used in grease-proofing are the subject of a voluntary phaseout agreement.

8.2.2.12 Other Federal Agency Actions

Other U.S. federal agencies and programs are actively involved in PFAS-related matters; however, their work largely focuses on data generation and analysis to help inform regulations/restrictions/regulatory action. These federal programs often provide valuable information, guidance, and resources for state regulatory and public health agencies. For example, the U.S. Centers for Disease Control and Prevention (CDC) National Health and Nutrition Examination Survey (NHANES) program provides valuable information about human exposure to chemicals (**CDC 2023**). Since 1999, the NHANES program has been providing an assessment of the exposure of the U.S. population to a small subgroup of PFAS. This information (PFAS concentrations in blood, serum, urine samples) is useful to scientists and regulatory agencies to understand "background" (that is, likely nonsite-related) human exposure levels and trends over time. In 2013-2014 CDC expanded their NHANES analysis to include evaluation of PFAS in serum and urine (**Kato et al. 2018**).

Under the Superfund Amendments and Reauthorization Act of 1986 (SARA) [42 U.S.C. 9601 *et seq.*] amendment to CERCLA (or Superfund) [42 U.S.C. 9601 *et seq.*], the U.S. Department of Health and Human Services, Agency for Toxic Substances and Disease Registry (ATSDR) was established to assess the potential public health risk from exposure to hazardous substances commonly found at National Priorities List facilities. CERCLA provides ATSDR with the authority to develop toxicological profiles that describe the health effects of these hazardous substances and to support site-specific response actions with health consultations and/or exposure investigations. A description of ATSDR's actions regarding PFAS is on their web page (**ATSDR 2018**). In May 2021, ATSDR released a final *Toxicological Profile for Perfluoroalkyls* (**ATSDR 2021**). In this revision, the agency discussed potential human health risks related to 14 specific PFAS and derived "provisional intermediate Minimal Risk Levels" (MRLs) for PFOA, PFNA, PFOS, and PFHxS.

ATSDR (2023) has posted an online calculator that the general public can use to estimate the increase in their blood serum levels from exposure to PFOA, PFOS, PFNA, or PFHxS in drinking water.

The U.S. Geological Survey (USGS) has had an emerging contaminants program for over a decade within which they measure emerging contaminants, including PFAAs, in various environmental media and ecological receptors. The objective of their work is to characterize environmental occurrence, sources, and source pathways that may contribute to environmental exposure. This has been a useful source of

information for scientists and regulatory agencies on occurrence, fate, and transport of PFAS. Information on the USGS program can be found on their web page (**USGS 2017**).

The U.S. Department of Defense SERDP and ESTCP are jointly managed with USEPA and the U.S. Department of Energy to develop the latest science and technology to improve DOD's environmental footprint and mission capabilities. Beginning in fiscal year 2011, SERDP and ESTCP have funded a significant number of projects related to developing a better understanding of PFAS occurrence, fate and transport, ecotoxicity, and remediation treatments, as well as investigating the next generation of fluorine-free firefighting foams. More information on SERDP and ESTCP funding projects and statements of need can be found on their website (**SERDP-ESTCP 2019**).

8.2.3 State PFAS Regulations and Guidance

State regulatory agencies often have the delegated authority to regulate and enforce environmental and public health requirements, although the states and US territories have different priorities, resources, and processes. Many states have been actively involved with addressing PFAS contamination across multiple regulatory programs. Examples of key state programs for water, soil, remediation, hazardous substances, and consumer products are described below, and information about regulatory, advisory, and guidance values is discussed in **Section 8.3**. The information below is meant to provide examples only; the **Environmental Media Values Table** Excel file should be consulted for more current and detailed information.

The Association of State and Territorial Solid Waste Management Officials (ASTSWMO) has a PFAS resources website that includes links to PFAS information for states and territories (**https://pfas.astswmo.org**). The Environmental Council of the States (ECOS) published their updated white paper, Processes and Considerations for Setting State PFAS Standards, in April 2024 (**ECOS 2024**).

ITRC has developed the **PFAS Regulatory Programs Summary** Excel file that summarizes the regulations and programs in each state that target PFAS. The focus of the table is on PFAS regulations that have been enacted by any of the states or territories of the United States. The table also includes state programs that may not be mandated by a specific regulation, but which state agencies are pursuing on a discretionary basis. This table does not include any numeric criteria, but instead includes a description of the type of regulation or program, and a link to the applicable website. For specific regulatory values, the **Environmental Media Values Table** Excel file should be consulted.

The following subsections describe several different categories of state-adopted laws and regulations along with a brief explanation of each; please refer to the **PFAS Regulatory Programs Summary** Excel file for the most up-to-date information. Note that due to the state legislative review and finalization process, only bills that have been finalized into law are included in the **PFAS Regulatory Programs Summary** Excel file.

8.2.3.1 Product Labeling and Consumer Protection Laws

Several states have programs regulating PFAS in consumer products, including product labeling. Some of these regulations include PFAS in food packaging, children's products, firefighting gear, and other products. More specific information is available in the **PFAS Regulatory Programs Summary** Excel file with details available at the links provided.

8.2.3.2 Designation of Hazardous Waste or Hazardous Substance

Regulations that target select PFAS as hazardous wastes or hazardous substances have not been promulgated in most states. Formal PFAS regulations as hazardous substances have been promulgated

in a number of states, and are under development in several other states. Please refer to the PFAS Regulatory Programs Summary Excel file for detailed information.

8.2.3.3 Drinking Water, Groundwater, Soil, and Remediation Programs

Several states have developed standards and guidance values for PFAS in drinking water, groundwater, and soil (see the Environmental Media Values Table Excel file). Some states adopted (by default) the USEPA LHAs published in either 2016 or 2022, while others adopted values developed via a risk assessment process, regulatory process, or legislative action. Some others use the LHA concentrations as advisory, nonregulated levels to guide the interpretation of PFAS detections. The May 2022 RSL table lists screening values for soil and tap water for six PFAS. Section 9 provides more information on site-specific risk assessment for PFAS.

In addition to the process using the USEPA RSL table mentioned above, some states have developed screening levels for various PFAS in soils assuming direct contact and/or ingestion.
See the Environmental Media Values Table Excel file and **USEPA (2021)** Certain states have also developed values for the protection of groundwater (see the Environmental Media Values Table Excel file).

Some states have "antidegradation" policies aimed at protecting the quality of groundwater and high quality (or Tier 2) surface waters. Those polices can be used in decisions on cleanup and discharge under permits. Please see the PFAS Regulatory Programs Summary Excel file as well as the Environmental Media Values Table Excel file for more information.

8.2.3.4 Surface Water Discharge and Permitting

National Pollutant Discharge Elimination System (NPDES) permits use a standard process for developing effluent limits for pollutants. Effluent and receiving water limitations for PFAS would be established in the same manner as other pollutants. A number of states have established surface water quality standards for PFAS. More information on surface water effects can be found in **Section 16**.

8.2.3.5 Other State Regulations or Programs

Another concern for PFAS is in the application of biosolids from municipal wastewater treatment plants to land for disposal or reuse. A number of states are currently in the process of considering and/or developing such regulations (**ECOS 2023**). An example of this type of regulation may include a law to prohibit the land application of sludge as well as the sale and distribution of products containing sludge and septage. Other potential regulations may focus on reducing PFAS inputs into wastewater treatment plants while further assessing the impacts associated with land application of biosolids containing PFAS. See Section 3 for a more detailed discussion of PFAS in biosolids.

Some states have developed an ambient air limit for PFAS. See the **PFAS** Environmental Media Values Table and the PFAS Regulatory Programs Summary Excel file for more information.

Finally, some states have issued state regulations or programs related to AFFF. For example, some states have established AFFF take-back programs to reduce the potential discharge of PFAS associated with AFFF into the environment. Other states are in the process of developing an AFFF take-back program. See **Section 3** for a more detailed discussion on AFFF and related regulations and guidance. A number of states have banned the manufacture, sale, and use of PFAS-containing AFFF in most applications (see PFAS Regulatory Programs Summary Excel file).

8.3 Differences in the Available Regulations, Advisories, and Guidance

Human health protection is the primary focus of the PFAS regulations, guidance, and advisories developed to date. Internationally, including in the United States, the nonpolymer PFAS have been the regulatory focus. Several toxicity evaluations are available for certain PFAS. This is an area of active research and regulatory activity. Additional information is presented in Sections **7.1** and **17.2**.

Table 8-2. Definition of terms associated with drinking water and/or groundwater standards or guidance.

Term	Acronym	Agency	Definition	Link
Minimum Risk Level	MRL	CDC ATSDR	An MRL is an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure. MRLs are intended to serve as screening levels to identify contaminants and potential health effects that may be of concern. MRLs are not intended to define cleanup or action levels for ATSDR or other agencies (**ATSDR 2018**). Importantly, the MRL is a daily dose, applicable for any oral exposure; it is not a threshold concentration in water or other environmental media.	https://www.atsdr.cdc.gov/mrls/index.asp
Regional Screening Level	RSL	USEPA Regions	Default screening level tables including chemical-specific concentrations for individual contaminants in air, drinking water, and soil that may warrant further investigation or site cleanup. Generic screening levels (SLs) are based on default exposure parameters and factors that represent reasonable maximum exposure conditions for long-term/chronic exposures and are based on the methods outlined in EPA's Risk Assessment Guidance for Superfund, Part B Manual (1991) and Soil Screening Guidance documents (1996 and 2002). It should be emphasized that SLs are not cleanup standards. (**USEPA 2019**)	https://www.epa.gov/risk/regional-screening-levels-rsls-users-guide#intro
Health Advisory	HA	USEPA Office of Water	Health advisories provide information on contaminants that can cause human health effects and are known or anticipated to occur in drinking water. EPA's HAs are nonenforceable and provide technical guidance to state agencies and other public health officials on health effects, analytical methodologies, and treatment technologies associated with drinking water contamination. (**USEPA 2019**)	https://www.epa.gov/dwstandardsregulations/drinking-water-contaminant-human-health-effects-information
Maximum Contaminant Level Goa	MCLG	USEPA Office of Water	The MCLG is the maximum level of a contaminant in drinking water at which no known or anticipated adverse effect on the health of persons would occur, allowing an adequate margin of safety. MCLGs are nonenforceable public health goals. MCLGs consider only public health and not the limits of detection and treatment technology effectiveness. (**USEPA 2018**).For contaminants classified as known or likely human carcinogens, it is USEPA policy to set the MCLG at zero (0). (**USEPA 2023**)	https://www.epa.gov/ground-water-and-drinking-water/national-primary-drinking-water-regulations
Maximum Contaminant Level	MCL	USEPA Office of Water	The highest level of a contaminant that is allowed in drinking water. MCLs are set as close to MCL goals as feasible using the best available treatment technology and taking cost into consideration. MCLs are enforceable standards. (**USEPA 2018**)	https://www.epa.gov/ground-water-and-drinking-water/national-primary-drinking-water-regulations

Human health–based guidance values and/or regulatory standards have thus far been derived for a number of PFAS, including PFAAs, polyfluoroalkyl precursors, and fluorinated ether carboxylates (FECA) by state and/or federal agencies in the United States. The health-based values for these nonpolymeric PFAS vary across programs, with differences due to the selection and interpretation of different key toxicity studies, use of human or animal data as the basis, use of a noncancer reference dose or a cancer slope factor, choice of uncertainty factors when a reference dose is used, and approaches used for animal-to-human extrapolation. The choice of exposure assumptions, including the life stage and the percentage of the reference dose assumed to come from non-drinking water sources, also differs. Most available guidance values and/or regulatory standards are for PFOA and PFOS, and the key differences in

regulatory and guidance decisions within the United States for those chemicals can be seen in the ECOS white paper (**ECOS 2024**).

Table 8-2 provides the underlying definition and context for the various federal regulations, standards, and guidance values that may apply to PFAS in the United States.

8.3.1 Toxicity Values

As stated above, available PFAS regulations, guidance, and advisories are generally based on human health protection. However, the available values that are deemed protective of human health vary across international and U.S. jurisdictions. In general, there are similarities and differences in the understood toxicological effects, potencies, and modes of action for various PFAS, and there are differences in the interpretation of relevant toxicological data for individual PFAS.

Toxicological data from both animal and human epidemiology studies are used as the basis for U.S. state and federal PFAS human health toxicity factors and related standards or guidance. The European Food Safety Authority's tolerable weekly intake for the total of PFOA, PFOS, PFNA, and PFHxS is based on human data (**EFSA 2020**). More recently, California EPA and USEPA have developed draft reference doses for PFOA and PFOS (**CA OEHHA 2023**; **USEPA 2023**), as well as for PFHxS (**USEPA 2023**) and PFDA (**USEPA 2023**), and a draft cancer slope factor for PFOA (**USEPA 2023**; **CA OEHHA 2023**) based on human general population data that are far below current values based on animal data. See **Section 7** for a review of the toxicology data for PFAS. Many scientific considerations and decision points are involved in developing human health toxicity factors (RfDs and cancer slope factors) from animal toxicology data or human epidemiology data. For PFOA and PFOS, different scientific and regulatory policy conclusions have been made for nearly every decision point by different agencies. Some of the key topics that account for toxicity value differences are discussed below. More specific information on these differences can be found in the **Environmental Media Values Table** Excel file; as well as the **PFAS Regulatory Programs Summary** Excel file and the ECOS white paper (**ECOS 2024**).

Although previous PFAS regulations, standards, and guidance have largely been based on potential noncancer effects, several recent draft or proposed values are based on cancer risk. RfDs have been used by most U.S. states to describe the estimate of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime (**USEPA 2019**).

The New Jersey Drinking Water Quality Institute (NJDWQI) and California Office of Environmental Health Hazard Assessment (OEHHA) also considered potential cancer endpoints for PFOA and PFOS. In its recent proposed PFAS MCL rule, **USEPA (2023)** classified both PFOA and PFOS as likely human carcinogens and developed cancer slope factors for both. **NJDWQI (2023)** concurred with **USEPA (2023)** that PFOA is a likely human carcinogen. However, at the time of New Jersey's recent analysis, the **NJDWQI (2023)** was unaware of the information identified by **USEPA (2023)** that is the basis for its conclusion that PFOS is also a likely human carcinogen. The methodology for deriving chemical-specific toxicity values is generally applicable to both cancer and noncancer endpoints where dose-response relationships and weight-of-evidence analyses of available data sets are evaluated, and is described in detail.

The first step in deriving a human health-based toxicity value (RfD or CSF) is the review of applicable data to identify potential human health hazards (toxicity endpoints) based on sensitive effects that are consistently seen across several studies, are deemed related to an adverse health outcome or its known precursor, and are relevant to humans based on mode of action considerations. Not all agencies have utilized the same candidate studies and health endpoints for PFOA and PFOS due to differences in selection criteria and differences in opinion on the relevancy to human health and on adversity of effects seen in recent studies.

The estimation of an RfD includes two additional components: the selection of the dose-response method and uncertainty factors. For dose-response evaluation, either the benchmark dose or the study NOAEL or LOAEL is utilized as the point of departure. Uncertainty factors used include the standard risk assessment extrapolations, and the choice of uncertainty factors also varies by agency.

8.3.2 Exposure Assumptions

General exposure factors that are used in derivation of PFAS regulations and guidance values are discussed below.

8.3.2.1 Body Weights, Drinking Water Ingestion, and Exposure Durations

Once a human health toxicity value is derived in units of ug/kg-day (or ng/kg-day or mg/kg-day), the toxicity value is combined with exposure parameters to result in the ultimate threshold concentration in drinking water (guidance or standard). The choice of exposure parameters used can be a flexible science- and/or policy-based decision based on default assumptions or chemical-specific data, or may be set based on regulatory framework. The exposure parameters used under the U.S. CERCLA program (for example, USEPA regional screening levels) include default exposure parameters and factors that represent conditions for long-term/chronic exposures, including an exposure frequency of 350 days per year, exposure duration of 6 years for a 15-kg child who drinks 0.78 L water per day, or 26 years for an 80-kg adult who drinks 2.5 L of water a day. In contrast to CERCLA, drinking water guidance values and standards (MCLs and MCLGs) developed by USEPA or states are generally based on lifetime exposure using default adult parameters, and they do not usually include a duration of exposure parameter. For PFOA and PFOS, USEPA and state agencies have not always relied upon these default exposure parameters. Some have decided to utilize exposure parameters that are specific for more sensitive subpopulations (infants, children, or lactating/pregnant women) and/or a toxicokinetic model that considers exposures to the developing fetus and the higher exposures to the breast-fed infant. For example, MDH developed a toxicokinetic model to estimate the total exposure to breast-fed and formula-fed infants (**Goeden, Greene, and Jacobus 2019**), and this model was used to derive standards in Minnesota, New Hampshire, and Michigan.

8.3.2.2 Relative Source Contribution

Humans can be exposed to nonpolymeric PFAS, including precursor chemicals, via multiple sources, including air, food, and consumer and industrial products. The relative source contribution (RSC) term is used in health-based guidance and standards developed by the USEPA under the federal SDWA and related state programs to account for potential non-drinking water exposures to chemicals. In general, the concept ensures that when a criterion based on an RfD for noncancer effects is established for a single exposure pathway, such as drinking water, potential exposures that occur from other pathways are accounted for so that total exposure does not exceed the RfD (**USEPA 2000**). The default RSC of 20% means that the drinking water pathway is assumed to contribute only 20% of the RfD, and all other exposure pathways contribute the remaining 80%. In practice, therefore, the drinking water concentration based on RfD and drinking water consumption assumptions is multiplied by the RSC (for example, 20%) to account for exposure via the other pathways.

The RSC term generally does not exist in CERCLA/RCRA-based remediation programs because baseline risk assessments specifically investigate and quantify risks associated with all potential site-specific exposure routes (not just drinking water), and then consider a receptor's cumulative risk. Therefore, there is no downward adjustment to a residential groundwater (termed "tap water" by USEPA) drinking water screening level, for example, to account for potential other exposures—all site-specific exposures are quantified. See Section 9 for more information on site-specific risk assessments for PFAS.

9 SITE RISK ASSESSMENT

This section discusses the specific challenges associated with assessing and characterizing potential risks to human and ecological receptors exposed to PFAS in the environment. This includes challenges associated with quantifying the degree of exposure, assessing the hazard associated with PFAS, quantifying the dose-response relationship, and characterizing risks to support effective risk management decision-making. Generally, the challenges associated with performing a site risk assessment where the release of PFAS to the environment is suspected are not necessarily unique. Like any other chemical for which there is limited information, knowledge, or other technical complexity, working through the steps necessary to complete a risk assessment would be similar.

Section 17.3 provides additional information related to PFAS risk assessment, including (1) exposure pathways relevant for different exposure media, (2) considerations when calculating exposure point concentrations, and (3) selecting bioconcentration/bioaccumulation factors.

Section Number	Topic
1.4	**Priority Topics for Human and Ecological Health (2025)**
1.7	**Priority Topics for Biosolids Land Application (2025)**
9.1	**Human Health Risk Assessment**
9.2	**Ecological Risk Assessment**
9.3	**Uncertainty**
15.3	**Risk Assessment Case Study**
17.3	**Additional Information for Risk Assessment**

9.1 Human Health Risk Assessment

9.1.1 Toxicity Assessment

The toxicity assessment of a site risk assessment involves (1) hazard identification and (2) dose-response assessment. Hazard identification involves determining whether exposures to a chemical can cause an increased risk of an adverse human health effect; dose-response assessment involves quantifying the relationship between the degree of exposure to the chemical and the incidence or severity of the potential adverse effects. More background on each of these steps is detailed in other guidance (**USEPA 1989**; **ITRC 2015**) and is not repeated here.

This section discusses specific complications that may be encountered in completing the toxicity assessment for a site risk assessment involving PFAS.

The Priority Topics for Human and Ecological Health Effects include information about health effects of ultra-short-chain (ultrashort) PFAS (see **Section 1.4.4**).

9.1.1.1 Availability of Toxicity Values from a Variety of Sources

A toxicity value (for example, oral cancer slope factor (CSF), or reference dose (RfD)) is a numerical expression of the dose-response relationship for a given substance. It is used in combination with estimates of chemical exposure to calculate quantitative estimates of cancer risk or noncancer hazard (**USEPA 1989**). Several state, national, and international regulatory and advisory agencies have developed human toxicity values for various PFAS that could be potentially used in conducting risk assessments or

in support of establishing policies for PFAS risk management. Given this variety of sources, specific complications can be encountered in determining which toxicity values to use in conducting a risk assessment:

- Selection of toxicity values for PFAS is dependent on which PFAS are present at a given site. PFAS identification and quantification may vary based on analytical method.
- Differences among toxicity values for PFAS could arise because agencies may rely on different toxicity value derivation methods; select critical studies by different criteria, including animal or human data; use different uncertainty factors; and prioritize individual PFAS differently for toxicity value derivation. **Table 9-1** provides an example for PFOA and PFOS, showing that USEPA used human data while ATSDR used animal data.
- Available toxicity values may change over time as the results of new studies become available. Newer toxicity values derived by regulatory agencies may be based on more recent and/or different information, methods, and studies than older values, as well as differences in scientific professional judgment and/or different statutory policy requirements. These differences are described in more detail in **Section 8.3**.
- States may choose to derive their own toxicity values rather than use those developed by the USEPA, and values developed by other countries may differ from USEPA's.
- Some states may perform route-to-route extrapolation (from oral toxicity values to inhalation toxicity values) for evaluation of the inhalation pathway. However, uncertainties should be noted if using route-to-route extrapolation.

Table 9-1. Example of variability in noncancer toxicity factors for PFOA and PFOS—USEPA (2024), 2024 RfDs and ATSDR (2021) MRLs.

Noncancer Toxicity Values for Human Health Risk Assessment (ng/kg body weight*day)				
Source	***PFOA***	***Basis***	***PFOS***	***Basis***
USEPA Office of Water (2024) USEPA (**2024**) USEPA (**2024**) Reference Doses (RfDs)	0.03	Decreased antibody response to tetanus and diphtheria vaccinations in children, low birth weight, and increased total cholesterol	0.1	Low birth weight and increased total cholesterol in humans
ATSDR (**2021**) Minimal Risk Levels (MRLs)	3	Behavioral and skeletal effects in mice (following developmental exposure)	2	Delayed eye opening and decreased pup weight in rats

The most recent RfDs available should be used when preparing a human health risk assessment.

There are several options and procedures for selection of toxicity values, as has been described in ITRC guidance (**ITRC 2015**). For site risk assessments performed in the United States, USEPA, DOD, and other agencies have recommended a tiered hierarchy (Tier 1–Tier 3) of toxicity value sources to guide selection and use (**USEPA 2003**, **2013**); (**ECOS-DOD 2007**). This recommendation has since been implemented in numerous USEPA OSWER (Currently known as Office of Land and Emergency Management) directives

(**USEPA 1993**, **2003**, **2023**) that further establish a hierarchy and process for selecting toxicity criteria. For PFAS chemicals as of April 2024:

- Tier 1 values are peer-reviewed toxicity values published on the USEPA's Integrated Risk Information System (IRIS).
    - IRIS values are available for PFBA (**USEPA 2022**), PFHxA (**USEPA 2023**), PFDA (**USEPA 2024**), and PFHxS (**USEPA 2025**)
    - A draft IRIS assessment and toxicity values are available for PFNA (**USEPA 2024**). The status of the PFAS IRIS assessments can be found in the latest IRIS Program Outlook, available at **https://www.epa.gov/iris/iris-program-outlook**.
- Tier 2 toxicity values include Provisional Peer-Reviewed Toxicity Values (PPRTV).
    - PPRTV values are available for PFBS (**USEPA 2021**)
- Tier 3 toxicity values include those from additional USEPA and non-USEPA sources. They can include values that may or may not have been peer reviewed. As recommended by **USEPA (2003)**, in using values from Tier 3 sources, it may be appropriate to prioritize those that are the *most current*, have a *transparent* basis, are *publicly available*, have been *peer reviewed*, and are acceptable to local jurisdictions. USEPA (**2023**) prioritized available Tier 3 sources of toxicity values in its regional screening level (RSL) guidance, with the current relevant sources for PFAS identified as:
    - ATSDR minimal risk levels (MRLs) (for example, the oral MRLs for PFOA and PFOS (**ATSDR 2021**))
    - USEPA Office of Research and Development (for example, the oral toxicity value for PFPrA (**USEPA 2023**)
    - USEPA Office of Water health advisories or human health toxicity assessments (for example, the oral toxicity value presented in the drinking water health advisory for GenX [**USEPA 2021**; **USEPA 2022**])
    - Wisconsin Department of Health Services (for example, the oral toxicity value for PFDoDA) (**WDHS 2020**)
- Additional definitions and discussion of PFAS toxicity values that are available for use are provided in **Section 7** and **Section 17.2**.

The USEPA will continue to develop toxicity values for PFAS. In addition, USEPA may continue reviewing available Tier 3 toxicity values and recommending values in RSL table updates. Individual risk assessors can also select Tier 3 values as appropriate (when no Tier 1 or 2 values are available).

9.1.1.2 Characterizing Cancer Risk for Exposure to PFAS

The USEPA documents that provide the toxicological basis for the proposed USEPA maximum contaminant level goals (MCLGs) for PFOA and PFOS conclude that both PFOA and PFOS are likely to be carcinogenic to humans (**USEPA 2024**, **2024**). The USEPA MCLGs for PFOA and PFOS are zero, consistent with USEPA's general approach for MCLGs for known or likely human carcinogens. The International Agency for Research on Cancer (**IARC 2016**) classified PFOA as possibly carcinogenic to humans (Class 2B). IARC is currently re-evaluating the carcinogenic potential of PFOA and is evaluating the carcinogenic potential of PFOS (**IARC 2023**). A recent review by **NJDWQI (2023)** concurred with USEPA that PFOA is a likely human carcinogen; this review also concluded that PFOS has suggestive evidence but was not aware of some animal tumor data relevant to this evaluation that was considered by **USEPA (2024)** (see **Section 17.2.5.3**).

For GenX, USEPA concluded that there is suggestive evidence of carcinogenic potential in humans based upon liver, pancreatic, and testicular tumors observed in chronic rat studies, but also concluded that these data lacked a dose-response relationship and therefore did not support development of a CSF (**USEPA 2022**).

Although most risk-based values and screening levels developed by states have been primarily based on noncancer effects, USEPA and some select states (for example, **New Jersey—NJDWQI 2017**, **2018**; **California—OEHHA 2023**) have derived oral CSFs for PFOA and PFOS. **NJDWQI (2017)** developed identical drinking water concentrations for PFOA using the RfD for noncancer effects and the CSF and the 1 in 1 million cancer risk level. For PFOS, **NJDWQI (2018)** concluded that, although the CSF was too uncertain for use as the quantitative basis to develop a drinking water level, the level based on noncancer effects did not pose an unacceptably high cancer risk. CalEPA's **CA OEHHA (2019)**, however, issued notification levels for drinking water exposure, and developed draft public health goals (PHGs) for PFOA and PFOS that are driven by carcinogenicity (**CA OEHHA 2023**). The draft PHG for PFOA is based on kidney cancer in humans; the PHG for PFOS is based on liver and pancreatic tumors in rats (**CA OEHHA 2023**). As part of the basis for the USEPA MCLs for PFOA and PFOS, USEPA (**2024**; **2024**) developed a CSF for PFOA of 0.0293 $(ng/kg/day)^{-1}$ (i.e., 29,300 $[mg/kg/day]^{-1}$) based on kidney cancer in the human general population and a CSF for PFOS of 39.5 $(mg/kg/day)^{-1}$ based on liver tumors in rats. For site risk assessments, the derived CSFs developed by these agencies could be used.

Further discussion of the carcinogenicity of PFAS is presented in **Section 17.2.4.2** (Carcinogenicity), **Section 17.2.5.3** (Chronic Toxicity and Tumorigenicity), and **Section 8.2.2.6** (CERCLA).

9.1.1.3 Lack of Toxicological Values for Many PFAS

There are several thousand PFAS that could have been, or may be, on the global market (**OECD 2018**), although the uses of all of these PFAS may not be known (**KEMI 2015**). More information about PFAS in use is included in **Section 2**. In general, PFAS are considered to be bioavailable (i.e., following exposure, they are absorbed and enter the systemic circulation). However, toxicity values have been developed for only a few PFAS for which sufficient information is available. Because of the lack of hazard and dose-response information for other PFAS and the extensive level of effort needed to develop toxicity values, there are no readily available toxicity values for the majority of PFAS.

This lack of information precludes the establishment of compound-specific risk-based concentrations that can be helpful for a variety of applications, including data screening (used to help guide site investigation) and site-cleanup decision-making. In the absence of toxicity values, regulatory agencies and the regulated community are left with uncertainty regarding the potential risks associated with human exposure to impacted environmental media at sites, difficulties with creation of technically defensible risk management programs, and inability of the regulated community to be responsive to concerns about environmental risk.

An approach often used in HHRA in the absence of compound-specific toxicity values is to use toxicity values developed for structurally or chemically similar surrogate compounds with similar biological activity. In the case of PFAS, this would be for PFAS from the same structural subgroup (for example, long-chain perfluorocarboxylic acids). The use of surrogates, however, introduces uncertainty, because surrogates may produce adverse health effects by mechanisms different from the compound of concern, the dose-response curve for a surrogate may be different, and the target organ or toxicity endpoint may be different from the compound of concern. In the absence of chemical-specific toxicity values, preparation of health risk assessments may be limited to qualitative methods and have a higher level of uncertainty in the human health risk assessment as a result.

Further information and guidance are needed to identify appropriate surrogates for PFAS that do not currently have available toxicity values. USEPA's PFAS Action Plan (**USEPA 2019**) noted that USEPA would be working on developing an approach to PFAS toxicity testing that could lead to a methodology for inferring the toxicology of a given PFAS based on the toxicology of a PFAS subset whose toxicology is known. This involves "applying computational and high throughput toxicology tools for PFAS toxicity testing on a larger scale to enable faster understanding of potential toxicity for the universe of thousands of PFAS, most of which have little or no published toxicity data" (**USEPA 2022**). A discussion of new approach methodologies (NAMs) can be found in **Section 7.1.6** and **17.2.8**.

The USEPA has developed its National PFAS Testing Strategy in which PFAS manufacturers will be issued orders under Toxic Substances Control Act (TSCA) authorities to perform toxicity testing on compounds representative of certain PFAS classes (**USEPA 2021**). These classes are organized by similarities in structure, physical-chemical properties, and existing test data on compound toxicity. Thus, there is a plan to obtain toxicity information for each class via a representative compound that will potentially serve as a surrogate for the other compounds in the class.

9.1.2 Exposure Assessment

The exposure assessment of a site risk assessment involves characterizing the exposure setting, identifying relevant exposure pathways and scenarios, and quantifying the magnitude, frequency, and duration of potential human exposure to chemicals in environmental media. More background on the performance of exposure assessments is detailed in other guidance (**USEPA 1989**; **ITRC 2015**) and is not repeated here.

This section discusses specific complications that may be encountered in completing the exposure assessment for a site risk assessment involving PFAS. It should be recognized that the exposure assessment does not generally account for the presence of all PFAS at a site due to limitations in analytical methods. Therefore, there are uncertainties in the characterization of exposures (and associated risks) at PFAS sites that should be acknowledged in the uncertainty analysis section of the risk assessment.

PFAS may be present in biosolids at levels of potential concern. If biosolids contain PFAS and are applied to agricultural fields, the PFAS may contaminate crops and livestock. The Priority Topics for Biosolids Land Application provides updated information about biosolids (see **Section 1.7**).

Blaine et al. (2013) evaluated the uptake of PFAAs contained in industrially impacted biosolids-amended soil and municipal biosolids-amended soil by various crops and confirmed “that the bioaccumulation of PFAAs from biosolids-amended soils depends strongly on PFAA concentrations, soil properties, the type of crop, and analyte.” In addition, **Lindstrom et al. (2011)** evaluated the impacts of PFAS-contaminated biosolids from a local municipal wastewater treatment facility (that historically received waste from fluorochemical facilities) used as a soil amendment in local agricultural fields. Results showed relatively high transport from soils to surface water and groundwater in the vicinity of the agricultural fields. Based on these studies, two potential exposure pathways to PFAS in biosolids are drinking water ingestion and food ingestion. A discussion of the leaching potential from soil to groundwater for biosolids is provided in **Section 6.2.3**. As indicated in **Section 6.2**, a 2021 review of reported values for biosolids, compost, and related biowastes highlights the wide concentration range of reported PFAS (primarily PFAAs) and the relationship of biowaste source to resulting concentrations (**Bolan et al. 2021**).

Biosolids as a potential source of PFAS are mentioned in **USEPA’s (2021)** PFAS Strategic Roadmap. USEPA has developed a draft risk assessment for PFOA and PFOS in biosolids (**USEPA 2025**).

9.1.2.1 Determining Scenarios for Potential Human Exposure

A site-specific conceptual exposure model should be developed during the planning stage of the HHRA, confirmed by stakeholders, and updated as additional information and data are obtained, (see **Section 3** of the RISK-3 guidance (**ITRC 2015**)). The specific exposure scenarios that are applicable to an HHRA for PFAS include those that could occur in media at the release area (the site) and in media at distant locations (with the extent depending on PFAS properties and the site setting). In general, an HHRA for PFAS may be complex in comparison to HHRAs for other types of chemicals due to the persistence of PFAS, the complexities associated with PFAS toxicity, and complexities associated with estimating future concentrations or modeling their fate and transport, and the need to include more media than is typical. Figures **9-1**, **9-2** and **9-3** are provided below to illustrate conceptual site models (CSMs) for four sources (two sources are illustrated in **Figure 9-3**) of PFAS. **Section 2.6** discusses potential environmental releases of PFAS. A detailed discussion of fate and transport processes for PFAS and environmental media that may be affected is presented in **Section 5**.

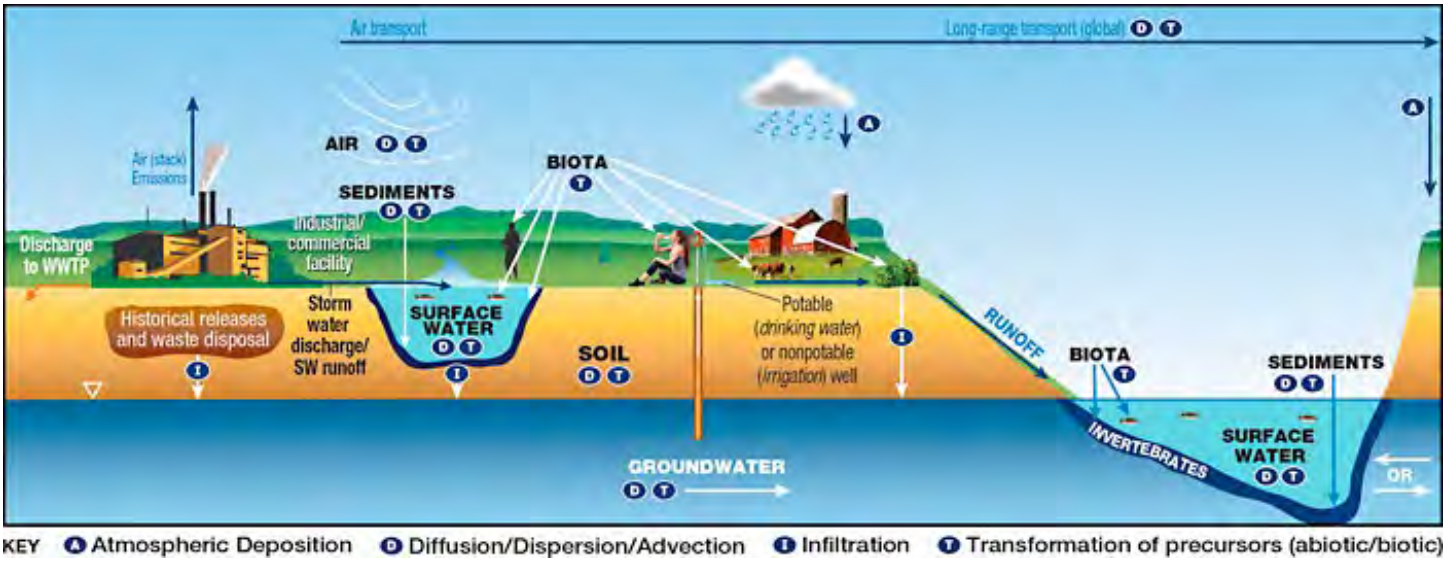

Figure 9-2. CSM for industrial sites.

