Laboratory and instrument contamination is of particular concern for PFAS, given that the limits of detection are in the ppt range. Additionally, nonpolymer PFAS may be found at trace levels as impurities in some polymer products (**3M 1999**). PFAS are found in commonly used laboratory items such as PTFE products, solvent lines, and methanol, which could lead to method interferences and elevated baselines in chromatograms if not checked. The evaluation criteria for equipment and standards that is applicable depends on the analytical method used. For instance, USEPA Methods 537.1 and 533 recommend that all of the above items must be "less than 1/3 the MRL (minimum reporting limit) for each method analyte under the conditions of analysis by analyzing laboratory reagent blanks." (**USEPA 2020**, pg. 7). USEPA Method 533 further specifies that the isotopically labeled analogs of method analytes and isotope performance standards meet this same requirement (**USEPA 2019**, pg. 7).

Most vendors have a PFAS kit available that replaces as many PFAS-containing components as possible. In addition, the liquid chromatograph can be fitted with an isolator or delay column to separate contamination arising from the solvent delivery systems. This can reduce the contribution of PFAS from the pump apparatus to the analysis and reduce detection limits. Guard columns should be used to protect analytical columns.

Ion Transition Selection (Recommended Transitions for Primary and Confirmation Ions, Including Ratio Criteria)

Quantification by LC/MS/MS may be accomplished using a variety of techniques. For relatively simple matrices such as drinking water, USEPA Method 537.1 quantifies analytes by comparing the product ion of one precursor ion and retention time in samples to calibration standards. For more complex matrices, additional product ions and their ion ratios can be used to distinguish analytes from matrix interference. In an MS/MS system, most analytes can be fractured into more than one ion. By monitoring the area of each ion and comparing the ratio of those area counts, a more definitive identification can be made. This identification allows the analyst to distinguish true target analytes from false positives. This more detailed quantification is not required for drinking water matrices, but it is useful for more complex matrices. USEPA SW-846 Method 8327, USEPA Method 1633A, and DOD AFFF01 all require two ion transitions from precursor to characteristic product ions be monitored and documented for each analyte, with the exception of those analytes without a suitable secondary transition (for example, species with nondetectable or low signal secondary transitions, such as PFBA, PFPeA, PFMPA, and PFMBA). These methods determine ion transition ratio criteria by comparison with the analysis of analytical standards and use these ratios to evaluate potential bias in sample results.

Mass Calibration, Calibration Criteria, and Calibration Verification

All LC/MS/MS instruments require mass calibration prior to initial calibration. Mass calibration and mass calibration verification should be performed at setup, after performing maintenance that is required to maintain instrument sensitivity and stability performance, and as needed based on QC indicators, such as calibration verifications, as required by USEPA Method 1633A. Mass calibration should be performed according to the manufacturer's instructions. In addition to the manufacturer-specified mass calibration verification, the method also requires the accuracy of the ion masses monitored by the method be verified.

Following mass calibration and mass calibration verification, an initial calibration should be performed and verified. All of the published USEPA methods and the DOD method contain requirements for instrument calibration and calibration verification specific to the PFAS concentrations expected in the media for which the method is applicable. USEPA Method 537.1 uses internal standard quantitation, while USEPA Method 533 and USEPA Method 1633A use isotope dilution and extracted internal standard quantitation. USEPA SW-846 Method 8327 uses external calibration quantitation. Isotope dilution quantitation is recommended for complex matrices. The instrument is required to be calibrated at setup and as needed following QC failures, such as initial calibration verification (ICV) or continuing calibration verification (CCV) failure. The lowest calibration point should be a concentration at or below the Minimum Reporting Limit (MRL), Minimum Level (ML), or Limit of Quantitation (LOQ), depending on the method. Most methods require the analysis of a standard at the MRL, ML, or LOQ concentration at least daily to document the instrument's ability to accurately quantitate down to that concentration. In addition, some methods also require a reporting limit check QC sample (for example, LLLCS or LLOQ verification sample) to be included with each sample preparation batch to demonstrate adequate quantitation at the lowest concentration is achievable using the sample preparation techniques required by the method.

Some methods, such as USEPA SW-846 Method 8327, require analysis of an ICV, which is a calibration verification standard prepared from a source separate from the calibration standards and analyzed after each initial calibration and before sample analyses are performed.. CCVs or CVs should be analyzed at the frequency specified in the analytical method. Most USEPA methods require at a minimum a CCV/CV to be analyzed prior to sample analysis on days an ICV is not analyzed, after every 10 field samples, and at the end of the analytical sequence. Some methods rotate the concentration of CCVs/CVs to cover the entire calibrated range of the instrument and vary the acceptance criteria depending on the concentration. For example, in USEPA Method 537.1, the calibration acceptance criteria for each analyte at the lowest calibration point must be within 50–150% of its true value while the other calibration points must be within 70–130% of the true values.

Isotope dilution and extracted internal standard quantitation can correct bias resulting from loss during sample preparation, such as in USEPA Methods 533 and 1633A. In the case of USEPA SW-846 Method 8327, isotopically labeled analogs are used as surrogates to monitor for loss without being used for recovery-correction of target analyte concentrations. Isotope dilution is a quantitation technique that considers sample matrix effects on each individual PFAS quantitation in the most accurate and precise manner possible. This technique quantifies an analyte of interest against the isotopically labeled analog of that analyte, which is added to the sample prior to the onset of sample preparation. EIS quantitation is the comparable technique used when an isotopically labeled analog of an analyte is not commercially available. Addition of EIS prior to sample preparation helps account for loss of analyte during the preparation process and for bias associated with the instrumentation. Calibration criteria for methods using isotope dilution and EIS quantification schemes can be found in USEPA Methods 533 and 1633A. Methods using isotope dilution should include isotopically labeled analog recovery for each sample and analyte in data reports. Isotopically labeled analog recoveries should be reported, and minimum/maximum isotopically labeled analog recoveries may be required by specific analytical procedures. For instance, USEPA Method 1633A determines the recovery of these analogs through comparison to the response of analogs typically called non-extracted internal standards (NIS) added to

the sample after extraction and prior to analysis. Depending on project DQOs, low isotope recovery may indicate that quantitation was inadequate; the data are then reported as estimated values or not at all.

Instrument Blanks: When Are They Needed, Criteria, and Corrective Actions to Take

Due to the extensive use of PFAS, instrument blanks are critical in determining if the instrument is potentially affecting PFAS concentrations in samples. Some methods, such as USEPA Method 1633A, require instrument blanks to be analyzed following the highest calibration standard analyzed, daily prior to sample analysis, after each CCV/CV, and following samples that exceed the calibration range to ensure carryover does not occur. The acceptance criteria for instrument blanks are dependent on the method. For example, USEPA SW-846 Method 8327 requires the concentration of each analyte to be ≤ ½ the LLOQ or < 10% of the sample concentration. USEPA Method 1633A is the only method which states that if instrument blanks indicate contamination following the highest calibration standard, corrective action, such as calibrating with a lower concentration for the highest standard, must be taken and successful analysis of an instrument blank following the highest standard analyzed determines the highest concentration for which carryover does not occur.

Matrix Interferences

Aqueous

Interferences related to the matrix can be caused by the co-extraction of contaminants from the sample. These matrix interferences can have considerable variation from sample to sample. For example, there are problems associated with high total organics content (TOC) in water, which can cause matrix suppression of target analytes and lead to poor recoveries.

Tissue

Interferences related to the matrix can be caused by the co-extraction of bile salts (for example, taurodeoxycholic acid, taurochenodeoxycholic acid, and tauroursodeoxycholic acid) with PFOS from the tissue sample. These bile salts can vary considerably from sample to sample and by species. The use of carbon clean-up steps, such as those required by USEPA Method 1633A, helps eliminate these interferences in most extracts; however, when excessive amounts are present in the extract, these steps may only reduce the amount of these bile salts. To address the potential interference, USEPA Method 1633A requires that the chromatographic conditions are adjusted such that these bile salts elute at a retention time beyond 1 minute from the retention time window of PFOS. Since bile salts can be associated with other matrix types (for example surface waters and wastewaters), the method requires this chromatographic separation to be demonstrated with each analytical sequence, regardless of the matrix type of the sample.

11.2.2 Qualitative Techniques

The Priority Topics for Sampling and Analysis include information about ultrashort-chain PFAS analysis (see **Section 1.5.3**), consumer product testing (see **Section 1.5.4**), and field screening tools (see **Section 1.5.7**).

Several techniques employing indirect measurement have been developed that can more comprehensively assess sites for a wider range of PFAS contaminants than in the typical LC/MS/MS or GC-MS/MS methods. These qualitative techniques are not yet standardized through a published USEPA method and range in commercial availability. To date, these techniques have not undergone multilaboratory validation and tend to be inherently nonquantitative; accordingly, data from these methods may supplement, but not replace, the results of quantitative methods.

11.2.2.1 Overview of Qualitative Techniques

Because of the large number of PFAS and their varied structural characteristics, a single targeted method on either LC/MS/MS or GC-MS/MS may be unable to quantify all PFAS that may be present in a sample. When the release source is well understood and the types of PFAS present are both known and amenable to regular PFAS analysis methods (for example, LC/MS/MS of ionic PFAS or GC-MS/MS analysis of neutral PFAS), a targeted analytical approach may be sufficient to adequately characterize a release. For releases that are not well understood or consist of multiple sources, alternative ways of measuring PFAS in a more comprehensive but less targeted fashion may be desirable. Additionally, PFAS that are in polymeric form, such as those used in coatings for paper and textiles, are not amenable to LC- and GC-based separation techniques; they may also not be effectively extracted, even with rigorous methods.

Five primary techniques have been developed to characterize unknown PFAS in a sample. Only USEPA Method 1621 has been multilaboratory validated but none have been promulgated by USEPA. They are described in more detail in the sections below.

- The total oxidizable precursor (TOP) assay measures PFAA precursors.
- Particle-induced gamma-ray emission (PIGE) spectroscopy measures elemental fluorine isolated on a thin surface.
- USEPA Method 1621, Determination of Adsorbable Organic Fluorine (AOF) in Aqueous Matrices by Combustion Ion Chromatography (CIC) and extractable organic fluorine (EOF), also paired with CIC, measure the organofluorine content of a sample as fluoride on an ion chromatograph.
- High-resolution mass spectrometry techniques, such as quadrupole time-of-flight (qTOF) MS/MS, can tentatively identify PFAS structures through library matching or in-depth data analysis.
- Chemical Ionization Mass Spectrometry (CIMS) technique detects gas-phase PFAS, particularly fluorotelomer alcohols (FTOHs) and other oxygenated PFAS.

11.2.2.2 TOP Assay

Technique Description

The TOP assay converts PFAA precursor compounds to PFAAs through an oxidative digestion. The increase in PFAAs measured after the TOP assay, relative to before, is an estimate of the total concentration of PFAA precursors present in a sample, because not all PFAS present will be subject to quantitation or oxidation, and some will remain as undetected PFAS. The PFAAs generated have perfluoroalkyl chain lengths equal to, or shorter than, the perfluoroalkyl chain lengths present in the precursors (**Houtz et al. 2013**; **Houtz and Sedlak 2012**; **Weber et al. 2017**; **Dauchy et al. 2017**).

The TOP assay is a technique developed to estimate oxidizable precursors that can transform to PFAA end products that are included in the target analyte list (**Houtz et al. 2013**; **Houtz and Sedlak 2012**). A sample is analyzed using conventional LC/MS/MS to determine the baseline levels of PFAAs present in the sample. A separate aliquot of the sample is then exposed to a highly basic persulfate solution and then placed in a sealed container at an elevated temperature (for example, 85°C, in a water bath or other heating device) to thermolyze persulfate into a sulfate radical. At elevated pH, the sulfate radical is scavenged by hydroxide and forms a hydroxyl radical, which then converts the free PFAA precursor compounds to PFAAs. The predominant products (for example, > 95% in control experiments) of the precursors are the perfluoroalkyl carboxylates, whether or not the precursors contain sulfonamido or telomer functionalities. After sufficient time has elapsed to convert all the persulfate, the samples are removed from the heated environment (for example, a water bath), cooled to room temperature, and

neutralized prior to LC/MS/MS analysis. The increased concentrations of PFAAs generated after the oxidation step provide an estimate of the concentration of oxidizable PFAA precursors.

The technique can be applied to aqueous (**Houtz et al. 2013**; **Houtz and Sedlak 2012**; **Houtz et al. 2016**; **Weber et al. 2017**; **Dauchy et al. 2017**) and solid samples (**Houtz et al. 2013**). In most cases, samples need to be pretreated prior to oxidation to remove competitive organic compounds. For aqueous samples, dilution may be sufficient, although extraction techniques may be used to further remove matrix effects. Soil samples are extracted prior to persulfate treatment, and the extracts are cleaned with ENVI-Carb prior to treating the evaporated extract. The specific extraction procedure used may affect which PFAA precursors are retained for oxidation. For example, acidic extraction procedures may be required to remove cationic precursor compounds from soils (**Barzen-Hanson 2017**; **Mejia-Avendaño et al. 2017**).

Possible Technique Uses

The TOP assay may be used to estimate a total concentration of free PFAA precursors in a sample. In some cases, oxidation can be incomplete (**Ventia 2019**). The total PFAA precursor or total PFAS concentration is considered conservative for the reasons explained below in Technique Limitations. Because the method depends on a compound containing a perfluoroalkyl group, it is highly specific to PFAS. The chain lengths of the PFAAs generated after oxidation provide an indication of whether the precursors are predominantly short- or long-chained, although the production of a particular Cn (where "n" signifies the number of carbons in the alkyl chain) PFAA is not equivalent to the concentration of PFAA precursors containing the same chain length. However, if significant amounts of PFOA are generated after oxidation, that is an indication that the sample contains a comparable concentration of C8 or longer PFAA precursor compounds.

The TOP assay is the most widely commercially available of the qualitative techniques and is typically accepted as a means of determining PFAS load on remediation media to estimate the replacement cycle, but not for site characterization.

Technique Limitations

As mentioned above, the TOP assay does not differentiate between precursors that contain telomer or sulfonamide functionalities, because all these precursors are chemically oxidized primarily to perfluoroalkyl carboxylates. This is significant because a precursor that would likely form PFOS in the presence of a mixed consortium of aerobic bacteria will convert to PFOA under the conditions of TOP assay. The production of branched perfluoroalkyl carboxylates could be attributed to precursors derived from an ECF-based manufacturing process, but environmental samples may not contain the same distribution of branched and linear isomers as was originally generated from the ECF manufacturing process.

The TOP assay results in a mixture of PFCA products from the conversion of fluorotelomer-based compounds (**Houtz and Sedlak 2012**). For example, 8:2 FTS was converted to 3% PFNA, 21% PFOA, 27% PFHpA, 19% PFHxA, 12% PFPeA, and 11% PFBA in control experiments. Two limitations of the technique arise because of this effect. First, the production of PFOA, for example, is not equivalent to the C8 precursor concentration, because PFOA can be generated from longer-chain telomer compounds and is only a partial product of C8 telomer products. Second, some shorter-chain PFCA products of telomer compounds are not captured, depending upon the analytical methods used for measurement. For example, only 73% of 6:2 FTS was recovered, from a mass balance standpoint, as PFCA products PFBA and longer in control experiments (**Houtz and Sedlak 2012**). As a result, the TOP assay may under-quantify short-chain PFAA precursors, including those that are telomer-based. Sulfonamido compounds in control experiments did not exhibit a distribution of products; the Cn precursor forms the Cn PFCA in a 1:1 molar ratio.

Some studies have been published on the effectiveness of the oxidative process of the TOP assay on large molecular weight polymer compounds or newer ether-linked PFAS such as ADONA (**Zhang et al. 2019**). Because PFAS polymers have shown limited ability to biodegrade (**Russell et al. 2008**; **Russell et al. 2010**; **Washington et al. 2009**) relative to low molecular weight free PFAA precursor compounds (**Wang et al. 2005**; **Lee, D'eon, and Mabury 2010**; **Wang et al. 2011**; **Harding-Marjanovic et al. 2015**), the TOP assay may be similarly ineffective at converting PFAS polymers to free PFAAs. The TOP assay cannot be used to measure large molecular weight polymeric PFAS unless they are proven to break down in the assay.

For many samples, the TOP assay requires adjustments in dilution, sample preparation, or reagent dosing to achieve complete conversion of PFAA precursors. Standardized quality guidelines are needed to ensure that TOP assay data reflect full conversion of PFAA precursors.

11.2.2.3 PIGE

PIGE is a nondestructive analytical technique that takes advantage of the unique gamma-ray wavelength emission of fluorine when impacted with a proton ion beam. The technique is not compound-specific, but is able to assess total fluorine content of a variety of materials isolated on a thin surface (0.22 mm) (**Ritter et al. 2017**). The sample is secured in the instrument and bombarded ex vacuo under a 3.4 MeV beam with an intensity of 10 nA for approximately 180 seconds. Two gamma rays characteristic of the decay of the 19F nucleus (110 keV and 197 keV) are measured and the responses integrated. Quantification is achieved with comparison to fluorine-based calibration standards.

In the published literature, PIGE has been used to demonstrate total organofluorine concentrations in papers and textiles (**Ritter et al. 2017**; **Robel et al. 2017**) and in food packaging (**Schaider et al. 2017**). It has also been used on an experimental basis to evaluate organofluorine concentrations in extracted water and soils, but those results are not yet available in the peer-reviewed literature.

Possible Technique Uses

PIGE is a rapid screening technique to measure fluorine on surfaces. If a sample does not contain significant amounts of fluoride or can be prepared to remove inorganic fluoride, PIGE can become a technique specific for organofluorine; however, it is not specific for PFAS. It is a proven way to measure total fluorine in matrices containing high concentration of fluorinated polymeric material, which is a limitation of both the TOP assay and AOF. It also requires relatively minimal sample preparation to analyze fluorine content in commercial products. Sample preparation of environmental samples for PIGE analysis is likely to require a similar level of sample preparation, along with the limitations of extraction techniques, as the TOP assay or AOF.

Technique Limitations

PIGE is not specific to PFAS and, depending on the preparation, it is also not specific to organofluorine. The polymeric compounds that PIGE has been used to detect in consumer products may not contain perfluoroalkyl groups or may not be capable of breaking down to free PFAS. In addition, PIGE cannot distinguish between organic and inorganic fluorine; therefore, the presence of inorganic fluorine can cause results to be biased high.

PIGE also does not provide any differentiation on PFAS perfluoroalkyl chain length present in a sample. Depending on how the sample is prepared prior to the instrumental analysis, samples may be biased toward measurement of long-chain PFAS, as with the TOP assay and AOF.

Extraction methods for PFAS in environmental samples have not yet been demonstrated for this technique. When using SPE to extract environmental aqueous samples prior to PIGE analysis, cartridges

that are suitable to hydrophobic and anionic PFAS may not retain positively charged PFAS of interest. For soil samples, the extraction method also determines the PFAS likely retained. However, by using targeted extraction techniques for PFAS in environmental samples, the method becomes much more specific for PFAS.

The range of operating conditions for PIGE has not been standardized and so far, the technique has been demonstrated with only one academic laboratory.

11.2.2.4 Adsorbable Organic Fluorine with Combustion Ion Chromatography

USEPA Method 1621, Determination of Adsorbable Organic Fluorine (AOF) in Aqueous Matrices by Combustion Ion Chromatography (CIC) measures the fluorine content of environmental samples (**USEPA 2024**). An aqueous sample is passed through a carbon-based sorbent on which the fluorine-containing organics adhere. A nitrate wash of the sorbent is used to eliminate inorganic fluorine. The carbon sorbent is then combusted at high temperatures and the gaseous stream is passed through deionized water, which is then analyzed for fluorine content (as fluoride) by ion chromatography.

The AOF/CIC and EOF/CIC techniques have also been demonstrated on human blood samples (**Miyake et al. 2007**; **Yeung et al. 2008**) and various environmental aqueous samples (**Miyake et al. 2007**; **Wagner et al. 2013**; **Dauchy et al. 2017**; **Willach, Brauch, and Lange 2016**). Presumably, the method could be adapted to other types of matrices to measure organofluorine in soils or biota. The matrices could be extracted for PFAS, the extract resuspended into an aqueous solution that could adhere to the activated carbon, and then analyzed with CIC. As with the TOP assay, the specific extraction procedures would influence whether some or all PFAS are retained and ultimately measured as combusted fluoride product. Alternatively, it is possible that the technique could be used without extraction to directly combust organofluorine-containing products.

Possible Technique Uses

AOF can be used to measure PFAS or other fluorine-containing compounds as an aggregate organofluorine concentration. It can be a screening tool to determine if a significant concentration of fluorine-containing compounds is present in an aqueous sample or other sample from which the organofluorine content can be extracted. A pooled MDL of 1.5 µg f^-/L is listed in EPA Method 1621 as achievable by a well-prepared laboratory (**USEPA 2024**).

Technique Limitations

Like PIGE, AOF is not specific to PFAS. If a sample contains relatively high concentrations of chemical compounds that are not targets of the investigation (for example, fluorine-containing pharmaceuticals), then the organofluorine may be falsely attributed to PFAS content and bias “total PFAS” measurements high.

AOF does not provide any differentiation on PFAS perfluoroalkyl chain length present in a sample. Some short-chain PFAS may be unable to sorb to the activated carbon material that is combusted, but this will depend significantly on laboratory-specific procedures.

Extraction methods for PFAS in commercial products and solid samples, coupled with this technique, have not yet been demonstrated. A high concentration of inorganic fluoride concentrations may be challenging to remove from some matrices and would result in samples biased high for total organofluorine that was actually attributable to fluoride.

Like PIGE, the range of operating conditions for AOF-CIC has not been standardized. In addition to the limitations mentioned above, some matrices may contain sufficient competitive organics or other materials that coat the activated carbon to prevent complete retention of organofluorine compounds.

11.2.2.5 High-Resolution Mass Spectrometry

Technique Description

Quadrupole time-of-flight mass spectrometry (qTOF/MS) can be used to determine both the chemical formula and structure of unknown PFAS in a sample however, analytical standards are required for unequivocal structural identification. More information is available in **Section 11.4.3**.