Source: Adapted from figure by L. Trozzolo, TRC. Used with permission.

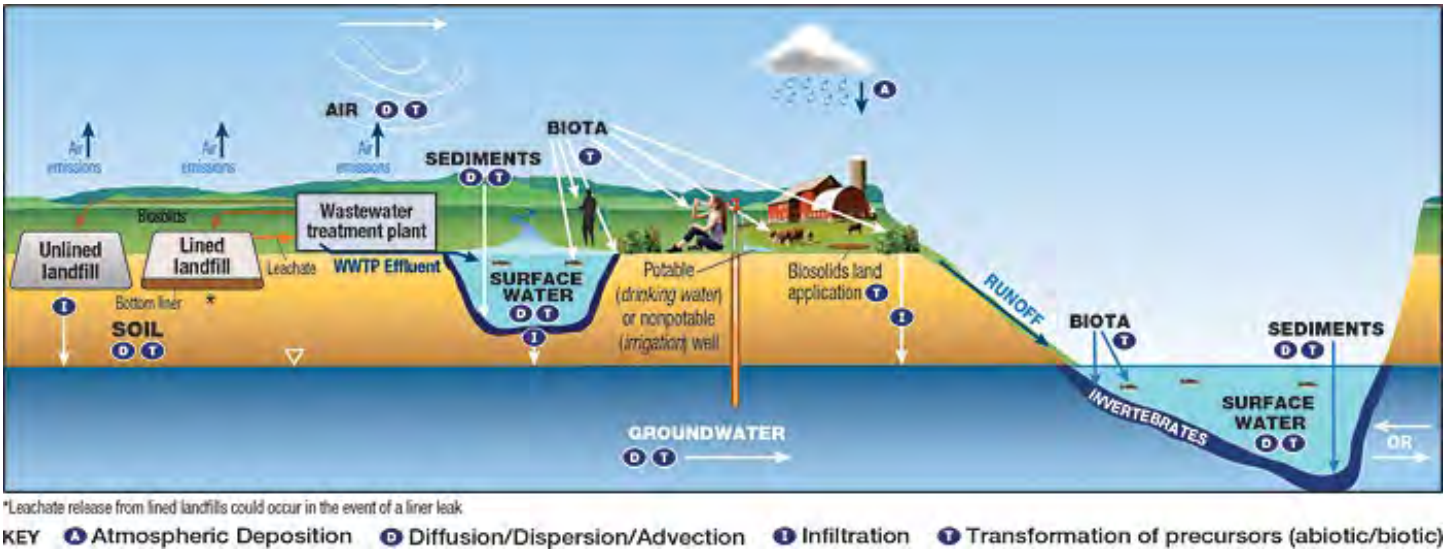

Figure 9-3. CSM for landfills and WWTPs.

Source: Adapted from figure by L. Trozzolo, TRC. Used with permission.

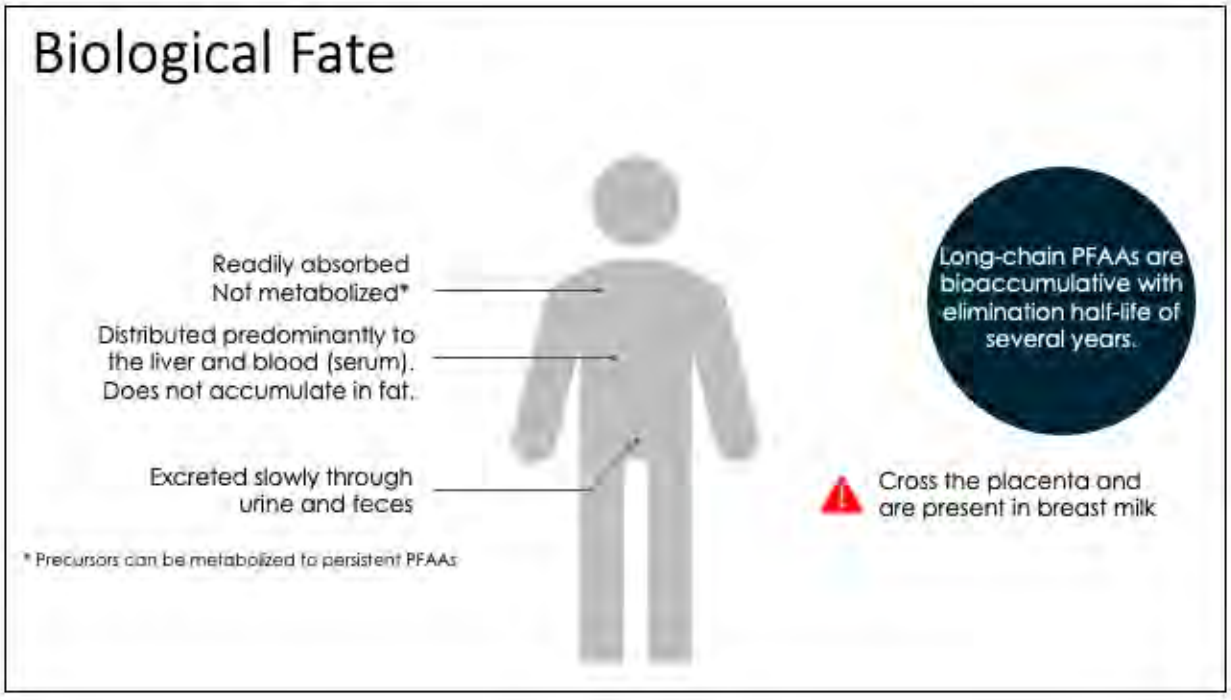

Figure 9-4. Biological fate of long-chain PFAAs.

Various exposure scenarios may be possible for a given site. Specific exposure scenarios that could be included in an HHRA are a site-specific decision.

The highest exposures to PFAS can occur during early life stages (**Goeden, Greene, and Jacobus 2019**). Exposures to infants from breast milk of exposed mothers (**Figure 9-4**) or formula prepared with contaminated water are higher (on a body weight basis) than in older age groups (**Fromme et al. 2009**; **Mogensen et al. 2015**; **Verner et al. 2016**, **Verner et al. 2016**; **Post, Cohn, and Cooper 2012**; **Goeden, Greene, and Jacobus 2019**). The higher exposures during pregnancy and to infants are of concern because fetuses and infants are potentially sensitive subpopulations for developmental effects of some

PFAS, including PFOA and PFOS (**USEPA 2024**, **USEPA 2024**), as discussed in **Section 7.1**. Therefore, exposure scenarios that include fetuses, infants, children, adolescents, and women of childbearing years should be considered in HHRAs.

Figure 9-5 illustrates the predominant exposure pathways. More detailed information about these exposure pathways, as well as other environmental medium-specific issues affecting potential human exposure scenarios, are provided in **Section 17.3.1**.

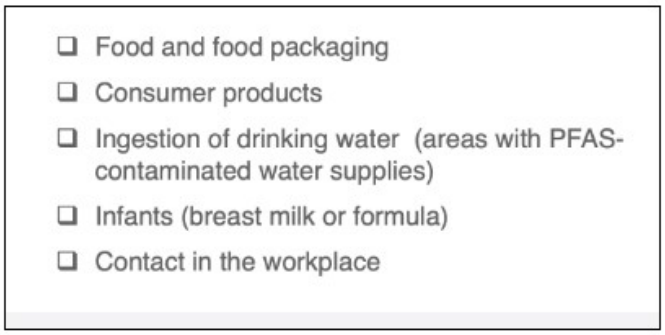

Figure 9-1. Predominant human exposure pathways.

9.1.2.2 Calculating Exposure Concentrations for PFAS via Fate and Transport Models

When using fate and transport models to calculate exposure point concentrations (EPCs) for PFAS, it is important to note that individual PFAS have different chemical properties that affect their fate in the environment (**Section 5**). Some PFAS are mobile, persistent, and bioaccumulative (in wildlife and humans), and others are not. Perfluoroalkyl acids (PFAAs) are persistent, and long-chain PFAAs bioaccumulate in humans (**USEPA 2003**; **ATSDR 2020**; **NTP 2016**; **CONCAWE 2016**). USEPA has compiled an online resource for PFAS information that includes guidance on environmental behavior and site characterization (**USEPA 2017**). The National Groundwater Association (NGWA) has also published a resource on PFAS that includes information about fate and transport (**NGWA 2017**). **Section 5.2.3** provides a discussion of fate and transport modeling for PFAS, including numerous citations. Additional information is included in **Section 17.3.2**.

When using environmental fate and transport models for estimating EPCs in biota, modeling should be focused on the part of the organism that may be consumed either by humans or by ecological receptors, recognizing that patterns of consumption may be influenced by a number of socioeconomic and cultural factors. PFAS generally bind to proteins and accumulate in protein-rich tissues, including the blood, liver, and kidneys (**ATSDR 2020**). Plant uptake and bioaccumulation and partitioning within the plant appear to depend on PFAS chemical structure and the plant species (see Section **5.6**). **Section 17.3.3** includes information about selecting bioaccumulation and bioconcentration factor values.

Measured concentrations at exposure points may differ from modeled EPCs. This may be due to other sources of PFAS (for example, a nearby site that had a PFAS release to the ground and that subsequently leached to groundwater) also contributing to concentrations at the exposure point and the limitations of the models currently available.

In surface water bodies, PFAS concentrations in foam formed at the air-water interface from wind or wave action may be much higher than PFAS concentrations present in the water column (see **Section 16.5**). Therefore, in surface water bodies where foam is present, the need to evaluate exposures to foam should be considered when planning an HHRA. At sites where foam exposures are evaluated in the HHRA, EPCs should be established separately for foam and surface water so that potential risks to foam are not underestimated.

9.1.3 Risk Characterization

The risk characterization of a site risk assessment combines the results of the exposure assessment and the toxicity assessment to provide a quantitative estimate of risk (**ITRC 2015**). It also may include a qualitative narrative designed to provide decision makers with information regarding key assumptions, uncertainties, or other issues that would be important to understand when making risk management

decisions. More background on the performance of risk characterizations is detailed in other guidance (**USEPA 1989**; **ITRC 2015**) and is not repeated here.

Because risk characterization involves combining the toxicity assessment and exposure assessment, the complexities discussed in **Sections 9.1.1** and **9.1.2** manifest themselves in the risk characterization. There are, however, additional specific complications that may be encountered in completing the risk characterization for a site risk assessment involving PFAS. This section discusses those specific complexities.

9.1.3.1 Assessing the Cumulative Effects of Exposure to PFAS

The overall potential for noncancer effects due to human exposure to more than one chemical is estimated using the hazard index (HI), which is computed as the sum of calculated chemical-specific hazard quotients (HQ). As explained by **USEPA (1989)**, "This approach assumes that simultaneous subthreshold exposures to several chemicals could result in an adverse effect. It also assumes that the magnitude of the adverse effect will be proportional to the sum of the ratios of subthreshold exposures to acceptable exposures." Risk characterizations commonly produce initial estimates of HI by calculating the sum of all HQs. When the HI is estimated to be greater than 1, there may be potential concern for adverse health effects. However, when this initially estimated HI is greater than 1, refinement of the HI estimate by segregating HIs by effect and mechanism of action may be appropriate to support a risk management decision.

Table 9-2. Summary of potential noncancer health effects of various PFAS.

Compound	# of Carbons	Liver	Develop-mental	Repro-ductive	Immune	Hema-tologic	Thyroid	Neuro-behavioral	Tumors
Perfluoroalkyl Carboxylates									
PFBA	4	■	■	■	□	■	■	□	□
PFPeA	5	□	□	□	□	□	□	□	□
PFHxA	6	■	■	■	□	■	■	□	□ (Negative)
PFHpA	7	■	□	□	□	□	□	□	□
PFOA	8	■	■	■	■	■	■	■	■
PFNA	9	■	■	■	■	■	■	□	□
PFDA	10	■	■	■	■	■	■	■	□
PFUnA	11	■	■	□	■	□	□	□	□
PFDoA	12	■	■	■	■	■	□	■	□
Perfluoroalkyl Sulfonates									
PFBS	4	■	■	■	■	■	■	□	□
PFHxS	6	■	■	□	□	■	■	■	□
PFOS	8	■	■	■	■	■	■	■	■
Per- & Polyfluoroalkyl Ether/Polyether Carboxylates; Fluorotelomer Alcohols (Examples)									
ADONA	6	■	■	□	□	■	□	□	□
GenX (HPFO-DA)	6	■	■	■	■	■	■	□	■
ClPFPECAs	8-14	■	□	□	■	■	■	■	□
6:2 FTOH	8 (6 fluorinated)	■	■	■	■	□	□	□	□

Notes: The colors used for the PFAS names distinguish between short-chain PFAS (green) and long-chain PFAS (blue). A filled-in (black) box indicates that the effect was reported in one or more laboratory animal studies. An empty box indicates that the effect was evaluated but not found, or effect has not been evaluated.

*Source: Adapted from (**ATSDR 2022**).*

USEPA has developed a Framework for Estimating Noncancer Health Risks Associated with Mixtures of Per- and Polyfluoroalkyl Substances (PFAS) (**USEPA 2024**). This document recommends assessment of noncancer health risks of PFAS mixtures based on dose additivity (for example, a hazard index [HI]

approach). **USEPA (2024)** is the basis for a MCLG and MCL of an HI of 1 for mixtures of four PFAS (PFBS, PFHxS, PFNA, GenX) (**USEPA 2024**). The draft MCLG and MCL use the "general" HI approach in which the HI considers toxicity values based on differing toxicological endpoints for the components of the mixture. More information on risk assessment of PFAS mixtures is found in **Section 7.1.5**.

As discussed in **Section 7.1**, several possible adverse health effects are associated with exposure to PFAS (**Table 9-2**). The type of information shown in this table can be used to segregate HIs by potential adverse effect in the risk characterization (i.e., the "Target Organ-Specific Hazard Index") when risks associated with exposure to specific PFAS are being evaluated and target organ-specific toxicity factors are available.

9.2 Ecological Risk Assessment

This section summarizes information that is currently available to conduct ecological risk assessment (ERA) of PFAS. The information presented is based on a review of current regulatory guidelines from within the United States and other jurisdictions, peer-reviewed publications, and other sources as noted. Sufficient information needed for performing ERAs exists only for some PFAS. When possible, discussions in this section indicate to which PFAS the discussions apply. Three recent publications funded by the US DOD, **Conder et al. (2020)**, **Divine et al. (2020)**, and **Argonne (2021)** discuss PFAS ERA in detail and provide a summary of much of the available data needed for conducting PFAS ERA within the U.S. These are the most comprehensive reports to date for completing PFAS ERAs within the U.S. The European Union (EU) also has a substantial amount of data available within their Environmental Quality Standards (EQS) for performing PFAS ERA, but the EQS use different guidelines and approaches than those in the U.S. Use of these data will likely result in conflicting values and differing conclusions on data usability and adequacy for performing an ERA. The Priority Topics for Human and Ecological Health Effects include information for evaluating risk to livestock from PFAS exposure (see **Section 1.4.7**).

This section discusses challenges within three key components of ERA: ecological effects assessment, exposure assessment, and risk characterization. **Conder et al. (2020)** and **Divine et al. (2020)** are referenced throughout those discussions as applicable. In addition, a workshop sponsored by the Society of Environmental Toxicology and Chemistry (SETAC) was held in August 2019 and focused on the state-of-the-science supporting risk assessment of PFAS. A breakout group within that workshop focused specifically on ecotoxicology and ecological risks of PFAS. The expert panel in that breakout group produced a detailed manuscript describing the currently available information, data gaps, and uncertainties, and approaches to address these needs (**Ankley et al. 2020**). Like the **Conder et al. (2020)** and **Divine et al. (2020)** reports, the recommendations of **Ankley et al. (2020)** are also directly related to conducting PFAS ERAs and are mentioned here to provide readers an understanding of subjects that are relevant but that still have uncertainty so they can assess the importance of those subjects for their specific needs. **Ankley et al. (2020)** is referenced throughout this section as applicable. Additional recommendations from **Ankley et al. (2020)** not included later in this section are listed below:

- a need for prioritizing which PFAS to study and evaluate relative to ecological risk and toxicity
- environmental monitoring beyond PFOS and PFOA
- advancing the understanding of PFAS uptake, elimination, and bioaccumulation
- broader understanding of toxicity across taxa
- the use of new approach methods (often referred to as NAMs) and
- studying and assessing PFAS as mixtures.

The remaining text for this section is organized into three main components of ERA: ecological effects assessment, exposure assessment, and risk characterization.

9.2.1 Ecological Effects Assessment

Identification of ecological risk-based toxicity thresholds is a challenge for many PFAS. Toxicity data are available as discussed in **Section 7.2**. Some of these data have been used to establish thresholds as discussed below. Some major considerations for ecological effects assessment are identifying ecological screening thresholds, understanding ecological receptor variability, and evaluating ecological toxicity of mixtures. These are discussed in the following sections.

9.2.1.1 Ecological Screening Thresholds

The recently published manuscript by **Ankley et al. (2020)** includes a discussion of media-specific ecological screening thresholds that are available for certain PFAS around the world: PFOS, PFOA, PFBA, PFPeA, PFHxA, PFBS, and PFHxS. **Ankley et al. (2020)** did not claim the list of thresholds to be comprehensive of all ecological thresholds for PFAS around the world. The discussion here in this section presents thresholds that are included within that document with discussion relevant to ITRC's intended audience. **Ankley et al. (2020)** can be referenced for a more detailed discussion and complete table of available thresholds from around the world.

U.S.—Federal Thresholds

USEPA has published draft national recommended aquatic life criteria for PFOA and PFOS in freshwater for public comment (**USEPA 2022**, **2022**) and a fact sheet for the criteria (**USEPA 2022**). In addition, USEPA had published their responses to external peer reviews of the draft criteria (**USEPA 2022**, **2022**). The draft criteria include acute and chronic water column values for freshwater environments and acute criteria for estuarine/marine environments. Tissue criteria are also proposed for whole body fish and benthic invertebrates and for fish muscle. These criteria are aimed at protection of aquatic life but are not protective of consumption by aquatic dependent wildlife (for example, birds and mammals foraging in aquatic environments). Currently, there are no ecological risk-based PFAS guidelines or media screening thresholds that are recommended by the USEPA for other PFAS.

In support of the Air Force Civil Engineer Center, Argonne National Laboratory developed ecological screening thresholds for surface water and soil (**Argonne 2021**). Values were developed for 4-, 6-, 8-, 9-, and 10-carbon linear PFCAs and the 4-, 6-, and 8-carbon linear PFSAs (see **Section 2** for detailed naming conventions). The soil screening values are protective of terrestrial plants, invertebrates, and mammalian and avian wildlife. The surface water values are protective of aquatic life and aquatic dependent wildlife. Work was completed in consultation with Tri-Services Environmental Risk Assessment Working Group, and USEPA's Ecological Risk Assessment Forum (**Ankley et al. 2020**).

There have also been a number of published studies and reports that follow U.S. federal guidelines (**USEPA 1995**) for developing aquatic life criteria. **Giesy et al. (2010)**, **Salice et al. (2018)**; **Conder et al. (2020)**, and **Divine et al. (2020)** all calculated thresholds protective of aquatic organisms exposed to PFOS in freshwater environments, though these were published before USEPA released their draft criteria. **Giesy et al. (2010)** also reported a Tier II freshwater value for PFBS, while **Conder et al. (2020)** derived Tier I values for PFOS in both freshwater and marine environments and for PFOA for freshwater. **Divine et al. (2020)** developed Tier I freshwater values for PFOS and PFOA and Tier II values for 23 other PFAS. Tier I values meet the data required described in **USEPA (1995)** guidelines while Tier II values are developed with methods that incorporate uncertainty factors when the availability of required data is insufficient. Section 16.3 provides greater detailed discussion on the methods for developing thresholds protective of aquatic life.

U.S.—Thresholds for Specific States

Several states have established some criteria that are intended to protect aquatic organisms in their respective surface waters. The text below is not intended to be exhaustive and summarizes only some of the values that were available at the time this text was developed (Spring 2021).

In Michigan, AWQC have been established for PFOS and PFOA based on Rule 57 17 (**MI EGLE 2019**). This rule is based on the USEPA Great Lakes Initiative (**USEPA 1995**), which provides procedures and methodologies to derive numerical criteria that are protective of aquatic ecosystems. Rule 57 presents a two-tiered methodology in which Tier I procedures are essentially the same as the methods used to derive federal national water quality criteria (NWQC) (**USEPA 1985**) and Tier II procedures can be used to derive values where the full extent of the toxicity data requirements of NWQC are not fulfilled. Rule 57 presents procedures to develop three categories of numeric criteria—final chronic values (FCVs), aquatic maximum values (AMVs), and final acute values (FAVs)—which can be developed under either Tier I or Tier II. Due to the greater uncertainties associated with Tier II values, and given their lesser data requirements, these values tend to be more conservative than those derived with Tier I methodologies. The PFOA and PFOS numeric criteria for Michigan are all Tier II values due to the limited amount of peer-reviewed aquatic toxicity data. The final chronic values for the protection of aquatic life (flora and fauna) for PFOA and PFOS were 880 and 140 µg/L, respectively, while aquatic maximum values were 7,700 and 780 µg/L, respectively. In addition, the Michigan Department of Community Health (**MDCH 2015**) derived provisional PFOS surface water values for mammalian and avian wildlife based on Rule 57 guidance. The surface water avian wildlife value, based on eagles, kingfishers, and herring gull characteristics, was 0.035 µg PFOS/L. The mammalian wildlife value, based on otter and mink characteristics, was 0.084 µg PFOS/L.

The State of Minnesota has also derived several surface water criteria for the protection of aquatic biota. These values are based on guidelines in Minnesota Rules chapter 7050 (MR7050). Continuous chronic criteria for the protection of aquatic biota in surface water are available for PFOA (1,700 µg/L) and PFOS (19 µg/L) (**Stevens and Coryell 2007**; **Stevens and Coryell 2007**). Florida has established Provisional Surface Water Screening Levels that are in the same range as those for Minnesota: 1,300 µg/L PFOA in freshwater, 37 µg/L PFOS in freshwater, and 13 µg/L PFOS in salt water (**FL DEP 2020**).

Table 9-3. SFB RWQCB groundwater ESLs: Aquatic habitat ecotoxicity levels for PFOS and PFOA (SFB RWQCB 2020).

Protected Organisms	PFOS (µg/L)	PFOA (µg/L)
Direct exposure ecotoxicity: Freshwater	0.56	540
Direct exposure ecotoxicity: Saltwater	2.6	540
Secondary poisoning ecotoxicity: Freshwater and saltwater	0.075	4.4

Table 9-4. Soil ESLs: Terrestrial habitat levels (SFB RWQCB 2020).

Protected Organisms	PFOS (mg/kg)	PFOA (mg/kg)
Significantly vegetated areas		
Plants and invertebrates	7.7	0.084
Mammals and birds (NOAEL-based)	0.013	0.57
Minimally vegetated areas		
Plants and invertebrates	33	0.84
Mammals and birds (LOAEL-based)	0.05	1.1

In California, the San Francisco Bay Regional Water Quality Control Board (SFB RWQCB) has released Interim Final Environmental Screening Levels (ESLs) for PFOS and PFOA (**SFB RWQCB 2020**). These values were specifically developed for use within the jurisdiction of the specific water board, not the state of California, not the California Department of Toxic Substances Control, and not the entirety of the United States. Other jurisdictions may use these values, as is often the case with many published thresholds. However, with the number of different water boards in California, it is important to understand the applicability of these ESLs. These values include groundwater protection levels that are protective for direct exposure to freshwater and marine organisms, including rare, threatened, and endangered species. The values are based on a 99% protection level (lower 1st percentile of a species sensitivity distribution [SSD]) compared to a 95% protection level (lower 5th percentile of an SSD) used for a typical AWQC. There are also groundwater ESLs that are protective of adverse effects to birds and mammals from the consumption of aquatic prey (**Table 9-3**). These wildlife protection values (listed by the SFB RWQCB and in **Table 9-3** as secondary poisoning ecotoxicity) are based on values published in **Divine et al. (2020)**. Separate soil ESLs are included in the SFB RWQCB document that are protective of (1) plants and invertebrates or (2) birds and mammals. There are two soil ESLs for each chemical for both significantly vegetated and minimally vegetated areas for a total of four distinct values each for PFOS and PFOA as shown in **Table 9-4**.

International Thresholds

Environment and Climate Change Canada (ECCC, previously known as Environment Canada) has proposed ecological Federal Environmental Quality Guidelines (FEQGs) for PFOS in surface waters, fish tissue, wildlife dietary values, and bird eggs (**ECCC 2018**). The PFOS threshold for surface waters was derived from a SSD based on long-term toxicity data that included data for amphibians, fish, invertebrates, phytoplankton, and macrophytes. The guideline to protect all aquatic life forms for indefinite exposure periods to PFOS in surface waters is 6.8 µg/L, and a whole-body fish tissue guideline value of 9.4 mg/kg wet weight (ww) was based on these fish data and bioaccumulation factors for bluegill from **Drottar, Van Hoven, and Kruger (2002)**. The tissue threshold is intended for both freshwater and marine environments. It was not calculated with both food and water (direct media) BAFs, and thus it could be underprotective. However, **Giesy et al. (2010)** did use **Drottar, Van Hoven, and Kruger (2002)** data to calculate an acute no-effect threshold of 87 mg/kg ww whole-body fish. To protect mammalian and avian consumers of aquatic biota, ECCC derived wildlife dietary toxicity reference values (TRVs) using mammalian studies and avian chronic toxicity data. For mammals, the dietary value for PFOS was 4.6 µg/kg ww food while the avian dietary value was 8.2 µg/kg ww food. Based on the avian reproduction studies that were the basis for the dietary values, a guideline of 1.9 µg/g ww whole egg was also derived for PFOS.

Screening level assessment values have also been derived for PFOA (**Environment Canada 2012**). Environment Canada derived several predicted no-effect concentrations (PNECs) for PFOA for ecological species. PNECs are intentionally conservative concentrations of chemicals designed to represent a concentration at which no adverse effects are likely. These PNECs for PFOA were based on LOAEL values from a limited set of single organism toxicity studies adjusted with uncertainty factors. FEQG values are developed from a distribution of acute and chronic studies conducted on groups of organisms with an intent to be protective of a set percentage of organisms in that category (for example, a 95% protection threshold). Thus, these PFOA PNECs are not equivalent to FEQGs, though they still provide utility for screening level ERA. The PNEC for aquatic organisms, based on a study with the freshwater alga *Pseudokirchneriella subcapitata*, was 20 µg/L; a mammalian wildlife study based on cynomolgus monkey *(Macaca fascicularis)* derived a liver-based PFOA PNEC of 158 µg/kg ww. However, given the uncertainties associated with these values, care should be taken in their application to ERA. FEQGs for PFOA are currently under development by ECCC (**ECCC 2018**).

The Australian and the New Zealand Environment and Conservation Council and Agriculture and Resource Management Council of Australia and New Zealand (ANZECC/ARMCANZ) have established

draft protective concentrations for freshwater organisms exposed to PFOS and PFOA. The values, as shown in **Table 9-5**, were developed by the Cooperative Research Centre for Contamination Assessment and Remediation of the Environment **(CRC CARE) (2018)**. Only the freshwater values have been adopted in the PFAS National Environmental Management Plan for Australia and New Zealand (**HEPA 2020**). The protocol for developing guideline values in Australia (**Warne et al. 2018**) includes some specifications for full lifecycle and multigenerational testing that were not sufficiently represented in the limited available marine studies. Instead, the freshwater values have been identified as interim thresholds for marine waters. The values from CRC CARE incorporated multiple studies and were based on SSD for each compound. The 90 and 95% protective thresholds for PFOS are 2.0 and 0.13 µg/L, respectively. These values are within the range of other published values (**Giesy et al. 2010**; **Qi et al. 2011**). A 99% protection value for PFOS was also proposed as 0.00023 µg/L, though this may be below ambient concentrations. It should be noted that the freshwater SSD and subsequent protection values are influenced by a multigenerational study (**Keiter et al. 2012**) with zebra fish (*Danio rerio)* that produced data that are noticeably lower than other data. Efforts to validate the data by repeating the study and its methods are ongoing at the US Army Corps of Engineers Environmental Research and Development Center (**Gust et al. 2021**). The ongoing work includes an expanded and more carefully determined dosing range, greatly increased replication base on statistical power analysis, expanded analytical chemistry with external validation, and an expanded suite of endpoints to improve overall toxicological context (**Gust et al. 2021**). All three of the PFOS protection values are taken from an SSD that includes studies on the low end that are well below the majority of other data points. Further, as indicated in table B3 of **CRC CARE (2018)**, data used in the SSD include a mix of effect levels (EC10) and no-effect levels (NOECs). Thus, decisions based on these values should be made with careful consideration.

For PFOA, the 90 and 95% protective thresholds were 632 and 220 µg/L, respectively; these are similar to those derived in Minnesota and Michigan. Marine threshold values for PFOS were 32 and 7.8 µg/L for the 90 and 95% protective levels. For PFOA, the 90 and 95% protective thresholds for marine water were 14,000 and 8,500 µg/L, respectively. It is of note that the threshold values for marine species were at least 1–2 orders of magnitude greater than those from freshwater. Thus, one should take care in using freshwater toxicity data or threshold values when evaluating marine and brackish systems, given the apparent differences in species sensitivity between these two environments. Likewise, caution should be used if employing marine values to evaluate other PFAS for which there are no freshwater threshold values.

Table 9-1. Aquatic thresholds developed by CRC CARE (CRC CARE 2018).

Species Protection (%)	PFOS (µg/L)	PFOA (µg/L)
Freshwater		
80	31	1,824
90	2	632
95	0.13	220
99	0.00023	19
Marine		
80	130	22
90	32	14
95	7.8	8.5
99	0.29	3

A number of thresholds for PFOS are also available from the European Union (EU) as described in the Environmental Quality Standards Dossier (EQS) for PFOS (**European Union 2011**, **2013**). These include maximum acceptable quality standards (MAC-EQS) for freshwater and marine ecosystems, and annual average quality standards (AA-EQS) for the same ecosystems. Standards are also available for secondary poisoning (that is, consideration of biomagnification through the consumption of contaminated prey). These values are shown in **Table 9-6**.

Table 9-6. Environmental quality standards (EQS) for PFOS (European Union 2011, 2013).

Category/Description	Units	Value
MAC-EQS (freshwater) (European Commission 2011, 2013)	µg/L	36
MAC-EQS (marine) (European Commission 2011, 2013)	µg/L	7.2
Pelagic Community EQS (freshwater) (European Commission 2011)	µg/L	0.23
Pelagic Community EQS (marine) (European Commission 2011)	µg/L	0.023
$QS_{biota,\ sec\ pois}$ (European Commission 2011)	mg/kg (ww)	0.033
$QS_{biota,\ sec\ pois}$ (freshwater) (European Commission 2011)	µg/L	0.002
$QS_{biota,\ sec\ pois}$ (marine) (European Commission 2011)	µg/L	0.00047
EQS (biota) (European Commission 2011, 2013)	µg/L	9.1
AA-EQS (freshwater) (European Commission 2011, 2013)	µg/L	0.00065
AA-EQS (marine) (European Commission 2011, 2013)	µg/L	0.00013

Notes: MAC-EQS = maximum acceptable environmental quality standard
AA-EQS = annual average environmental quality standard
QS biota, sec pois = secondary poison standard for concentration in fish tissue
QS = quality standard
EQS (biota) – environmental quality standard

Other Considerations for Thresholds

A survey of reports from various regulatory agencies demonstrates that although ecotoxicity data are available for various PFAS, including PFBA, PFBS, and fluorotelomers (including 8:2 FTCA, 8:2 FTUCA, and several FTOHs), to date these typically consider only a few aquatic species that include *D. magna*, a green alga, and perhaps a fish species. Some regulatory programs (for example, **USEPA 1985**; **Warne et al. 2018**) require a robust data set covering several classes of organisms, and due to limitations in the number of classes of organisms represented in the published peer reviewed data, it is difficult to derive ambient surface water quality criteria for other PFAS (beyond PFOS and PFOA). Limited relevant toxicity data is a greater issue for terrestrial wildlife given that the only chronic, reproductive studies with two PFAS (PFOS and PFOA) that have been conducted to date are in two species, the bobwhite quail (*Colinus virginianus*) and mallard duck (*Anas platyrhynchos*). However, more data are becoming available for other PFAS (for example PFHxS and PFHxA) in avian laboratory models (**Dennis et al. 2021**). Importantly, no ecologically relevant studies have been conducted with mink or an adequate surrogate. As a result, the development of benchmark or threshold concentrations for wildlife and aquatic organisms has been slow but information is beginning to emerge.

Research on observed effects in benthic invertebrates and other benthic aquatic life with direct exposure to sediments contaminated with PFAS is limited. However, more recent literature is becoming available for sediment exposures (**Marziali et al. 2019**), there are no published benchmarks and publications are few. Research has focused more on aqueous exposure pathways. Observational data and monitoring have been used in some cases to develop an understanding of what exposure may be associated with effects. The Norwegian Pollution Control Agency (NPCA) established a sediment no-effect threshold of 220 µg/kg, a chronic toxicity range of 220–630 µg/kg, and an acute short-term effects range of 630–3,100 µg/kg (**NPCA 2008**; **Bakke et al. 2010**) for benthic invertebrates. The technical basis for the NPCA values relied on the principles of equilibrium partitioning (EqP) between sediment and surface water using a partitioning coefficient (Kd). **Argonne (2021)** also outlines this approach for determining site-specific sediment thresholds. The NPCA no-effect sediment value is based on a PNEC of 72 µg/L from a limited data set and an unspecified Kd. A sediment screening value of 6.7 µg/kg (wet weight) from the United Kingdom's **UK Environment Agency (2004)** was also developed using EqP with a PNEC of 2.5 µg/L and a river sediment Kd of 8.7 L/kg. **Simpson et al. (2021)** have estimated sediment thresholds of 60

µg/kg PFOS and 250 µg/kg PFOS (both normalized to 1% organic carbon) protective of 99% and 95% of species, respectively, based on EqP using a Kd of 10 L/kg with an HC1 of 6 µg/L and HC5 of 25 µg/L. HC5 and HC1 are commonly established for contaminants from SSDs developed for the contaminant. These HCx (for example a HC5) represent the concentration above which the lower x proportion of species in the distribution may see adverse effects.