High-resolution mass spectrometry has been used to tentatively identify the molecular formulas and structures of unknown PFAS (**Newton et al. 2017**; **Moschet et al. 2017**; **Barzen-Hanson et al. 2017**). Similar to targeted PFAS analysis, techniques such as LC or GC are used to separate compounds in a sample so that individual PFAS can be resolved. The mass is measured using a time-of-flight or other high-resolution detector, and the molecular formula is proposed. If an MS-MS technique is used, the fragments of the precursor compound can be used to piece together the structural arrangement of the compound. To identify compounds that are specifically PFAS, versus other organics present in the sample, compounds with negative mass defects (that is, the accurate mass is slightly less than the nominal mass) can be selected. Fluorine is one of the few elements that has a negative mass defect, and the inclusion of multiple fluorines in a PFAS molecule means that net mass defect of the molecule will likely be negative. Compounds that are either 50 or 100 mass units apart also identify homologous series of PFAS separated by one or two CF2 groups. MS libraries of previously identified PFAS exist for targeted matching, although they will not definitively identify an unknown compound.

Possible Technique Uses

Such high-resolution mass spectrometry analyses of PFAS can tentatively identify the structures of unknown PFAS and can also be used, in comparison with analytical standards of known compounds, to semi-quantitatively estimate their concentrations. Accurate identification of compounds using high-resolution MS is a time-intensive and expensive process. Therefore, a high motivation for knowing the exact PFAS structure, for instance in differentiating forensically between two different sources, may be the biggest driver of its use for PFAS analysis. High-resolution MS is best suited for media in which unknown PFAS are likely to be present in significant concentrations. When many other non-PFAS are present in the sample, the MS signal of competing compounds will likely obscure the signal of PFAS. Sample preparation steps can inadvertently or intentionally select for certain types of PFAS. As user skill and data interpretation time increase, accurate identification of PFAS is likely to improve.

Technique Limitations

High-resolution mass spectrometry cannot definitively identify the exact structure or formulas of PFAS without comparison to reference materials or analytical standards.

Not all PFAS, even if present in a prepared sample, can or will ionize under the conditions to which the instrument is tuned. A skilled instrument operator may be able to adjust the instrument conditions to match the types of compounds expected.

False positives are much more likely to result using high-resolution MS than with the TOP assay, AOF, or PIGE. Compounds may be mistakenly identified as PFAS, and even when correctly identified, their concentrations may be greatly over- or underestimated when other compounds are used for comparative quantitative purposes.

11.2.2.6 Chemical Ionization Mass Spectrometry

Chemical ionization mass spectrometry (CIMS) can be used to detect gas-phase PFAS, particularly fluorotelomer alcohols (FTOHs), and other oxygenated PFAS.

Although GC/MS has only been applied to PFAS analysis in stack emissions with the release of OTM-50, it is also particularly applicable to (ambient) atmospheric samples. Other than OTM-50, there are no published methods for using GC/MS for PFAS analysis, despite the distinct advantages for certain compound classes (for example, fluoro-telomer alcohols) of using GC/MS directly or after derivatization (chemical reaction to convert analyte of interest to a GC/MS-amenable "derivatized compound") (**Langlois et al. 2007**), or using large-volume injection (**Scott et al. 2006**).

11.3 Data Evaluation

Evaluation of data involves looking at all the factors that indicate whether the data are:

- precise (agreement between results that are supposed to be similar)
- accurate (how close they are to the true concentrations)
- representative (results characterize the site properly)
- comparable (data compare well to other data)
- complete (all the samples and compounds requested were reported, especially for critical samples that represent a point of exposure, such as drinking water)
- sensitive (nondetect data reported with concentrations below required regulatory or risk-based level)

These factors are illustrated in **Figure 11-1**, and guide users through the process of looking at their data (field collection and laboratory information) with a critical eye.

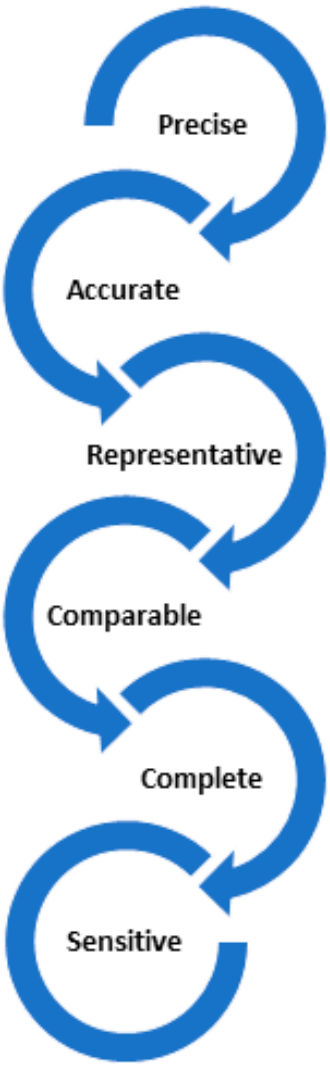

Figure 11-1. Data evaluation factors.

Source: H. Albertus-Benham, Wood Environment & Infrastructure, used with permission.

The USEPA has guidance to aid in evaluating PFAS drinking water data generated in accordance with USEPA 537 as well as a technical bulletin to aid in the review of PFAS data generated for all other media (**USEPA 2018**, **2019**). The USDOD EDQW has published PFAS Data Validation Guidelines, for evaluation of PFAS data generated in accordance with the *DOD/DOE Quality System Manual (QSM) Table B-24* (**USDOD 2022**). ASTM has published a Standard Guide for PFAS Data Evaluation (**ASTM 2025**).

11.3.1 Pre-sampling Planning

To ensure the usability of the data, communication with the laboratory that is performing the analysis is important. It is incumbent on the data user to collect information about the methodology to be employed by the laboratory. **Figure 11-2** contains laboratory considerations related to data usability in order to plan a sampling program.

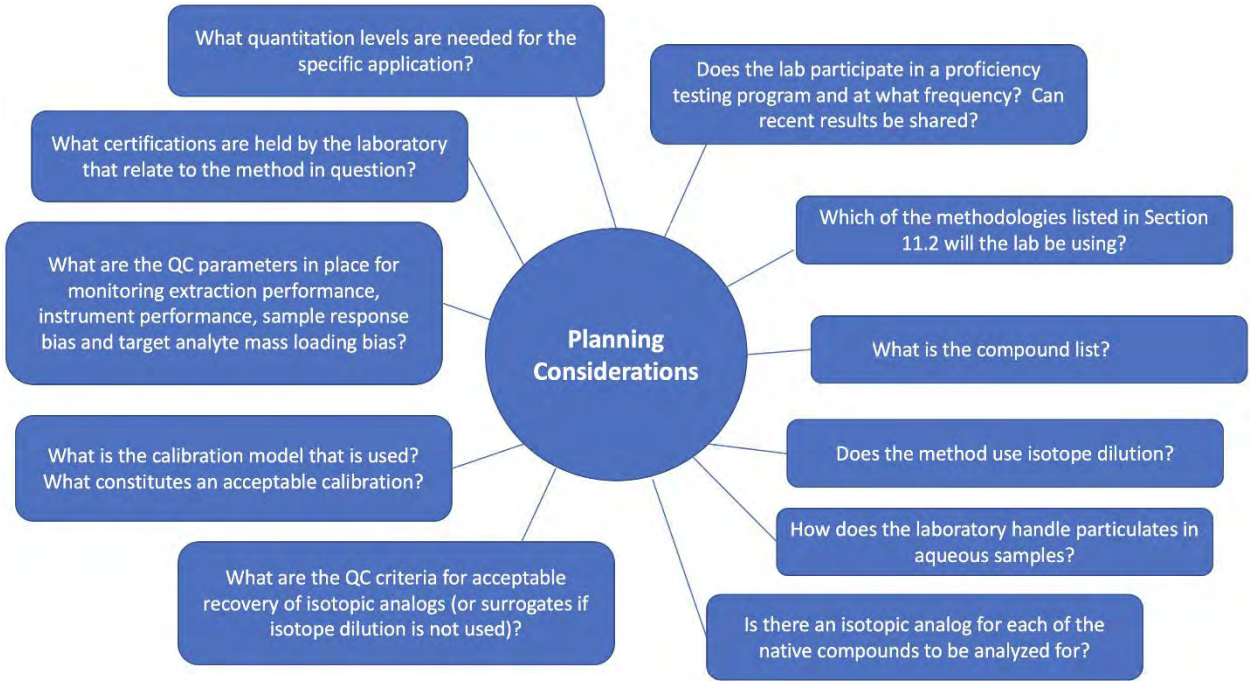

Figure 11-2. Laboratory planning considerations for data usability.

Source: Modified from figure by H. Albertus-Benham, Wood Environment & Infrastructure. Used with permission.

Throughout the rest of Section 11.3, pre-sampling planning will be indicated by these yellow call-outs.

The most important goal of data usability is to ensure that the PFAS data generated are usable to meet the stated data needs and that the user understands any limitations in the use of the data due to potential uncertainty or bias. Overall usability of data is judged by evaluating the quality of the results compared to the data quality objectives (DQO) of the project. Therefore, establishing these project DQOs and communicating them to the field sampling team and the laboratory prior to sample collection and sample analysis is vital to ensuring that the correct methods, correct compounds, and adequate sensitivity are reported for your samples.

11.3.2 Overall Usability of the Data

Three questions are most important in evaluating data: (1) Have the results exceeded a level of concern?, (2) Do these results make sense?, and (3) Are data of acceptable quality? To judge whether results have exceeded a level of concern, the potential bias or uncertainty in the data should be evaluated along with the sensitivity of the results. At a minimum, it is recommended that a report from the laboratory contains a cover letter (or narrative) explaining sample receipt, analytical methods, and any QC deviations plus data sheets for field samples and QC samples (method blanks, laboratory control samples, sample duplicates, matrix spikes), which should also contain results for sample-specific QC (such as internal standard recoveries). Often the most critical data for a project are the non-detects to prove the absence of compounds of concern at specific concentration levels (quantitation limits). Therefore, before evaluating QC associated with your samples, the data should be evaluated to ensure that all compounds required are reported with quantitation limits at or below the project's required sensitivity objective. If this sensitivity is not acceptable, then the data may be of very limited use.

If the reported compound list and quantitation limits are acceptable, then the associated QC results (for example, EIS recoveries, results of blanks, laboratory control sample recoveries, etc.) can be compared to

project DQOs to evaluate potential uncertainty in the data. The formal systematic process of this QC evaluation is called data review or validation. The approach to data validation is well documented; for example, see the USEPA National Functional Guidelines (**USEPA 2020**, **USEPA 2020**), and beyond the scope of this document; however, evaluation of all of the QC associated with the sampling and analysis of a set of samples will lead to an understanding of the uncertainty in the data.

Some critical QC issues might result in unusable data or concern for project actions. For example, if the data are considered biased low based on low QC results and the sample concentrations are at or near the level of concern or an action level, it may be that the true sample concentration exceeded the action level. Conversely, if the sample data are considered biased high based on high QC results and the sample concentrations are near but below the levels of concern or action level, then there is added certainty that the data do not exceed the action levels.