All of these sediment thresholds were reported for PFOS concentrations in marine sediments, though they provide some basis for screening level risk decisions for both marine and freshwater. Caution should be observed in using these values because associated effects, if any, are unclear, and the original work is not readily available. Caution should also be used in applying these NPCA sediment values from marine waters to freshwater because the freshwater organisms could be more exposed (as explained in **Section 9.1.2**) and either more or less sensitive than marine organisms. In its EQSD for PFOS, the **European Union (2011)** took the position that there is insufficient data available to confirm the need for a sediment quality standard and insufficient data to derive a threshold, thus electing not to develop a value. Similarly, a workgroup in northern Italy concluded that there was no need for a sediment environmental quality standard (EQS) for PFOA, PFBS, PFBA, and PFPeA and that data for a sediment EQS for PFHxA were insufficient (**Valsecchi et al. 2017**).

For soil, CRC CARE developed soil screening thresholds from SSDs for both PFOS and PFOA. The Canadian Council of Ministers of Environment (**CCME 2018**) has also developed several draft thresholds for PFOS in soil. A value protective of direct toxicity was developed from an SSD of plant and invertebrate IC25 values (the concentration at which a 25% reduction in a non-lethal biological measurement, such as growth or reproduction, occurs). Food chain models were used to develop values protective of soil and food ingestion by wildlife. **CCME (2018)** also developed a soil screening value protective of aquatic life for use at sites where off-site migration to nearby surface water bodies may be a concern. These values from CCME were issued draft for public comment, and final FEQGs have not yet been established. Soil threshold values for other PFAS, however, are limited.

9.2.1.2 Ecological Receptor Variability

Another major challenge with toxicity assessment for ERA is accounting for the large number of receptor types and the associated unknown variable sensitivity to PFAS. Although it is commonly understood that sensitivity to contaminants can vary widely across kingdoms or across classes of animals, the challenge for PFAS may be greater due to the lack of knowledge about this family of compounds. Studies have documented the presence of PFAS in various aquatic species since the 1950s (**Danish EPA 2015**; **Giesy and Kannan 2001**, **2002**), such as bottle-nosed dolphins (**Houde et al. 2006**), seals (**Butt et al. 2008**), squid (**Yang et al. 2012**), alligators (**Bangma et al. 2017**), and polar bears (**Smithwick et al. 2005**; **Smithwick et al. 2005**; **Greaves and Letcher 2013**). The detection of PFAS within organisms is clear evidence of exposure. Unlike many other commonly detected contaminants, however, the availability of toxicological data for PFAS is limited relative to the broad range of organisms within which PFAS have been detected.

Standard ERA practice includes developing TRVs that consider measures of exposure and effects that could adversely impact populations of wildlife (for example, chronic studies on reproduction, growth, and survival). Mammalian studies on numerous sublethal endpoints (for example, systemic, immunological, developmental, respiratory, cardiovascular, gastrointestinal, ocular, hepatic) have been conducted for PFOS, PFOA, and other PFAS and are well described in the *Toxicological Profile for Perfluoroalkyls* (**ATSDR 2021**), but these are less commonly used for TRV development for ERAs. These sublethal, mostly systemic or organ function-based TRVs are really only used for ERAs in the absence of reproduction, survival, or growth data. Mammalian TRVs for the purposes of ERA can be developed for the majority of the Third Unregulated Contaminant Monitoring Rule (UCMR3) PFAS compounds listed in **Section 8.2.2.2**. Recommendations for selecting TRVs from available data for conducting ERAs are included in **Divine et al. (2020)**, **Conder et al. (2020)**, and **Johnson et al. (2021)**. Avian oral dosing studies useful for ERA are

less available. The dietary acute and chronic studies by **Newsted et al. (2005)**; **Newsted et al. (2007)** examining PFOS exposure in mallard and bobwhite quail were the first published work relevant to ERA. **Divine et al. (2020)** and **Conder et al. (2020)** presented the data from their studies as well as data from other studies and for other PFAS that can be used for selecting avian TRVs. More recent publications relevant to ERA include that of **Bursian et al. (2021)**, who looked at oral exposure of Japanese quail (*Cortunix japonica*) to PFOS, PFOA, and AFFF (both 3M and Ansul products), and (**Dennis et al. 2020**, **2021**, **2021**) who looked at northern bobwhite quail exposed to PFOS, PFHxS, and PFHxA. **Newsted et al. (2005)** and **Molina et al. (2006)** have also reported the results of bird egg injection studies using PFOS, while **Cassone et al. (2012)** and **Norden, Berger, and Engwall (2016)** have published in ovo studies with other PFAS. A caution with interpreting these egg studies is the uncertainty as to whether naturally accumulated concentrations have the same adverse effect as concentrations administered via injection in ovo. There also can be differences when measuring whole egg, yolk, or albumin (**Custer, Gray, and Custer 2010**). Finally, there is currently not enough data for modeling egg tissue concentration for these chemicals.

Reptiles are among the least studied vertebrate taxa in ecotoxicology (**Hopkins 2000**; **Weir, Suski, and Salice 2010**) despite contamination threatening reptile populations worldwide (**Gibbons et al. 2000**). A recent study (**Furst, Weible, and Salice 2019**) exposing brown anoles (*Anolis sagrei*) to PFOS and PFHxS provides data relevant to ERA. Measures of apical endpoints included decreased growth of juveniles exposed to PFOS, while exposure to PFHxS resulted in decreased egg viability in female anoles. There are two more recent reptile studies on lizards (**Zhang et al. 2020**) and snakes (**Lettoof et al. 2023**), both of which suggest that PFAS exposure may result in decreased growth and/or body condition in reptiles. See **Section 7.2.3.2** for more information.

Amphibian toxicity data are also limited, though more are available than are reptile data. **Pandelides et al. (2023)** provides a comprehensive, critical review of recent amphibian ecotoxicity studies and the USEPA ECOTOX Database includes PFAS toxicity studies on toads, frogs and salamanders (**USEPA 2024**). See **Section 7.2.3.2** for more information.

For lower trophic-level organisms such as plants and invertebrates, toxicological data are typically generated through studies with direct exposure to spiked media. Studies are available to develop thresholds for use in ERAs, as has been done by **ECCC (2018)**, **CRC CARE (2017)**, **Conder et al. (2020)**, and **Divine et al. (2020)**. SSDs produced by **CRC CARE (2017)** showed lettuce to be more sensitive to PFOS than earthworms, but found the opposite occurred for PFOA. **Divine et al. (2020)** calculated Tier I water quality values for PFOS and PFOA, Tier II water quality values for another 21 PFAS, and soil screening values for plants and soil invertebrates for 6 PFAS each. **Giesy et al. (2010)** and **ECCC (2018)** generated PFOS SSDs for freshwater aquatic organisms, from which thresholds were derived. CRC CARE presented SSDs for PFOS and PFOA for marine waters and for soil to establish their thresholds. **Giesy et al. (2010)** noted that some guidelines for developing criteria from SSDs rely heavily on the four lowest effect concentrations; thus, results can be skewed if one genus or species is significantly more sensitive than others. In the freshwater SSD for PFOS generated by **Giesy et al. (2010)**, *Chironamous tentans* (a species of midge) were 40 times more sensitive than the next most sensitive species, the fathead minnow (*Pimephales promelas*). However, the **ECCC (2018)** SSD does not show the same difference in sensitivity with a reported 14-day growth LOEC for Japanese rice fish (*Oryzias latipes*) below the *C. tentans* 10-day NOEC. For marine waters, fish are among the most sensitive organisms for both PFOS and PFOA as shown in SSDs (**CRC CARE 2017**), but they are more sensitive by just an order of magnitude or less. Additional studies by **Simpson et al. (2021)** and **Hayman et al. (2021)** have expanded the understanding of potential toxic effects in aquatic organisms in marine waters but an SSD that includes data from both of these studies has not been published.

SSDs have not been published for avian, mammalian, reptilian, or amphibian species. Although SSDs could possibly be generated for laboratory mammalian species exposed to some PFAS, data are insufficient to generate robust SSDs that are applicable to wildlife species. Mammalian SSDs would

include mostly rat and mouse studies with a few monkey and rabbit studies. Extrapolation to other orders would be required. Existing data would be more conducive to an effects distribution because the number of species within the class of organisms would be so limited. A limited amount of published data is available for avian, reptilian, or amphibian animals, but these data are insufficient to determine a robust SSD or even an effects distribution.

Available toxicological data clearly do not adequately cover the range of organisms that are exposed to PFAS or within which PFAS have been detected, nor do the data have much breadth for chemicals beyond PFOS and PFOA. Sensitivity variation for aquatic organisms is evident from the SSDs, and likely sensitivity ranges for untested wildlife leave a clear knowledge gap for some or even most ERAs. However, this problem is not unique to PFAS. As with many other bioaccumulative and biomagnifying compounds, this knowledge gap can be addressed by using available data from surrogate organisms (for example, the closest taxonomic laboratory test species) and making some assumptions. The uncertainty in the potential difference in sensitivity needs to be acknowledged and discussed within ERAs. However, pending the outcome of quantitative analysis, risk conclusions and even risk management decisions are possible on a site-specific basis. Although extrapolations with surrogates is a common practice in ERA, caution should be used and decisions should be made in concurrence with regulatory agencies or other applicable stakeholders.

9.2.1.3 Ecological Toxicity of Mixtures

An additional major challenge in effects assessment for PFAS is considering the toxicity of mixtures. PFAS nearly always occur as complex mixtures in natural environments with multiple PFAS present at concentrations that vary by site and source of PFAS. At this time there are only limited data available to understand the toxicity of more than just a few chemicals based on single chemical exposure experiments such as direct toxicity to lower trophic level organisms or dietary exposures to upper trophic level wildlife. Thus, the ability to understand the toxicity of mixtures is limited by the scarcity of available toxicity data. However, in the absence of such data, several strategies using structural and physical properties and toxicity information from PFAS with available data may be helpful to infer potential mixtures effects, including mixtures with PFAS of unknown toxicity. These strategies include the use of in silico predictive techniques (for example, quantitative structure-activity relationships (QSARs)), using read-across from data-rich PFAS to inform data-poor PFAS, and estimating potential mixture risk using dose-addition risk assessment methods (for example, hazard index or relative potency factor approaches). Examples of published studies using QSAR for estimating PFAS toxicity include **Hoover et al. (2019)**, **Kovarich et al. (2012)**, and **Cheng and Ng (2019)** and additional citations within each of those publications. These studies typically evaluate an in vitro endpoint (such as cell death (**Hoover et al. 2019**)) or in silico measurements (such as the binding ability of known PFAS to specific cellular proteins (**Cheng and Ng 2019**; **Kovarich et al. 2012**) and then use QSAR to estimate how other PFAS would respond to that same endpoint or target. Similarly, **Droge (2019)** derived phospholipid membrane–water partition coefficients (K_{MW}) that were used within a model to predict induction of narcosis ($LC_{50,narc}$) and which could be used in the future with K_{MW}-QSARs.

Most of these studies aim to fill data gaps for individual PFAS. Since it is not yet clear how PFAS may cause toxicity to various ecological receptors, the applicability of these data to ecological risk assessment of mixtures is unknown. However, with additional chemical-specific data, methods for estimated combined toxicity, such as hazard index or relative potency factors, could then be applied. Caution should be used when applying any of these approaches; some of these methods are novel and others may be well established but are predicated on specific data-supported assumptions that have not been universally accepted. Standardized toxicity tests, such as those performed with terrestrial and aquatic invertebrates and plants, are available for performing controlled dosing experiments and for exposure tests with field samples containing natural mixtures. Laboratory dosing experiments with whole mixtures, mixtures of prioritized PFAS, or with specific formulations, and with exposure concentrations that bracket environmental relevance, are all needed to inform ecological toxicity of mixtures.

There are a number of ongoing research projects investigating simultaneous exposure of ecological receptors to multiple PFAS (primarily the UCMR3 chemicals) and their precursors, with these studies mostly using binary mixtures (**Lee et al. 2017**; **Flynn et al. 2019**; **Bursian et al. 2021**; **Dennis et al. 2020**; **McCarthy et al. 2021**). However, the relative toxicity, additivity, or synergistic effects of PFAS remain incompletely understood and still uncertain. **McCarthy, Roark, and Middleton (2021)** discussed some of the challenges with designing, conducting, and interpreting toxicity tests with mixtures of PFAS. The understanding of PFAS mixtures is still developing and there is little consensus in the scientific community regarding how to assess the potential adverse impacts of PFAS mixtures. Complicating a limited understanding of PFAS mixture toxicity is that both absolute and relative concentrations of PFAS mixtures will vary across sites and across time. Reliance on empirical data such as site-specific toxicity sampling or community structure studies ultimately may be needed to fully understand the potential impacts of mixtures.

9.2.2 Ecological Exposure Assessment

Detections of PFAS in tissues of top predators within both aquatic and terrestrial ecosystems (**Section 6.5**) points to ongoing exposure from bioaccumulative and possibly biomagnifying PFAS (**Section 5.5.3**). Thus, accuracy and realism within exposure and risk estimates for PFAS are important to making informed risk management decisions. With the challenges of accounting for multiple exposure pathways, building strong food web and ecological exposure pathway models is an important foundation of PFAS ERAs. Once completed, these models can be used to identify the key receptors and measures of exposure to complete the assessments.

For aquatic ecosystems, published data from laboratory studies and specific field sites are available that include both BCFs, BAFs, and biota-sediment accumulation factors (BSAFs). These values, some of which are discussed and presented in **Section 5** and Table 5-1 (provided as a separate Excel file), can be used to model the measures of exposure for aquatic ecosystems. (**Larson, Conder, and Arblaster 2018**) used such data to conduct food chain modeling in four different avian receptors. Published values for fish are common; however, to date these values are not standardized in how they are reported (for example, wet versus dry weight; organic carbon or lipid normalization). Most importantly, these data are highly variant (**Table 5-1**); **Environment Canada (2006)** reported that field BAFs for PFOS in Canadian biota range from 6,300 to 125,000. **Burkhard et al. (2012)** reported that within published data sources (**Giesy et al. 2010**; **Houde et al. 2006**), laboratory and field bioaccumulation metrics usually do not agree. According to **Burkhard et al. (2012)**, field-generated BAFs (wet weight tissue to field water plus some ingestion) for PFOS exceed BCFs (wet weight tissue to lab water) predicted in the laboratory. This is undoubtedly due to the inability or inaccuracy of laboratory models to account for both direct and food ingestion exposure pathways. **LaRoe et al. (2017)** pointed out that laboratory values include only accumulation across the gill membrane. Thus, ERAs are challenged with attempting to address both pathways. **Larson, Conder, and Arblaster (2018)** demonstrated that using environmentally relevant sediment concentrations with standard food chain models with both BSAFs and BAFs suggested sediment pathways may be underrepresented and studied. Although the combination of direct and ingestion pathways is primarily a challenge for aquatic systems, assessing risk to wildlife exposed to multiple media (for example, amphibians, semiaquatic wildlife) is also problematic. As noted by **Divine et al. (2020)**, there are differences between the numeric value of BSAFs developed from field data versus laboratory methods, and also between values from laboratory studies using the same methods.

In addition to fish, accumulation values for benthic organisms (California black worm, *Lumbriculus variegatus*, Higgins (**Higgins et al. 2007**) and (**Lasier et al. 2011**); oysters, *Ostrea edulis*, (**Thompson et al. 2011**) and pelagic invertebrates (*D. magna)*, (**Dai et al. 2013**)) have also been reported. Example BSAF values from **Lasier et al. (2011)** for PFOS, PFOA, PFNA, PFBS, and PFHpA range from 7 to 49 kg sediment/kg tissue wet weight (as reported by authors). **Divine et al. (2020)** and **Conder et al. (2020)** summarized BSAFs for aquatic invertebrates and bivalves and for aquatic crustaceans for 15 PFAS. Both reports also discussed a variety of PFAS BAFs for amphibians, aquatic plants, benthic invertebrates,

crustaceans, and fish. There is overlap, as well as difference, in the studies discussed and presented by **Conder et al. (2020)** and **Divine et al. (2020)**. Much of this data is also described in **Section 5.5**. The **Conder et al. (2020)** report leans toward describing available data while the **Divine et al. (2020)** report goes a step further and attempts to apply the data to develop screening values from wildlife food web models, similar to the secondary poisoning values available in the EU (**Table 9-6**).

Data for terrestrial systems are limited to primarily plants (agricultural crops) and earthworms, with little available for vertebrate prey tissue. One exception is **Müller et al. (2011)**, which published data for a soil-to-caribou-to-wolf BAF used by **ECCC (2018)** in establishing a soil threshold protective of terrestrial carnivores at 2.6 mg PFOS/kg soil. In nearly all cases, these BAFs and BSAFs are available only for PFOS, though the **Lasier et al. (2011)** study can be used to identify BSAFs for five of the six UCMR3 PFAS.

Caution should be used in applying any of the published bioaccumulation or biomagnification data for desktop exposure estimates that are in turn used to justify remedial action. Several factors and uncertainties are associated with performing desktop food chain modeling with the limited amount of published data. Some of these considerations include the following:

- differences in diets of receptors at investigation sites versus that of studies documented in the published literature: differences in the proportions of prey items; differences in the uptake and elimination rates of PFAS or overall bioaccumulation of PFAS by the prey

- differences in physiology between the site receptors and those in published literature: capacity and magnitude of transformation; metabolism and uptake and elimination rates of PFAS; the amount/composition of protein-containing tissues to which PFAS bind; species home range and migration

- differences in physiochemical properties of the abiotic media containing PFAS between investigation sites and published study sites: bioavailability and uptake of PFAS; environmental processes (photolysis, hydrolysis, microbial aerobic and anaerobic metabolism); the presence of precursors. There is not a sufficient set of bioaccumulation data to date to account for these variations. Such studies were part of the 2019 Statements of Need for **Strategic Environmental Research and Development Program**(SERDP) grant projects.

These uncertainties are not completely unique to PFAS, as there are many other contaminants for which risk assessments are performed. Though there is some uncertainty with desktop food chain models for PFAS based on abiotic media, quantitative modeling does not need to be avoided. Two conclusions should be reached through food chain modeling with abiotic media and literature based BAFs/BSAFs/BCFs: either concentrations at the site are sufficiently low such that it can be concluded that risk to the environment is negligible and acceptable or concentrations suggest further evaluation by either refined baseline problem formulation or a baseline ecological risk assessment (BERA). Conducting BERAs for sites with PFAS should not be substantially different from BERAs for sites with other chemicals. Either in situ or ex situ direct toxicity tests with representative organisms can and should be performed when exceeding the limited ecological risk thresholds that are available. Likewise, measured concentrations of PFAS in prey should be obtained if desktop food chain modeled exposure exceeds TRVs. But the biggest challenges for measuring PFAS in biota have to do with the unique analytical chemistry method issues (**Section 11**). Challenges such as selecting the correct biota to sample, matching the prey items to the diets of upper trophic level biota, or obtaining sufficient tissue volume for chemical analysis may exist, but these issues are not unique to PFAS investigations.

9.2.3 Risk Characterization

Some aquatic toxicity data are available for environmental risk assessment for a few PFAS, but wildlife data are still incomplete. Adequate, though not abundant, data are available for completing wildlife risk

assessment, primarily for PFOS. The ability to complete risk assessments for other PFAS regularly analyzed and detected in environmental investigations (**Section 6**) is limited. However, with the exposure data discussed in **Section 5.5** and **Section 6.5**, and methods discussed in **Section 9.2.2**, the foundations of a quantitative risk characterization can be completed for PFOS and to an extent, PFOA. Risk assessment for other PFAS can be made with some conservative assumptions and use of PFOS data as a surrogate. The ability to combine effects thresholds (**Section 7.2**) and exposures to characterize risk to environmental receptors is outlined in a few publicly available sources. **McCarthy, Kappleman, and DiGuiseppi (2017)**, **Conder et al. (2020)**, and **Divine et al. (2020)** have identified exposure factors and effects thresholds that can be used for completing quantitative ERA within current regulatory frameworks.

The risk characterization of any chemical has uncertainty associated with it, and ecological effects characterization for PFAS is no exception. However, at this time based on the data presented in this section, meaningful PFAS risk management decisions can be supported in some situations using the current state of ecological risk assessment science. Broad risk management decisions regarding the ecological risk of PFAS should not be made for most risk assessments. In some cases, with consideration of the knowledge gaps and uncertainties for the site-specific scenarios being evaluated, stakeholders can work together to reach defendable scientific management decisions. Such risk characterizations using non-site-specific abiotic media, surrogate information, and tools can form the basis of screening level assessments. These screening assessments can be used to make more informed decisions regarding the need for site-specific assessments, including the collection of site-specific tissue data. However, within these screening assessments, discussion of the uncertainties and data gaps and assumptions made should be included to inform the risk management decisions.

9.3 Uncertainty

In performing a site risk assessment, including information and a discussion regarding key factors of uncertainty in the risk characterization can be important. As noted by **USEPA (1989)**, the source and degree of uncertainty associated with the risk characterization is needed to help decision makers (for example, risk managers, stakeholders), with sufficient level of detail to allow them to make informed risk management decisions (**National Research Council 2009**).

As noted throughout this guidance, while the science of characterizing and evaluating potential risks associated with PFAS exposure continues to develop, there are still uncertainties that arise in conducting site-specific risk assessments for sites with PFAS impacts. This section lists potentially critical uncertainties that, depending on the methodologies and assumptions used in a particular site-specific risk assessment, may warrant a discussion to help decision makers and stakeholders interpret and appropriately use the results of a risk assessment.

9.3.1 Fate and Transport

Site-specific risk assessments typically characterize risks associated with potential contaminant exposure that could occur currently or in the future. To characterize potential future exposures, conservative models are often used as tools to predict the fate and transport of chemicals in the environment. With regard to PFAS fate and transport, uncertainties can be introduced as follows:

- Estimating future environmental concentrations due to airborne wet and dry deposition (**Section 5.3.2**)
- Estimating the transformation of PFAA precursors to PFAA daughter end products (**Section 5.4.2**, **Section 10.4.4**) in the environment

- Modeling groundwater transport considering such factors as chemical-specific retardation (**Section 10.4.1**) and back-diffusion (**Section 10.4.3.3**)

- Estimating the bioaccumulation/bioconcentration of PFAS (**Section 5.5.2**, **Section 9.2.1**, **Section 9.2.2**) in a particular animal/plant or via food chain modeling

9.3.2 Human Toxicity

Human health risk assessments typically involve the use of toxicity values that are derived in a manner that is intended to represent a "reasonable conservative estimate" (**USEPA 2012**) of the dose-response in humans. Most of the toxicity values that have been derived by agencies for PFAS for use in site risk assessments are based upon animal studies, with human data used to support the hazard identification component of the risk assessment. However, it is noted that USEPA (**2023**, **2023**, **2023**), as well as **CA OEHHA (2023)** recently used human epidemiological data as the basis for draft noncancer toxicity factors (RfDs) for PFOA and PFOS and CSF for PFOA (**Section 7.1.4**). Additionally, there is a lack of toxicity values for many PFAS, which with their absence could result in an underestimation of the risks associated with PFAS exposure.

Overall, with regard to PFAS human toxicity, uncertainties in conducting a risk assessment can be introduced as follows:

- Missing dose-response information for site-related PFAS to which receptors could be exposed (**Section 7.1**, **Section 9.1.1.2**)

- Using toxicity values for a particular PFAS as a surrogate for another (**Section 9.1.1.2**)

9.3.3 Ecological Toxicity

As with human health risk assessments, ERAs often use TRVs that are generic and not site-specific. These generic TRVs are conservative by design because they are used for screening purposes (**USEPA 2004**). Likewise, there is a degree of conservatism incorporated into the derivation of generic criteria (for example, ambient water criteria) to account for uncertainty (**Section 9.2.1**).

Overall, with regard to PFAS ecological toxicity, uncertainties in conducting a risk assessment stem from using toxicological information from surrogate organism(s) to evaluate potential risks for organisms for which toxicity studies do not exist (**Section 9.2.1**)

9.3.4 Accounting for Nonsite-Related PFAS

Site-specific risk assessments rely on site characterization information (and as needed, modeling) to help estimate the amount of exposure receptors could be subject to currently or in the future. Given the widespread presence of PFAS in the environment (**Section 6**), including the potential of upgradient off-site PFAS impacts to migrate onto subject properties (**Section 10.5**), discerning "background" anthropogenic or off-site PFAS impacts at a site from site-related impacts can be challenging. To streamline risk assessments, it may be conservatively assumed initially that concentrations of PFAS are entirely site-related. Doing so, however, may overestimate the risks associated with site-related releases.

10 SITE CHARACTERIZATION

The intent of this section is not to present general site characterization principles, but to highlight unique considerations or examples for this family of emerging contaminants. It is assumed that site characterization will follow all applicable state and federal (for example, CERCLA or RCRA) guidelines. The general principles of site characterization are similar for PFAS as for any contaminant, in that the physical setting, release specifics, proximity to receptors, and fate and transport characteristics will determine the sampling locations and requirements. Because of the toxicity, persistence, mobility, ubiquity, the large number of compounds in this family of chemicals, the variability and uncertainty of specific compounds and their criteria being regulated, and the emerging nature of PFAS, it is necessary to consider specific concerns in PFAS site characterization efforts.

Section Number	Topic
1.1	**Priority Topics for History, Use, and Naming Conventions (2025)**

10.4	**Data Analysis and Interpretation**
10.5	**Source Identification**
15.1	**Site Characterization Case Studies**

Exposure to PFAS can occur through a variety of transport pathways involving all environmental media, as is described in **Section 5**. Because ingestion of water is deemed a major route of exposure in humans, and the emerging nature of PFAS as contaminants of concern, regulatory interest has in the past several years been centered on this pathway. In turn, this focus has led to an increased emphasis on investigation of the connection between drinking water sources and groundwater, including direct use of groundwater as drinking water and connections between surface water and groundwater. Because of this regulatory and investigatory focus, this section places more emphasis on characterization of groundwater plumes than characterization of other media. Although groundwater may have in the past been more commonly the initial regulatory and investigatory focus, regulatory focus is broadening to other media such as surface water and biota and as a site-specific characterization process advances data are generally required from one or more other media including soil, sediment, surface water, stormwater, air, biota, or other media depending upon the nature, duration, and time of the release. **Section 2.2** includes detailed information about the wide range of PFAS chemistry. **Section 4** includes information about physical and chemical properties.

The guidelines below include general considerations for the most common types of PFAS sites. Many of the papers referenced in this section are products of studies sponsored by SERDP/ESTCP. A list of SERDP/ESTCP research projects related to PFAS and AFFF can be found at **https://www.serdp-estcp.org**.

10.1 Site Characterization Issues Relevant to PFAS

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about site characterization tools and techniques (see **Section 1.3.8**).

Historical investigations may have missed the potential for PFAS contamination at a site because, until recently, these chemicals were not regulated, were not considered a health or environmental concern, or PFAS sampling and analytical procedures may not have been available. As a result, PFAS plumes had years to develop and migrate without detection or characterization. Reviewing available site information such as a timeline for processes, layout, chemical use, release history, and fire training and/or firefighting events when AFFF was used in comparison with the time period of PFAS use can be helpful in evaluating the types and potential occurrences of PFAS releases. Once the potential for a PFAS release(s) is reasonably established, initial sampling could be completed to verify whether PFAS is present. If PFAS is determined to be present at levels warranting further assessment, a site investigation would be completed to characterize the nature and extent of the release and subsequent PFAS distribution. However, a PFAS site may be one of the many without an identified source (**ATSDR 2021**).

The following are some important considerations specific to PFAS sites.

10.1.1 Evolving Science and Regulations

State of the science: Understanding of many aspects of PFAS, such as toxicology and behavior in the environment, is changing rapidly. This may require reevaluation of earlier assumptions and conclusions throughout the site characterization process.

Analytical methodologies: Analytical methodologies continue to be developed and improved. Specific attention must be paid to a wide variety of factors, such as analytical methods, detection/reporting limits, and parameter lists that are continuing to expand (see **Section 11.2**).

Sampling methodologies: Cross-contamination potential may exist due to the presence of PFAS in consumer products; many regulatory agencies require a precautionary approach to sampling prohibiting the use of materials that may be treated with PFAS. See **Section 11.1**, Sampling, for more details.

Regulatory environment: The regulatory environment remains in flux, with changing regulatory limits, sampling procedures, and compounds of interest. Investigators should review current regulatory requirements to identify impacts to the site characterization (see **Section 8**, and the **Regulatory Programs Summary Excel file**).

10.1.2 Source, Fate, and Transport Properties

Sources: PFAS sources are discussed in **Section 2.6**. AFFF releases are discussed in more detail in **Section 3.3**. In addition, **Salvatore et al. (2022)** proposed that PFAS releases to the environment could have occurred at AFFF discharge sites, industrial facilities included in 38 specific North American Industry Classification System (NAICS) codes, and PFAS-containing waste sites. There are also "secondary sources," such as PFAS concentrating into one portion of a plume (for example, groundwater into surface water) that then acts as a source to further groundwater contamination.

Further, because of the large number and varying chemical and physical properties of PFAS, and widespread use of PFAS-containing products, there may be multiple locations that act as a source of PFAS at a site. In addition, PFAS are often detected at low levels in samples from locations without any apparent or nearby sources. In those instances, there may be a need to evaluate the site-specific

anthropogenic ambient background concentrations and determine their contribution to PFAS concentrations in environmental media at a site. See, for example, **Strynar et al. (2012)**.

The Priority Topics for History, Use, and Naming Conventions include information about semiconductor industry uses of PFAS (see **Section 1.1.1**), less-publicized PFAS Sources (see **Section 1.1.2**), and less-studied PFAS (see **Section 1.1.3**), including ultrashort PFAS, cyclic PFAS, volatile PFAS, and fluorinated gases. The Priority Topics for Biosolids Land Application (See **Section 1.7**) include information that supplements the biosolids information in **Section 2.6.4**. See also the **PFAS and Vapor Intrusion Fact Sheet** developed in 2025. The Priority Topics for PFAS and Microplastics provide information about the interconnections between PFAS and Microplastics (see **Section 1.8**).

Pathways: PFAS may be present or migrate via pathways that are not typically observed with other compounds. For example, PFAS may be present in groundwater at a site via air deposition and no direct on-site release.

Complex transitions between media: The behavior of PFAS in the environment may deviate greatly from typical contaminants. Transitions between media may be complex because of specific characteristics of these compounds. For example, PFAS may disperse more upon reaching the water table than is typical for most other compounds, or a groundwater plume discharging into a surface water body may infiltrate into groundwater elsewhere, with contamination in the surface water acting as a secondary source. See Sections **5** and **6** for additional detail.

Partitioning: Because of their physical and chemical properties and the variability of those properties, certain PFAS may partition from water through different mechanisms (including hydrophobic effects, electrostatic interactions, and interfacial behaviors) to other media or forms, including air, micelles, foam, solids, NAPL, and interfaces between these phases. Physical and chemical properties are discussed in more detail in **Section 4** and phase partitioning is discussed in more detail in **Section 5.2** and as appropriate in several subsections in this section.

Secondary Sources

Sources created through movement of contaminated media into an area that was previously uncontaminated (for example, contaminated water from irrigation wells or reuse and application of biosolids, or atmospheric deposition) or an area where physical or chemical processes have concentrated PFAS, resulting in an additional source (for example, multi-media interfaces; see Sections **5** and **6**).

10.2 Initial Steps

A comprehensive initial assessment commonly starts with developing an understanding of potential PFAS uses in the area; history of the site operations that potentially used PFAS-containing materials; areas where fluorine-containing Class B firefighting foams were stored, used, or released; on-site or off-site air deposition patterns where PFAS may have been produced or processed (for example, manufacturer and/or industrial facilities that produce PFAS or use materials containing PFAS and are likely to have airborne emissions), and the regional geologic and hydrologic framework as it relates to contaminant transport to surface waters or drinking water wells. Following the initial assessment, several phases of site investigations may be required at a sufficient resolution to capture the effects of the heterogeneities that direct contaminant distribution, fate and transport, and remediation effectiveness. However, there may be a need to prioritize the evaluation of certain exposure pathways (for example, drinking water wells) during the beginning investigations to quickly assess potential human exposures and because of constraints on resources and schedule.

When historical PFAS releases have occurred upgradient of drinking water sources, drinking water sampling may be the first indication that there is a

Site-Specific Anthropogenic Ambient Background

Concentrations of PFAS present in environmental media at the site that are not the result of or influenced by site activities or releases.

problem. In areas where there is a concern that a PFAS source may be present, identification and sampling nearby drinking water sources (for example, groundwater and surface water) have in certain circumstances preceded typical site investigation work and can be considered in future situations to determine if PFAS are present in potable water sources and evaluate the potential exposure to human receptors. In cases where sources are not well defined, reconnaissance sampling may be useful to inform the development of the conceptual site model (CSM) and site investigation. Prior to further site characterization, proper notification to consumers and evaluating options to reduce or eliminate PFAS exposures, including alternative drinking water sources, may be required. In cases where sources are not well defined, reconnaissance sampling may be useful to inform the development of the CSM and site investigation plan.

CSMs are useful tools for the presentation and evaluation of site characteristics, releases, contaminant fate and transport, and exposure pathways, and it may be appropriate to develop an initial CSM prior to or as a part of preparing a site investigation plan. Generalized CSMs are presented in Figures **9-1**, **9-2**, and **9-3**. The referenced CSMs present most known and potential PFAS source areas, transport mechanisms, and pathways on a simplified physical setting. The CSMs also illustrate exposure routes and receptors.

CSM development is an iterative process over the project life cycle with information obtained during site investigation, remedy design, remedy implementation and optimization, and post-remedy monitoring (if applicable). Similar to the USEPA's data quality objectives (DQOs), it relies on a systematic objectives-based site characterization process (**ITRC 2015**). The CSM for a PFAS site is developed with information on potential ecological and human receptors, and PFAS sources and releases (whether occurring on site or off site from groundwater, surface water, sediment, or air), and should be updated as new information becomes available through site characterization, evaluation of all pathways, and potential receptors. Because many PFAS sites have had releases of other contaminants and subsequent follow-up site investigations, it is possible that a CSM may exist for the site that could serve as the basis for modifications to address PFAS.

10.3 Site Investigation

This section highlights some important considerations for site investigation that are relevant for PFAS. The general principles of site investigation are similar for PFAS as for any chemicals. In 2024, USGS published a guidance that reviews a broad range of considerations for site investigation and sampling in the context of Natural Resource Damage Assessment and Restoration (**Pulster et al. 2024**).