Once the data have been adequately reviewed for accuracy to determine if there are limitations to their use or uncertainties to be considered during use, the results should be evaluated by answering the following questions:

- Do field duplicates, if performed, indicate acceptable precision for the sampling and analysis?
- Do the data from the current sampling event compare well with historical data?
- Do the data make sense from a spatial and temporal point of view?
- Do the data make sense from a spatial point of view from one sampling point to the next across the project area?

Evaluating results may lead to overall project changes such as a need to increase sampling density to improve data representativeness, correction of procedures for collecting samples to minimize contamination, changes in methods of analysis to achieve project sensitivity requirements, etc.

This type of review can point out data trends or areas of concern (for example, interferences with project analytes) that could not be elucidated by looking at a single data point and may lead to overall project changes, such as a need to increase sampling density to improve data representativeness, correction of procedures for collecting samples to minimize contamination, changes in methods of analysis to achieve project sensitivity requirements, etc. Following this review, the data user can determine whether the data set is complete and sufficient for project decisions and data uses or whether additional samples need to be collected and analyzed.

11.3.3 Sensitivity

A quantitation limit (QL), or Limit of Quantitation (LOQ) is the limit of accurate quantitation for a specific analyte in a specific sample after any adjustments have been made for sample amount, dilutions, or percent moisture. Typically, the QL or LOQ concentration is selected as the lowest nonzero standard in the calibration curve for each analyte. It considers the sample size, matrix effects, and any dilutions made during the analysis of that particular sample. Because of varying properties between samples, the QL can vary from sample to sample and analyte to analyte. The QL should represent the level at which reliable qualitative and quantitative information is routinely reported (Table 11-3, included in the **PFAS Analytical Methods** Excel File). When project-specified decision levels or action levels are near the QL, at least one QL check is recommended in all sample batches to demonstrate adequate quantitation at the lowest concentration.

Sensitivity is related to the QL in that sensitivity refers to the capability of a method or instrument to identify a given analyte at a given concentration and reliably quantitate the analyte at that concentration. If a specified analyte is not reported by a laboratory to be in a specified sample, it does not necessarily

mean that the chemical is not present; it is an indication that the concentration of the analyte may be below the method sensitivity.

Detected PFAS results between the method detection limit (MDL) and QL (that is, "J" values) can generally be reported if all qualitative identification criteria are achieved. Typical QLs for PFAS are as follows:

- common PFAS analytes in aqueous matrices: 1–16 ng/L (ppt)
- common PFAS analytes in solid matrices: 0.16–1.6 ng/g (ppb)

It is imperative that the QLs (and not the MDLs) for each method are evaluated versus the project screening criteria prior to submitting samples to the laboratory. The QLs should be below the project screening criteria to ensure achievement of project objectives.

Sometimes even though lower QLs were planned for, the laboratory may have to perform dilutions, which causes the QLs to be elevated. Ensure that the dilution performed by the laboratory was reasonable. If there are elevated concentrations of specific target analytes or interferences, then the dilution is likely justified and the presence of elevated QLs may not be an issue if these other target analytes are present at very high levels.

If a dilution was performed and it is not obvious why (for example, low concentrations or nondetect results for target analytes), then inquire with the laboratory why the dilution was performed. This could happen due to elevated concentrations of non-target compounds but should be documented.

The QLs can also be affected by the sample preparation parameters, the mass of solid sample or volume of aqueous sample used in the extraction, or the final volume of the extracts. If a complex matrix is encountered, the sample sizes may be reduced and/or the extract volumes may be increased, causing the QL to be elevated accordingly.

11.3.4 Target Analyte Lists

The data user should work with the laboratory to ensure that the correct list is being reported, as dictated by the project objectives and regulatory compliance.

Target analyte lists for PFAS will vary by laboratory and regulatory program. The data user should work with the laboratory to ensure that the correct list is being reported, as dictated by the project objectives. In general, Table 11-4 (included in the **PFAS Analytical Methods** Excel File) includes the common PFAS reported by existing laboratories. The selected list may be dependent upon project objectives, regulatory requirements, as well as the potential source of PFAS contamination (for example, AFFF, landfill, chromium electroplating). Note that a published method may not include analytes important to characterization of a particular matrix, for example, diPAPs for biosolids characterization (**Dickman and Aga 2022**).

11.3.5 Linear and Branched Isomers

It is also important to note that PFOS and PFOA (and other PFAS as well) contain a mixture of linear and branched isomers, which can be significant when the laboratory is quantifying these chemicals. Very few standards are available for branched isomers; some standards are for qualitative evaluation and some are quantitative. If branched isomers are not included in the sample quantitation by the lab, the resulting concentrations will be underestimated.

In general, all laboratories should be reporting the sum of the linear and branched isomers for PFHxS, PFOS, PFOA, PFNA, PFOSA, NMeFOSE, NEtFOSE, NMeFOSA, NEtFOSA, NMeFOSAA, and NEtFOSAA because these are the PFAS for which both linear and branched analytical standards are available as of this publication. In the absence of a standard that includes branched isomers, only the peak associated with the linear isomer is integrated. As more analytical standards become available, more PFAS should be reported as linear and branched in the future.

Figure 11-3 shows an example of the integration performed correctly and incorrectly. It is the responsibility of the data user to ensure that the laboratory is performing the integration of the target PFAS to include both linear and branched isomers. This requires upfront communication with the laboratory and a possible independent review of the laboratory raw data by a qualified chemist/data user to verify the integrations were properly performed.

Ensure that the contracted laboratory is performing the integration of the target PFAS to include both linear and branched isomers.

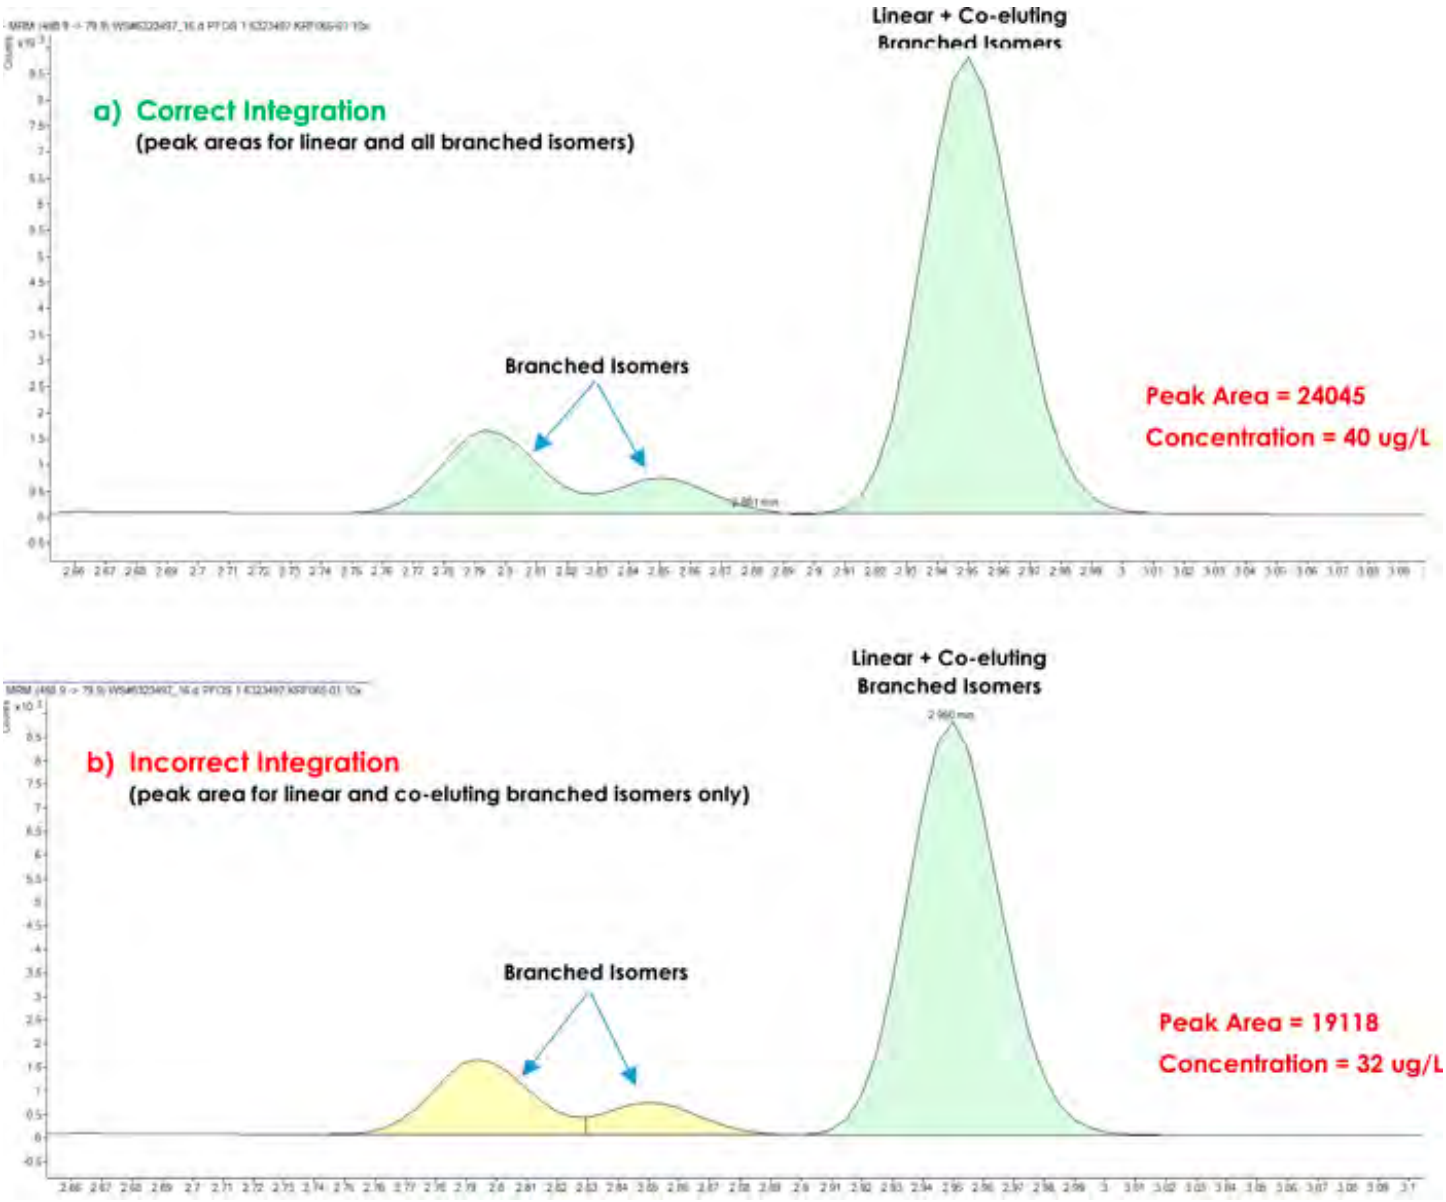

Figure 11-3. LC/MS/MS data illustrating a) complete integration of linear and branched PFOS, and b) partial integration of PFOS. Discrepancies in concentration will depend on the fraction of branched versus linear PFAS present, but in the current example PFOS concentrations in b) were 20% lower than in a).