10.3.1 Development of Site Investigation Work Plan

PFAS investigation work plans should take into consideration the information provided in this guidance document (for example, Sections **2**, **4**, **5**, **6**, **9**, and **11**), including items such as sampling procedures and equipment to prevent cross-contamination, analytical methods, compounds to be reported, quality assurance/quality control, geographically variable and changing regulatory requirements and criteria, site-specific environmental setting, human health and/or ecological risk assessment, and potential treatment technologies and remedial approaches (see **Section 12**). From a general perspective the work plan will depend on the type of PFAS source and subsequent transport via various media, both of which should be discussed in the CSM section of the work plan. Investigative approaches should consider potential nearby sources and secondary sources, such as irrigation, sludge, or biosolids applications; atmospheric deposition; landfill leachate; and wastewater treatment plant discharge. As noted below, it is critical for the investigation to generate data that directly support subsequent risk assessments, feasibility studies, EE/CAs, and/or other evaluations of potential remedial alternatives. For PFAS, this may require a relatively high data collection effort, given typical release scenarios (for example, as a mixture of different PFAS) and low criteria values, and require more than one phase of investigation.

10.3.1.1 Geologic and Hydrogeologic Investigation

Evaluation of the geologic and hydrogeologic framework associated with the site is critical, and sometimes that framework may need to be addressed on a regional basis, as the PFAS impacts may extend significant distances from the site.

The amount of information to be collected to complete an adequate assessment is a site-specific determination based on many factors, such as complexity of stratigraphic and lithologic variability, project objectives, and available budget. In development of a work plan, consideration should be given to understanding the geologic history and geomorphology of the site and to evaluating how the subsurface materials and geometry control the fate and transport of contaminants. High-resolution site characterization (HRSC) techniques are normally appropriate to obtain adequate subsurface information (for example, grain size, lithological interfaces, and high transmissivity zones) to complete stratigraphic assessments (**USEPA 2016**). ITRC has guidance on implementing advanced site characterization tools (**ITRC 2019**).

Environmental sequence stratigraphy (ESS) is also an approach that may be applicable depending on site-specific circumstances. ESS is a method for understanding the geologic framework and related subsurface contaminant transport pathways, both regionally and underlying a site. The ESS approach is presented in USEPA Groundwater Issue Paper "Best Practices for Environmental Site Management: A Practical Guide for Applying Environmental Sequence Stratigraphy to Improve Conceptual Site Models" (**USEPA 2017**). A case study describing the use of ESS for PFAS investigations is described in **Section 15.1.3**.

The geologic and hydrogeologic investigation should define the hydrogeologic and geochemical parameters that are pertinent to PFAS migration and applicable to subsequent remedial actions. A thorough understanding of site soil types (for example, f_{oc}, bulk density, surface charge, anion and cation exchange capacity, grain size, minerology, and water content) and geochemistry (for example, ionic concentrations, ionic strength, dissolved oxygen, oxidation-reduction conditions, and pH) is needed to assess PFAS transformation, partitioning (including desorption), and migration in groundwater or soil. Hydrogeologic parameters such as groundwater recharge, hydraulic gradient, infiltration rate, permeability, hydraulic conductivity, and seepage velocity are vital components of the site investigation and help define the potential migration rate of PFAS. A thorough evaluation of the site hydrogeology will aid in evaluating and designing remedial alternatives. For example, the site geochemistry, including cations, anions, total dissolved solids, and fouling parameters (for example, iron, manganese, hardness, biochemical oxygen demand (BOD)), as well as other organic compounds in groundwater, may have a significant impact on the selection, design, and implementation of potential groundwater remedies.

Similarly, understanding the range of concentrations of PFAS in varying soil types and PFAS distribution in the vadose zone compared to the saturated zone is an important objective of site characterization. At sites with soils of varying permeabilities, the PFAS distribution within these different soil types should be established to better understand the feasibility of various remedial options, such as those that involve amendment distribution within the subsurface. This type of information is also beneficial for documenting natural processes that may be contributing to retention of PFAS within source areas and influencing downgradient transport.

10.3.1.2 Surface Water Body Secondary Sources

Because certain PFAS are mobile and resistant to breakdown in the environment, there have been cases of surface water creating very large dilute groundwater plumes through recharge (**ATSDR 2008**). Infiltration of PFAS along the course of surface water systems, including tidal zones, may result in widespread secondary sources to groundwater, further enlarging the contamination area (**Ju et al. 2008**).

A study assessing PFAS concentrations in river and groundwater from several locations found that concentrations and trends in groundwater were generally similar to those observed in surface water, suggesting the aquifer was contaminated with the same source as the surface water (**Sharma et al. 2016**). Areas with high hydraulic conductivity allow for the rapid spreading of PFAS over large areas. However, even in lower permeability geologic deposits, PFAS contamination is a problem because the combination of long groundwater residence times and persistence of most PFAS results in a long-time presence of these compounds in water resources (**Banzhaf et al. 2017**). In situations where PFAS-contaminated surface water is recharging groundwater, investigation of the potentially impacted groundwater should be conducted to fully characterize site-related contamination (**Divine et al. 2023**). Complicating surface water being a secondary source is that PFAS have been shown to concentrate at the surface water-air interface (**Ju et al. 2008**). PFAS contamination may also concentrate in naturally occurring surface water foam (due to an affinity to organic material in the foam and the higher PFAS concentrations at the surface water-air interface where the foam is formed). Therefore, site characterization must consider whether or not surface water bodies are the most downgradient extent of contamination. **Section 5.3.4** includes information on transfer of PFAS between surface water, sediment, and groundwater, including how changing conditions in the hyporheic zone are likely to affect PFAS transformation and partitioning. A brief discussion of surface water–groundwater interactions extending the areal impact of PFAS contamination is discussed in a case study in **Section 15.5**, and surface water quality is discussed in **Section 16**.

When evidence suggests that PFAS contamination is being transported between surface water and groundwater, it may be important to identify site-specific conditions of the hyporheic zone and to quantify PFAS concentrations in sediments or porewater, mass flux between groundwater and surface water, and factors such as redox conditions, salinity, and composition of sediment or suspended particulates (organic and mineral content) that may affect PFAS sorption and transformation (see Sections **5.2.3** and **5.3.4**).

PFAS levels in sediments can be an expression of the average deposition conditions of discharges that are episodic. Sampling of sediments on a dry-weight basis provides information on PFAS sorbed to sediments, but may underestimate or miss PFAS in mobile porewater, which makes passive porewater samplers practical tools to characterize the concentration and mass flux of PFAS in or across the hyporheic zone and correlate it with the sediment PFAS content. Some types of passive samplers allow accumulation of contaminants over time, thus generating a time-weighted mean concentration rather than a snapshot of concentration at a discrete time point as given by discrete porewater sampling. Therefore, depending on study objectives, passive sampling may provide data that are more representative of PFAS mass flux between surface water and groundwater as compared to sediment sampling or discrete porewater sampling. However, careful consideration of study objectives must be given when selecting the type of passive sampler, as equilibrium devices may not be appropriate for measuring episodic discharges. See Sections **11.1.7.4** and **11.1.7.7** for more information on porewater and sediment sampling for PFAS, respectively.

10.3.1.3 PFAS-Specific Tools for Site Screening or Characterization

Investigative techniques to characterize source soils and determine the three-dimensional extent of soil and groundwater contamination should be considered. HRSC technologies, while providing near real time subsurface lithological and hydrologic information, can be used to efficiently obtain discrete groundwater samples in the intervals of interest, such as the high transmissivity zones and lithological interfaces. Analytical procedures that can be used in a mobile laboratory and achieve ng/L detection limits are becoming more available and can be used on site in conjunction with discrete HRSC sampling techniques (**Quinnan et al. 2021**). Use of a mobile laboratory can be expensive and is cost-effective only in specific situations when a sufficient number of samples can be collected in a short time period to keep the mobile laboratory at or near its capacity. Use of a mobile laboratory and the quick turnaround of results they provide allow for adaptive selection of additional sampling locations for delineation or other

objectives. One of the main drawbacks associated with current field-screening methods is the inconsistency of results associated with measurement sensitivity to site-specific factors, including varying soil types and compositions. Furthermore, field screening methods should not be anticipated to replace fixed-laboratory analysis in terms of satisfying regulatory requirements.

Other field-screening methodologies have either been tried or are in the research and development phase, including ion selective electrodes to quantify PFOS and a mobile field-screening unit for PFOS and PFOA, both of which are attempting quantification to ng/L levels (**Deeb 2016**). Another method in the development stage is "a synergistic approach for the targeted affinity-based capture of PFOS using a porous sorbent probe" (**Cheng et al. 2020**) that may be able to obtain a detection limit for PFOS in water at about 0.5 ng/L. **Rodriguez et al. (2020)** provided a review of PFAS-detecting sensors and expected future direction for sensors. Multiple technologies for PFAS site investigation including passive and no-purge samplers, passive flux meters, mobile labs, real-time sensors, and novel techniques for reliable detection in complex matrices have been recently reviewed (**Horst et al. 2022**).

10.3.2 Nature of PFAS Sources

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about characterizing PFAS in groundwater at or near facilities with septic systems (see **Section 1.3.2**).

The nature of primary and secondary PFAS sources at a site will largely determine the extent of PFAS contamination at the site. Multiple factors may contribute to the nature of PFAS sources at a site. Key factors to consider in development of a work plan include:

- Leaching from the vadose zone to the saturated zone: PFAS present in unsaturated soils due to retention mechanisms (for example, partitioning at the air/water interface and sorption to organic matter) are subject to downward leaching during precipitation or irrigation events (**Section 5.2**).
- Matrix diffusion: PFAS dissolved in groundwater that diffuses from higher permeability zones and accumulates in lower permeability silt/clay layers below the water table and may diffuse back into the higher permeability zones due to changing relative concentrations (**Section 5.3.1**).
- Desorption: PFAS resulting from desorption from solids in the vadose or saturated zones and resolubilizing in porewater or groundwater could occur when **adsorption** (that is, partitioning) is reversible (**Milinovic et al. 2015**); such desorption would have the effect of sustaining PFAS concentrations in porewater or groundwater.
- Nonaqueous phase liquids (NAPL) dissolution: PFAS entrained in NAPL in the subsurface may be associated with releases of chlorinated solvents and/or petroleum hydrocarbons.
- Other sources: Given the widespread use of some PFAS, additional sources upgradient or within a plume may be contributing to PFAS concentrations at a site. Collecting samples to allow for evaluation of anthropogenic ambient background and/or commingling of plumes may be necessary if it is suspected that other sources are a contributing factor.
- Atmospheric deposition: PFAS are sometimes associated with stack or other air-emission sources and may contribute to regional PFAS concentrations.
- Overland runoff: Runoff and stormwater conveyance systems can impact surface water locations downstream of the actual source or groundwater along the course of the conveyance system.

- Groundwater discharge to surface water or surface water recharge of groundwater: Gaining or losing surface water body (for example, rivers, streams, lakes, ponds, impoundments, and wetlands) conditions may influence the extent of a plume. Discharge or recharge (seepage) rates and directions may change seasonally, with extreme weather events, or during periods of drought or precipitation.

- Subsurface features, including utility lines: Preferential pathways may result from subsurface features. For example, flow may seep into or out of nonwatertight sewer lines based upon groundwater elevations relative to the utility. The bedding material of a subsurface line may also convey groundwater.

- Multicomponent mixtures: At some sites, numerous PFAS may be present in one or more source zones. Mixtures may be present for several reasons, including, but not limited to, the following: multiple sources, varying time frames, and a mixture of compounds introduced during production (Sections **5** and **10.5**).

- Precursors: Delineating, as practicable, the extent of precursors that may degrade to PFSAs and PFCAs will help the investigator understand sources and potential long-term concentrations.

10.3.3 Extent of PFAS

As with other chemicals, a site investigation for PFAS relies upon understanding the nature of sources as well as the lateral and vertical extents. A PFAS release can be localized or highly extensive, both horizontally and vertically. The extent is a function of many factors, such as site conditions, the nature of the PFAS source, transformation of precursors, and the relevant migration pathways. For example, some PFAS may be highly mobile in groundwater and some PFAS plumes may have had many years to develop and could consist of many compounds that are not expected to degrade, as discussed above. Therefore, PFAS plumes could be larger or deeper than expected, although there are currently limited quantitative data on PFAS plume lengths or depths in groundwater as compared to other contaminants. Sufficient delineation of PFAS extent in groundwater requires a monitoring well network with wells located throughout the plume (for example, source area, midplume, distal end, side-gradient, and clean sentry wells to define the plume boundaries). Such a well network will provide data to evaluate dissolved phase migration, potential precursor transformation trends, and/or plume stability.

Detailed vertical delineation as a component of HRSC should consider soil sampling at predetermined depths and distinct lithologic units within the vadose zone, the zone of water table fluctuation, and beneath the water table to a depth necessary to determine the vertical extent of impacts. In addition, consideration should be given to groundwater sampling of all saturated units to an appropriate depth. Collection of these data may necessarily be an iterative process requiring more than one phase of investigation to determine the vertical extent of PFAS impacts. This information is beneficial for evaluating potential accumulation points, matrix diffusion potential, varying groundwater conditions, and risk assessment, and to support remedial alternative evaluation.

At sites where PFAS has been released to the subsurface and reached groundwater, the velocity of groundwater movement (advection) is a key consideration for understanding plume migration potential, as well as those processes that act on PFAS during advective transport (for example, sorption, diffusion). At some sites, more mobile shorter chain PFAS have been observed to extend relatively farther in groundwater than longer chain PFAS due to less retardation in groundwater. The partitioning behavior of PFAS is discussed in **Section 5.2**.

Another factor in the extent of PFAS at mature sites is prior remediation intended to address other contaminants. For example, groundwater pump and treat systems designed and operating to address other contaminants may have partially captured PFAS or their discharge may have spread PFAS. Other

remediation methods such as oxidation may result in a change in the relative concentrations of individual PFAS (for example, oxidation of precursors).

Depending upon site-specific conditions, several pathways need to be considered to assess potential upgradient sources. PFAS migration in air from industrial or commercial sources can influence soil or groundwater a great distance from larger sources (**Section 6.1**), for example, see **Barton (2010)** and **Shin et al. (2011)**. Data from urban soils and groundwater indicate that for sites near metropolitan areas, there may be measurable contributions of PFAS from other sources, unrelated to site-specific sources, see the site-specific anthropogenic background text box in **Section 10.1.3** and **Xiao et al. (2015)**.

Commingling of contaminants has a potential to impact PFAS extent (note that PFAS commingling with other contaminants could also affect several other facets of a site characterization and/or risk assessment). For example, for PFAS sites associated with industry, fire training, or emergency response that have a chlorinated solvent or other NAPL source, investigators need to consider potential effects on PFAS in the subsurface and related data collection requirements. Laboratory studies have demonstrated that sorption or partitioning of PFAAs may increase in the presence of trichloroethene DNAPL in bench-scale tests (**McKenzie et al. 2016**). Conceptual modeling of published PFAS data suggests that NAPL-water partitioning and NAPL-water interface interactions may significantly increase retardation of some PFAS in source zones (**Brusseau 2018**; **Brusseau 2019**; **Brusseau et al. 2019**, **2019**; **Costanza, Abriola, and Pennell 2020**; **Lyu and Brusseau 2020**; **Schaeffer et al. 2019**; **Silva, Šimůnek, and McCray 2020**; **Sima and Jaffe 2021**). These enhanced attenuation processes are discussed in **Section 5.2.4.1** (partitioning adsorption to air/water interfaces) and **Section 5.2.5** (NAPL-water interface). This research suggests that if PFAS and NAPL are present in media that make effective source treatment unlikely—for example, in low-permeability soils or fractured rock—that fraction will represent a long-term contributor to groundwater plume persistence. At older sites where in situ (for example, oxidation) or pump and treat methods have been employed to reduce NAPL source areas prior to awareness of PFAS, those remedies may complicate characterization and distribution of PFAS. Depending upon the method employed, mobilization of some PFAS may have changed following treatment, and remedial actions may affect distribution and relative concentrations of individual PFAS (**McKenzie et al. 2016**; **McGuire et al. 2014**).

At most sites where PFAS is present in groundwater, the extent of PFAS contamination is likely to be a key objective for site characterization and used for identifying appropriate remedial options (if warranted). Estimating the plume advancement rate may provide beneficial information for the remedial decision process. For example, a plume that is advancing relatively slowly and without nearby receptors may be more amenable to different remedial approaches, such as in situ sorption or barrier-based approaches (see **Section 12.2.4**) or other less aggressive techniques (**Newell et al. 2022**), than plumes that are advancing rapidly towards nearby receptors. Determining plume stability (**Section 10.4.8**) and/or conducting contaminant transport modeling (**Section 10.4.9**) provide valuable data for assessing risk and evaluating remedial alternatives.

10.3.4 Investigation-Derived Waste (IDW)

The Priority Topics for Treatment Technologies include considerations for management of PFAS-impacted investigation-derived waste (see **Section 1.6.3**).

How to handle IDW that contains PFAS is currently a complicated topic, with differing laws and guidance in different states that affect on-site management, storage, labeling, and off-site transportation requirements (**ASTM 2024**). Investigators must remain vigilant to identify current state and local requirements for IDW generated during site characterization efforts. Site-specific waste handling and disposal plans should be provided in the site's Health and Safety Plan (HASP), Quality Assurance Project Plan (QAPP), or Sampling and Analysis Plan (SAP) prior to waste generation. During a typical site characterization effort, IDW generated consists of purge water, decontamination water, soil, sediments,

solids such as concrete and asphalt, single-use field equipment (for example, bailers, tubing), and personal protective equipment (PPE).

In general, industry has been using two methods to dispose of PFAS-containing solids IDW off-site: landfill disposal and thermal treatment. For liquid wastes containing PFAS, sorption treatment, thermal treatment, or underground injection has been used. On-site treatment of water IDW using existing aboveground treatment systems or temporary mobile units is another option. Treatment conducted on-site can minimize the volume of liquids requiring off-site disposal and may allow treated liquids to be discharged to a publicly owned treatment works or handled off-site as nonhazardous waste. As of March 2023, no PFAS meet the federal definition of a hazardous waste; therefore, most PFAS-impacted IDW is being disposed of as nonhazardous waste.

In 2020, the USEPA published a guidance document, Interim Guidance on the Destruction and Disposal of Perfluoroalkyl and Polyfluoroalkyl Substances and Materials Containing Perfluoroalkyl and Polyfluoroalkyl Substances, Version 2 was published in 2024 (**USEPA 2020**, **USEPA 2024**). This interim guidance document outlined IDW that contains PFAS, destruction and disposal technologies currently available and in use, considerations for vulnerable populations that live near these destruction and disposal sites, and current research on this topic. Its focus is on providing options that have the potential to destroy the C-F bonds (thermal treatment) or that control migration of PFAS (with landfilling or underground injection).

Several guidance documents exist for managing PFAS-impacted IDW at U.S. Department of Defense (DOD) installations, including U.S. Army, U.S. Navy, and U.S. Air Force sites. Therefore, any PFAS-impacted IDW generated from a DOD installation should follow the associated required procedures (**USDOD 2018**; **USDOD 2020**; **USDOD 2020**). State or local requirements may be more restrictive than the DOD guidance.

10.3.4.1 IDW Options

Thermal Treatment

Thermal treatment is a broad category that includes several heating technologies: hazardous waste combustors, nonhazardous waste combustors, carbon reactivation units, and thermal oxidizers. Incineration specifically has come under scrutiny recently for its potential to affect communities adjacent to and downwind of incineration facilities through stack emissions if the PFAS are not broken down completely and data gaps associated with the control of products of incomplete combustion (**Schroeder et al. 2021**; **Stoiber, Evans, and Naidenko 2020**; **USEPA 2024**; **Galloway et al. 2020**; **Vollet Martin et al. 2022**). Please note—the definition of "incineration" varies based on different state or federal regulations or guidance.

On April 26, 2022, the DOD issued a memorandum to temporarily prohibit the incineration of DOD PFAS materials, until DOD issues guidance on implementing the USEPA guidance on the destruction and disposal of PFAS. The DOD published a memo with interim guidance about destruction or disposal of materials containing PFAS on July 11, 2023 (**USDOD 2023**). A follow-up statement was published on July 17, 2023 about additional planning and coordination that is needed before incineration is implemented (**USDOD 2023**).

On June 8, 2022, Illinois passed a law that bans the disposal by incineration of any PFAS, including, but not limited to, AFFF. Incineration was defined as any burning, combustion, pyrolysis, gasification, or use of an acid recovery furnace or oxidizer, ore roaster, cement kiln, lightweight aggregate kiln, industrial furnace, boiler, or process heater.

Landfill

The practice of disposing of PFAS via landfill works to control contaminants of concern through containment. For PFAS and PFAS-containing materials, hazardous waste landfills or lined municipal solid waste landfills could be viable disposal options if the landfills are willing to accept PFAS IDW. Current landfills can serve as long-term containment sites for PFAS, but they are not explicitly designed to control and hold PFAS and PFAS-containing materials. The ability for landfills to safely contain PFAS and PFAS-containing materials is an active area of research by the USEPA and state regulatory agencies.

Subtitle C (hazardous waste) landfills have a bottom liner and leachate collection system, and have been used to contain PFAS IDW. The utilization of Subtitle D (nonhazardous, municipal waste) landfills to contain PFAS IDW is state-dependent due to the potential for leaching into the subsurface. However, there remain concerns with Subtitle C landfills regarding how to handle the collected leachate. Typically, landfill leachate is disposed and treated off-site at municipal wastewater treatment plants, where the leachate is mixed with wastewater and then treated. However, a landfill that contains elevated PFAS in the leachate presents a difficulty for treatment. In addition, research has found that soluble PFAS with high vapor pressures can be emitted into the atmosphere via the gas generated at landfills (**Ahrens et al. 2011**; **Hamid et al. 2018**; **Wang et al. 2020**; **Weinberg, Dreyer, and Ebinghaus 2011**). This is an active area of research. Due to these concerns, not all Subtitle C landfills will accept PFAS wastes.

Deep Well Injection

Underground injection could be an option for liquid PFAS IDW. Disposal using this technology occurs under USEPA's underground injection control (UIC) regulations.

The UIC regulations give the USEPA the authority to permit the disposal of PFAS and PFAS-containing liquid IDW in Class I underground injection wells. Class I wells in either the nonhazardous or the hazardous waste categories are designed to dispose of and isolate liquid PFAS and PFAS-containing IDW. Class I underground injection wells are deep injection wells that inject the liquid of concern into a stable geologic formation below the lowermost underground sources of drinking water (USDW).

Underground injection to Class I nonhazardous and hazardous waste wells reduces the risks associated with surface-based disposal methods by avoiding a potential discharge of liquid IDW to surface and shallow groundwater and generating little to no air emissions of PFAS. Class I wells must be sited in areas that are geologically stable without the presence of natural fractures and faults that could allow the injected material to migrate into USDWs (**DeSilva 2019**; **Marine 2020**; **McCurdy 2011**; **USEPA 2001**; **USEPA 2015**).

Other/Developing Technologies

Additional methods, and methods in development for disposing of PFAS and PFAS-containing materials, are discussed in Section 12, including in situ and ex situ disposal methodologies for both soil and liquid PFAS and PFAS-containing IDW.

10.3.4.2 Other Considerations

PFAS IDW may also contain other commingled nonhazardous or hazardous substances. This will impact the options available for handling and disposal and should be considered during the project planning process. Of particular concern are wastes from sites where incineration of PFAS is not permitted that have co-contaminants usually disposed of through incineration (such as Toxic Substances Control Act wastes). In these cases, site managers may need to weigh the site characterization needs against the IDW disposal requirements and avoid generation of co-contaminated wastes.

10.4 Data Analysis and Interpretation

There are a number of approaches, methods, and tools available for analyzing and interpreting site characterization data from a wide range of contaminated sites. Examples of approaches, methods, and tools that may be relevant to PFAS sites are described below, but site-specific objectives and characterizations should be considered when determining an appropriate approach.

10.4.1 Vadose Zone Leaching

The Priority Topics for Sampling and Analysis include updated information about leaching methods (see **Section 1.5.1**). The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about vadose zone characterization and transport (see **Section 1.3.1**).

Recent research has illuminated the complexities of PFAS fate and transport in the vadose zone. The majority of this work has focused on lab-based or modeling studies, with an effort to understand how PFAS **surfactant** properties can enhance or reduce PFAS sorption, in particular at high concentrations such as those encountered at release locations (Sections **5.2.2.2**, **5.2.3**, and **5.2.4.1**). As indicated in Section 5, soil chemistry plays a major role in PFAS fate and transport.

For example, **Guo, Zeng, and Brusseau (2020)** conducted a sophisticated modeling study indicating that PFOS in the vadose zone at a hypothetical fire training site is primarily sorbed at the air-water interface and only 1–2% of PFOS is in the aqueous phase under the modeled conditions (see **Section 5.2.4**). This indicates that strong PFOS attenuation may occur in the vadose zone over time, although **Guo, Zeng, and Brusseau (2020)** showed that eventually there still may be discharge of PFOS to the underlying water table under their modeled conditions. This is consistent with high concentrations of PFOS observed at some fire training sites. **Rovero et al. (2021)** reviewed literature-reported sorption coefficients (Kd) of eight anionic short (C4)- to long- (C10) chain PFAS, including PFOA and PFOS. Given the broad range in Kd values from 3 to 5 log units, no single value seemed appropriate for estimating PFAS leaching using existing soil-water partition equations. Regression analysis was used to determine if any of the fifteen experimental parameters identified in the literature might be used to predict Kd values. The authors found that none of the values could individually explain variability in reported Kd values, but significant associations existed between Kd and soil calcium and sodium content, suggesting that soil cation content may be critical to PFAS sorption. Organic carbon was found to only be significant at elevated levels (>5%).

Zeng and Guo (2021) developed a three-dimensional model to evaluate the effects of surfactant-induced flow and heterogeneity on PFAS leaching in the vadose zone. Based on simulations using this model, they found that: 1) surfactant-induced flow had little impact on long-term PFAS leaching; 2) subsurface heterogeneity led to preferential flow that results in early arrival and accelerated leaching of PFAS; and 3) acceleration of PFAS leaching in high water-content preferential pathways or perched water above capillary barriers was more prominent than for conventional contaminants due to destruction of air-water interfaces (reduction of air-water interfacial area (A_{aw})). The authors of this study also recommended that multidimensional models be used to predict PFAS leaching in heterogeneous soils. Note that these conclusions were based on modeling results, and validation of the results using field data was beyond the scope of the study.

Modeling can be used to try to simulate PFAS transport in the vadose zone; however, it should be performed with careful selection of input values and should note appropriate caveats (see **Section 10.4.9**). For example, parameters that are important to understanding PFAS leaching processes, such as the air-water interfacial area (A_{aw}), may be challenging to estimate and/or not adequately captured using current models.

Analytical leaching methods such as the Synthetic Precipitation Leaching Procedure (SPLP) [SW-846 Method 1312 (**USEPA 2021**)] and the Toxicity Characteristic Leaching Procedure (TCLP) [SW-846 Method 1311 (**USEPA 2021**)] may be able to provide site-specific insight into the leachability of PFAS from vadose zone materials. The TCLP "is designed to determine the mobility of both organic and inorganic analytes present in liquid, solid, and multiphasic wastes" for waste characterization purposes (**USEPA 2021**). The SPLP is designed to determine the mobility of both organic and inorganic analytes present in liquids, soils, and waste to evaluate the potential of contaminants to leach into groundwater (**USEPA 2021**). Therefore, the SPLP is typically used for soils in site characterization contaminant leaching studies and allows for less acidic extraction fluids (simulating exposure to acid rain) than the TCLP test (simulating exposure in a landfill) so it can better represent environmental conditions expected to be encountered at a site. Currently some state agencies include the SPLP test as part of their PFAS assessment guidance, so state-specific guidance or requirements should be verified.

USEPA has also developed a Leaching Environmental Assessment Framework (LEAF). LEAF is a leaching evaluation framework consisting of four leaching tests (SW-846 Methods 1313, 1314, 1315, and 1316), a data management tool, and approaches for estimating constituent releases from solid materials (**USEPA 2019**). The four leaching tests discussed have been validated for inorganic constituents, but the methods and/or framework may be helpful when evaluating leaching of PFAS in the environment.

Optimizing LEAF leaching tests for use with PFAS is one component of an in-progress SERDP-ESTCP sponsored study: Development and Validation of Novel Techniques to Assess Leaching and Mobility of Per- and Polyfluoroalkyl Substances (PFAS) in Impacted Media, ER20-1126 (**SERDP-ESTCP 2021**). The project overview states that the study has the overarching goal of developing a framework for evaluation and prediction of the release of PFAS from AFFF-impacted media. Identified specific objectives include: 1) development of a standard leaching assessment methodology for AFFF-impacted media; 2) utilization of approaches including high-resolution mass spectrometry (HRMS), mid-infrared spectroscopy (MIR), and chemometrics to evaluate and develop a predictive model of PFAS sorption and desorption to AFFF-impacted media; and 3) comparison of results of laboratory testing to leaching and mobility under field-relevant conditions to develop an approach for translation of bench-scale test results to site-scale implications. Other SERDP-ESTCP sponsored studies include ER20-5088, which is evaluating how PFAS leaching is influenced by factors such as the soil to groundwater ratio (PFAS Leaching at AFFF-Impacted Sites: Insight into Soil-to-Groundwater Ratios), and ER18-1389: Baseline Data Acquisition and Numerical Modeling to Evaluate the Fate and Transport of PFAS within the Vadose Zone.

Many studies describe the complexity of soil retention mechanisms for an increasing number of nonpolymeric PFAS. This complexity is due to multiphase retention mechanisms that can include air-water interfacial sorption mechanisms as well as both hydrophobic and electrostatic interactions with the surface chemistry of soil particles (**Sima and Jaffe 2021**; **Sharifan et al. 2021**; **Guelfo et al. 2021**). In addition, studies have demonstrated rate-limiting solid-phase sorption kinetics (**Brusseau et al. 2019**), nonlinear sorption to both solids and air-water interfaces (**Schaefer et al. 2019**; **Li et al. 2019**), and desorption hysteresis (**Zhao et al. 2014**; **Ololade 2014**; **Schaefer et al. 2021**). Solution chemistry effects have also been shown to affect retention processes (**Cai et al. 2022**). All together, these multiphase retention mechanisms may complicate efforts to accurately predict long-term leaching potential from legacy source zones.

Stahl et al. (2013) completed a study evaluating the behavior of PFOA and PFOS in soil and the carryover from soil to plants. Plant samples and percolated water collected by a lysimeter were analyzed for PFOA and PFOS throughout a period of 5 years. PFOA was found to pass through the soil much more quickly than PFOS, and of the original mass applied, 96.88% of the PFOA and 99.98% of the PFOS was still present in the soil after a period of 5 years. Plants were found to have accumulated 0.001% of the PFOA and 0.004% of the PFOS. Loss through the soil leachate was reported to be 3.12% for PFOA and 0.013% for PFOS.

Given the complexity of estimating the mass discharge of PFAS from vadose soils to groundwater, care should be taken when selecting an approach(es) to estimate PFAS leachability to ensure it is appropriate for the site's physical environmental setting, and consideration should be given to developing multiple lines of evidence. Further, because of the limitations and uncertainties of the available estimation tools, care should be taken when evaluating and interpreting results. Currently available tools to consider include leaching methods (for example, SPLP or LEAF) as discussed above, modeling as discussed in **Section 10.4.9.1**, and soil lysimeters discussed below and in **Section 11.1.7.5**. Applicable regulatory guidance and requirements should also be considered.

Like grab samples, lysimeter samples represent a single-time result, which makes the representativeness of lysimeter results suspect when evaluating impacts to groundwater over a season or from year to year. Suction lysimeter samples are good for qualitative comparisons, but they cannot be used for quantitative analysis unless the variabilities of parameters involved are established (**ASTM International 2018**).

Collection of porewater data via lysimeters may provide pertinent empirical data for one line of evidence for qualitatively evaluating site-specific leaching of PFAS from the vadose zone to the groundwater. **Anderson (2021)** completed systematic measurements of porewater PFAS concentrations using lysimeters installed within relevant portions of a site. Mass discharge was estimated by multiplying observed lysimeter porewater concentrations by estimated vadose zone infiltration rates to determine the mass of PFAS leaching from the vadose zone to groundwater. However, lysimeter data may be biased by factors such as preferential flow, and samples may not be representative in dry or wet conditions. **Isch et al. (2019)** completed a study of water and bromide in bare soil using lysimeters compared to field plots and found that the transport of water and bromide in bare soil observed in lysimeters could not be directly compared to their transport observed in field plots. **Radolinski et al. (2022)** completed a study using lysimeters of how preferential flow alters solute mobility in soils and found that there was "evidence that (1) bypassing water flow can select for compounds that are more easily released from the soil matrix, and (2) this phenomenon becomes more evident as the magnitude of preferential flow increases."

Lysimeters have been suggested as a tool that can be used to measure the mobile mass fraction of PFAS concentrations in soil porewater (**Anderson 2021**). Lysimeters have been used by researchers investigating transport of AFFF at impacted field sites to benchmark the accuracy of laboratory batch extraction methods (**Schaefer et al. 2022**; **Quinnan et al. 2021**) and to understand temporal trends in PFAS concentrations in porewater (**Anderson et al. 2022**).

Fate and transport processes can have differential impacts on the individual components of chemical mixtures such as PFAS (see for example, **Bock et al. 2022**). Differences in the fate and transport process affecting chemical mixtures can result in changes in the relative abundance of these components. For example, more easily transported PFAS in a mixture could be preferentially leached in the source area and enriched downgradient. These processes should be considered when evaluating fate and transport, as well as when conducting a forensics evaluation of PFAS. It should be noted that chemical transformations, such as the conversion of PFAS precursors, will also result in changes in the relative abundance of PFAS in a mixture. These processes emphasize the importance of developing accurate estimates to predict the behavior of PFAS, including PFAS behavior in the vadose zone.

10.4.2 Retardation Coefficients and Travel Time in Groundwater

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include updated information about groundwater partitioning, colloidal transport, and groundwater-surface water interactions (see **Section 1.3.4**).

The time that it takes for a contaminant in groundwater to travel to a particular downgradient location is highly influenced by the groundwater velocity, and the plume extent is further influenced by processes that may act on the contaminant during transport, as well as by physical chemical properties of the

contaminant itself (for example, solubility). As an initial step for evaluating PFAS transport, it may be helpful to estimate retardation coefficients for PFAS to evaluate contaminant-specific velocity and travel time in groundwater, particularly for longer PFAS plumes. As discussed in **Section 5.2.3**, a linear sorption isotherm is typically assumed for PFAS sorption to organic matter in soil, and sorption coefficients. The Physical and Chemical Properties Table (**Table 4-1**) provided as a separate Excel file presents a range of available organic carbon partitioning coefficients for environmentally relevant PFAS. Hydrophobic, electrostatic, air-water sorption in the vadose zone, and hydrophobic and electrostatic sorption in the saturated zone also play a role in transport mechanisms (**Newell et al. 2021**).

However, as noted in **Section 5.2.3**, it is important to evaluate the PFAS present and quantify the fraction of organic carbon for estimating K_{oc}. The current state-of-science supports K_{oc} being reported in relatively broad ranges on a compound-specific basis. **Section 4.2.9** presents a discussion of potential limitations in using K_{oc} values as a predictor of sorption and PFAS mobility. It is also important to note that other geochemical factors (for example, pH, presence of polyvalent cations, and electrostatic processes), possible hysteresis, and nonlinear sorption behavior might influence transport across different PFAS concentration ranges, and isomeric differences may impact PFAS sorption to solid phases (**Section 5.2.3**). Due to the variability of K_{oc} estimates, it may be appropriate to evaluate transport of an individual PFAS using a range of partitioning coefficients. In addition, empirical estimation of site-specific K_{oc} values in different areas of a site (for example, source zone versus downgradient plume) may be necessary if quantification of the retardation coefficient is important to its characterization.

For example, **McGuire et al. (2014)** described the calculation of site-specific K_{oc} values for various PFCAs and PFSAs at an AFFF-impacted site. These site-specific Koc values were calculated based on seven pairs of co-located groundwater and soil samples, and fraction of organic carbon (f_{oc}) measurements at each sampling location. The soil samples were collected near or at the water table, which was about 4.6–6.1 m below ground surface. **McGuire et al. (2014)** found that there was a range of between one and three orders of magnitude in site-specific K_{oc} values for the PFAAs analyzed. This may reflect the enhanced sorption of PFAS that occurs at the NAPL-water or air-water interface (**Brusseau 2018**). There may be smaller ranges in K_{oc} values for PFAAs at greater depths below the water table and downgradient of a source zone (where NAPL is not present). When using this type of site-specific K_{oc} analysis method, it is also important that the groundwater samples be representative of conditions where the point soil samples are collected.

As another alternative to the use of K_{oc} values and the assumption of a linear sorption isotherm, in situ or ex situ studies may be used to develop parameters for simulation of PFAS transport. Such studies could allow development of pseudo-constants to use in model simulations. In groundwater, a bulk retardation factor can be estimated by comparing the observed length of a PFAS plume to the distance that groundwater would be expected to travel during the time since the PFAS release occurred. This method provides an estimation and assumes that the release date is known, but it accounts for the multiple processes influencing PFAS migration in groundwater (as opposed to just hydrophobic partitioning to soil organic carbon).

Desorption of PFAS from solids below the water table could occur when partitioning is reversible; such desorption would have the effect of maintaining PFAS concentrations in groundwater. There is uncertainty regarding the extent to which sorption is irreversible and rate-limited versus an equilibrium process (**Section 5.2.3**). It may be important to characterize the extent and kinetics of desorption that may occur as a result of remedial activities at the site. Assuming equilibrium desorption may result in overestimation of PFAS removal during remediation activities (**Sima and Jaffe 2021**).

Because retardation coefficients, travel time, and many other fate and transport processes are based on the physicochemical properties of the individual PFAS, these processes may not affect all PFAS in a mixture equally. As predicted for PCBs in **Johnson and Bock (2014)**, in which aggressive physical weathering was simulated, differential fate and transport trends affecting the components of a chemical

mixture can manifest as changes in the chemical profile. For PFAS, more easily transported PFAS in a mixture could be depleted in the source area and enriched at the plume front. A simple model demonstrating the effect for PFAS mixtures based on Koc and foc using the RemChlor-MD model (**Farhat et al. 2018**) from **Bock et al. (2022)** predicts that these processes can have important ramifications for PFAS forensics.

10.4.3 Matrix-Diffusion

When evaluating fate and transport of PFAS in a groundwater plume, including time frame for remediation of PFAS, matrix diffusion may be an important process to consider (**Section 5.3.1**). As such, understanding the potential impacts of diffusion on PFAS persistence in natural soils is a topic of ongoing research.

During the characterization of PFAS plumes, it may be beneficial to collect PFAS soil samples from the transmissive zone directly above a silt/clay layer, and at different depths into the silt/clay layer, to evaluate the potential for back-diffusion to be occurring presently or in the future if there is a decline in PFAS concentrations in the transmissive zone (see **Parker, Cherry, and Chapman (2004)** and **Chapman and Parker (2005)** for an example of this sampling approach). Using this approach, **Adamson et al. (2020)** reported that the majority of the PFAS mass at an AFFF release site was associated with lower permeability soils, highlighting the importance of matrix diffusion on PFAS retention.

Diffusion coefficients for PFAS are generally uncertain but are in development using measurements and models (**Pereira et al. 2014**). **Schaefer et al. (2019)** calculated aqueous diffusivity values for nine PFAAs; however, prediction of the influence that diffusion from lower permeability material to a flow zone (i.e., back-diffusion) will have on PFAS remediation time frame remains uncertain because the back-diffusion of PFAS from low-permeability materials involves desorption. As discussed above, PFAS desorption may be a rate-limited process, and these rates have a high degree of uncertainty (**Sima and Jaffe 2021**). In addition, the irreversible fraction of PFAS in low permeability materials is uncertain at this time. Therefore, the uncertainty associated with modeling remediation time frames of PFAS back-diffusion should be noted. Further discussion of matrix diffusion modeling is included in **Section 10.4.9**.

10.4.4 Mass Flux/Mass Discharge

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about using mass flux analysis for understanding PFAS migration in groundwater and potential discharge to surface water (see **Section 1.3.8.2**).

Mass flux and mass discharge can be valuable metrics for CSMs and understanding PFAS transport and supporting remedy selection. **ITRC (2010)** presented a variety of methods available for estimating mass flux and mass discharge, including the use of multiple transects of temporary or permanent monitoring wells across the width of a plume. Even simple methods such as chemical isoconcentration maps are suitable for developing an initial order of magnitude estimate for mass discharge. Calibration of solute transport models is another method that may be used to estimate the mass discharge of PFAS from a source zone, at a point in a plume, or to a surface water body. In addition, mass discharge estimates may be useful for understanding PFAS exchange between groundwater and surface water (**Divine et al. 2023**), and PFAS retention at the air-water interface could be an important fate and transport process (see **Section 5.3.2**) and may be considered when estimating the mass discharge from the vadose zone soils to groundwater. See **Section 10.4.1** for additional discussion of leaching that should be considered when estimating mass discharge from the vadose zone to groundwater.

Changes in mass discharge over time, as well as changes in mass discharge with distance from a source, can be used to assess attenuation/retention (see **Section 10.4.5**; **Newell et al. 2021**). At sites where multiple sources are present, it could also be used to identify the relative contribution of different sources

for prioritization purposes (see **Section 10.4.5**). Note that it may be challenging to estimate the relative mass flux contribution of different sources where low PFAS concentrations are present in porewater and groundwater. In addition, it is important to consider the potential for increases in dissolved mass flux of some PFAS due to biotransformation reactions, desorption between transects, and/or spatially varied infiltration.

10.4.5 Contributions from Different Sources

The potential impact to a site from multiple sources, particularly in proximity to urban or developed locations, needs to be accounted for when assessing site data or identifying data gaps. Each source then needs to be assessed in terms of its specific contributions, and their relative importance or magnitude. Although there are no naturally occurring background levels of PFAS, it may be important to gain an understanding of the Site-specific anthropogenic background (see the text box in **Section 10.1.2**) concentrations that may be present at a site, as these can have significant implications for site characterization, assessing exposures, evaluating ecological and human health risks, and establishing site action and cleanup levels. Most states have guidance on how to establish site-specific background concentrations for their regulated contaminants.

Tools available to quantify relevant contributions from different types of sources are discussed below.

10.4.5.1 Atmospheric Deposition

Certain PFAS may be present in ambient air and may be elevated near sources such as landfills, WWTPs, fire training facilities, and manufacturing plants (**Section 2.6**). Many PFAS exhibit relatively low volatility; however, airborne transport of some PFAS can be a relevant migration pathway for some industrial releases. Sections **5.3.2** and **6.1** provide an overview of transport of aerosols and particulates via air. To assess relative contributions from atmospheric sources, air sampling for PFAS can be conducted. Additionally, air dispersion models, such as AERMOD or Industrial Source Complex (ISC3) Model, can be employed to estimate airborne PFAS concentrations and total wet and dry deposition rates at designated receptor locations. Examples where AERMOD could be beneficial during site characterization activities include sites with no obvious source area and sites in industrial areas with multiple potential sources of airborne PFAS. See **Section 2.6** for additional details on the most typical PFAS source scenarios.

10.4.5.2 Upgradient Site Contributions

> ***Alternate Sources***
>
> Sources that may exist within, upgradient of, or near a site under investigation, that are distinct from the PFAS source being investigated.

PFAS persistence in the environment and their use in a multitude of industrial processes and commercial products result in potential for nonsite-related inputs, similar to other mobile contaminants (Figures **9-1**, **9-2** and **9-3**). Assessment of potential upgradient site inputs is recommended. The very low health advisory criteria for groundwater only increase the potential importance of identifying what might otherwise be considered “minor” upgradient sources and may result in alternate source identification (Sections **10.3.2** and **10.5**). As part of site investigation of an air deposition release, soil data can be statistically compared to background samples, evaluated for vertical stratification, and assessed for spatial distribution relative to the potential source. Groundwater data from the site may be compared to data from other locations using cluster analysis (i.e., a data analysis technique that explores the naturally occurring groups within a data set, which are known as clusters) to assess whether there was evidence of other source terms, or if the site in question appeared to be the sole source.

10.4.6 Transformation Pathways and Rates

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about PFAA precursor biotransformation (see **Section 1.3.3**).

As discussed in **Section 5.4**, the transformation of precursors may result in increasing concentrations of PFAAs such as PFOS and PFOA along the flow path of a dissolved plume. Transformation reactions may occur due to aerobic biological or chemical oxidation. For example, **McGuire et al. (2014)** concluded that infusion of dissolved oxygen to bioremediate hydrocarbons downgradient of a former burn pit also likely caused the transformation of precursor compounds to PFAAs such as PFHxS. Some methods that may be used to assess the degree to which transformation is affecting PFAS plume extent and stability include:

- plotting concentration isopleths for precursors and various PFAAs, for example, **McGuire et al. (2014)**
- use of the total oxidizable precursor (TOP) assay to identify whether precursors are present that may be available for transformation to PFAAs at a point in the plume (**Section 11.2.2**)
- assessment of ratios of precursor and daughter product species at monitoring wells situated along the centerline of a plume, or the ratio of various PFAAs in various portions of a plume. For example, **McGuire et al. (2014)** plotted an isopleth map for the ratio of PFHxS to PFOS to show that in areas where dissolved oxygen was injected this ratio was as high as 50, and in other areas where bioremediation was not conducted this ratio was less than 1.
- use of concentration trends along a plume centerline and quantitative methods described in **USEPA (1998)** to estimate precursor transformation rates
- use of concentration trends along a plume centerline for precursors identified using high-resolution analytical techniques (see Section 11.2.2.5) to evaluate if transformation to presumptive intermediates and end products is occurring during plume transport (**Nickerson et al. 2020**)
- calculating the site-wide mass of precursors remaining vs. mass of PFAA end products (PFAAs) to estimate the time-averaged transformation rate since the time of release
- groundwater modeling to demonstrate that the relative plume lengths of different PFAAs with different retardation coefficients can be explained only through the transformation of precursors, for example, **McGuire et al. (2014)**.
- a literature review to identify potential precursor transformation mechanisms and evaluate whether site geochemistry and redox conditions are favorable for the occurrence of these mechanisms.

Another method that may be used to illustrate the occurrence of these transformations is radial diagrams. See the case study in **Section 15.1.1**.

Figure 10-1 shows three radial diagrams based on data from an AFFF release site (**McGuire et al. 2014**). Each radial diagram compares groundwater concentrations at a monitoring well within the oxygen infusion zone to concentrations at a well approximately 76 m upgradient. The radial diagram shown at the left of Figure 10-1 compares concentrations for five PFCAs between these two wells; the middle diagram shows concentrations from the TOP assay conducted using samples from each well; and the radial diagram on the right compares concentrations for four PFSAs.

These radial diagrams illustrate that oxygen infusion into groundwater likely stimulated the production of mainly PFHxA, PFPeA, PFHxS, and PFBS. The middle radial diagram shows that the difference in TOP assay results between the upgradient well and the well in the oxygen infusion zone does not explain the large PFAAs concentration increases that were observed at the well in the oxygen infusion zone. The TOP assay results were low at both wells throughout the area. This suggests that desorption and subsequent transformation of precursors were occurring within the oxygen infusion zone. These radial diagrams are also useful for evaluating relative concentrations of various PFAAs at each monitoring well. The use of radial diagrams for additional types of trend analysis is discussed further in **Section 10.4.9.4**.

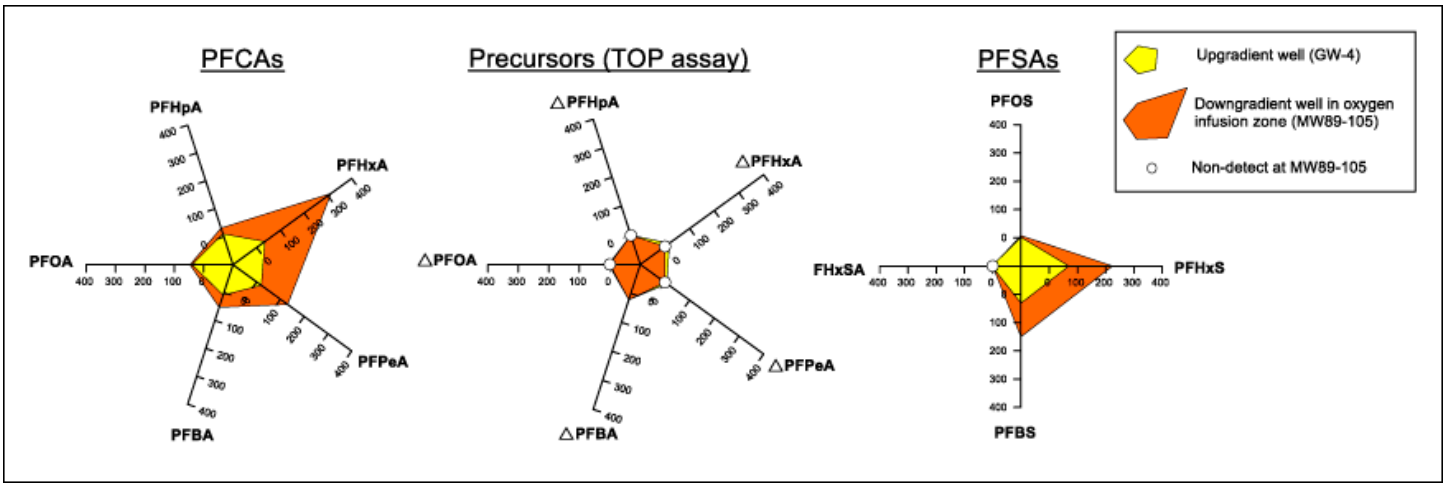

Figure 10-1. Radial diagrams showing the production of various PFAAs in the vicinity of an oxygen infusion zone at an AFFF release site remediated for hydrocarbons in groundwater.

10.4.7 Assessing Retention, Migration, and Attenuation Processes

The degree to which PFAS are retained, migrate, and/or attenuate in site media has significant implications for site remediation and management. Migration of PFAS in groundwater is a primary concern at most sites, and the migration rates are influenced by the physical-chemical properties of individual PFAS, as well as different processes that act on PFAS during transport. Depending on site-specific conditions, several nondestructive processes can contribute to decreasing PFAS concentrations with respect to distance from the source area(s) or in the source area itself over time. Understanding these processes is critical for confirming that sufficient data have been collected to identify the relevant site-specific processes, establish migration rates, assess plume stability (see **Section 10.4.8**), model fate and transport (see **Section 10.4.9**), and ultimately inform further remedial decision-making (see **Section 12**). **Table 10-1** summarizes the types of data that could be collected and analyzed to evaluate and quantify PFAS retention, migration, and attenuation processes at a site. This table summarizes information in previous subsections and is structured similarly to the methodology included in **Newell et al. (2021)** as the basis for evaluating natural attenuation as part of a site remediation and management strategy. However, it should be recognized that this process is also applicable to any setting where the information would improve the CSM and remedy evaluation process for PFAS. Lastly, it is essential to understand that individual PFAS have unique properties that affect their retention and attenuation. Therefore, an evaluation of site-specific retention and attenuation processes should consider variations between individual PFAS. For example, it may be possible that PFOS may be significantly retained at a site whereas PFNA may experience less retention and/or attenuation.

Table 10-1. Methods to Assess PFAS Retention, Migration, and Attenuation (adapted from Newell et al. (2021)).

Topic	Investigative Method	Supporting Investigative Method
Evaluating whether sorption to solid-phase and/or air-water interface and matrix diffusion contribute to retention of PFAS	• Detailed sampling of soil and groundwater to establish distribution of PFAS mass between vadose zone vs. saturated zone, low permeability vs. high permeability soil zones, and sorbed vs. aqueous phase • Calculating the ratio of PFAS mass to PFAS mass discharge (high ratio implies higher retention) • Calculating the ratio of saturated zone PFAS mass to PFAS mass discharge (high ratio implies higher retention/attenuation)	• High-resolution stratigraphic data to facilitate estimation of matrix diffusion (for example, high percentage of low-permeability soils in groundwater-bearing unit is consistent with matrix diffusion effects • Collection of hydrogeologic and geochemical data such as organic carbon, anion and/or cation exchange capacity, salinity, moisture content, porosity, bulk density, and mineral content to evaluate their relationships with PFAS concentrations • Measurement and comparison of relative plume lengths for individual PFAS, PFAS subgroups, and/or PFAS chains
Evaluating transformation of precursor compounds and impact on migration	• Detailed sampling of soil and groundwater to establish distribution of PFAS between precursor forms vs. PFAAs throughout site • Evaluation of PFAA concentration and/or PFAAs as percent of total PFAS	• Estimation of bulk precursor attenuation rates using field data • Estimation of precursor attenuation rates using fate and transport modeling • Geochemical data showing where conditions are more supportive of degradation (aerobic) vs. less supportive of degradation, as well as influences of these conditions on observed trends (for example, where is majority of precursor mass: anaerobic or aerobic zones)
Quantifying influence of processes on PFAS migration/persistence	• Evaluation of concentration trends with distance along plume centerline • Evaluation of mass discharge with distance along plume centerline • Evaluation of mass discharge from vadose zone to groundwater over time • Evaluation of source area concentration(s) over time • Evaluation of whether the plume footprint is stable or shrinking over time • Evaluation of the advancement rate of the plume footprint and whether downgradient zones have sufficient assimilative capacity zones	• Comparison of expected PFAS plume length in the absence of retention/attenuation (i.e., length if plume was advancing at the groundwater seepage velocity) to the observed PFAS plume length • Predictions of plume behavior over time using screening-level fate and transport models that include multiple PFAS retention processes • Predictions of plume behavior over time using more detailed 3-D contaminant transport models that incorporate additional flow data and other site-specific parameters

10.4.8 Assessing Plume Stability

At sites where PFAS has been detected in groundwater, it may be necessary to evaluate PFAS plume stability—whether the plume is stable, receding, or expanding. Plume stability and plume advancement rates are an important consideration for remedy selection. Many PFAS plumes are expected to be long-lived and possibly expanding due to the presumed lack of transformation of PFAAs and the mobility characteristics of many PFAS (especially those with shorter carbon chain lengths and anionic functional groups). Methods for evaluating plume stability include qualitative evaluations of temporal plume trends or statistical evaluations such as Mann-Kendall (**ITRC 2013**; **ITRC 2016**; **AFCEC 2012**; **USEPA 2009**).

Data uncertainties may have a greater than usual impact on plume stability evaluations for PFAS sites because of the low concentrations assessed. Monitoring records may be relatively limited, both in terms of the number of locations and the number of events that are available to evaluate. Biotransformation of precursors may also have an impact on plume stability evaluations. As such, more frequent or longer duration monitoring may be required to confirm trends or plume stability. A fate and transport model may also help provide predictions of plume behavior over time, and may be adjusted as additional site-specific data become available to aid calibration.

10.4.9 Modeling PFAS Fate and Transport

Some modeling of PFAS fate and transport has been conducted for vadose zone, groundwater, and atmospheric dispersion (**McGuire et al. 2014**; **Barr 2017**; **Carey et al. 2019**; **Guo, Zeng, and Brusseau 2020**; **Persson and Andersson 2016**; **Gassmann, Weidemann, and Stahl 2021**). **Sima and Jaffe (2021)** provided a critical review of applicable transport processes, modeling approaches, and potential limitations and uncertainty associated with modeling PFAS transport using existing approaches. Modeling the fate and transport of PFAS may have significant uncertainty contributed by precursor concentrations, transformation pathways and rates, and other factors. Because several of the key PFAS have not been shown to degrade naturally in the subsurface, other processes such as sorption, diffusion, and dispersion may be more important for understanding PFAS behavior upon release. However, many of these processes, such as desorption, are not well understood for PFAS (**Sima and Jaffe 2021**), and the accurate measurement or estimation of input parameters can be difficult. Although modeling of PFAS transport may be desirable and appropriate under certain conditions, the uncertainty of PFAS transport simulations requires that the results be qualified. Site-specific data are important for evaluating some potential model input parameters such as K_{oc}, which can exhibit significant spatial variation. This is particularly true in source zones, vadose zones, and at or near the water table. There are situations where modeling of PFAS transport may not be appropriate due to a lack of site-specific input parameters or reliable physical chemical properties for a particular PFAS.

10.4.9.1 Vadose Zone Modeling of PFAS Fate and Transport

There may be cases where an investigator wants to conduct a general screening-level evaluation of PFAS transport in the vadose zone under different scenarios. In such cases, the use of an existing vadose zone model may provide some benefit, but only if there is a thorough understanding of the inherent limitations of the model and if the uncertainty in the results is properly communicated.

Vadose zone models such as USEPA's VLEACH (information and model available at https://www.epa.gov/water-research/vadose-zone-leaching-vleach), and Seview's Seasonal Soil (SESOIL) compartment model (information and model available at http://www.seview.com/aboutsesoil.htm) can simulate one-dimensional vertical transport in the vadose zone via diffusion, adsorption, volatilization, biodegradation, cation exchange, and/or hydrolysis. Most PFAS are resistant to biotic or abiotic degradation, and in general PFAS are far less volatile than many other contaminants. With the exception of the few volatile PFAS such as the FTOHs (**Section 4.2.5** and

Table 4-1), the most important vadose zone processes to model are the physical transport processes. However, these models do not include air-water interfacial processes that appear to be important for vadose zone migration of PFAS. Other limiting factors for these models include that they simulate flow in only one dimension (vertical), and they may not adequately capture complex nonlinear or rate-limited sorption processes for PFAS. It is also important to note that these existing models have not been validated for use with PFAS. For these reasons, these models may not be appropriate for use with PFAS at this time.

The Michigan Department of Environment, Great Lakes, and Energy (EGLE) completed a review in 2020 that evaluated several vadose zone models (**MI EGLE 2020**) to simulate transport of PFOA and PFOS from municipal biosolid-amended soil through the unsaturated zone to the saturated zone. Models were initially screened and nine models were selected for critical review. From the nine models reviewed, HYDRUS, an unsaturated flow and transport model (information and model available at **https://www.pc-progress.com/en/Default.aspx?hydrus**), was recommended as the most suitable model for vadose zone modeling of PFOA and PFOS at the time of the EGLE review. (**MI EGLE 2020**).

Several research groups are attempting to develop models for PFAS transport in the vadose zone that more accurately represent some or all of the relevant processes. In some cases, these efforts involve modifying HYDRUS to incorporate these processes, while other groups are developing their own vadose zone models to do the same. Several studies discussing vadose zone modeling are presented below with a simplified, possibly more efficient model discussed in **Guo et al. 2022**.

Guo, Zeng, and Brusseau (**2020**) (referenced in **Section 10.4.1** above) developed what they believed to be "the first mathematical model that accounts for surfactant-induced flow and solid-phase and air-water interfacial adsorption." They applied the model to simulate PFOS transport in the vadose zone at a model fire-training area site impacted by AFFF. The simulations were useful in developing general concepts of PFAS retention as described in **Section 10.4.1**. In addition, and more generally, the mathematical model provides a quantitative framework that can be extended to examine the complex interactions between dynamic flow and adsorption processes at field sites (**Guo, Zeng, and Brusseau (2020)**).

Zeng and Guo (2021) went on to develop a three-dimensional model for PFAS leaching in the vadose zone that allows for quantification of impacts from subsurface heterogeneities, which the authors concluded to be among the primary sources of uncertainty for predicting PFAS leaching and retention in the vadose zone.

"Due to significant computational cost and the requirement for detailed input parameters for the models," developed by **Guo, Zeng, and Brusseau (2020)** and **Zeng and Guo (2021)**, **Guo et al. (2022)** developed a simplified model better suited for a screening tool to quantify vadose zone PFAS leaching. The derived analytical solutions incorporate multiple transport processes (with simplifying assumptions such as linear sorption) and allow for varied initial conditions. The solutions were "then validated by application to miscible-displacement experiments under a wide range of conditions and by comparisons to a state-of-the-art comprehensive model under both experimental and field conditions applicable to PFAS-contamination sites" (**Guo et al. 2022**). Based on these results, the authors concluded that "the simplified analytical model provides an efficient and accurate screening-type tool for quantifying long-term PFAS leaching in the vadose zone" (**Guo et al. 2022**).

Silva, Simunek, and McCray (2020) modified the one-dimensional and two-dimensional versions of HYDRUS "to simulate the effects of non-linear air-water interface (AWI) adsorption, solution surface tension-induced flow, and variable solution viscosity on the unsaturated transport of PFAS in the vadose zone." Available literature-derived unsaturated transport data for PFOA and PFOS were used to validate the revised models and provide example simulations. The study simulations showed that while AWI adsorption of PFAS can be a significant source of retention within the vadose zone, it is not always the dominant source of retention (**Silva, Simunek, and McCray (2020)**. The contribution of solid-phase

sorption can be considerable in many PFAS-contaminated vadose zones (S**ilva, Simunek, and McCray 2020**). Further, the effects of soil textural heterogeneities on PFAS unsaturated transport are demonstrated in the example results.

A follow-up to a leaching study performed by **Stahl et al. (2013)** (referenced in **Section 10.4.1**) was completed by **Gassmann, Weidemann, and Stahl (2021)**. The study used 8 years of data from a lysimeter and MACRO—a one-dimensional, process-oriented, dual-permeability model for water flow and reactive solute transport in soil (information and model available at https://www.slu.se/en/Collaborative-Centres-and-Projects/SLU-centre-for-pesticides-in-the-environment/models/macro-52/). The study evaluated the ability of MACRO to simulate leaching and plant uptake of PFOA and PFOS using two adsorption concepts: a kinetic two-side sorption concept usually applied for pesticide leaching (scenario I) and the formation of what **Gassmann, Weidemann, and Stahl (2021)** called non-extractable residues (NER) (scenario II). NER are adsorbed PFAS that either do not leach or leach very slowly from soil. Leaching of PFOA and PFOS could be adequately simulated for scenario II, but scenario I was not able to reproduce sampled leaching concentrations (**Gassmann, Weidemann, and Stahl 2021**). Plant uptake was simulated well in the first year after contamination but was not simulated well in the following years (**Gassmann, Weidemann, and Stahl 2021**). The model results suggest that more than 90% of the original mass of PFOA and PFOS is present as NER after 8 years, which the team concluded was a larger percentage of the mass compared with other studies (**Gassmann, Weidemann and Stahl 2021**). The authors also concluded that even though there are open questions that necessitate additional research, "the study showed that it is possible to use an existing leaching model for the long-term simulation of PFOA and PFOS leaching in unsaturated soils and the short-term simulation of plant uptake." Furthermore, they concluded that even though not all environmental processes are yet understood, this model may already provide valuable information for groundwater protection and crop safety.

10.4.9.2 Groundwater Modeling of PFAS Fate and Transport

The development and application of modeling approaches for PFAS in groundwater is relatively limited to date, likely reflecting the complexity of PFAS fate and transport processes, the range of chemical properties, and the uncertainty regarding appropriate parameter values to use in existing models. Several processes that are expected to influence PFAS fate and transport (see **Section 5**) pose challenges for modeling PFAS in groundwater, including:

- Nonlinear sorption. Linear sorption implies that the distribution of a compound between its dissolved phase and any solid phases that are present (for example, soil particles) is independent of the concentration of the compound itself. PFAS sorption has been shown to be concentration-dependent, such that models that account for this behavior are better suited for applications with wide concentration ranges. However, this adds complexity because it relies on an understanding of the appropriate PFAS sorption isotherm(s) and associated parameters for the site-specific application.

- Rate-limited sorption. Solute transport models typically rely on an initial assumption of equilibrium partitioning between dissolved and sorbed phases on a compound. However, several studies have demonstrated that PFAS sorption-desorption is a rate-limited process. This requires a more detailed approach in which both the dissolved and sorbed phases are modeled to incorporate mass transfer between the phases.

- Precursor transformation. PFAS are typically released as mixtures of different compounds, a portion of which may not be identifiable using current analytical approaches. Solute transport models that rely on simplified assumptions (for example, first-order kinetics, stepwise reaction pathways) may not be able to accurately capture in situ transformation patterns. Even for PFAS transformation pathways that have been identified as potentially relevant using lab or field data, there is little understanding of in situ rates to use for modeling purposes.

Despite the challenges groundwater modeling is being attempted for some situations. Some groundwater modeling studies from the literature are discussed.

Pietrzak (2021) completed a review of available software for modeling organic pollutants in groundwater. One example, simulated transport using MODFLOW/MT3DMS (**Shin et al. 2011**), which summarized simulation of PFOA transport in several media, including groundwater, from a manufacturing source and linking the models. **Shin et al. (2011)** concluded that their models may be useful for estimating past and future concentration of PFOA in water wells in the study area. However, the effort did not include all processes that are now recognized as relevant for PFAS fate and transport.

Groundwater modeling studies published to date have focused on the impacts of specific processes and/or remediation on PFAS plume development. For example, **Gefell et al. (2022)** modeled hypothetical PFOA groundwater plumes using MODFLOW and MT3D based on purely hypothetical remediation and data. The study evaluated the differences between a plume resulting from a PFOA-only source compared to a source with precursors located in the overlying vadose zone. Because the plumes from both scenarios exhibited relatively similar concentrations and lengths in the absence of remediation, the authors concluded that source zone characterization is particularly important when predicting long-term plume behavior and that it may be appropriate to calibrate a model to both a terminal PFAA-only source plume and one from a precursor source. After remediation of the source and an extended postremediation flushing period, the scenario with a precursor-based source resulted in a longer plume with higher concentrations. The results for this scenario were sensitive to the precursor degradation rate, and the authors used literature values in their simulations that were derived from a combination of lab-based and field-based data.

As another consideration to improve modeling transport of PFAS in groundwater, the REMChlor-MD model (**Farhat et al. 2018**) has been proposed for evaluating the possible effects of matrix diffusion processes on PFAS distribution (**Newell et al. 2021**). This includes a study by **Kulkarni et al. (2022)** in which this screening-level model was used to estimate the impact of matrix diffusion on the PFOS plume extent using field data from a well-characterized AFFF site where significant PFAS mass was known to be present in lower permeability soils. The model predictions suggested that matrix diffusion contributed to a PFOS plume length at this site that was approximately 40% of the length that would have been observed in the absence of matrix diffusion. The study predicted that matrix diffusion was reducing the plume advancement rate, and that source remediation would have limited impact on the rate of future plume advancement. Another study used REMChlor-MD modeling to examine the types of sites where matrix diffusion processes would be most relevant, and the authors concluded that aquifers with embedded lower permeability layers and lenses exhibited shorter PFOS plumes than aquifers with underlying and/or overlying aquitards (**Farhat et al. 2022**). Long time frames were needed for plume stabilization, but these predictions were highly sensitive to dispersion parameter values since PFOS was assumed to not degrade over time. These results emphasize the site-specific nature of various PFAS fate and transport processes and highlight the importance of site-specific assessments.

In addition, selecting a representative source term for modeling may be difficult due to a lack of available data and/or limitations in the model for handling potentially complex source behavior. Ideally, groundwater transport models for PFAS should incorporate data from vadose zone models and air deposition models to provide a more holistic representation of the source term. As mentioned above, this linked approach was used in a 2011 study that examined regional transport of PFOA from a manufacturing source (**Shin et al. 2011**), but the model did not include all processes that are now recognized as relevant for PFAS fate and transport. In other cases, groundwater transport modeling with discharge to surface water was used to evaluate PFAS distribution within watersheds or regional scales (**Raschke et al. 2022**), though the level of complexity of such integrated modeling approaches may be high and could introduce additional uncertainty, particularly if the data available to calibrate the models are limited.

Another use of groundwater modeling is to evaluate groundwater surface interactions. **Divine et al. 2023** provided a brief discussion of the current state of modeling PFAS and concluded that current models lack do not include complexities such as mass transfer rate limitations and precursor transformation. Additional model development and verification is needed.

10.4.9.3 Air Modeling of PFAS Fate and Transport

Modeling PFAS transport in air is receiving more attention, and USEPA has recently developed an air quality model named the Community Multiscale Air Quality model (CMAQ) for these purposes (**USEPA 2022**). From a personal communication with James A. Thurman, Ph.D., USEPA/OAQPS/AQAD, Air Quality Modeling Group, CMAQ can handle any kind of atmospheric reactions PFAS would undergo during transport and would also include long-range transport, more than 50 km from the source of PFAS. As more information is learned about PFAS, CMAQ can be updated to include the atmospheric reactions for PFAS. See **D'Ambro (2021)** for an example of the use of CMAQ to evaluate a mixture of PFAS from a fluoropolymer manufacturing facility.

Another example of atmospheric modeling of PFAS was performed by **Moreno (2019)**. **Moreno (2019)** modeled transport of PFOA and HFPO-DA from two manufacturing facilities using CALPUFF, a non-steady state, long-range transport model. In addition, air quality models such as AERMOD or IISC3 Model are identified in **Section 10.4.5.1**. An example use of AERMOD can be found in **Barr 2017**. AERMOD was used to simulate the emission of PFOA from stacks at former manufacturing facilities in Bennington, Vermont, and the resulting air dispersion and deposition. The facilities applied PTFE to some fiberglass fabrics.

AERMOD is applicable in the near field, less than 50 km from the source of PFAS for qualitative assessment of local deposition from a source of PFAS when atmospheric reactions are not necessarily important (From a personal communication with James A. Thurman, Ph.D., USEPA/OAQPS/AQAD, Air Quality Modeling Group). AERMOD deposition fields could be used to analyze the spatial distribution of deposition near the source and identify areas of interest to consider for further study. More information for AERMOD can be found in **USEPA (1995)**; **Wesley, Doskey, and Shannon (2002)**; and **USEPA (2003)**.

USEPA provides a Support Center for Regulatory Atmospheric Modeling (SCRAM) website at https://www.epa.gov/scram (accessed August 10, 2023) that includes links to air quality models and tools.

10.4.9.4 Visualization Methods

One of the challenges associated with characterization of PFAS sites is the analysis of trends for a number of PFAS constituents that may be sampled in soil and groundwater, and then the communication of the results of these analyses to a less technical audience. Typical site characterization visualization methods such as plume maps, cross-sections, fence diagrams, 3D models may be used to depict the horizontal and vertical extent of PFAS plumes. Several other visualization methods may be helpful when analyzing PFAS data, including:

- bar charts that show the relative concentrations of individual PFAS constituents at each location to help evaluate PFAS composition trends in soil and groundwater (for example, figures 6 and 7 of 7 **Field (2017)**, **Figure 15-1**)
- radial diagrams to illustrate:
    - transformations of precursors to PFCAs and/or PFSAs along a flow path (for example, see **Section 15.1.1**)

- relative concentrations of constituents at each sample location to assist with source fingerprinting and to identify potential risk drivers in different parts of a plume
- locations of potential hot spots
- general extent of a PFAS plume.