11.3.6 Isotope Dilution Standard Results and Surrogates

Isotope Dilution Standards

The isotope dilution technique involves quantitation of a compound of interest using a labeled isotope of that very compound. A variety of isotopically labeled analogs (for example, carbon-13 analogs of the compounds of interest) are added to a sample prior to extraction or prior to analysis when extraction is not required. These isotopically labeled analogs are sometimes referred to as extracted internal standards, as defined in USEPA Method 1633A, or isotope dilution analogues, as defined in USEPA Method 533, and function from a data usability standpoint as both an internal standard (used in the calculation of the target compounds) and as a surrogate standard (calculation of the recovery of the standard). Ideally, the number of isotopically labeled analogs used in the isotope dilution technique matches the number of target compounds. Non-extracted internal standards, as defined by USEPA Method 1633A, or isotope performance standards, as defined by USEPA Method 533, are also added to the sample or extract immediately preceding analysis and are used to calculate recovery of the extracted internal standards.

For the isotope dilution methods, quantitation of the target compounds is performed relative to the response of the isotopically labeled analog, which should recover in a manner similar to how the nonlabeled compounds recover. Effectively, the sample data are recovery-corrected for losses that might have occurred during sample processing. The isotope dilution recovery correction procedure greatly improves the accuracy of the analysis and is an improvement over other techniques for the analysis of complex samples for analytes requiring high sensitivity. Chemical standards manufacturers are working to make a wider variety of labeled isotope compounds available to further improve accuracy of the methods for all compounds under investigation (for example, fluorotelomers, precursors, various isomers of carboxylates and sulfonates).

Acceptance criteria or control limits for isotopically labeled analog recoveries are either developed by the laboratory or dictated by the requirements of the project (for example, work plan or QAPP-specified criteria, regulatory criteria, or method criteria). Poor recovery of EIS in complex matrices is common; however, if a project requires ongoing analysis of a problematic matrix, the laboratory should perform method development to improve recovery, if possible (for example, change in cleanup procedures, change in the transition ions monitored, etc.). If EIS recovery is very low (for example, < 10% recovery), nondetections associated with the EIS may be false negatives and may not be useable for project objectives. If EIS recovery is low but ≥10%, there may be an indeterminate bias for the affected PFAS. If EIS recovery is high, there will be no effect on non-detects, but positive results for PFAS may have an indeterminate bias.

In the case where an isotope dilution extract is analyzed and requires re-analysis at a high dilution, the sample extract may need to be refortified with labeled isotope compounds or, if possible, a smaller aliquot of sample may need to be extracted to obtain adequate responses of EISs. In reporting the final data, the isotope recovery results from the initial analysis should not be used to adjust the data from the secondary dilution analysis because these recoveries may be affected by ion suppression or ion enhancement due to the elevated concentrations of target PFAS and therefore may not be reflective of the extraction efficiency or other matrix interferences. The result from this scenario is no longer quantitated from an isotope dilution but is calculated from an internal standard calculation and should be noted as such in the case narrative.

Surrogates in Non-Isotope Dilution Procedures

Method 537.1 uses four surrogates for 18 target compounds, while EPA Method 8327 uses 19 surrogates for 24 target compounds. Injection internal standards are also added to the sample extract immediately preceding analysis. Quantitation of the target compounds and surrogates is performed relative to these

injection internal standards. The results from the non-isotope dilution technique report concentrations of the target compounds and recovery results for surrogates, and it is up to the data user to determine the impact (that is, bias) of the extraction and analysis on the sample results because results are not recovery-corrected.

Acceptance criteria or control limits for surrogate recoveries are either developed by the laboratory or dictated by the requirements of the project (for example, work plan or QAPP-specified criteria, regulatory criteria, or method criteria). Poor recovery of surrogates in complex matrices is common; however, if a project requires ongoing analysis of a problematic matrix, the laboratory should perform method development to improve recovery, if possible (for example, change in cleanup procedures, change in the transition ions monitored, etc.). If the recovery for a surrogate is below criteria, compounds associated with this surrogate may be biased low. If surrogate recovery is very low (for example, < 10% recovery), nondetections associated with the surrogate may be false negatives and may not be useable for project objectives. If surrogate recovery is high, there will be no effect on non-detects but positive results for PFAS may be biased high.

11.3.7 Blank Contamination

As a consequence of the extensive use of PFAS, samples that may not contain PFAS can become contaminated if they come into contact with samples or materials containing PFAS. The types of blanks commonly used to evaluate contamination are field-based blanks and lab-based blanks. Field-based blanks include field reagent blank (field blank), source water blank, and equipment rinse blank. Laboratory-based blanks include method blank, lab reagent blank, and instrument blank. Reagent, source, field, and method blanks are prepared and analyzed using the same procedures as for the field samples. Instrument blanks are analyzed periodically to verify the instrument is clean for analysis of subsequent samples.

The possible sources of contamination that may occur during field collection activities and sample preparation and analysis and the recommended procedures to minimize contamination have been previously addressed in Section 11.1.

The lab reagent blank is used to evaluate the potential PFAS contamination from the reagent water source used to generate the field-based and laboratory-based blanks. A systematic review of all of the blank results compared to the associated field sample results (the group of samples associated with the field-based and lab-based blanks, or the analytical batch of samples associated with a specific method blank) must be made to determine whether the field sample results are accurate. For example, if the reagent water source used in the field is nondetect for PFAS, but contamination is found in any of the other field-based blanks, this indicates potential contamination of the associated field samples from the sample bottle itself and/or during collection, handling, or transport to the laboratory. However, if a laboratory-based blank is also contaminated, the contamination observed in the field-based blanks may have been due to sample handling at the laboratory.

If the conclusion of this systematic blank data review is that an associated sample result may have been contaminated, then the sample result is considered to be biased high or may be a false positive, depending on the magnitude of the blank contamination compared to the field sample result. A general rule of thumb is that if a sample contains a contaminant within 5x–10x the concentration in the associated blank, the results may be biased high or result in a false positive in the sample (**USDOD 2019**).

11.3.8 Duplicate Results

Laboratory replicates are two separate aliquots of the same sample prepared at the laboratory and put through the entire sample preparation and analytical procedures. Field duplicates are two separate samples collected at the same location at the same date and time that are prepared and analyzed in the same manner. Laboratory replicates may be performed in lieu of an LCS duplicate or MSD. It should be noted that sometimes laboratories report the results of laboratory replicates performed on samples that

are from a different project (that is, batch QC); if the laboratory replicates reported are not from a sample at the site of interest, then these results should not be used in the evaluation of sample data.

During data evaluation, the relative percent difference of each detected analyte versus the acceptance limits should be reviewed. The acceptance limits should be provided within the laboratory report and are either regulatory- or method-specific. When both results are < 2x the QL, the potential uncertainty increases, and therefore, the acceptance criteria may need to be adjusted.

Review regulatory or method-specific acceptance limits with the laboratory, whether from a QAPP or laboratory-generated.

- If both results are < 2x the QL, relative percent difference criteria can be doubled.
- If one result is detected and one result is not detected, then the evaluation will depend on whether the detected result is > 2x the QL or not. If one result is > 2x the QL and the other result is nondetect, then the variability is considered unacceptable and there may be potential uncertainty in the results for this sample.

Variability in laboratory replicate and field duplicate analyses could be from the sampling process, such as inefficient homogenization procedure in the field. It could also be from the laboratory aliquoting process, or it could be due to heterogeneity in the sample matrix. The effect on project objectives will depend on the screening criteria and how far above or below these criteria the results are. If the results are close to the criteria with significant variability, this may require collection of more samples to better represent the location. If results are significantly above or below the screening criteria with high variability, it may not adversely affect the ultimate decision-making process.

11.3.9 Acid Versus Anion Form of PFAAs

The data user should be aware of the form of PFAS the laboratory is reporting when comparing to project screening criteria. PFAS are typically formulated as acids, but they are present in the environment and in humans in the anionic form. The differences in names used are the result of the different names for the acid form and the **anion** form of the chemical (see also **Section 2.2.3.1**). For example, when perfluorobutanoic acid (PFBA) disassociates and loses its hydrogen in water, it becomes the anionic form (perfluorobutanoate). This becomes more important when looking at physical and chemical properties of these chemicals, because whether they exist as an acid, an anion, or a salt will affect how they behave in the environment. Typically, laboratories are reporting the acid form of the perfluorocarboxylic acids and perfluorosulfonic acids.

Some target PFAS, such as PFHxS and PFOS, are not available as acids, but rather as their corresponding salts (for example, K^+, Na^+, and Li^+). These salts are acceptable starting materials for the stock standards, provided the measured mass is corrected for the salt content according to the equation below. Note that this correction will result in a minimal change to the mass of the acid but still should be performed for consistency and comparability with other results to ensure the data user that the correct form of PFAS is represented in the final concentration.

$$mass_{acid} = \text{measured } mass_{salt} * (MW_{acid}/MW_{salt})$$

MW_{acid} = molecular weight of PFAA

MW_{salt} = molecular weight of purchased salt

CAS numbers will change depending on if the acid, anion, or salt form of the PFAS is reported (**Table 11-7**).

Table 11-2. Example of CAS number differences between acid and anion.

Chemical	CAS number
PFOA: Perfluorooctanoate (anion)	45285-51-6
PFOA: Perfluorooctanoic acid (acid)	335-67-1

11.4 Source Identification

As discussed in **Section 10.5** and **Section 1.3.7**, one area of focus for PFAS investigations has been environmental forensics, specifically source identification. With so many industrial processes and transport pathways from which PFAS contamination can originate, attributing the occurrence of one or more PFAS to a particular source is of growing interest.

Source identification relies on the compilation of multiple lines of evidence from analytical data and site information, and the use of uni- and multivariate statistical analyses. Analytical lines of evidence include:

- Extended Target Lists
- Linear/Branched Speciation
- Non-Targeted Analysis (NTA)

These methods are briefly described in this section.

11.4.1 Extended Target Lists

Many commercial laboratories now analyze for more than 40 individual PFAS and some of these compounds may be indicative of a particular product or industrial process. Analyzing samples taken from or near these possible sources and comparing the profiles of those results to the area of concern, also known as chemical fingerprinting, may provide a demonstration of comparability.

11.4.2 Linear/Branched Speciation

The separate reporting of branched and linear PFAS can provide some indication of the process used to synthesize the PFAS detected. Electrochemical fluorination (ECF) produces a larger number of branched isomers than fluorotelomerization, which may be useful in differentiating sources (**Benskin, DeSilva, and Martin 2010**). Separate reporting of branched and linear PFAS is not typically the default laboratory reporting and should be requested in advance. However, due to isomer-specific differences in instrument response, and fate, transport and organism uptake/depuration, the use of speciated data for any inference more than presence/absence of a manufacturing source type is challenging.