Case study examples of these different methods are discussed in **Section 15.1**.

10.5 Forensics and Source Identification

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information source identification, differentiation, and forensics (see **Section 1.3.7**).

The field of environmental forensics is a formal technical discipline that spans chemistry, environmental science, and engineering (for example, **Morrison 2000**; **Morrison and Murphy 2006**; **Mudge 2008**; Murphy and Morrison 2015; **Sullivan et al. 2001**; **Wang and Stout 2007**). Environmental forensics is used to address problems such as source identification, timing of releases, and contaminant fate and transport. As compared to legacy contaminants such as PAHs and PCBs, the application of forensics to PFAS forensics is in its nascent stages. Researchers are still conducting studies to more fully understand the fate and transport of PFAS in the environment, and they continue to evaluate tools to investigate changes in PFAS composition for the purposes of source attribution. Multivariate methods have been applied to investigate sources of PFAS, including human exposure in the Faroe Islands (**Hu et al. 2018**), contributions to surface water in the northeast United States (**Zhang et al. 2016**), and contributions to surface water and sediment in South China (**Pan et al. 2014**). **Benotti et al. (2020)** and **Charbonnet et al. (2021)** both advocated the use of a variety of tools that are applied in a tiered approach for characterizing the PFAS signatures associated with source materials and environmental contamination. It has been observed that the PFAS sources profiles associated with different PFAS uses are frequently highly variable. Until a more complete understanding of the chemical composition of source materials is available, and until researchers understand the full scope of forensic information that may help elucidate sources, source libraries associated with different usage profiles are incomplete at best. Given these uncertainties, the best approach for associating or dissociating environmental contamination from one or more sources is to compare PFAS information in environmental samples to similar information from site-specific source areas. An overview of PFAS source identification analyses can be found in **Dorrance, Kellogg, and Love (2017)**.

To that end, any site-specific investigation begins with a careful review of available records. In a best-case scenario, such records may directly link a source to environmental contamination without significant contribution from any other potential sources. More often than not, source attribution of PFAS contamination is more complicated. Groundwater plumes of PFAS contamination can be heterogeneous due to weathering and differential rates of subsurface transport between PFAS. Care must be taken not to attribute changes associated with fate and transport to different sources. Recent experience shows that multiple groundwater plumes with a similar or disparate profiles are commonly observed to intersect and commingle. If there are two or more likely sources contributing to mixed contaminant plumes, defining the footprint associated with these different sources can be challenging. In addition, atmospheric transport and deposition of PFAS can be important and result in PFAS sources with regional impacts (**Ahrens et al. 2016**; **Davis et al. 2007**; **Galloway et al. 2020**).

When identifying PFAS sources, some important factors to consider include:

- *data quality*, where care must be taken to ensure that analytical results from different time periods, different methods, or different labs are comparable, as older data sets may provide incomplete information when compared to more recent data

- *target PFAS list*, where a reduced compound list may prevent full differentiation between sources. Linear versus branched (isomer) distinction may also be important in differentiating sources
- *matrix effects*, care must be taken to account for differences in PFAS profiles associated with different matrices. For example, soil PFAS profiles can be significantly altered during leaching to groundwater
- *temporal effect*, where an understanding of historical production, use, and release of PFAS becomes important, as is an understanding of differences between samples due to weathering processes that may be interpreted as different sources
- *spatial effect* of long-distance air deposition and regional sources versus local sources
- *sample collection procedures* to ensure there is no cross-contamination from other sources during sampling
- *rigorous exploration of potential sources* to ensure that all sources of potential interest have been identified and considered
- *weight of evidence* based on multiple lines of inquiry

The following sections describe some of the source identification tools that may be used or considered for use in identifying sources of PFAS.

10.5.1 Source Identification Tools

Chemical fingerprinting often involves the evaluation of the relative proportions of different substances in a mixture to link contaminants in the environment to one or more known or suspected sources (see the text box in **Section 10.4.5.2**). The data from available analytical methods can be evaluated using various graphical, statistical, and geospatial techniques. These methods have been commonly used for legacy contaminants such as petroleum and chlorinated compound source identification and can potentially be applied to PFAS mixtures. The following sections describe some of the forensic information that may be useful to evaluate sources, as well as some tools for comparing samples within a data set.

10.5.1.1 Manufacturing Signatures

PFAAs (PFCAs and PFSAs) can be produced as a mixture of homologues of different chain lengths depending on the various manufacturing process(es) used (**Section 2.2**). PFAAs produced by electrochemical fluorination (ECF) can include both even and odd chain-length homologues. PFAAs produced by fluorotelomerization contain mostly even chain-length homologues. However, transformation of some of the fluorotelomer precursors results in the formation of odd chain length PFCAs (**Prevedouros et al. 2006**; **Dasu, Liu, and Lee 2012**; **Liu and Mejia Avendano 2013**). Most commercial laboratories can report PFCA homologues ranging from C4 to C14 and select PFSA homologues between C4 and C12. **USEPA (2009)** published PFCA profiles in various commercial products that showed different patterns of PFCA chain lengths. So, while chemical fingerprinting for source identification may be useful for PFAS sites, changes in raw materials and processes over time, as well as environmental fractionation, must be taken into account.
Laboratories generally report the concentration of a given PFAA as the total of the branched and linear forms; however, the concentration of the linear form and an estimated concentration for the branched form can often be reported independently. The concentration of branched forms typically must be estimated because standards do not yet exist for most branched-chain PFAA (**Section 11.2.1**). **Benskin (2011)** used the absence of branched PFCA isomers in dated sediment cores of two lakes to support the conclusion that oxidation of FTOH was the major atmospheric source of PFCAs in the lakes and not

direct transport of PFOA. **Fredriksson (2016)** used isomer profiles along with homologue patterns to assess the sources of PFAS in avian eggs. However, the potential for environmental fractionation must be taken into account when evaluating isomer profiles because linear and branched-chain isomers have different physical and biological properties, adsorption, and bioaccumulation (**Fredriksson 2016**; **Miralles-Marco and Harrad 2015**). Other examples of isomer analysis for PFAS source identification include **Shi et al. (2015)**, **Benskin, DeSilva, and Martin (2010)**, and **Karrman et al. (2011)**.

Chiral fingerprinting through enantiospecific isomer differentiation is a potential method for source identification, although its use is still under development. **Asher et al. (2012)** applied this method to identify PFAS sources to an aquatic foodweb. However, they noted several limitations and assumptions when using this method for PFAS source identification.

10.5.1.2 High-Resolution Mass Spectrometry (HRMS)

High-resolution mass spectroscopic methods using quadrupole time-of-flight mass spectrometry (qTOF/MS) can be used to determine both the chemical formula and structure of unknown PFAS in source materials (see **Section 11.2.2.5** for further information on qTOF/MS) (**Newton et al. 2017**; **Moschet et al. 2017**; **Barzen-Hanson et al. 2017**; **Battelle 2020**; **Washington et al. 2020**; **Getzinger, Higgins, and Ferguson 2021**; **Guelfo et al. 2021**). PFAS suspect screening libraries have been developed to include broader lists of PFAS analytes found across many different PFAS sources (**Newton et al. 2017**; **Moschet et al. 2017**; **Barzen-Hanson et al. 2017**; **Getzinger, Higgins, and Ferguson 2021**). Because analytical standards are not available for most PFAS included under this extended list of analytes, often these analytical tools are used for qualitative/semiqualitative analysis. These methods have the potential to greatly increase the number of identified PFAS, including precursors and the transformation products, and hence provide more accurate source identification (**Washington et al. 2020**, Getzinger, Higgins, and **Ferguson et al. 2021**; **Guelfo et al. 2021**). The addition of a broader list of analytes increases the power to resolve differences in PFAS profiles and therefore characterize sources and source footprints.

10.5.1.3 Visual Representations of Data

It is common to show representations of measured PFAS in figures or graphs to give the reader a visual sense for relative abundance. Two common graphs for representing PFAS data are bar graphs and radar plots. If one is considering the role of concentration, then it may be helpful to plot PFAS concentrations on the axes. However, if one is considering the patterns of data, then it is helpful to plot relative abundance, or the concentration of each PFAS divided by the sum of all measured PFAS, on the axes. It is also suggested to group subclasses of PFAS together and order them by perfluorinated alkyl chain length. For example, PFCAs ordered from the shortest to longest perfluorinated alkyl chain length, followed by PFSAs ordered from the shortest to longest perfluorinated alkyl chain length, followed by fluorotelomer sulfonates ordered from the shortest to longest perfluorinated alkyl chain length allows the viewer to compare changes in compositional patterns both within and between different subclasses of PFAS to assess changes that may occur due to environmental fate and transport. When showing data in this fashion, it is common to report estimated concentrations or J-flagged values and use the value of zero (0) for nondetects. However, other methods for assessing nondetects could be considered (**Johnson et al. 2015**). A comparison of PFAS signatures between two samples (Sample A and Sample B) using either bar graphs (**Figure 10-2**) or radar plots (**Figure 10-3**) is shown below.

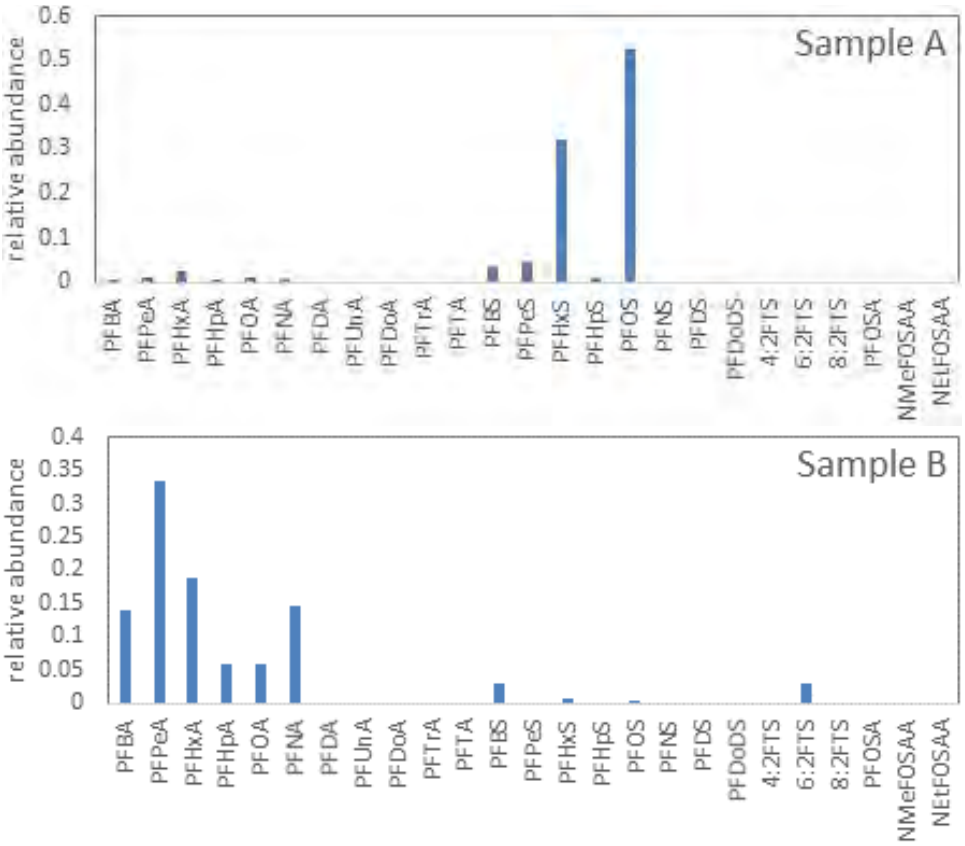

Figure 10-2. Comparison of PFAS signatures in Sample A and B using bar graphs. The concentration of each PFAS has been divided by the sum of all measured PFAS to represent the relative abundance of PFAS in each sample.

Source: M. Benotti, NewFields. Used with permission.

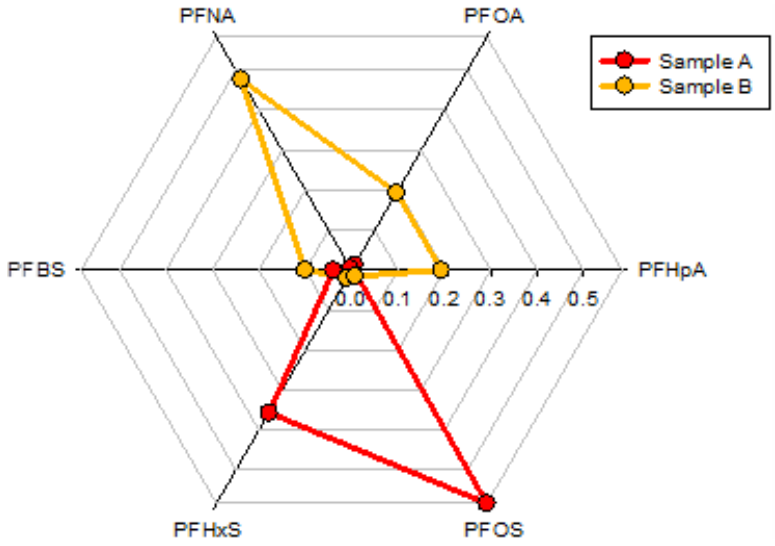

Figure 10-3. Comparison of PFAS signatures in Sample A and B using radar plots. The concentration of each PFAS has been divided by the sum of all measured PFAS to represent the relative abundance of PFAS in each sample.

Source: M. Benotti, NewFields. Used with permission.

10.5.1.4 Diagnostic Ratios

In some applications of PFAS forensics, it may be beneficial to show similarities or differences between sample signatures using relative abundances of one or more PFAS or diagnostic ratios, or double ratio plots. Without a comprehensive library of PFAS source materials, such ratios should be site-specific, and should be selected to query the data for a site-specific question and to show similarity or differences between contamination throughout the site and those in known or purported source area/s. Examples of factors that may help identify suitable diagnostic ratios include the relative abundance of PFCAs, PFSAs, or FTSs, the ratio of PFCAs to PFSAs (or more specifically the ratio of PFOA to PFOS), the ratio of even-numbered to odd-numbered PFCAs, the relative abundance of linear to branched isomers of selected PFAS, and others. **Table 10-2** shows some example diagnostic ratios for PFAS in Sample A and Sample B above.

Table 10-1. Example diagnostic ratios to compare PFAS signatures of Sample A and Sample B.

	Sample A	Sample B
relative abundance of PFCAs	0.062	0.93
relative abundance of PFSAs	0.94	0.041
relative abundance of FTSs	0	0.029
PFCAs/PFSAs	0.066	22
PFOA/PFOS	0.0217	13

10.5.1.5 Multivariate Statistical Tools

The statistical methods used in fingerprinting chemical mixtures range from simple visual comparisons of the relative chemical composition in environmental samples to more sophisticated multivariate statistical analyses of large environmental data sets (**Bock et al. 2021**; **Cejas and Barrick 2021**; **Wenning and Erickson 1994**; **Johnson et al. 2006**; **Otto 2016**; **Brereton 2009**). Multivariate statistical tools are ideally suited to the analysis of chemical mixtures. These tools have been applied to chemical mixtures such as PCBs, hydrocarbons, and dioxins for many decades. PFAS data sets, including TOP assay data, are similarly amenable to a variety of multivariate numerical data analysis techniques that provide a means to categorize PFAS compositional data. The advantages of multivariate numerical methods are that they provide a convenient means to analyze large data sets and reduce the output into relatively straightforward graphical output that describes the most important factors affecting chemical variability throughout the data set. Principal component analysis (PCA) is a multivariate statistical procedure that uses an orthogonal transformation to convert a set of observations of possibly correlated variables into a set of values of linearly uncorrelated variables called principal components. In other words, it identifies and graphically shows the most important features of data that describe similarities and differences between sample chemistries within a data set. The investigator can use this tool to identify samples that have similar or different PFAS signatures and what changes are driving those differences. Changes in PFAS patterns may be attributable to changes associated with fate and transport, or there may be changes that can be explained only by additional sources. **Figure 10-4** presents an example PCA scores plot, which demonstrates the similarity or dissimilarly of PFAS signatures between all samples in a data set. PCA is most effective when supplemented with other lines of evidence such as cluster analysis, ratios, and geospatial methods.

Examples of chemical fingerprinting for PFAS source identification can be found for wastewater treatment plants (**Clara et al. 2008**), differentiating AFFF sources (**KEMI 2015**; **Hatton, Holton, and DiGuiseppi 2018**; see also **Section 3.5**), landfills (**Lang et al. 2017**; **Xiao et al. 2012**), surface water (**Xie et al. 2013**), sediment (**Qi et al. 2016**), and groundwater (**Yao et al. 2014**). Multivariate statistical analyses (that is, PCA, cluster analysis, and unmixing models) and geospatial analysis have been used extensively to distinguish PFAS sources. **Guelfo (2017)** emphasized the importance of geospatial distribution of PFAS for source identification. **Qi et al. (2016)** used PCA–multiple linear regression, positive matrix factorization, and unmix models to identify four PFAS sources (textile treatment, fluoropolymer processing aid/fluororesin coating, textile treatment/metal plating, and precious metals). **Zhang et al. (2016)** used PCA, hierarchical clustering, and geospatial analysis to determine sources in the northeast

United States, and Lu et al. (2017)[652] used factor analysis to classify three categories of PFAS in impacted groundwater. **Pan et al. (2014)** used PCA in water and sediment samples to distinguish between rural/agricultural and urban/industrial sources.

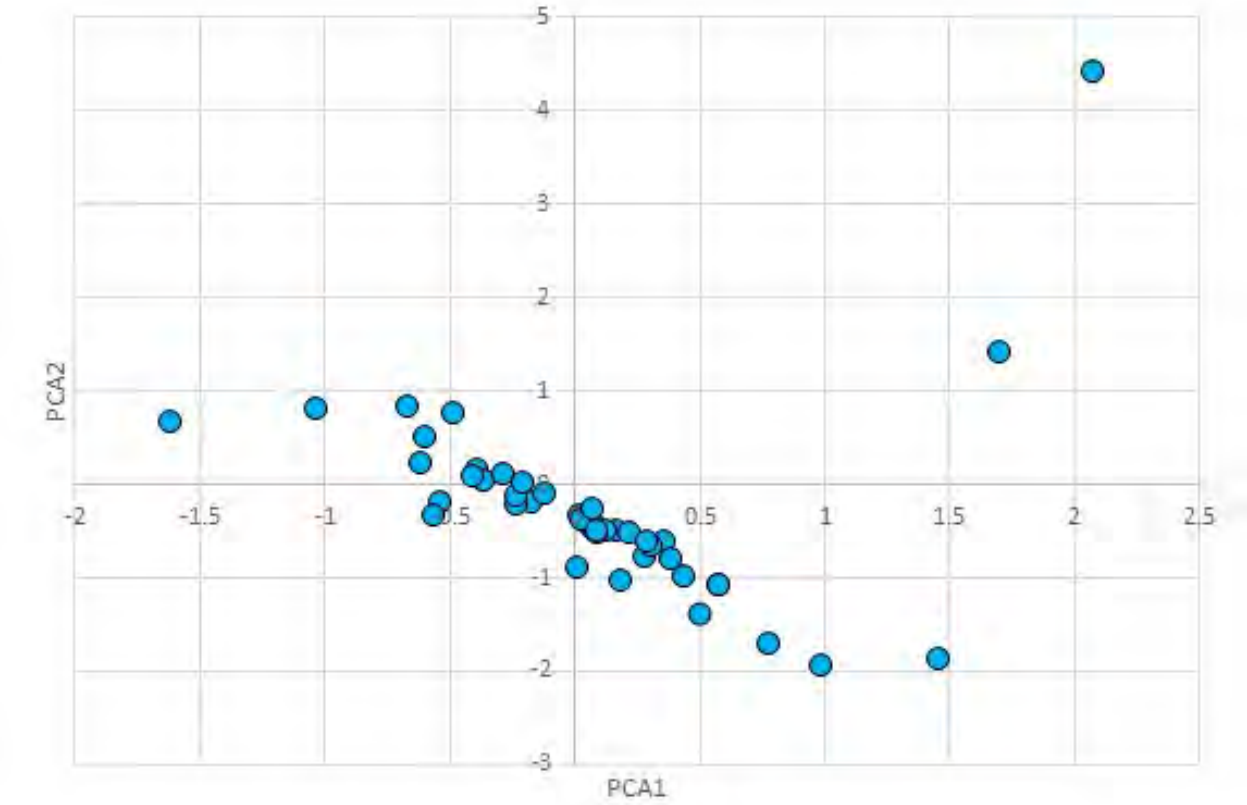

Figure 10-4. PCA scores plot of the analysis of a PFAS data set. Each circle represents the pattern of PFAS contamination of an individual sample. Samples that plot close together have similar PFAS signatures. Samples that plot apart have dissimilar PFAS signatures.

Source: M. Benotti, NewFields. Used with permission.

Other methods that have been applied to other chemical mixtures, such as statistical unmixing and big data/machine learning methods, also hold promise for the analysis of PFAS mixtures. As with any complex data analysis method, these methods have strengths and weaknesses that must be understood by the user. Thus, PFAS forensics practitioners must keep current on new developments in chemical forensics and statistical analysis. Given differences in the environmental fate and transport of different types of chemical mixtures and the complex behavior of PFAS, the forensics scientist must carefully evaluate any data analysis method to ensure it is being applied and interpreted appropriately. Because of the many complexities associated with PFAS production, historical usage, and fate and transport processes, the risk of incorrect conclusions can be especially high. We advocate for a weight of evidence approach based on (1) historical information regarding usage and other information, (2) a detailed consideration of transport pathways such as air emissions, spills, and wastewater discharge, (3) an analysis of transport processes such as local groundwater transport, the presence of groundwater divides and other barriers, and air speed and direction, (4) concentration gradients, (5) the analysis of diagnostic ratios, (6) multivariate statistical methods, (7) a consideration of branched versus linear isomers, and (8) other information that can be used to understand sources, discharges, and fate and transport.

11 SAMPLING AND ANALYSIS

Due to the extensive use of a wide array of PFAS resulting in trace levels of PFAS in most environmental media across the globe and the low parts-per-trillion screening and action levels, all aspects of a sampling and analysis protocol require a heightened level of rigor to avoid cross-contamination and achieve the level of accuracy and precision required to support defensible project decisions. This section focuses on providing the user with the appropriate tools and information to develop a site-specific sampling and analysis program to satisfy the project data quality objectives (DQOs). Accurate and representative data support the development of a defensible conceptual site model (CSM), and ultimately the final remedy.

Section Number	Topic
1.5	**Priority Topics for Sampling and Analysis (2025)**
11.1	**Sampling**
11.2	**Analytical Methods and Techniques**
11.3	**Data Evaluation**
11.4	**Source Identification**

Information on sample collection for PFAS is sparse, with only a handful of guidance documents available for a practitioner to reference. However, there are two peer-reviewed studies (**Denly et al. 2019**; **Rodowa et al. 2020**) on the potential for cross-contamination from commonly used sampling materials. These studies indicate that the potential for cross-contamination from the equipment used or possession of items that could potentially contain PFAS (for example, bug spray, food wrappers, and sunscreen) is extremely low and difficult to document. As of the date of this publication, most guidance documents default to a conservative approach due to a lack of information at the time of publication. Although the actual methods of sample collection are similar to those used for other chemicals, there are several considerations for the practitioner when establishing a sampling program for PFAS. These include selection of proper personal protective equipment (PPE), documentation of protocols for sample handling and decontamination procedures, use of nonbiasing material (for example, tubing, sample bottles, pumps) that will or could reasonably come into contact with the sample media, and implementation of quality control (QC) protocols to meet project DQOs, among other considerations. This section will give practitioners the tools needed to prepare a sampling program that adequately addresses project-specific DQOs and limits, to the extent practicable, potential cross-contamination and sources of potential bias.

Analytical methods are still evolving for PFAS analysis, with several in development (**USEPA 2024**). Although some methods have been published (**PFAS Analytical Methods** provided as an Excel spreadsheet), not all are discussed in this document because details included in these methods are subject to change prior to the methods being finalized.

The USEPA Office of Water has validated and published sample preparation procedures and analysis procedures applicable to groundwater, surface water, wastewater, landfill leachate, soil, sediment, biosolids, and tissue in EPA Method 1633A (**USEPA 2024**).

The USEPA Office of Land and Emergency Management has validated and published sample preparation procedure and analysis procedures applicable to groundwater, surface water, and wastewater. USEPA SW-846 Method 3512 is a sample preparation method, and USEPA SW-846 Method 8327 is the associated analytical method.

Three USEPA methods are validated and published for the analysis of PFAS in drinking water: USEPA Method 537 (**USEPA 2009**), USEPA Method 537.1, Version 2.0 (**USEPA 2020**), and USEPA Method 533 (**USEPA 2019**). For simplicity in the text, subsequent references to USEPA Method 537.1 assume the most current version. These methods are required for PFAS analyses of drinking water and include performance data for drinking water from surface water and groundwater sources. These methods are prescriptive in that changes to preservation (including sample collection, in the case of USEPA Method 537.1), sample extraction steps, and quality control requirements are prohibited by the methods.

The DOD has also validated and published a method (DOD AFFF01) for the determination of PFOA and PFOS in AFFF concentrates for demonstration of compliance to MIL-PRF-24385 (**Willey 2021**).

This section will be updated as new information on sampling considerations and analytical methods/procedures becomes available.

11.1 Sampling

11.1.1 General

Sampling conducted to determine PFAS concentrations in drinking water, other aqueous media, soil, sediment, air, biota, and other media is similar to that for other chemical compounds, but with several additional specific considerations and protocols. Typical guidance and procedures, such as ASTM International D 4823-95 and D 4448-01, USEPA compendium EPA 540/P-87/001a, OSWER 9355.0-14, USEPA SESDPROC-513-R2, and USEPA SESDPROC-305-R3, remain the basis for a PFAS sampling protocol. Because of the need for very low laboratory quantitation limits and the widespread use of PFAS in common materials, field and equipment blanks are needed in greater amount and frequency than in other analyses. In addition, special consideration may be needed to address the potential for background sources of PFAS in the environment, sample cleanup criteria, and the potential need for modified decontamination measures.

Examples of USEPA region-specific or program-specific PFAS sampling protocols include:

- **USEPA (2019)** Region 4, Laboratory Services and Applied Science Division, Athens, GA, *Field Equipment Cleaning and Decontamination at the FEC*, ASBPROC-206-R4, 2019

- DOD AFFF01 *Determination of Perfluorooctanoic acid and Perfluorooctanesulfonic acid in Aqueous Film Forming Foam (AFFF) for Demonstration of Compliance to MIL-PRF-24385* (**Willey 2021**)

- State guidance:
    - **MA DEP (2023)** Massachusetts Department of Environmental Protection, *Sampling and Analysis for PFAS at Disposal Sites Regulated under the Massachusetts Contingency Plan*.
    - **Washington Department of Ecology (2017)** *Quality Assurance Project Plan; Statewide Survey of Per- and Poly-fluoroalkyl Substances in Washington State Rivers and Lakes.*
    - **NH DES (2022)** New Hampshire Department of Environmental Services, *Laboratory Testing Guidelines for Per- and Polyfluoroalkyl Substances (PFAS) at Waste Sites,*
    - **MPCA 2022** Minnesota Pollution Control Agency, *Guidance for Per- and Polyfluoroalkyl Substances (PFAS): Sampling*
    - Michigan Department of Environment, Great Lakes, and Energy (EGLE) PFAS Sampling Guidance Documents including:
        - **MI EGLE (2024)** PFAS Sampling Guidance

- **MI EGLE (2019)** Surface Water Foam PFAS Sampling Guidance
- **MI DEQ (2018)** Wastewater PFAS Sampling Guidance
- **MI DEQ (2018)** Surface Water PFAS Sampling Guidance
- **MI DEQ (2019)** Fish Tissue Sampling Guidance

The list provided above is not comprehensive; project teams should consider state-specific and USEPA guidance as available.

A work plan (that is, a quality assurance project plan (QAPP)) should be implemented to address PFAS-specific considerations. If a work plan is not created for a project, the sampling and quality control (QC) elements outlined in **Section 11.1.6** should be implemented. If regulatory procedures, methods, or guidelines are inconsistent with the needs of a PFAS sampling program, such as requiring the use of fluoropolymer tubing, the governing agency should be contacted directly to determine if an exception can be made or an alternate approach is needed. A CSM (if available, see **Section 10.2**) should be evaluated to support development of the project-specific DQOs as part of the work plan. The review should include information on previous site uses, PFAS use/manufacturing/handling practices, other possible contaminants and their uses, and/or related remediation activities and historical PFAS data, to determine all possible source areas of PFAS. Previous or ongoing remediation of other contaminants of concern can add a layer of complexity to a site's geochemistry and the fate and transport of PFAS.

Although some sampling elements (for example, sample bottle, preservation, and holding times) are defined by analytical methods, these methods do not provide all the information that is needed to conduct a sampling event for PFAS. However, DOD AFFF01 contains the information needed to conduct sampling of AFFF concentrates. Tables 11-2 and 11-5 are included in the **PFAS Analytical Methods** Excel File, and cover the sample container types, sample size, number of containers required, and holding time and preservation requirements for each of these published PFAS analytical methods, respectively.

Communication with the laboratory before, during, and after sampling is conducted is critical in ensuring that project needs are met. If a sample is from an area known or suspected to be highly contaminated with PFAS, it is important that this is communicated to the laboratory. The chain-of-custody form should indicate samples that potentially contain a high concentration of PFAS. As stated in USEPA Method 1633A (**USEPA 2024**), laboratories should prescreen all samples to select the necessary sample preparation procedures and to avoid contamination of their laboratory equipment and contamination of other field samples.

Any water used for field QC blanks (for example, field and decontamination blanks) should be supplied by the laboratory performing the analysis. The laboratory should provide documentation verifying that the supplied water is PFAS-free. "PFAS-free" is the project-defined concentration that associated blank concentrations must be below (examples: less than the detection limit; less than half the limit of quantitation (LOQ)) to ensure an unacceptable bias is not introduced into the sampling and analysis processes and project data quality objectives can be met. The work plan should clearly state the project's definition of "PFAS-free." Review of the laboratory's standard definition of "PFAS-free" upfront is necessary to ensure that it meets project needs and is a critical step in laboratory selection for a project. Laboratories verify the PFAS content of each batch of supplied water through analysis. Documentation of this verification should be maintained for data validation purposes and should be reviewed by the project team to ensure that the project's definition of "PFAS-free" is met. If the water was not supplied by the laboratory, a sample of the water used in the field should be sent to the laboratory for testing.

11.1.2 Equipment and Supplies

Many materials used in environmental sampling can potentially contain PFAS. There is published research or guidance on how certain materials used by field staff or in sampling equipment affect sample results (see **Denly et al. 2019**; **Field et al. 2021**, Assessing the Potential for Bias in PFAS Concentrations during Groundwater and Surface Water Sampling, SERDP Project ER19-1205; **Rodowa et al. 2020**). However, a conservative approach is recommended to exclude materials known to contain the PFAS that are the target of the analysis from a sampling regimen, and such an approach should be documented accordingly in the work plan. Obtain and review all Safety Data Sheets (SDSs) before considering materials for use during PFAS sampling, as product manufacturing formulations can change over time. If PFAS or the terms "fluoro" or "halo" are listed on the SDS, it is recommended that piece of equipment/supply not be used. Exclusion from the SDS does not necessarily mean the equipment/supply is not contaminated with PFAS. PFAS may not have been used as a component of the equipment/supply, but as a material used in the manufacturing process itself (for example, mist suppressant or mold coating), which can result in the manufactured equipment/supply containing PFAS. If necessary, materials in question can be sampled and analyzed for PFAS, or thorough decontamination and collection of equipment blanks can provide sufficient quality assurances. Ultimately, a sampling program should produce defensible data, and the best way to protect the integrity of samples is to ensure they are not compromised by contaminants originating from sampling equipment or otherwise.

Due to the extensive use of a wide array of PFAS, sampling crews should review all materials and sampling protocols to avoid contamination and possible sorption issues. Examples of materials that, if used and contacted, could potentially introduce bias to samples include, but are not limited to:

- polytetrafluoroethylene (PTFE)
- waterproof coatings containing PFAS
- fluorinated ethylene-propylene (FEP)
- ethylene tetrafluoroethylene (ETFE)
- low-density polyethylene (LDPE)
- polyvinylidene fluoride (PVDF)
- pipe thread compounds and tape.

A tiered approach should be implemented for materials restrictions, where the first tier would include restrictions on the sampling materials that will come in direct contact with the sample media, and the second tier would include restrictions on what materials are allowed on sampling personnel or within the staging area. The focus on restrictions within the second tier should consider how reasonable the potential for contact with the sample media is when good sampling practices are employed, the practicality of the restriction (for example, does it compromise employee safety or increase an exposure risk), and the documentability of the requirement (can the restriction or measure be properly documented). Program-specific sampling protocols such as those previously listed in this section often identify materials and equipment that can be used in PFAS-focused investigations, as well as materials that should be avoided because they are known or suspected to be potential sources of PFAS. However, as noted in peer-reviewed studies (**Denly et al. 2019; Rodowa et al. 2020**), the potential for cross-contamination from sampling materials that are not likely to contact the sample media or incidental contact (for example, rain splatter off a treated raincoat) is minimal, therefore, the focus should be on material in direct contact with the sample media and with a reasonable potential for contact. It is also recognized that a PFAS-free alternative may not be readily available or confirmable. In such instances a robust quality assurance (QA) program consisting of appropriate equipment blanks can be implemented to address this.

There may be instances when it is not possible to eliminate sampling materials that may affect sample results. For example, problematic materials may be needed at sites where co-contaminant or facility hazards warrant the use of PPE such as Tyvek suits or flame-retardant coveralls for worker safety.

Additionally, this could be an issue in emergency response scenarios if a sampler needs to collect a sample before a proper program is established or before proper sampling materials can be obtained.

11.1.3 Bottle Selection

Sample container material recommendations are dependent on the analytical method. Containers should be supplied by the laboratory and laboratory-verified to be PFAS-free, as defined by the work plan. USEPA SW-846 Method 8327 was validated using polypropylene containers for groundwater, surface water, and wastewater sampling. However, USEPA SW-846 Method 8327 states that other types of containers such as high-density polyethylene (HDPE) may be used if the needs of the project can be met with their use. USEPA Method 533 and USEPA Method 537.1 require the use of polypropylene or other plastic containers, such as polyethylene, that meet the QC requirements (**Section 11.1.7.1**). USEPA Method 1633A requires the use of HDPE containers for wastewater, groundwater, surface water, landfill leachate, biosolids, soil, sediment, and tissue sampling.

The volume of aqueous sample that is required for analysis varies from method to method and the mass of solid material required for analysis is dependent on the matrix of the sample.

Non-potable water samples do not require a chemical preservative, unless otherwise required by the cited analytical method(s). Clean laboratory-provided HDPE or polypropylene bottles are recommended; typically, 125-mL to 1-L bottles may be used, but the sample volume may depend on the analytical method used.

In USEPA Method 1633A, samples are prescreened to determine if they contain high concentrations of PFAS analytes or other potential interferences (for example, landfill leachates) that would prohibit the whole aqueous sample from being prepared. For prescreening analysis, the method requires collection of an additional, smaller aliquot of wastewater, groundwater, or surface water. This second aliquot allows the laboratory to prescreen the sample without affecting the integrity of the sample collected for analysis. Coordinating with the laboratory is crucial to ensure an adequate number of each type of required sample container is provided for the field activity.

Best practices in sample preparation should be used when selecting the size, volume, and representativeness of samples. To minimize effects from analyte sorption on sample containers, USEPA Methods 537.1 and 533, and USEPA Method 1633A all require the laboratory to prepare the entire aqueous sample collected, including sample container rinsate(s). DOD AFFF01 requires the container holding the diluted AFFF concentrate be prepared in its entirety, including a rinse of the container.

11.1.4 Sample Preservation, Shipping, Storage, and Holding Times

Sample preservation, shipping, storage, and holding time requirements are dependent on the method used. Drinking water methods (USEPA Method 537.1 and 533) are the only USEPA methods requiring the addition of a chemical preservative at sample collection. USEPA Method 537.1 requires the addition of Trizma®, while USEPA Method 533 requires the addition of ammonium acetate, as detailed in section 8 of each of the methods. According to both methods, samples must be chilled during shipment and not exceed 10°C during the first 48 hours after collection. When they are received by the laboratory, samples must be at or below 10°C and stored in the laboratory at or below 6°C until extraction. These two methods differ in their required holding times, as USEPA Method 537.1 requires samples to be extracted within 14 days of collection, while USEPA Method 533 requires samples to be extracted within 28 days of collection.

The shipping, storage, and holding time requirements for wastewater, groundwater, and surface water samples stated in USEPA SW-846 Method 8327 differ than those provided by USEPA Method 1633A. USEPA SW-846 Method 8327 requires all samples and sample extracts to be chilled from the time of

sample collection to analysis and not exceed 6°C. Since a holding time study was not performed in conjunction with the validation of USEPA SW-846 Method 8327, the method offers a holding time of 14 days from sample collection to sample extraction and a 30-day holding time from sample extraction to sample analysis as a guideline.

The shipping, storage, and holding time requirements contained in USEPA Method 1633A are based on a published holding time study for PFAS by **Woudneh et al.2019**, as well as the holding time studies conducted in conjunction with the single- and multi-laboratory validation studies for USEPA Method 1633 (**Willey et al 2021**, **2023**, **2023**, **2023**, **2023**). While the statistically determined holding time requirements are similar for each matrix, they are not identical (see Table 11-5, included in the **PFAS Analytical Methods Excel File**). Observed losses and/or gains in the concentration of some PFAS, most likely caused by transformation of precursors, resulted in shorter holding times for samples and extracts. As stated in Method 1633A (**USEPA 2024**) for aqueous samples, "conversion of certain perfluorooctane sulfonamide ethanols and perfluorooctane sulfonamidoacetic acids have been observed after 7 days. Specifically, NMeFOSE and NEtFOSE may undergo transformation to NMeFOSAA and NEtFOSAA respectively when stored at 0 - 6 ºC, but not when stored at or below -20 ºC. Therefore, if NMeFOSE, NEtFOSE, NMeFOSAA and/or NEtFOSAA are analytes of concern for a given permit or project, either store the samples at or below -20 ºC, or extract the samples within 7 days of collection." Also, due to the observed extreme loss of NFDHA, an additional caveat in the method recommends samples be extracted and analyzed for solids and tissues as soon as possible if NFDHA is an important analyte for the project (**USEPA 2024**). This issue was addressed by the DOD Environmental Data Quality Workgroup in a March 2025 memo when using 1633A for PFAS investigations (**USDOD 2025**).

11.1.5 Decontamination Procedures

Sampling equipment should be thoroughly decontaminated before mobilization to each investigation area and between sample locations at each investigation area or as required in the site-specific work plan. Field sampling equipment, including oil/water interface meters, water level indicators, nondisposable bailers, and other nondedicated equipment used at each sample location requires cleaning between uses. The SDSs of detergents or soaps used in decontamination procedures should be reviewed to ensure fluorosurfactants are not listed as ingredients. Use laboratory-verified PFAS-free water for the final rinse during decontamination of sampling equipment. Decontaminate larger equipment (for example, drill rigs and large downhole drilling and sampling equipment) with potable water using a high-pressure washer or steam. To the extent practical, rinse parts of equipment coming in direct contact with samples with PFAS-free water. Heavy equipment is best cleaned within a decontamination facility or other means of containment (for example, a bermed, lined pad and sump, or a portable, self-contained decontamination booth). Potable water sources should be sampled in advance and analyzed for PFAS, as well as during the sampling event to verify the water remained PFAS-free. If the potable water source does not meet the project-defined criteria for PFAS-free water, an alternate water supply should be considered. Wherever possible, rinse equipment with laboratory-verified PFAS-free water immediately before use.

An example of decontamination procedures as published in the Minnesota Pollution Control Agency "Guidance for Per- and Polyfluoroalkyl Substances (PFAS): Sampling" (**MPCA 2022**) is as follows:

- Equipment caked with drill cuttings, soil, or other material will initially be scraped or brushed. The scrapings will be collected, containerized, and disposed in accordance with government regulations.
- Equipment will then be sprayed with potable water using a high-pressure washer.
- Washed equipment will then be rinsed with laboratory-verified PFAS-free water.

- Decontaminated downhole equipment (for example, drill pipe, drive casing, bits, tools, bailers, etc.) will be placed on clean plastic sheeting (PFAS-free) to prevent contact with contaminated soil and allowed to air dry. If equipment is not used immediately, it will be covered or wrapped in plastic sheeting to minimize airborne contamination.

- Field sampling equipment and other downhole equipment used multiple times at each sample location will require cleaning between uses utilizing a four-stage decontamination process. The equipment will first be rinsed in a bucket containing a mixture of potable water and PFAS-free soap. The equipment will then be rinsed in each of two buckets of potable water. Water used for the final rinse during decontamination of sampling equipment will be laboratory-verified PFAS-free water.

Decontamination solutions should be replenished between sampling locations as needed. Spent decontamination fluids should be containerized, properly labeled, and appropriately disposed of as investigation-derived waste (IDW), based on plans included in the site-specific QAPP or work plan.

11.1.6 Field QC Samples

Field QC samples are a means of assessing quality beginning at the point of collection. Such field QC samples typically include field reagent blanks, source water blanks, equipment rinse blanks, and field duplicates. Collection and analysis of field QC samples are important for PFAS investigations because of very low detection limits and regulatory criteria (parts per trillion (ppt)), to ensure accuracy and representativeness of the results for the sampled media, and to assess potential cross-contamination due to the extensive use of PFAS. A sampling program should be designed to prevent cross-contamination and anthropogenic influence. However, the widespread commercial use (historical and current) of PFAS-containing products, and especially their prevalence in commonly used sampling materials and PPE, should inform the sampling program. PFAS sites may also have a wide range of concentrations with varying families of PFAS, as well as co-contaminants. Furthermore, PFAS sites have the potential to be high profile in nature. Therefore, a comprehensive site-specific QAPP or work plan addressing DQOs and field QC samples, including frequency, criteria, and procedures, is vital to a PFAS sampling program (see also **Section 11.3**, Data Evaluation).

Table 11-1. Typical field QC samples.

QC Sample	Description	Minimum Suggested Frequency
Field reagent blank (FRB)	Laboratory-provided PFAS-free reagent water that, in the field, is poured into an empty sample bottle or a sample bottle containing only preservative (if required)	One per day per matrix per sample set
Source water blank	Water collected from potable water source that is used during the sampling processes (such as decontamination and drilling processes)	One per site, preferably prior to sampling event (if possible) and at least once during sampling event
Equipment rinse blank (ERB)	Final rinse sampling equipment with laboratory-verified PFAS-free water (decontamination blank); prior to the sampling event	One prior to the start of a sampling event per piece of sampling equipment following an initial decontamination One per day per piece of sampling equipment used for each matrix sampled (during or at the end of the day) following decontamination
Field duplicate	Two samples collected at the same time and location under identical circumstances	One per day per matrix, or one per 20 samples per matrix, whichever is greater

When planning QC sample frequency, the risk of cross-contamination should be considered. Cross-contamination can occur from several sources, including field conditions, ineffective decontamination, incidental contact with PFAS-containing materials, and sampling equipment and materials that were manufactured alongside PFAS-containing equipment.

Of all the USEPA PFAS methods, only USEPA Methods 537, 537.1 and 533 contain specific requirements for the field QC samples that must be collected and accompany samples to be analyzed for PFAS. These include field duplicates, matrix spikes and duplicates, and a minimum of one field reagent blank for each set of samples per sampling site. USEPA Methods 537, 537.1 and 533 specify the frequency of the field duplicate or matrix spikes in terms of extraction batch (one per extraction batch, not to exceed 20 field samples), not collection frequency. Although the other USEPA PFAS methods do not contain any field QC sample requirements, **Table 11-1** provides a list of field QC samples typical for the collection of these matrix types and their typical minimum frequency. Once field QC sample data are obtained, they should be evaluated against the field samples by a person knowledgeable on the DQOs set forth in the site-specific QAPP or work plan. For laboratory QC considerations, see **Section 11.2**, Analytical Methods/Techniques.

11.1.6.1 Field Reagent Blank

A field reagent blank (FRB), as described in USEPA Methods 537, 537.1 and 533 for collection of drinking water samples, consists of a sample bottle filled with PFAS-free reagent water prepared in the laboratory, sealed, and shipped to the sampling site along with the sample bottles. An empty sample bottle containing only preservatives (same as those used for the samples) is shipped along with each FRB into which the sampler pours the unpreserved PFAS-free reagent water contained in another bottle that was sent to the field and seals and labels the bottle for shipment along with the samples back to the laboratory for analysis. FRBs help to determine if PFAS were introduced into the samples during sample collection/handling and help to account for additional factors, such as introduction of contaminated airborne particles. A laboratory reagent blank is also analyzed in a laboratory setting to ensure that background contamination is not being introduced in the laboratory from reagents or water supplies.

FRBs may also be warranted during collection of sampling media other than finished drinking water. In lieu of using a prepared quantity of laboratory reagent water/preservative solution as for drinking water FRB, a field blank can be prepared in the field using laboratory-verified PFAS-free water (may be equivalent to the laboratory reagent water) and filling an empty sample container in the field, which is then sealed and labeled as a field blank. This sample will be analyzed in the same manner as the normal samples and can indicate whether or not PFAS were introduced during sample collection/handling, and help to account for additional factors, such as introduction of airborne particulates.

As discussed above, the frequency of FRB samples for finished drinking water sampling is one FRB for every sample set at each site. A sample set is described in USEPA Methods 537.1 and 533 as “samples collected from the same sample site and at the same time” (**USEPA 2020**; **USEPA 2019**).

11.1.6.2 Source Water Blank

Large quantities of water may be necessary to carry out a field sampling program for various reasons, including decontamination and certain drilling techniques (**Section 11.1.5**, Decontamination Procedures). Site groundwater or surface water should not be used as source water at sites that are under investigation for PFAS, as they have potential to contain PFAS. PFAS test results of publicly supplied water at a site should be evaluated when considering it for use as source water. Regardless, it is imperative that any water used as source water be sampled and analyzed. For equipment that may come into contact with samples of any media type, a multistep process is common to adequately prevent cross-contamination. Quantities of laboratory-verified PFAS-free water are generally limited and can be costly. Therefore, potable water sources are typically used in initial decontamination steps. It is

imperative that these water sources be sampled and analyzed in the same manner as normal samples, prior to and even during a PFAS sampling program, to ensure that source water is not contributing to PFAS detections in normal samples. Further, many laboratories do not provide a verification of the laboratory-supplied DI water being PFAS-free unless specifically requested. Submission of a laboratory deionized water blank could be required based on DQOs of the specific project.

Collect a sample from the source the same way it is collected for use (for example, if the source water is collected through a hose, collect the source water blank from that same hose). If there are unnecessary fittings or hoses attached for collection of the source water, consider removing them for the duration of the sampling program to avoid contamination from PFAS that may be present in these materials.

Frequency of collection of such source water blanks is up to the professional judgment of the project manager, site owner, and other stakeholders and is detailed in the project-specific work plan. The source water should be sampled at least once prior to starting the field sampling program and once during the sampling event in case the analysis reveals that a different water source should be found. A more conservative sampling program may include provisions for additional periodic sampling in cases where the conditions of the source water may change.

11.1.6.3 Equipment Rinse Blank

Equipment Rinse Blanks (ERB) should be collected from nondedicated equipment/supplies at the start of the sampling event prior to sample collection to verify that nondedicated equipment/supplies are PFAS-free (**Section 11.1.2**). Thereafter, ERBs should be collected from nondedicated sampling equipment at a minimum rate of once per day (either during or at the end of each day) following decontamination and prior to its next use for the duration of the sampling event.

ERBs are those collected by rinsing a piece of field sampling equipment/supplies with laboratory-verified PFAS-free water and collecting the rinse water in a sample container for PFAS analysis. ERB collection is not required by USEPA Methods 537.1 or 533 because drinking water compliance samples are generally collected from the source without the use of other equipment. ERB collection for other programs is dependent on the sampling media and methods that are employed at a site. Generally, any equipment that is reused throughout the sampling program, or is nondedicated, and must be decontaminated, should have an ERB collected from it. That is, if a piece of equipment is decontaminated, an ERB should be collected from it after decontamination and prior to its next use. The frequency of collection of ERBs can be reduced by using all dedicated or disposable equipment where possible. However, many of these options are limited due to the extensive use of PFAS in many of these equipment materials. ERBs should also be considered for dedicated equipment prior to and during a sampling event if the PFAS contribution from equipment is unknown or suspected.

Field ERB collection frequency is largely up to the professional judgment of the project manager or other stakeholders and is dependent on the sampling media and methods and project-specific DQOs. For instance, collection of ERBs prior to initiating an event may be appropriate if rental equipment or subcontractor material that could have been used on another site is being used. The project team may also consider collecting an ERB from each piece of equipment used by the sampling team (ERB per sample setup) when multiple sampling setups are being implemented. Collection of an ERB from decontaminated soil sampling trowels may only warrant a frequency of once per day, whereas groundwater pumps may warrant an ERB prior to the pump being deployed down each well, due to their more rigorous decontamination procedure and higher contact time with the groundwater being sampled.

11.1.6.4 Field Duplicate

Field duplicate (FD) samples are two samples collected at the same time and location under identical circumstances and treated exactly the same throughout field and laboratory procedures. The analytical

results from these identical samples are used to evaluate the precision of sample collection, preservation, storage, and laboratory methods.

USEPA Methods 537.1 and 533 do not specify the frequency of FD collection for finished drinking water samples; however, they do specify the frequency of preparation (once per extraction batch, not to exceed 20 field samples). A more conservative sampling program may indicate a frequency of one FD per 10 field samples per matrix. FD collection frequency should be discussed with stakeholders, as necessary, and be evaluated as part of the comprehensive site-specific QAPP or work plan.

11.1.6.5 Additional QC Samples

In addition to the field quality control samples described above, replicate volume or mass may be collected for split samples and/or matrix spikes to provide project managers additional quality assurance regarding identification of PFAS target analytes and precision and bias in measured sample concentrations. Split samples are defined here as co-located quality control samples, taken at the same time and each sent to a different laboratory. These types of samples do not apply to routine compliance monitoring situations and may not be required in all sampling events. Aqueous QC samples should not be split into two samples from the original container. Analysis of these QC samples provides a measure of interlaboratory variability.

A performance evaluation (PE) sample, which contains project analytes with known concentrations of PFAS, may be submitted to the laboratory as a blind sample. Analysis from this sample provides a positive control from a second source.

11.1.7 Sampling Procedures

The Priority Topics for Sampling and Analysis include information about leaching methods (see **Section 1.5.1**), fish sampling and laboratory homogenization (see **Section 1.5.2**), consumer product testing (see **Section 1.5.4**), ISM for PFAS sampling (see **Section 1.5.5**), and concrete and asphalt sampling and analysis (see **Section 1.5.6**).

Standard sampling procedures and practices can be used at most PFAS sites and only require extra care and attention paid to the types of materials used. However, there may be some exceptions and additional considerations related to PFAS behavior and issues associated with potential use of PFAS-containing or PFAS-adsorbing sampling equipment and supplies, as previously discussed. A site-specific QAPP or work plan must contain the standard operating procedures incorporating these considerations and regulatory agency or client requirements. Refer to **Section 11.1.2** for materials to avoid during sampling and drilling. Consult the supplier to determine if PFAS-free options are available.

Pretesting any equipment or supplies to be used is ideal, although it is recognized that this is not typically feasible. As such, ERBs are recommended to ensure the decontamination of supplies (for example, bailers, pumps, beakers, and dippers) is effective.

In addition, the sampling team must document any observations during the sampling event that could be a source of bias (for example, the presence of PTFE tape on a faucet).

11.1.7.1 Drinking Water

Sampling a “potable water source,” as defined by the USEPA SDWA (Section 1401(4), August 1998), is conducted according to protocols established in USEPA Methods 537.1 and 533. These protocols define sample bottle preparation, sample collection, field reagent blanks, sample shipment and storage, and sample and extraction holding times. The drinking water source is further defined here as a public drinking water supply, as opposed to a private drinking water supply, as it applies to USEPA Methods

537.1 and 533. USEPA Methods 537.1 and 533 may also apply in instances when the water quality of the private drinking water supply source is similar to finished drinking water (for example, has low level of total organic content). The following summarizes the sampling considerations described in these protocols:

- For Methods 537 and 537.1: Sample bottle is a laboratory-provided 250-mL polypropylene bottle fitted with a polypropylene screw cap. For finished (treated) drinking water sampling only, a preservation agent is provided inside each bottle prior to sample collection. This agent acts as a buffer (Trizma®, pH 7, 5 g/L) and removes free chlorine from chlorine-treated drinking water supplies.

- For Method 533: Sample bottle is a laboratory-provided 100–250-mL polypropylene, or other plastic that meets method QC requirements, bottle fitted with a polypropylene screw cap. For finished (treated) drinking water sampling only, a preservation agent is provided inside each bottle prior to sample collection. This agent (ammonium acetate, 1 g/L) sequesters free chlorine to form chloramine in chlorine-treated drinking water samples. The sample handler must avoid PFAS contamination during sampling by thoroughly washing their hands and wearing nitrile gloves.

- Open the tap and flush the water (approximately 3–5 minutes) to obtain a "fresh" sample. Collect the sample while water is flowing, taking care not to flush out preservative. Samples do not need to be headspace-free. Cap the bottle and, if applicable, agitate to completely dissolve preservative.

- Keep sample sealed and place sample on ice for shipment.

- Samples must be chilled during shipment and must not exceed 10°C during shipment.

- Laboratory extraction of the sample must take place within 14 days of collection (USEPA Method 537.1) or within 28 days of collection (USEPA Method 533).

Based on a review of industry experience and guidance, additional considerations for collecting drinking water samples for PFAS analysis are as follows:

- The sample should ideally be cold water collected from a tap or spigot located at or near the wellhead or pump house and before the water supply is introduced into any storage tanks or treatment units. If the sample must be collected at a point in the water line beyond a tank, a sufficient volume of water should be purged to provide a complete exchange of fresh water into the tank at the tap or spigot. If the sample is collected from a tap or spigot located just before a storage tank, spigots located downstream of the tank should be turned on to prevent any backflow from the tank to the tap or spigot. Several spigots may be opened to provide for a rapid exchange of water. If collecting a sample to characterize human or other exposure, the sample should be collected from the tap or spigot at the point of use.

- When sampling from a drinking water well that is not in regular use, purge water until water quality parameters (that is, pH, specific conductance, dissolved oxygen, oxidation-reduction potential, turbidity, and temperature) have stabilized according to project-specific requirements, to ensure formation water (as opposed to stagnant well column water) will be sampled. An adequate purge is achieved when the pH and specific conductance of the potable water have stabilized (for example, within 10% across three consecutive measurements) and the turbidity has either stabilized or is below 10 nephelometric turbidity units. Note: According to **USEPA (2013)**, pg. 21 *"[a] well with an intermittently run pump should, in all respects, be treated like a well without a pump. In these cases, [water quality] parameters are measured and the well is sampled*

from the pump discharge after parameter conditions have been met. Generally, under these conditions, 15 to 30 minutes will be adequate."

- When sampling from a tap, the tap must be protected from exterior contamination associated with being too close to a sink bottom or to the ground. Contaminated water or soil from the faucet exterior may enter the bottle during the collection procedure because it is difficult to place a bottle under a low tap without grazing the neck interior against the outside faucet surface. If the tap is obstructed in such a way that prevents direct collection into the appropriate sample container, it is acceptable to use a smaller container to transfer sample to a larger container. The smaller container should be made of HDPE or polypropylene and should be either new or decontaminated as specified in **Section 11.1.5**. Evaluation of the transfer container is recommended to ensure that it does not introduce a bias.

- When filling any sample container, care should be taken that splashing drops of water from the ground or sink do not touch either the interior of the bottle or cap.

- Leaking taps that allow water to discharge from around the valve stem handle and down the outside of the faucet, or taps in which water tends to run up on the outside of the lip, are to be avoided as sampling locations.

- Disconnect any hoses, filters, or aerators attached to the tap before sampling.

Taps where the water flow is not constant should be avoided because temporary fluctuation in line pressure may cause clumps of microbial growth that are lodged in a pipe section or faucet connection to break loose. A smooth flowing water stream at moderate pressure without splashing should be used. The sample should be collected without changing the water flow.

11.1.7.2 Groundwater

Groundwater is typically sampled from a well, and therefore specialized equipment is required. When constructing monitoring wells prior to groundwater sampling, care should be taken to ensure well-construction materials are free of PFAS. **Radford et al. (2023)** detected PFAS in coated and uncoated bentonite formulations with more individual PFAS present at higher concentrations in coated formulations. PFAS have also been added to various concrete formulations (**Kissa, 1994**). Drilling greases, grout, and all well construction materials should be confirmed to be PFAS-free prior to use. Additionally, water added to the formation for drilling purposes (mud mixtures, managing running sands, etc.) may need to be tested for PFAS prior to use and should be thoroughly developed out of the completed well prior to sampling. Some of the various types of purging and sampling equipment available for groundwater sampling are described in ASTM International Standard Guide for Sampling Ground-Water Monitoring Wells, D 4448-01 (**ASTM 2007**) or Compendium of Superfund Field Operations Methods (**USEPA 1987**).

Within the context of sample collection objectives outlined in a site-specific work plan, the sample depth selection should consider the potential stratification of PFAS within the aquifer, the potential for phase partitioning, and the tendency for PFAS to accumulate at the air/water interface. In addition to depth location within the water column, consideration should be given to the well construction, screened interval, and site geology to ensure that the well is representative of site conditions and all relevant chemicals of concern (COCs). For more information on phase partitioning, see **Section 5.2**.

The most inert material (for example, stainless steel, silicone, polypropylene, and HDPE), with respect to known or anticipated contaminants in the well(s), should be used whenever possible. Purging and sampling equipment could be manufactured from components that might include PFAS. For example, pump components, such as O-rings, gaskets, bladders, stopcocks, and wiring insulation, may contain

PFAS. Contact between the groundwater, the sample, and PFAS-containing equipment provides opportunities for the sample to become contaminated and should be avoided when possible. In some cases, components that contain PFAS can be switched out for HDPE or polyethylene. Consult with the equipment vendor to determine if they have PFAS-free alternatives. In addition to equipment, ensure that field supplies that may contact the sample, such as tubing or bailer twine, are PFAS-free and will meet the DQOs. Dedicated sampling equipment installed in existing wells prior to PFAS investigations may contain components that are not PFAS-free, and the equipment's chemical properties may be challenging to verify. It is best practice not to collect samples using dedicated equipment that may include PFAS-containing components. If samples are collected with dedicated equipment with some unknown components, PFAS detections should be evaluated in an uncertainty analysis.

Where sampling for co-contaminants requires use of PFAS-containing materials, sampling events should be separated to avoid contamination from these materials. The PFAS sampling event would be completed first, followed by the sampling event for the co-contaminants. In some cases, it may be acceptable to use the same equipment at a concurrent sampling event. For circumstances that warrant, such as very deep wells or sites with co-contaminants, samples may be collected in duplicate with and without existing dedicated equipment. If PFAS analyses show that the equipment does not impact results, the equipment may be kept and used long term. However, this determination is dependent upon project-specific requirements and should be allowed by a project manager only with full disclosure to all stakeholders. It may also be acceptable to simply collect an ERB after fully decontaminating equipment containing PFAS components to confirm it does not contribute to groundwater sample concentrations. A site-specific procedure should be outlined in the QAPP or work plan.

The practitioner should determine that the sampling method is compatible with the site DQOs, including whether the method:

- collects site-specific analytes of interest
- is effective at the expected concentrations
- provides sample volume that meets the lab method requirements
- minimizes turbidity
- minimizes purge water
- is likely to include equipment with PFAS-containing components that contact the sample

Low-flow or passive sampling techniques are preferred for collection of groundwater samples for PFAS to keep the turbidity of samples and purge-water volume to a minimum. PFAS are mobile in groundwater and have relevant transport pathways, including advection and diffusion, that are similar to those for other contaminants (**Section 5.1.2**) and conducive to passive sampling (**Section 11.1.7.6**) in groundwater. See **Section 11.2.1.2** for issues associated with elevated levels of suspended solids in aqueous samples.

Bailers should be used with caution due to the potential for PFAS to accumulate at the air/water interface, because they may increase turbidity, and because of the potentially large volume of purge water produced. If bailers are used, it is important to make sure that at least three well volumes are purged to remove static surface conditions and potentially stagnant or aerated water. Volume-purge pump sampling for PFAS is discouraged because of the large amounts of purge water generated and the tendency to increase turbidity.

For background guidance on the use of passive sampling, consult the ITRC's technical guidance document (**ITRC 2024**) which provides guidance on passive sampling technologies in aqueous environments (see also **Section 11.1.7.6**).

Samples should not be filtered, because filters may be either a source for contamination (**Ahrens et al. 2009**; **Arp and Goss 2009**) or PFAS may be adsorbed to the filter. If filtration is absolutely necessary, it

should be performed in the laboratory, using a validated procedure that includes steps to eliminate the bias that can occur due to sorption issues. As an alternative, laboratory-validated procedures may include centrifuging the sample due to potential filter sorption or contamination issues. See Preparation of Aqueous Samples with Particulates/Suspended Solids in **Section 11.2.1.2** for more details. In addition, USEPA Method 1633A strongly discourages composite sampling for Clean Water Act compliance monitoring, stating that samples from sources that flow freely are to be collected as grab samples.

11.1.7.3 Surface Water

Surface water PFAS sampling should be conducted in accordance with traditional methods such as those described in USEPA's Compendium of Superfund Field Operations Methods (**USEPA 1987**) with consideration for guidance developed specifically for PFAS by Michigan EGLE (**MI EGLE 2024**) and New York Department of Environmental Conservation (**NY DEC 2023**). Depending on the study objectives, sample collection should consider the potential stratification of PFAS in the water body and the tendency for PFAS to accumulate at the air/water interface due to partitioning, which will be of particular concern if foam is observed on the surface (see **Section 16.5** on PFAS-containing foam). Transfer containers such as beakers or dippers, which may be attached to extension rods, should be used. For additional information on surface water sampling, see **Section 16.4**.

- Within the context of sample collection objectives outlined in a site-specific QAPP or work plan, the sample location in the water column should consider the potential stratification of PFAS in solution and their tendency to accumulate at the air/water interface (see **Sections 5.2.2.2** and **5.2.4.1**). If possible, the sample container or transfer container will be lowered sufficiently below the water surface but above the bottom sediments.

- Transfer containers, such as beakers or dippers, which may be attached to extension rods, should be used only if sample containers have preservatives. Sampling by direct sample container immersion is not recommended in this case.

- Consider using a grab-sampler that seals the sample inside the device at the sample interval and isolates the sample from contact with water above the sample collection interval as the sampler is being removed.

11.1.7.4 Sediment Porewater

Similar in many ways to sampling techniques and equipment used in groundwater sampling for PFAS, porewater purging and sampling involves a variety of materials. The various types of purging and sampling equipment available for porewater sampling are described in *Pore Water Sampling Operating Procedure* (**USEPA 2013**). For PFAS sampling, peristaltic pumps with silicon and HDPE tubing are typically used for porewater sample collection, along with push-point samplers, porewater observation devices (PODs), or drive-point piezometers. Push-point samplers and drive-point piezometers are made of stainless steel, while PODs consist of slotted PVC pipe and silicon tubing. PODs and drive-point piezometers are permanent, or dedicated, sampling points typically installed and used for multiple sampling events, whereas push-point samplers are used as a temporary sampling location. Otherwise, the standard procedure for porewater purging and sampling using a peristaltic pump, as described in the *Compendium of Superfund Field Operations Methods* (**USEPA 1987**), can be followed. There is information on the development and commercialization of various diffusion-based passive samplers that may be an option to sample porewater within sediment (see **Section 11.1.7.6**). Installing samplers at interfaces between coarse and fine materials can capture perched porewater (**ASTM 2018**, section 7.5.2.8). This is consistent with the modeling work by **Zeng and Guo (2021)** described in **Section 10.4.1** in which PFAS was predicted to be found in perched water above capillary barriers.

11.1.7.5 Soil Porewater and Potential Lysimeter Use

The accurate characterization of PFAS in soil porewater within the vadose zone could provide valuable data for understanding the soil-water distribution of PFAS and its impact on groundwater concentration (see **Section 10.4.1**). One method that has been discussed is the use of lysimeters.

Lysimeters are devices installed within unsaturated soils that sample porewater either actively under positive and/or negative pressure (suction lysimeters) or passively during periods of excess drainage (drainage lysimeters). Lysimeters are widely available commercially and have been used as part of environmental investigations for decades (**Singh et al. 2018**). Early guidance documents on lysimeter sampling include **USEPA (1986)** and **ASTM (2018)**.

Sampling of suction lysimeters should occur immediately after infiltration events such as rainstorms, spring melts, or irrigations to capture higher porewater and contaminant flow rates (**USEPA 1986**, section 4.8.1; **ASTM 2018**, section 7.5.2.8). Pan lysimeters, or nonsuction porewater sample collection devices, may be more suitable at sites where macropore flow is expected (**USEPA 1986**, section 4.8.2; and **ASTM 2018**, section 7.6.1.6).

Prior to installation, lysimeters should be cleaned per the vendor's standard operating procedure, preassembled, and tested for air leaks. Typically, PVC pipe (equivalent to the depths of the borings) is attached to protect the sample tubes. If potential contaminant interactions with lysimeters is a concern, a laboratory study may be performed before installing at a site (**USEPA 1986**, section 4.8.3.2).

Like grab samples, lysimeter samples represent a single-time result and should be qualified as such when evaluating impacts to groundwater over a season or from year to year. Although suction lysimeter samples are good for qualitative comparisons, they cannot be used for quantitative PFAS investigation unless the variabilities of parameters involved are established (**ASTM 2018**, section 7.6.2.1). These parameters may include measured concentrations of PFAS in soil and porewater, as well as pH, permeability, total organic carbon (TOC), and anion and cation exchange capacity (AEC and CEC, respectively) in vadose zone soil; seasonal changes; weather; precipitation; depth; and soil type(s). Also consider measured PFAS concentrations in nearby groundwater wells.

There are limitations to the application of lysimeters, including on sites with:

- shallow groundwater at depths of around 5 feet or less from the surface (consult the manufacturer)
- bedrock that outcrops to the surface
- too little precipitation to result in sufficient soil moisture at depth
- insufficient co-located soil sample data including, but not limited to, TOC, pH, particle size, moisture content, CEC, and AEC

11.1.7.6 Passive Samplers in Aqueous Environments

Each aqueous medium (groundwater, surface water, or wastewater) has specific conditions that affect the transport of PFAS. These conditions will affect decisions regarding the use of passive samplers and the specific device deployed in the field. The following are advantages for the use of passive sampling devices for PFAS in groundwater:

- The elimination or reduction of purge water disposal and other wastes.
- May reduce or eliminate turbidity as compared to pumped samples.
- May reduce both the short-term and long-term costs of sample acquisition.
- Can be used to collect a representative sample in low-yielding wells.

Hydrogeologic conditions required for passive sampling in groundwater (**Imbrigiotta and Harte 2020** include:

- Adequate water in the saturated screen interval or the targeted open borehole interval so that the sampling interval is submerged at all times.
- Saturated screens that are not chemically degraded or clogged.
- Adequate residence time for equilibration of hydraulic (well flow), chemical (contaminant concentration), and field physiochemical characteristics (for example, pH, dissolved oxygen).

In most cases with saturated screens/open boreholes 10 feet in length or greater, passive samplers are positioned at the depth of highest mass flux of the constituent of interest. When the interval of highest mass flux is not known, a one-time profiling event can be performed in representative wells using multiple passive samplers deployed at two or more intervals in the saturated screen. When considering transitioning from pumping to passive sampling in wells that have saturated screens 10 feet in length or greater, a favorable comparison of side-by-side results in representative wells suggests that water is being sampled from the same source location by both methods. When the results do not favorably compare, profiling for the interval of highest mass flux is appropriate.

A publication on the use of dual membrane passive diffusion bag (DMPDB) samplers™ for PFAS (**Varhol and Varhol 2022**) provides results from bench and field tests that show a positive correlation with lab controls and with field samples taken by pumping methods.

Passive sampling methods can be selected to provide time-weighted average (TWA), time-integrated average, or instantaneous temporal data, as well as spatial contamination trends. Passive sampling devices (PSDs) are relatively low cost, simple to use, and do not generate IDW. Some passive samplers can also provide a means of correlating an organismal exposure with a biological effect to determine the biological importance of chemicals sampled by the device (**Alvarez et al. 2021**; **Burki et al. 2006**; **Vermeirssen, Suter, and Burkhardt-Holm 2006**).

There are several different approaches to passive sampling, most of which can broadly be categorized into three types: accumulation, equilibrium, and grab-samplers.

- Accumulation (integrative) devices concentrate the target chemical on a selective collecting medium such as an adsorbent or absorbent solid, a solvent, or a chemical reagent. Target molecules continue to accumulate on the collecting medium during the exposure period and do not come to concentration equilibration with the surrounding medium. The resulting sample mass, or flux, is used to calculate a TWA concentration of target compounds over the exposure period (**Huckins, Petty, and Booji 2006**; **Taylor et al. 2021**).

- Equilibrium devices use a semipermeable membrane to contain a collecting medium, which is usually a solvent such as deionized water or uses a performance reference compound (PRC) to calculate a fraction of equilibrium. Target molecules diffuse through the selective membrane and move from higher concentration to lower concentration, in and out of the sampler to maintain a dynamic equilibrium with the surrounding medium. After meeting a minimum residence time, in accordance with the device's specifications and the DQO's of the project, the device can be retrieved. Certain samplers can also be left in place at one event and recovered at another. The resulting aqueous sample represents the TWA concentration of target contaminants of the last few days prior to sampler retrieval.