11.4.3 Non Targeted Analysis (NTA)

The ability to identify compounds not targeted for measurement by existing methods is an important need. NTAs are critical to being able to identify these compounds. With NTAs, chromatography (liquid and gas) is combined with high resolution mass spectrometry and multiple ionization techniques to determine atomic molecular weight and associated fragments. These results can be compared to databases for tentative identification (**Liu et al. 2019**). Further spectral interpretation may result in structural identification. This is particularly useful where no chemical standards exist.

NTA includes high-resolution mass spectrometry and suspect screening and is discussed in more detail below.

11.4.3.1 High-Resolution Mass Spectrometry for Nontargeted Analysis

Although not widely commercially available, recent source research has focused on the use of high-resolution mass spectrometry (HRMS) for more comprehensive qualitative determination and fingerprinting for source attribution. See additional information in **Section 11.2.2.5**.

Many PFAS exist with no certified reference standard to make an initial calibration plot. As such, non-targeted PFAS may be present in samples that will not be identified or reported on a standard target analyte list, unless requested. HRMS is emerging as a means for discovery and reporting of non-targeted PFAS where each unknown peak may be tentatively identified and quantified at estimated concentrations. Non-targeted analytes can be reported by the identification of fragmented organic molecular ions (m/z) that are matched to an analytical reference library. The reporting includes detection of homologous series with or without the presence of nonfluorinated functional groups that create mass defects. Mass defect is the difference between the nominal and exact mass of an atom, which allows prediction of molecular formulas and is the key advantage to using HRMS for NTA. **Liu et al. (2019)** categorized PFAS into the main classes of:

- Per/polyfluoroalkyl carboxylic acids
- Per/polyfluoroalkyl sulfonic acids
- Fluorotelomers and per/polyfluoroalkyl sulfonamides
- Per/polyfluoroalkyl phosphates
- Per/polyfluoroalkyl alcohols
- Per/poly-fluoroalkylamides
- Per/polyfluoroalkyl sulfates
- N-per/polyfluoroalkyls

Tables are available on the NORMAN Suspect List Exchange (**https://www.norman-network.com/?q=node/236**). **Charbonnet et al. (2022)** defined the basic homologue series by CnF2n+1, where n > 2 with isomeric PFAS of the same chemical formula differentiated as structural isomers that may be linear, branched in the perfluoroalkyl tail or the head group, or have varying functional groups that could create mass defect.

As evidenced by SERDP-ESTCP funded projects listed below, the development of mass spectral libraries to match non-targeted analytes to source profiles is part of ongoing research. NTA uses HRMS such as time-of-flight (TOF), ion-trap, or Fourier transform ion cyclotron resonance (FT-ICR) to generate high resolution accurate mass data. As extensive data sets are generated using HRMS, informed data filtering approaches are used to filter the data specific to PFAS related analytes. The data are first screened against previously generated suspect screening libraries that contain chromatographic/spectrometric information for PFAS characteristic to sources such as AFFF formulation, industrial process, and/or manufactured products. Then, mass spectrometry-specific data analyses, such as Kendrick mass defect plots, and general uni- and multivariate statistical analyses, are used to attempt source identification based on the presence/relative abundance of PFAS identified against the suspect screening libraries and other information (**Benotti et al. 2020**; **Charbonnet et al. 2021**).

The Interstate Technology and Regulatory Council (ITRC) Contaminants of Emerging Concern (CEC) Team fact sheet on Adoption of Analytical Methods for Identifying CEC provides additional details on non-targeted analyses, including mass spectral libraries used and determining the confidence in compound identifications (**ITRC 2023**).

12 TREATMENT TECHNOLOGIES

Treatment technologies for PFAS in environmental media are still evolving and it is prudent to use caution in implementing long-term remedies. Selection of remedial actions should prioritize protection of drinking water sources and human health, with consideration of other objectives (such as reducing risk to ecological receptors and environmental resources, liability, source area mass, mass flux, generation of PFAAs from precursors). At some sites, it might be reasonable to take short-term site actions that address impacted or threatened receptors with the intent of applying more robust and cost-effective technologies as these are developed.

15.2	**Treatment Case Studies**

The treatment technologies described in this section are organized into three categories by degree of development and implementation: field-implemented technologies, limited application technologies, and developing technologies. The criteria for each category are further described below.

In the sections below there are boxes with lists of SERDP, ESTCP, and/or Water Research Foundation (WRF), projects for PFAS Treatment Technologies. Due to the volume of information, these boxes are no longer being updated. Current links and information about SERDP/ESTCP projects for PFAS Treatment Technologies can be found at **https://serdp-estcp.mil/** and Water Research Foundation projects at **https://www.waterrf.org/**.

12.1 Overview

Treatment technologies exploit a contaminant's chemical and physical properties to immobilize, separate and concentrate, or destroy the contaminant. The physical and chemical properties of PFAS make many treatment technologies ineffective, including those that rely on contaminant volatilization (for example, air stripping, soil vapor extraction) or bioremediation (for example, biosparging, biostimulation, bioaugmentation). Even technologies such as thermal treatment and chemical oxidation may not be completely effective at treating PFAS, and multiple treatment technologies may be needed for each treatment scenario to address the mixture of different PFAS that may be present.

Treatment technologies can be employed either ex situ or in situ. For example, when groundwater is extracted via pumping from wells and treated, this would be considered an ex situ approach. In contrast, when treatment materials are injected into the subsurface to separate, destroy, or immobilize contaminants in groundwater under the surface, this would be considered an in situ approach. Many existing treatment technologies have generally been shown to be inadequate; therefore, the unique chemical properties of PFAS often require new technologies or innovative combinations of existing technologies.

A range of technologies exists for treatment of either liquids or solids that may be performed either in situ or ex situ. However, field-implemented technologies for treating PFAS in liquids are mostly limited to ex situ technologies.

Field-implemented full-scale treatment of PFAS-impacted liquids or solids is limited to sequestration technologies that remove or bind PFAS but do not destroy them. Sorption using granular activated carbon (GAC) and ion exchange (IX) media has been proven effective at full scale (see **Table 12-1 Treatment Methods Table** Excel File). Destruction and mineralization technologies, including bioremediation, chemical oxidation, chemical reduction, and thermal technologies, are being tested. This section discusses treatment technologies for liquids (waters, leachates, or other liquid wastes) and solids (soil, sediment, or other solid wastes).

The treatment technologies described in this section are organized by the degree of development and implementation documented in practice or in peer-reviewed literature, regulatory acceptance, and a consensus process. A consensus for the ranking of each technology is determined by the best professional judgment of members of the ITRC PFAS team after evaluating the current information and considering input from other external parties during regular reviews of the document. The three levels used in this discussion are field-implemented technologies, limited application technologies, and developing technologies.

Although categorized in this way for this document, the state of development and application of treatment technologies is a continuum that is ever-changing and evolving quickly. Technologies may progress through these categories between revisions of this guidance document. Most important is that by categorizing, ITRC neither endorses nor repudiates any technology or its proponents regardless of its state of development. Each technology should be evaluated independently to determine the applicability of the technology for the site conditions and desired treatment objectives. The three categories are:

1) **Field-implemented technologies** –Technologies that have been demonstrated at multiple sites, under diverse conditions, by multiple practitioners, are commercially available, and are well documented in practice or peer-reviewed literature. Field-implemented technologies have been demonstrated to meet site-specific PFAS treatment objectives, at the intended final application scale, and are widely accepted in the regulatory and scientific community.

2) **Limited-application technologies** –Technologies that have been implemented on a limited number of sites, by a limited number of practitioners, either at full-scale or field pilot-scale. For this document, full-scale is defined as operation of a fully capable system, intended to entirely address the appropriate aspects of the remedial action objectives (RAOs) for the treated media, and which is not intended to be expanded or supplemented in the future to achieve those final project goals. Field pilot-scale refers to a demonstration project intended to prove the effectiveness of the treatment technology in the field, under site conditions. While these projects may not address the RAOs explicitly or completely, these demonstration projects typically involve continuous operation over months of activity, with robust analytical monitoring, and published results in the peer-reviewed literature. Limited application technologies are supported by a growing body of evidence that they are effective at treating PFAS, but differ from full-scale implemented solutions in that there may not yet be a large body of evidence or broad consensus in the scientific community, including peer-reviewed literature, that the technology meets the

criteria for a field-implemented technology. Limited-application technologies for liquids and solids are contained in the Table 12-1 Treatment Methods Table Excel File and discussed in Sections **12.6** and **12.7**.

3) **Developing technologies** –Technologies that have been researched at the laboratory or bench scale. Often, the results from developing technologies are reported by only one group (for example, one university, practitioner, or vendor) or lack detailed independent verification of the treatment effectiveness or mechanisms. Among a wide array of experimental technologies under development, only developing technologies that show promise and have some level of publicly available documentation demonstrating effectiveness are included in this guidance document.

The technology evaluations presented herein provide information on the effectiveness of each treatment technology. This information varies widely among technologies and the data provided are based on the reported test conditions and results. Ultimately, the feasibility of a technology to meet applicable regulatory guidance values and standards often depends on site-specific conditions.

As detailed in **Section 8.2.2.4**, in the United States, the regulatory standards for PFAS treatment are primarily driven by drinking water mitigation and focused on a small subset of PFAS. PFOS, PFOA, PFBS, and HFPO-DA are the only compounds with federal health advisories (**USEPA 2022**), and most regulatory discharge criteria for PFAS focus on these compounds. USEPA published a final rule in April 2024 that includes National Primary Drinking Water Regulations (NPDWRs) for six PFAS containing MCL and MCLG values (**USEPA 2024**). Some states have guidelines, and several have regulatory criteria for additional PFAS not contemplated in USEPA's April 2024 final rule. The technology evaluation information presented here provides data about PFAS tested for a given technology. This information varies widely among technologies. Additional information on regulations is provided in **Section 8** and the PFAS Regulatory Programs Summary Excel File.

12.1.1 Factors Affecting Technology Selection

Selection of a remedy, with confidence that treatment targets can be achieved, depends on several key factors, including the ability to reliably define the nature and extent of contamination, the availability of proven treatment technologies, and the capacity and tools to measure progress and compliance with desired regulatory criteria. A well-prepared conceptual site model (CSM) requires adequate information and is also fundamental to understanding and presenting the rationale and justification for the selected remedy. Additional information on CSMs is provided in **Section 2.6**, **Section 9**, and **Section 10**.

Moreover, proven treatment technologies are limited in capacity and demonstrated ability to meet chosen treatment targets. The comprehensive discussions contained herein reveal many questions and uncertainties that must be addressed.

As an example, factors affecting PFAS remedy selection can include:

- **characteristics of PFAS.** The wide-ranging chemical and physical characteristics of PFAS affect the treatment effectiveness. Key factors include recalcitrance with respect to common technologies due to the strength of the carbon-fluorine bond, ionic state (anionic, cationic, and zwitterionic), types of ionic groups (sulfonate or carboxylate), lipo- and hydrophobicity, chain length and branching, partitioning coefficients, phase behavior, volatility, solubility, acidity, total PFAS mass, and total concentration.

- **changes in PFAS properties**. Naturally occurring processes or remedial actions for other (commingled) contaminants, such as chlorinated solvents and petroleum hydrocarbons, can affect PFAS distribution and mobility in groundwater (**McGuire et al. 2014**). Example changes include:

  - The alkyl functional group of some PFAA precursors may be more readily subject to chemical or biological transformation than the fully fluorinated aliphatic chain (PFAAs).
  - Partial degradation of the carbon-carbon bonds in the aliphatic chain reported for some chemical remedies generates short-chain PFAS, which may be more mobile (**Guelfo and Higgins 2013**).
  - Modifications in aquifer properties (for example, redox or pH) during remediation of commingled contaminants results in a conversion of some precursors to the more stable and mobile PFCAs (**McKenzie et al. 2015**; **McKenzie et al. 2016**).

- **co-contaminants, organic matter, and geochemistry.** The presence of co-contaminants, total organic carbon, natural organic matter, minerals, and anions can significantly affect remediation. Some technologies that are designed and implemented to treat PFAS co-contaminants may transform perfluoroalkyl acid (PFAA) precursors into more stable perfluorocarboxylic acids (PFCAs) (**McKenzie et al. 2015**).

- **community acceptance.** Stakeholders, including community members, are often faced with trade-offs in terms of cost, level of cleanup, and residual contamination as part of remediation efforts.

An additional element of technology selection relates to the optimal conditions under which a specific technology should be considered, as documented in the literature. Not all technologies have been demonstrated as suitable or effective under multiple treatment circumstances. For example, although sorption technologies, such as granular activated carbon or ion exchange media, have been documented in the literature as being both technically effective and generally cost-effective in treating high volume, low concentration liquids, such as drinking water, they are less well suited for low volume, high concentration liquids such as thermal system condensate, ion exchange regeneration fluids, fractionated (for example, reconstituted) foam, or landfill leachate. Conversely, several destructive technologies, such as electrochemical oxidation, nonthermal plasma, hydrothermal alkaline treatment, and supercritical water oxidation, have been shown to be effective for treatment of high concentration, low volume liquids, but may be less suitable for high volume, low concentration liquids. See **Section 12.1.4** for considerations for specific environmental media.

For those directly engaged in assessing the suitability of PFAS treatment technologies, a structured process for systematic evaluation is currently under development via a Strategic Environmental Research and Development (SERDP)-funded project (ER18-1633). The project focuses on five lines of evidence to evaluate technology performance and will provide resources to identify relevant information and data gaps and address key questions necessary for that assessment. Additional information is provided in **Section 12.9**.

12.1.2 Tiered Remedial Approach

Along with the factors affecting technology selection (**Section 12.1.1**), practitioners should also consider the use of a tiered remedial approach to mitigate the risks posed by PFAS. This may include prioritizing protection of known human receptors from exposure to drinking water contaminated by PFAS by using point of entry (POE) or point of use (POU) treatment systems or connecting residents to public water supplies. Reducing the potential risk to human and/or ecological receptors may require upgrades to wastewater treatment plants; however, large-scale retrofits of wastewater treatment plants for PFAS have not been widely enacted at this time. Once these actions are taken to control risk and exposure, the source(s) of the PFAS contamination can be addressed using the appropriate remedial technology. Cutting off sources and controlling ongoing contaminant flux will influence whether PFAS plumes becoming stable or shrink. Once sources and pathways to receptors are controlled, addressing the pathways of contaminant migration (for example, groundwater plumes, stormwater drainage networks,

surface water) becomes the final aspect of the tiered approach. A similar approach for site characterization is described in **Section 10.2**.

12.1.3 Section Organization

The information presented in the following sections reflects the availability of performance results published, presented, or otherwise publicly available. **Section 1.6.6** includes updated technology review papers.

Those technologies that have been implemented in the field at multiple sites, by multiple parties, and have peer-reviewed or practical documentation of performance are discussed in **Section 12.2** and **Section 12.3**. Projects funded by SERDP and the Water Research Foundation (WRF) are also highlighted. This section discusses the following key elements for each of these field-implemented technologies:

- *treatment description*–background and development of technology
- *treatment mechanism*–separation, sorption, or destruction
- *state of development*–applications and degree of commercial availability
- *effectiveness*–documented treatment effectiveness on PFAS and common co-contaminants along with water quality considerations and pretreatment need and options
- *design/operating considerations* –critical or unique operational or design needs
- *sustainability*–footprint, community enhancement, and cost.

Treatment case studies are presented in **Section 15.2**.

12.1.4 Considerations for Specific Environmental Media

The Priority Topics for Treatment Technologies include considerations for management of PFAS-impacted investigation-derived waste (see **Section 1.6.3**). **Section 1.6.6** includes updated technology review papers.

12.1.4.1 Drinking Water

Public-serving system components are often required to be certified through NSF 61 (**https://www.nsf.org**), which certifies that they are acceptable for potable water use. Treatment for PFAS in these systems typically uses adsorbents such as GAC (**Section 12.2.1.1**), IX (**Section 12.2.1.2**), or RO (**Section 12.2.2**). **Section 18** provides guidance for sorption-based technologies for separation and concentration of PFAS from water.

Remedial actions for PFAS-impacted drinking water from private wells and other nondistributed sources can include providing alternative drinking water supplies, such as bottled water, new nonimpacted source wells or surface water, point of entry (POE) treatment (also referred to as POET), and point of use (POU) treatment. POE treats water as it enters a home or building (for example, immediately after a pressure tank for a private well system) and POU treats water at one or more specific locations (for example, at a kitchen faucet where water is typically directly ingested or used for cooking). POE systems provide "whole supply" treatment while POU provides selected usage point treatment.

NSF International has incorporated PFOA and PFOS into two standards – NSF/ANSI 53 for adsorption systems and NSF/ANSI 58 for reverse osmosis systems – to verify the ability of a water treatment device to reduce PFOA and PFOS to achieve the USEPA health advisory levels of 70 ng/L (**NSF 2021**; **NSF 2019**). This method does not evaluate the removal of other PFAS that also may adversely impact water supplies. Systems with this certification are mainly small-scale POU systems such as sink faucet filters, refrigerator water filters, and pour-through filters. It should be recognized that although this certification exists, it is not required. This means that other POU systems as well as POE systems (larger wellhead or large public-serving systems) may not be certified under NSF/ANSI 53 or NSF/ANSI 58 but may be acceptable treatment of PFOA and PFOS.

12.1.4.2 Landfill Leachate

Currently, a majority of landfill leachate is treated for conventional constituents by directly discharging or hauling the leachate to publicly owned treatment works (POTWs). POTWs have been designed to remove these conventional constituents (for example, organics and nutrients), but these treatment systems are not effective at removing PFAS. A relatively small percentage of landfills perform pretreatment to address conventional parameters (for example, BOD, COD, TSS, ammonia-N) prior to discharging to POTWs or perform leachate treatment on-site and discharge the treated effluent under National Pollutant Discharge Elimination System (NPDES) permits. There are currently very few landfills that treat or pretreat leachate specifically to remove PFAS, but this may change as national and state surface water and/or pretreatment regulations are developed.

Wei, Xu, and Zhao (2019) presented a comprehensive review of the state of the science on PFAS treatment technologies for landfill leachate. They noted that various technologies have been widely tested for treating PFAS in drinking water or groundwater, but knowledge is limited on the treatability of PFAS in landfill leachate and the effects of the complex leachate matrix. Leachate contains many competing organic and inorganic constituents, and this complex matrix creates significant challenges when choosing a treatment technology for PFAS removal. Oftentimes, pretreatment of the leachate may be required before applying common PFAS sorption technologies such as GAC or ion exchange resins. If pretreatment is not performed to remove these competing compounds, the sorptive treatment media will foul quickly, which may result in operationally complex and/or expensive systems to treat landfill leachate for PFAS using these traditional technologies. Additional information on integrated remedial solutions is presented in **Section 12.8**.

Destructive technologies such as plasma, advanced oxidation, reduction, photochemical processes, and sonolysis are largely unproven at present on landfill leachate, and their effectiveness is expected to be reduced when used for treating leachate due to the severe water matrix effect **(Wei, Xu, and Zhao 2019**). In addition, these technologies have typically not been as effective when scaled up from laboratory studies to the field. Supercritical water oxidation (SCWO) destruction of landfill leachate containing PFAS has been demonstrated but is not well documented in peer-reviewed literature. More information about SCWO is included in **Section 12.6.3.12**.

Filtration systems such as RO have been proven effective as a separation technology for leachate for a wide range of constituents, including PFAS, but can generate a significant fraction of concentrated residuals that requires management by other disposal/treatment technologies. Foam fractionation shows promise in recent studies for selectively separating large percentages of PFAS from leachate (particularly the longer chain PFAS) while generating manageable fractions of high concentration residuals at a much smaller volume relative to RO reject (**Burns et al. 2022**; **McCleaf, Kjellren, and Ahrens 2021**; **Robey et al. 2020**; **Smith et al. 2022**).

Overall, further research is needed to develop and demonstrate cost-effective treatments for landfill leachate PFAS removal that are effective at field scale.

12.1.4.3 Biosolids

The Priority Topics for Treatment Technologies include information on treatment of PFAS-contaminated sewage sludge and biosolids (see **Section 1.6.5**). The Priority Topics for Biosolids Land Application include information about PFAS in biosolids (see **Section 1.7**).

Biosolids generated by wastewater treatment plants have been historically managed through land application, use or disposal at landfills, or incineration. The regulatory landscape for management of biosolids is evolving, and some states have started to require testing, prohibit land application if concentrations of certain PFAS are greater than specific levels, or have implemented bans on land application. Current regulations and guidance are discussed in **Section 8** and in the **PFAS Regulatory Programs Summary** Excel File.

The fate of PFAS in various thermal treatment processes (for example, incineration, pyrolysis) is an active area of research to better understand the potential formation of byproducts or products of incomplete combustion (**USEPA 2024**) and is covered in more detail in **Section 12.4**.

Additional information on biosolids is presented in the ITRC factsheet for Biosolids and Per- and Polyfluoroalkyl Substances (PFAS) (**/fact-sheets/**) and **Section 2.6.4**.

12.2 Field-Implemented Liquids Treatment Technologies

These technologies have been implemented in the field by multiple parties at multiple sites and the results have been well-documented in practice or peer-reviewed literature. The liquid treatment technologies in this section may be applied to a variety of PFAS-impacted media, including drinking water (regardless of source), surface water, groundwater, wastewater, stormwater, or landfill leachate. Not all technologies would be appropriate for all applications. Site-specific evaluation is necessary to identify the best technology alternative for a given liquid, system size, treatment goal, and residual media management scenario.

12.2.1 Sorption Technologies

Section 18 provides guidance for sorption-based technologies for separation and concentration of PFAS from water.

Sorption technologies have been used for both ex situ and in situ water treatment applications. Multiple sorption media types may be used in series for ex situ applications to optimize overall concentration reduction and removal capacity. Adsorption and ion exchange (IX) are two “sorption” mechanisms by which PFAS can be removed from water. Adsorption is a physical mass transfer process that uses Van der Waals and/or other weak ionic forces to bind the entire PFAS molecule to the surface areas of the adsorptive media. Ion exchange is the exchange of ions of the same charge. Ion exchange targets and binds to the hydrophilic ionized or functional end of the molecule (for example, the sulfonate in PFOS) while releasing an equivalent amount of an innocuous ion (for example, chloride) into the treated water. This technology is generally considered more applicable to high volume, low concentration liquids than low volume, high concentration liquids.