- Grab samplers are devices that acquire a whole media sample in surface water or groundwater, at a specific interval. Once the sample is acquired, the sampler closes to isolate the sample from the surrounding fluids during retrieval. The resulting sample is an aqueous concentration representing the point in time when the sample was collected.

Practitioners have evaluated and used a variety of methods and devices for sampling PFAS in aquatic environments (**Taylor et al. 2021**; **Imbrigiotta and Harte 2020**; **Alvarez 2010**; **Gong et al. 2018**). A number of PSDs are currently in use and others are being investigated for monitoring PFAS in aquatic environments (**Becanova et al. 2021**; **McDermett et al. 2022**; **Godlewska, Stepnowski, and Paszkiewicz 2020**; **Fauvelle et al. 2017**; **Kaserzon et al. 2012**; **Wang et al. 2021**; **Yang et al. 2022**; **Divine 2020**; **Varhol and Varhol 2022**). Before using any passive sampling device, practitioners should ensure use of the proposed sampler has been validated with respect to the evaluation of the site-specific analytes of interest and is acceptable by the applicable regulatory agency. Refer to ITRC's Passive Sampling Document for more information on specific devices (**ITRC 2024**).

11.1.7.7 Sediment

Most core and grab sampling devices are constructed of stainless steel. Some core samplers include an HDPE sleeve inserted in the core barrel to retain the sample. Ensure that materials that contact the media to be sampled do not have water-resistant coatings that contain PFAS. Additional PPE may be required for sampling personnel, such as waders and personal flotation devices. Ensure materials that will potentially contact sampling media do not consist of water-resistant coatings or other PFAS-containing materials or substances. Ensure efficient and consistent homogenization procedures are followed in the field. Refer to **Section 11.1.2** for typical materials used during sampling and drilling.

11.1.7.8 Surface Soil

For surface soil sampling, refer to **Section 11.1.2** for equipment and supplies, and **Section 11.1.5** for decontamination procedures. Ensure efficient and consistent homogenization procedures are followed in the field. No additional considerations are recommended for PFAS sampling of surface soil.

11.1.7.9 Subsurface Soil

Ensure efficient and consistent homogenization procedures are followed in the field. No additional considerations are recommended for PFAS sampling of subsurface soil.

11.1.7.10 Biosolids

Biosolids sampling methods will vary based upon the state and homogeneity of the materials to be collected. Additionally, as the materials are often gathered and stored over days to weeks, varying PFAS concentrations in feedstock can cause varying concentrations within the biosolids matrix unless sufficient mixing is performed.

If high liquid content materials are stored for several hours or days, solids will settle from suspension. Mixing of the storage vessel prior to sampling is essential to ensure collection of representative materials. Dipper, bailer, or pump methods can be used to collect the samples from the midpoint of the storage vessel. If mixing cannot be performed, collection of multiple, stratified, liquid samples followed by compositing may be appropriate.

High solids content materials can often be sampled using traditional compositing techniques. Once again, the accumulation of biosolids over extended periods of time with varying feedstock characteristics can result in potential nonhomogeneous distribution of PFAS within the matrix being sampled. Nonhomogeneity can be reduced through thorough materials mixing and/or use of a high number of grab samples to form a composite for analyses.

For additional information regarding biosolid sampling plans, refer to the NEIWPCC Guide to Biosolids Sampling (**NEIWPCC 2006**) and the NEBRA PFAS Sampling (**NEBRA 2020**) guidances.

11.1.7.11 Fish

The Priority Topics for Sampling and Analysis include information about fish sampling and laboratory homogenization (see **Section 1.5.2**).

The species of fish collected, as well as the portion of fish sampled (whole versus fillet), depends on the project goals (for example, ecological risk or human health). Studies have shown that the majority of the PFAS in fish are stored in the organs, not the flesh (**Martin et al. 2004**) (**Yamada et al. 2014**). Communicating project objectives to the laboratory is important prior to fieldwork to determine the necessary quantity and quality of tissue, fish handling requirements, laboratory sample preparation (including single fish or composite fish samples, and whole or fillet preparation), and packing and shipping requirements. According to USEPA Method 1633A, whole fish or other biota samples should be wrapped in aluminum foil or food-grade polyethylene wrap and homogenized tissue samples should be placed in HDPE containers.

11.1.7.12 Air Emissions to Air and Ambient Air

There is an increasing need for the measurement of PFAS in emissions from stationary sources (for example, chemical manufacturing, industrial use, combustion and thermal treatment and other treatment systems not originally designed to treat PFAS from exhaust), as well as in ambient air. Due to the diverse nature of PFAS, multiple measurement approaches are needed to measure polar and nonpolar, volatile, semivolatile, and nonvolatile (particulate-bound) PFAS.

Emissions to Air

As of the date of this publication, there are no multilaboratory-validated sampling methods for PFAS in air emissions (for example, from thermal treatment in manufacturing plants or incinerators). In their absence, emissions measurements have been performed using modifications to USEPA SW846 Method 0010 (Modified EPA Method 5 Sampling Train) (**USEPA 1986**), a method designed for measurement of semivolatile organic compounds. Other methods have been adapted to capture specific individual compounds of interest.

USEPA and European groups (Verein Deutscher Ingenieure [VDI], an association of German engineers) are evaluating and investigating which sampling and analytical methods might be, in principle, the most suitable to capture PFAS and resulting byproducts in all fractions of the emissions (particles, moisture, gas phase).

PFAS can be partitioned in stack emissions into several different fractions due to the physical properties of these species. At the elevated temperatures typically encountered in stack emissions the vapor pressure can be sufficiently high that some PFAS are present in the gas phase. The lower molecular weight fluorotelomer alcohols (FTOHs) have lower boiling points and so may primarily be present as vapors. PFAS can adsorb to particulate matter, are highly water soluble, and can dissolve in water droplets if present in the stack. To measure these partitioned fractions, the stack effluent is sampled isokinetically (that is, the air enters the probe at the same velocity as it is moving in the stack, to accurately sample particles and droplets) and captured on a heated filter, an XAD-2 (polymer of styrene divinyl benzene) sorbent resin tube, and in water impingers. In some test programs a second XAD-2 sorbent cartridge is included in the sample train to determine if breakthrough has occurred. The filter, sorbent cartridge, and water impingers are recovered separately, and the sample train components are rinsed with a methanol/ammonium hydroxide solution.

In 2021, USEPA released Other Test Method (OTM) 45 *Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources* (**USEPA 2021**). In July 2024, USEPA released Revision 1 to OTM-45 (**USEPA 2024**). This performance-based method was made available by USEPA as a

recommended method that can be used to measure 50 specific semivolatile and nonvolatile polar PFAS from a variety of stationary sources. USEPA OTM-45 is largely based on the USEPA SW-846 Method 0010 (Modified EPA Method 5 Sampling Train) with several modifications. PFAS are collected in four sample fractions: 1) filter; 2) primary XAD-2; 3) impingers (containing water); 4) secondary XAD-2 (for breakthrough determination). Each fraction, with its associated rinses, is extracted and analyzed separately. Analyses are performed by isotope dilution LC/MS/MS. The analytical approach is based largely on EPA Method 533 and includes many of the same analytical qualification criteria, with the additional requirement of monitoring confirmatory secondary transition ions, similar to USEPA Method 1633A. USEPA OTM-45 was released as an "Other Test Method (OTM)" by USEPA's Emission Measurements Center to promote consistency and is considered by USEPA to represent the current best practices to sample and analyze PFAS from stationary sources. This method is under evaluation and will be updated as more data from stakeholders become available. Field sampling programs must include collection of field blanks as a means of assessing PFAS artifacts present in sampling media and potentially introduced during sample handling in the field. Other QC measures that should be considered include the use of isotopically labeled PFAS field spikes, which are useful for quantifying losses associated with field collection techniques. For a PFAS field spike, isotopically labeled spike compounds are typically applied/spiked by the laboratory into the XAD-2 sorbent media prior to field deployment. These compounds serve to assess analyte ("native PFAS in air") collection efficiency, breakthrough, and the accuracy of the combined sample collection and analysis method on a sample-specific basis.

In 2024, USEPA released OTM 50 *Sampling and Analysis of Volatile Fluorinated Compounds from Stationary Sources* Using Passivated Stainless-Steel Canisters (**USEPA 2024**). This performance-based method was made available by USEPA as a recommended method that can be used to measure a list of 30 specific volatile fluorinated compounds (VFCs) indicative of incomplete decomposition of some PFAS from a variety of stationary thermal treatment sources. This method also allows for the detection of additional VFCs and non-fluorinated volatile compounds via non-targeted analysis. Samples are collected using a 6-liter passivated silicon ceramic lined stainless-steel canister or equivalent. Samples containing low moisture (<3% volume/volume) or acid content can be sampled directly into the canister; otherwise, a moisture and acid management system comprised of a filter and impingers system similar to that which is included in OTM-45 is utilized. Like OTM-45, this method is under evaluation and will be updated as more data from stakeholders become available.

USEPA ORD is researching and evaluating multiple PFAS measurement approaches for polar and nonpolar, volatile, semivolatile and nonvolatile PFAS, including further development of USEPA OTM-45 for nonpolar PFAS. The development of an additional method, OTM-55, is currently underway by USEPA to measure nonpolar semivolatile and volatile PFAS, including fluorotelomer alcohols (FTOHs) and products of destruction (PIDs) using whole canister sampling and analysis. USEPA ORD is also evaluating the use of Fourier Transform Infrared (FTIR) spectroscopy to measure select volatile PFAS in real-time. Several of the PFAS capable of being measured are also being evaluated as potential indicators or surrogates of PFAS destruction performance.

Multiple PFAS emissions tests have been performed at a variety of sources for multiple purposes including source characterization, assessment of control technology performance, and evaluation of treatment technologies. Stationary source, or stack, emissions of PFAS have been measured in North Carolina (**NC DEQ 2019**) and New Hampshire (**NH DES 2019**) from industrial facilities that synthesized PFAS (Chemours, NC) or used PFAS in manufacturing processes (Saint Gobain Performance Plastics, NH) (**Beahm and Marts 2019**). These test programs confirmed that stack emissions from industrial facilities contribute to ground and surface water contamination (**NC DEQ 2019**). An additional study at Chemours, NC, reported on the commissioning of an installed thermal oxidizer control system (**Weston Solutions, Inc. 2020**).

Ambient Air

There are no USEPA Federal Reference Methods (FRM) or Toxic Organic Methods (TO series) available specifically for the measurement of PFAS in ambient air. In their absence, some sampling and analysis of ambient air have been performed using modified TO methods, such as TO-13A and TO-9 (**USEPA 2020**). Both methods use high-volume air samplers fitted with a particulate glass fiber filter/quartz fiber filter (GFF/QFF) and sorbent cartridge for the collection of particulate and gaseous phases, respectively. USEPA TO-13A specifies collection of air samples at a flow rate of approximately 225 liters/minute, resulting in an air volume greater than 300 m3. The solid sorbent used consists of a "sandwich" of polyurethane foam (PUF) and XAD-2.

PFAS in ambient air have been measured using both active (with actual flow) and passive (gas diffusion) sampling techniques. Most techniques have made use of solid sorbents such as PUF, XAD-2, and sorbent-impregnated PUF (SIP). (Finely ground XAD-4 resin is often the sorbent of choice for impregnating the PUF). Active samples also include a particulate filter (glass or quartz fiber) ahead of the sorbent module. To optimize detection limits, high-volume air samples have been used most often.

Detection limits of air and emissions methods can be greatly influenced by PFAS artifacts found in the neat filter, sorbent media, or components within the sampler itself. For example, use of Teflon gaskets in high-volume samplers is not recommended. Field sampling programs must include collection of field blanks as a means of assessing PFAS artifacts present in sampling media and potentially introduced during sample handling in the field. Other QC measures that should be considered include collection of field duplicate or co-located samples and the use of isotopically labeled PFAS field spikes. The latter compounds are typically applied/spiked by the laboratory into the sorbent media prior to field deployment. These compounds serve to assess analyte ("native PFAS in air") collection efficiency, breakthrough, and the accuracy of the combined sample collection and analysis method on a sample-specific basis.

Passive samplers should also make use of mass-labeled PFAS as a sample-specific quality control measure to account for native PFAS losses during each sampling event. Volatilization of labeled PFAS during the deployment period provides sampling rates on a site-specific basis and accounts for both temperature and wind influences.

USEPA and European groups (VDI) are evaluating and investigating which sampling methods might be, in principle, the most suitable to capture PFAS and resulting byproducts in all fractions of the emissions (particles, moisture, gas phase). An important consideration is that fluorinated polymers are used in common sampling equipment, which may cause contamination of the samples. For the purposes of PFAS determinations, this material must be replaced. In addition to concerns over using fluorinated polymers in sampling equipment being a source of contamination, there are also concerns about the potential for sorption of PFAS to fluorinated polymers, thereby effectively reducing the observed concentration, or affecting any attempt to quantify the phase distributions between condensed and non-condensed phases (for example. PM vs gaseous). This is related, in part, to the concerns about quantification of ambient air concentrations and distributions, as published by Johansson, Berger, and Cousins (**2017**), showing that the use of GFF (and chemically deactivated glass fiber filters) may irreversibly bind fluoro-carboxylates during collection of samples containing fluoro-acids, which can be in the gas phase depending on their vapor pressure and ambient temperature, and the corresponding carboxylates. This issue for ambient air appears to negatively impact the estimates of phase distributions and so far, may not have a technique that is applicable for quantitative recovery (no answer to this problem has yet been published). A related issue, though separate from the ambient sampling confounding issues, is that quantification of acids/carboxylates via LC/MS does not/cannot distinguish between these two oxidation states, which is important to the phase distribution in ambient air (and emissions to air). There are other techniques (GC/MS or Chemical Ionization Mass Spectrometry (CIMS)

(**Riedel et al. 2019**) that may help address these LC/MS deficiencies, particularly with regard to air measurements.

11.1.7.13 Human Blood, Serum, Tissue

There are no official or standardized methods for testing human blood, serum, or tissue. Laboratories and the Centers for Disease Control and Prevention (CDC) are in the process of developing best methods. A procedure developed by the CDC's National Center for Environmental Health has been published (**CDC 2016**). There are also several laboratories advertising this capability; however, the analytical methods and modifications from validated environmental laboratory protocols may not be consistent among these vendors. Human testing is outside the scope of this document; however reference points that could be used for comparison of whole blood or serum results to geometric mean serum levels generated from the U.S. population are included in the ATSDR ToxGuide for Perfluoroalkyls (**ATSDR 2020**).

11.1.7.14 Potential High Concentration Samples

The CSM or historical data may indicate areas of high concentrations of PFAS for which single-use, disposable equipment is recommended. If single-use is not possible, take additional precautions such as implementing a greater frequency of ERBs and not reusing equipment to sample potentially low PFAS concentration samples. High concentration samples may require smaller sample volumes to be collected for analysis. High concentration samples should be segregated during shipping to the laboratory, and clearly identified on the sample chain-of-custody form.

Some projects may require the analysis of AFFF product that has been used at the site. All AFFF product samples must be considered high concentration samples. The method DOD AFFF01 contains steps to prepare AFFF concentrate samples. This method requires that a dilution of a subsample of the AFFF concentrate be prepared for extraction. A critical step in this procedure is the amount of time that must elapse, a minimum of 3 hours (**Willey 2021**) from the time PFAS-free reagent water is added to the aliquot of AFFF concentrate to create the dilution to the time when extracted internal standard can be added to the diluted sample. It was determined during method development and validation that some AFFF concentrates can take up to 3 hours to fully dissolve in the reagent water. In addition, this method requires each AFFF concentrate sample to be prepared and analyzed in duplicate, using another aliquot of the collected sample. It is recommended that these samples be segregated from other samples during sampling and shipping to avoid cross-contamination and clearly identified on the sample chain-of-custody form.

11.2 Analytical Methods/Techniques

11.2.1 Quantitative Techniques

11.2.1.1 General

Analytical methods are still evolving for PFAS analysis. Several methods are multi-laboratory validated and published. Three multilaboratory-validated methods, USEPA Methods 537, Version 1.1 (herein referred to as USEPA 537), 537.1, and 533 have been published for analysis of drinking water samples (**USEPA 2009**; **USEPA 2020**; **USEPA 2019**) and two methods for non-drinking water matrices have been published. USEPA Method 1633A (**USEPA 2024**) has been published for analysis of groundwater, surface water, waste water, soil, sediment, biosolids, tissue, and landfill leachate. USEPA SW-846 Method 8327, has been published for analysis of groundwater, surface water, and wastewater samples. The DOD has published a multilaboratory validated method, DOD AFFF01 (**Willey 2021**), for the analysis of AFFF concentrates to demonstrate compliance to the military specification for AFFF (MIL-PRF-24385). The USEPA released OTM 45 (**USEPA 2021**) and OTM 50 (**USEPA 2024**) for measurement of PFAS in

emissions to air from stationary sources. Also in January 2024, USEPA released draft OTM 50 for measurement of fluorinated compounds in emissions to air from stationary sources by GC-MS.

- USEPA Method 537, Version 1.1 tests for 14 PFAS analytes
- USEPA Method 537.1 tests for 18 PFAS analytes (including 4 PFAS not included in USEPA Method 533)
- USEPA Method 533 tests for 25 PFAS analytes (including 11 not included in USEPA Method 537.1)
- USEPA SW-846 Method 8327 tests for 24 PFAS analytes (does not include all PFAS included in USEPA Method 537.1 or 533)
- USEPA Method 1633A tests 40 PFAS analytes (includes all PFAS included in USEPA Method 537.1, 533, and 8327 and 11 additional PFAS analytes)
- DOD AFFF01 tests for PFOA and PFOS
- USEPA Other Test Method (OTM) 45 tests for 50 specific semivolatile and nonvolatile polar PFAS
- ASTM D8421-22 Standard Method for Determination of Per- and Polyfluoroalkyl Substances (PFAS) in Aqueous Matrices by Co-solvation followed by Liquid Chromatography Tandem Mass Spectrometry (LC/MS/MS)
- Draft USEPA OTM 50 tests for 30 specific volatile nonpolar fluorinated compounds

Other methods have been published by other organizations. Lists of these methods, by various categories, are provided in the **PFAS Analytical Methods** Excel File in the **separate tabs**:

- External **Table 11-2**–Published Method Basics. Provides information on basic principles of each method (media type, validation status, method type, sample container requirements, holding time, preservation requirements, and analytical instrument.
- External **Table 11-3**–Published Methods Specifics. Provides more details of the methods such as sample preparation requirements, quantitation scheme, confirmation ion requirements, quantitation limits, and isomer profile.
- External **Table 11-4**–Provides summaries of the analyte lists for each of the methods. The method analyte list for each of these methods varies.
- External **Table 11-5**–Draft Published PFAS-Related Analytical Methods Basics. Provides information on basic principles of each method (media type, validation status, method type, sample container requirements, holding time, preservation requirements, and analytical instrument).

11.2.1.2 Sample Preparation

USEPA Methods 537, 537.1, 533, and 1633A, and DOD AFFF01 all require aqueous samples to be prepared using the solid-phase extraction (SPE) technique, but may use different solid-phase selectivities. USEPA Method 1633A and DOD AFFF01 both require cleanup procedures be used on extracts and all associated batch QC samples to help eliminate matrix interferences (for example, bile salts, gasoline range organics) that could be present. USEPA Methods 537.1 and 533, USEPA Method 1633A, and DOD AFFF01 all require extraction of the entire sample collected (in the case of DOD AFFF01, the entire prepared dilution), including a rinse of the sample container (in the case of DOD AFFF01, the dilution container).

USEPA SW-846 Method 3512 is for the preparation of groundwater, surface water, and wastewater samples by diluting the sample collected with an equal volume of methanol and does not require a rinse of the sample container to be included unless the sample had to be transferred to a larger container in order to allow for the addition of the appropriate volume of methanol. USEPA SW-846 Method 3512 does not use SPE or carbon clean-up steps, which is another significant difference from the other USEPA published methods. USEPA SW-846 Method 8327 states that during method development, some PFAS analytes showed a potential for loss during sample preparation or standard preparation using USEPA SW-

846 Method 3512. This method states that a minimum organic cosolvent content must be maintained in standards and samples, and it cautions against aqueous subsampling prior to adding sufficient organic solvent.

USEPA Method 1633A prepares groundwater, wastewater, surface water, and landfill leachates using solid phase extraction (SPE) followed by carbon clean-up steps to eliminate matrix interferences. USEPA Method 1633A uses solvent extraction for soil, sediment, biosolids, and tissue preparation, followed by use of SPE cartridges and carbon clean-up steps to eliminate matrix interferences. Regardless of the method used, care must be taken to prevent sample contamination during preparation and extraction because the limits of quantitation and detection are 1,000 times below (ppt) those for more routine analyses such as volatiles or semivolatile analysis (ppb). It is recommended that all supplies be checked and confirmed as PFAS-free prior to sample preparation. Intermittent contamination can occur due to vendor or manufacturing changes.

Some PFAS analytical methods, such as USEPA Method 533 and USEPA Method 1633A, use isotope dilution and extracted internal standard quantification schemes to calculate sample concentrations. Isotope dilution analysis (IDA) quantitation requires the use of extracted internal standards (EIS) that are the isotopically labeled analogs of the method analytes. Method analytes for which corresponding isotopically labeled analogs are not commercially available are quantitated using the isotopically labeled analogs of a method analyte of similar chemical properties. Since isotopically labeled analogs of PFOA and PFOS are commercially available, DOD AFFF01 uses isotope dilution quantitation. USEPA SW-846 Method 8327 uses an external quantitation scheme to calculate the percent recovery of isotopically labeled analogs that are added to the sample prior to dilution with methanol. This method does not use isotopically labeled analog recoveries to account for sample preparation and matrix interference biases in the sample result. All of the methods discussed above require these isotopically labeled standards be added to the sample at a designated point in sample preparation, depending on the sample matrix:

- aqueous samples–added to field samples while in the original container prior to extraction/dilution
- AFFF concentrates or high concentration aqueous samples – added to dilution of sample prior to extraction
- solid samples and biota–added after homogenization and subsampling, prior to addition of water or extraction solvent

Ensuring a representative sample/subsample for analysis is critical. For aqueous samples, the entire sample and rinsate of the sample container received by the laboratory must be extracted by SPE to recover any PFAS that adhere to the sample container. Filtration is not recommended for samples with high particulate content because retention of PFAS onto filters has been noted. Centrifugation is often used to reduce or separate out sample particulates. See Preparation of Aqueous Samples with Particulates/Suspended Solids below for more details.

USEPA Method 1633A requires the screening of all aqueous samples using a separate sample container from the one which will be used for sample preparation, absent project-specific requirements. Due to limitations in SPE cartridge capacity and potential contamination of sample preparation and/or analytical equipment, the method requires samples containing high concentrations of PFAS (for example, AFFF concentrates) to be diluted prior to SPE and sample clean-up. In these cases, sorption onto the original sample container is not an issue, depending on the identified project-specific DQOs, because the amount of PFAS adsorbed onto the container walls may be negligible compared to the amount of PFAS in the sample.

USEPA Method 1633A requires the entire soil, sediment, and biosolid sample that is collected be homogenized in the laboratory prior to subsampling. Tissue samples are to be prepared according to project requirements (for example whole fish versus fillet) and homogenized prior to subsampling.

Cleanup procedures can be used on extracts and all associated batch QC samples (for example, method blank and laboratory control samples) when matrix interferences (for example, bile salts, gasoline range organics) could be present. USEPA Method 1633A and DOD AFFF01 require carbon cleanup techniques to be used for all sample matrices. USEPA Method 1633A and DOD AFFF01 require samples to be slowly concentrated to remove methanol from the extract to avoid loss of neutral and other highly volatile method analytes. In addition, USEPA Method 1633A states that if methanol is not sufficiently removed, its presence during SPE can result in poor recovery of long-chain carboxylic acids and sulfonates. Care must be taken to avoid these outcomes.

The preparation batch QC samples that are required by these PFAS methods vary. Common laboratory QC sample nomenclature and typical use frequencies are as follows:

- Method blank – (one per preparation batch of 20 or fewer field samples) PFAS are ubiquitous and found in many analytical instrument systems, reagents, containers, and common laboratory environments. The method blank is a similar matrix as associated field samples and undergoes the same sample preparation procedure as the associated field samples. It is a vital indicator of the absence of PFAS contamination in laboratory equipment, supplies, and reagents. Note that method blank is also referred to as Laboratory Reagent Blank in EPA drinking water methods.

- Sample (or laboratory) duplicate – (minimum of one per preparation batch of 20 or fewer field samples) A sample that is prepared and analyzed in duplicate in a single laboratory to ensure the laboratory's subsampling procedures are capable of achieving a known level of precision as defined in the QAPP or work plan.

- Laboratory control sample (LCS), ongoing precision and recovery (OPR), or laboratory fortified blank (LFB) – (typically one per preparation batch of 20 field samples) Must contain all project-specific PFAS in similar media as the associated field samples and is used to evaluate bias associated with sample preparation as well as analytical processes.

- Low-level laboratory control sample (LLLCS) or low-level ongoing precision and recovery (LLOPR) – (one per preparation batch of 20 field samples) Must contain all project-specific PFAS at a specified concentration (for example, 0.5–2 times the LOQ for USEPA SW-846 Method 8327 or 2 times the LOQ for USEPA Method 1633A) in similar media as the associated field samples and is used to evaluate bias associated with sample preparation as well as analytical processes.

- Certified reference material (CRM) – (if available, one per preparation batch of 20 or fewer field samples) Unlike LCSs, which contain no matrix interferences, CRMs can be of significant value when dealing with complex matrices such as soil, sediment, and tissue.

- Matrix spike (MS) and MS duplicate (MSD) – (one pair per prep batch of 20 or fewer field samples) An MS/MSD is not needed if IDA can be used for all PFAS of interest because the EIS recoveries account for the influence of matrix interferences in each sample. If EIS standards are not available for a PFAS of interest, an MS/MSD may be warranted to assess the effects of matrix interference on that specific PFAS.

For samples with high concentrations of PFAS, it is recommended that an LCS duplicate and a sample duplicate are prepared in lieu of an MS and MSD. DOD AFFF01 requires the sample duplicate to be prepared using a different aliquot from the same sample bottle to create the sample duplicate.

Preparation of Aqueous Samples with Particulates/Suspended Solids

USEPA Method 1633A contains a procedure for determining the solids content of aqueous samples. This determination is to be performed using the second, smaller container that is required for each sample, not the sample container used to prepare the sample for the PFAS analysis. The sample preparation procedures for PFAS analysis in USEPA Method 1633A are applicable to aqueous samples containing less than 50 mg of solids. The method provides additional steps to take if particulates clog the SPE cartridge during extraction, including the use of additional SPE cartridges. Solids accumulate high concentrations of PFAS and specifically some of the longer-chain PFAS. Care should be taken to resuspend any solids and to rinse bottles so that measured concentrations reflect the entire sample.

When aqueous samples contain greater than or equal to 50 mg of solids, depending on the laboratory procedure, if the contaminant mass in the solids is not determined, the reported PFAS (fingerprint) could be inaccurate for effective comparison. Ultimately, the data user needs to work with the laboratory to determine the appropriate procedure to be performed, depending on the end use of the data (for example, remedial action, human health or ecological risk assessment, permit compliance, etc.). The project objectives may specify quantification of the total aqueous sample, water plus solids, or may only include evaluation of the aqueous fraction for end use as drinking water, where the solids will not be consumed.

A survey conducted in 2020 by ITRC received responses from 16 laboratories. These responses demonstrated that the laboratory community is *not* consistently preparing aqueous samples in the presence of suspended solids.

- Several laboratories centrifuge the samples and decant off the water portion for subsequent extraction.
- Some laboratories may also extract the remaining particulates and combine the extract with the aqueous extract. However, only one of the surveyed laboratories does this routinely; the others do this only if requested by the client.
- Routine laboratory procedures are not dependent upon whether the matrix is groundwater, surface water, or wastewater.
- Several laboratories filter the samples, if requested by the client. This may result in sorption of PFAS from the samples and potential cross-contamination, and should be implemented with care.
- After decanting, some laboratories rinse the remaining particulates in the bottle with solvent for the SPE.
- Not all laboratories disclose when samples require special preparation (decanting, centrifuging, or filtering) due to the presence of particulates. Therefore, this would not always be known to the data user.
- Laboratories have different procedures for when particulates clog the SPE cartridge; some labs may re-extract at a dilution, while others may start a new cartridge and attempt to continue with the extraction of the remaining sample.

Laboratories should clearly state whether reported concentrations are dissolved (water only) or “total” PFAS measurements (including sample particulates). The project team will determine whether dissolved or “total” PFAS measurements are appropriate to meet project objectives and confirm with laboratories that correct procedures are in place. Sampling procedures should be designed to gather representative

samples to meet project objectives. Some issues to consider in the determination of the need for a total or dissolved PFAS measurement are discussed in this section.

Groundwater

- If minimizing presence of particulates is within the project objectives, use of low-flow groundwater sampling or no-purge samplers should be considered.
- If turbidity is >10 NTU, consider a "total" measurement if sampling groundwater for compliance, delineation, remedial design, or risk assessment. "Total" can be defined as centrifuge, decant, and extract both phases, to report the dissolved concentration and the suspended/solid concentrations either individually or summed in the report.
- Collect samples for TSS analysis to assist in the evaluation of sample data. In lieu of TSS, turbidity measurements can also be helpful in the evaluation.

Drinking Water

- Particulates are not addressed in the drinking water methods.

Surface Water and Wastewater

- Use a "total" measurement if sampling surface water or wastewater for compliance, permitting, remedial design, or risk assessment.
- A "total" measurement may not be required if sampling for a line of evidence in a source area, rather than for a regulation.
- Collect samples for TSS analysis to assist in the evaluation of sample data. In lieu of TSS, turbidity measurements can also be helpful in the evaluation.

For laboratories performing centrifugation and subsequent decanting, it should be noted that it is important that the extracted internal standards are spiked into the aqueous samples prior to centrifugation. It is important to communicate with your laboratory prior to the collection of samples on the approach that will be used.

Biosolids

Biosolids sample preparation methods can vary based on laboratory-specific protocols, the moisture content of the sample, and/or client or regulatory requirements. Because of the variability in sample preparation methods for this matrix, communication with the laboratory prior to submitting samples is essential to understand the laboratory's options for sample handling and to ensure that the laboratory will meet the project objectives and/or regulatory requirements.

The following preparation methods are possible for biosolids and may be dependent on the laboratory's standard operating procedures.

- Typical solid sample extraction procedures (e.g., homogenization and solvent extraction) may be used regardless of the moisture content if there are visible or settleable solids. Because regulatory criteria for biosolids are typically established on a mass/unit mass basis (e.g., µg/kg), this may be an approach needed to satisfy regulatory requirements.

- If there are no visible or settleable solids, the laboratory may treat the biosolids sample as an aqueous sample (e.g., passing the sample through a solid phase extraction [SPE] cartridge).
    - When aqueous samples are treated as dissolved PFAS samples, laboratories may centrifuge the samples to separate out any solids or particulates. The aqueous phase would then be decanted and prepared using SPE.
    - Some laboratories may also extract the remaining solid/particulate phase after decanting using a solvent and then use the eluate of this solid sample to elute the PFAS off the SPE cartridge used to extract the aqueous phase, thus combining the aqueous and solid phases into one extract.
    - If samples are not centrifuged, solid particles may become entrained on the SPE cartridge and PFAS from these solid particles may be extracted during the methanol rinse. However, there is also a chance that the solid particles could cause clogging of the SPE cartridge, which would not allow for a complete extraction.

Laboratories may also be able to perform biphasic extraction and report results separately for the aqueous and solid phases.

11.2.1.3 Sample Analysis

Instrument Type–LC/MS/MS

All methods published by the USEPA and DOD for targeted PFAS analysis use liquid chromatography-mass spectrometry-mass spectrometry (LC/MS/MS), which is especially suited for analysis of ionic compounds, such as the PFSAs and PFCAs. Gas chromatography-mass spectrometry (GC/MS) can also be used for PFAS analysis, specifically the neutral and nonionic analytes, such as the fluorotelomer alcohols (FTOHs), perfluoroalkane sulfonamides, and perfluoroalkane sulfonamido ethanols. GC/MS may be appropriate for (ambient) atmospheric samples. PFAS are either directly detected using large-volume injection (**Scott et al. 2006**) or detected as a derivatized compound that is GC/MS amenable (**Langlois et al. 2007**). At this time, OTM 50 is the only published GC/MS method and there is very limited commercial availability for this technique for PFAS analysis.

In contrast, LC/MS/MS analysis of PFAS is widely available. LC/MS/MS is typically operated in multiple reaction monitoring (MRM) mode, which allows for selective monitoring of both the precursor and (potentially) unique daughter ions that are produced upon fragmentation in the mass spectrometer; this allows for specific and selective monitoring for compounds of interest. MRM is performed by specifying the mass-to-charge ratio of the compound of interest for fragmentation within the MS/MS. The precursor mass of the compound of interest undergoes MS/MS fragmentation, followed by monitoring for product ions. Ions arising from that fragmentation are monitored for by the MS/MS, which yields improved specificity and sensitivity.

Standards Preparation and Storage

Certified analytical standards are available from several manufacturers. Products may have variable purity and isomer profiles, which may compromise the accuracy, precision, and reproducibility of data. Certified standards of the highest purity available are standards that can be used for accurate quantitation. Standards manufacturers should provide a certificate of analysis (COA) with each standard, which provides the analyte concentrations and the purity information. Regarding expiration dates, laboratories should have their own policy in place for expiration date determination.

Quantitative standards containing linear and branched isomers are not commercially available for all applicable analytes. As of the date of this publication, quantitative standards are available for PFOA, PFOS, perfluorononanoic acid (PFNA), perfluorohexane sulfonic acid (PFHxS), perfluorooctane

sulfonamide (PFOSA), N-methyl perfluorooctane sulfonamide (NMeFOSA), N-ethyl perfluorooctane sulfonamide (NEtFOSA), 2-(N-methylperfluorooctanesulfonamido) acetic acid (NMeFOSAA), 2-(N-ethylperfluorooctanesulfonamido) acetic acid (NEtFOSAA), methyl perfluorooctane sulfonamido ethanol (NMeFOSE), and N-ethyl perfluorooctane sulfonamido ethanol (NEtFOSE).

Technical grade standards, or qualitative standards, that contain branched and linear isomers are available for other PFAS, but these standards do not have the accuracy needed for quantitation purposes. USEPA Method 1633A and DOD AFFF01 both require the analysis of technical grade standards to verify which peaks represent the branched isomers for method analytes when these standards are available.

Stock standards of PFAS analytes, internal standards, and surrogate standards supplied in glass ampoules by the manufacturer are acceptable. Manufacturers of the certified analytical standards often provide laboratories storage and shelf-life guidance for stock and working standards. USEPA Methods 533, 537.1, 8327, Method 1633A, OTM-45, and DOD AFFF01 contain storage requirements for both reagents and/or standards.

Steps to Help Eliminate Laboratory/Instrument Contamination (Verification of Supplies, Instrument Blanks, Isolator/Delay Columns)