Several influent water parameters can therefore be expected to impact the sorption efficiency for a specific PFAS. These include pH, ionic strength, the nature and concentrations of organic co-contaminants present (including naturally occurring organic matter [NOM]), competing inorganic ions normally present (for example, sulfate, nitrate, bicarbonate, and chloride), and any suspended solids, potentially precipitating impurities (for example, iron, manganese, calcium carbonate), or biological growth that can foul and degrade the performance of the media. Pretreatment steps may be necessary to

optimize the performance of such media, including coagulation, precipitation, filtration, pH adjustment, or oxidant removal. Ion exchange media used for PFAS removal from water use both the adsorption and ion exchange mechanisms. The use of two or more different media in series can be considered if the expected increase in overall removal efficiency can be used to justify the increased equipment cost.

Life cycle cost assessments can be used to compare the long-term cost-performance benefits of various sorption media types. Spent media management can be an important consideration when selecting a treatment technology. Common options for spent media management are off-site disposal by thermal destruction (via commercial incineration or cement kilns), reactivation/regeneration for reuse (which may require management of additional waste streams), and landfilling. Information on specific management considerations for spent media are discussed in the respective sections below.

Incineration and thermal reactivation/regeneration offer the possibility of destruction of PFAS waste streams, though incineration has received recent attention due to possible incomplete combustion and by-product generation and is the topic of current study to better understand the fate of PFAS. Incineration is discussed in **Section 12.4**.

12.2.1.1 Granular Activated Carbon (GAC)

Treatment Description: GAC is an effective sorbent media for organics that has historically been used to reduce contaminants in a variety of environmental media. The information contained in this section describes ex situ GAC treatment in which water is extracted and transferred from the source of contamination and directed through the treatment system.

Treatment Mechanism: Removal of PFAS by GAC is a physical mass transfer process (refer to **Section 12.2.1**) from the aqueous phase onto solid media that does not involve or trigger any form of chemical degradation or transformation.

State of Development: The application of GAC as a treatment technology for PFAS removal has been practiced for over 15 years at more than 45 military installations, as well as several industrial sites and publicly owned treatment works (**Forrester 2018**) involving private and municipal drinking water supplies.

Effectiveness: The following references were used to support the treatability effectiveness discussion presented below for PFAS by GAC: **Appleman et al. (2013)**; **Burdick et al. (2016)**; **Cummings (2015)**; **Dickenson (2016)**; **Ochoa-Herrera and Sierra-Alvarez (2008)**; **Szabo (2017)**; **Woodard, Berry, and Newman (2017)**; **Zeng et al. (2020)**. These references also include more comprehensive bibliographies if further details are needed on specific topics or studies. Literature and supporting column studies have shown that newly placed GAC can reduce effluent concentrations for PFAS listed in USEPA Method 537.1 (**Shoemaker and Tettenhorst 2018**) to below analytical detection limits until initial breakthrough begins to occur. Because GAC is generally used to treat many common groundwater contaminants, it is capable of also treating most organic co-contaminants that may be present, with the primary impact being increased GAC consumption due to greater loading per unit of time, which may require more frequent change-outs. Individual PFAS have different GAC loading capacities and corresponding breakthrough times (often defined as the number of bed volumes treated prior to detection in the effluent) (**Eschauzier et al. 2012**; **Zeng et al. 2020**). GAC removal capacity for PFOS is greater than PFOA, but both can be effectively removed (**McCleaf et al. 2017**). In general, shorter chain PFAS have lower GAC loading capacities and faster breakthrough times, but could be effectively treated if change-out frequency is increased. **Figure 12-1** provides an example of removal curves and breakthrough information for several PFAS performed at a specific influent concentration based on vendor-supplied column studies.

More studies are needed to confirm GAC treatment effectiveness for shorter chain PFAS or to identify complementary technologies/materials to supplement GAC removal capability. This may include studying the influence on sorption site competition from PFAS precursors that are often not quantified during the GAC system design. Recent accelerated column tests by vendors have shown the successful removal of a variety of PFAS, including the butyl (C4), pentyl (C5), and hexyl (C6) compounds (**Appleman et al. 2013**; **Dickenson 2016**; **Brewer 2017**; **Zeng et al. 2020**). Functional groups also impact the ability of GAC to adsorb PFAS. Compounds with sulfonate and sulfonamide groups are more readily adsorbed than those with carboxylates of the same chain length (**Appleman et al. 2013**; **Dickenson 2016**; **Zeng et al. 2020**). Studies in the developmental stage involve the use of other materials that can modify GAC surfaces to improve removal capabilities. Mixtures of powdered activated carbon, kaolinite, and amorphous hydroxide have been tested at the bench- and pilot-scale and have shown high removal rates for shorter chain PFAS in raw AFFF-impacted groundwater (**Chiang 2017**; **Kempisty, Xing, and Racz 2018**).

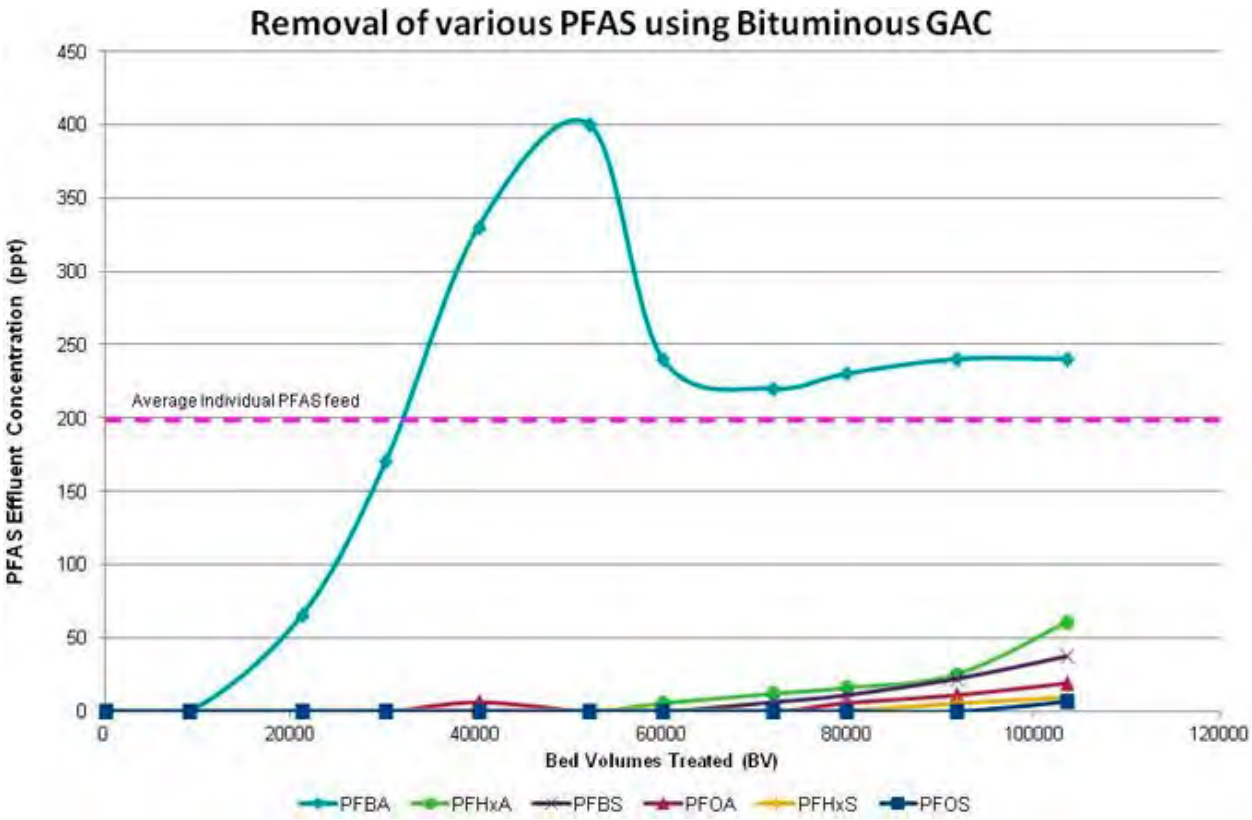

Figure 12-1. Example GAC removal curves at specific influent concentration (15-minute empty bed contact time).

Source: Used with permission from Calgon Carbon Corporation.

Most of the case studies on full-scale GAC-based systems used to treat PFAS in the literature are based on treatment of PFOA and PFOS in impacted drinking water sources. As such, limited information is available regarding the treatment of other PFAS, or PFAS in other source waters. The full-scale drinking water systems demonstrate that PFOA and PFOS can be removed to below analytical detection limits. More information is contained in the Table 12-1 Treatment Methods Table Excel File. Treatment of groundwater impacted with PFAS from an AFFF release area contaminated with PFAS such as fire training areas (FTAs) may require complex pretreatment and more frequent change-outs (higher influent concentrations compared to influent for drinking water treatment systems) and higher operation and maintenance (O&M) costs.

Design/Operating Considerations: Laboratory treatability tests (for example, rapid small-scale column testing (RSSCT) and accelerated column test (ACT)) are useful for evaluating treatability and determining initial design parameters. Larger scale pilot demonstrations are recommended to establish site-specific design parameters such as adsorption bed depth; GAC consumption rate to meet a given treatment objective; empty bed contact times (EBCTs); projections of breakthrough (based on bed volumes treated); and corresponding change-out frequency/costs. Column studies can also be used to compare loading capacity/breakthrough performance for different types of GAC (for example, different materials, preparation methods, and pore size distributions) offered by various vendors. These studies should always use site water to ensure that the effects of site-specific geochemical characteristics are assessed. Alternative analytical screening methods, for example, total oxidizable precursor (TOP) assay (**Section 11.2.2.2**), adsorbable organic fluorine (**Section 11.2.2.4**), and particle-induced gamma ray emission (PIGE) (**Section 11.2.2.3**), can be used to better estimate potential total mass load during the GAC remedial design phase. Field performance of GAC systems often varies significantly from that

predicted in the RSSCT and other bench tests. Proper monitoring is critical to demonstrate that the desired performance is being achieved, especially at system start-up and following media change-out events.

Temporary and permanent GAC systems can be rapidly deployed and require minimal operator attention, if intensive pretreatment is not needed. The GAC media are placed in packed-bed flow-through vessels generally operated in series (lead-lag configuration). EBCTs of 10–20 minutes per vessel are typical (**AWWA 2019**). PFAS breakthrough is monitored by testing the water, at a minimum, between the lead and lag vessels. Additional sampling ports can be added (for example, at 25%, 50%, and 75% of the depth of the media). When breakthrough exceeds identified change-out criteria, the lead bed is taken offline and the spent GAC is removed and replaced with either new or reactivated GAC. The spent media are disposed off site by thermal destruction or can be thermally reactivated for reuse. Treatment can be continuous if the lag bed is used as the lead bed while the media in the latter are changed out. **Figure 12-2** depicts a simple process flow diagram for a GAC treatment system.

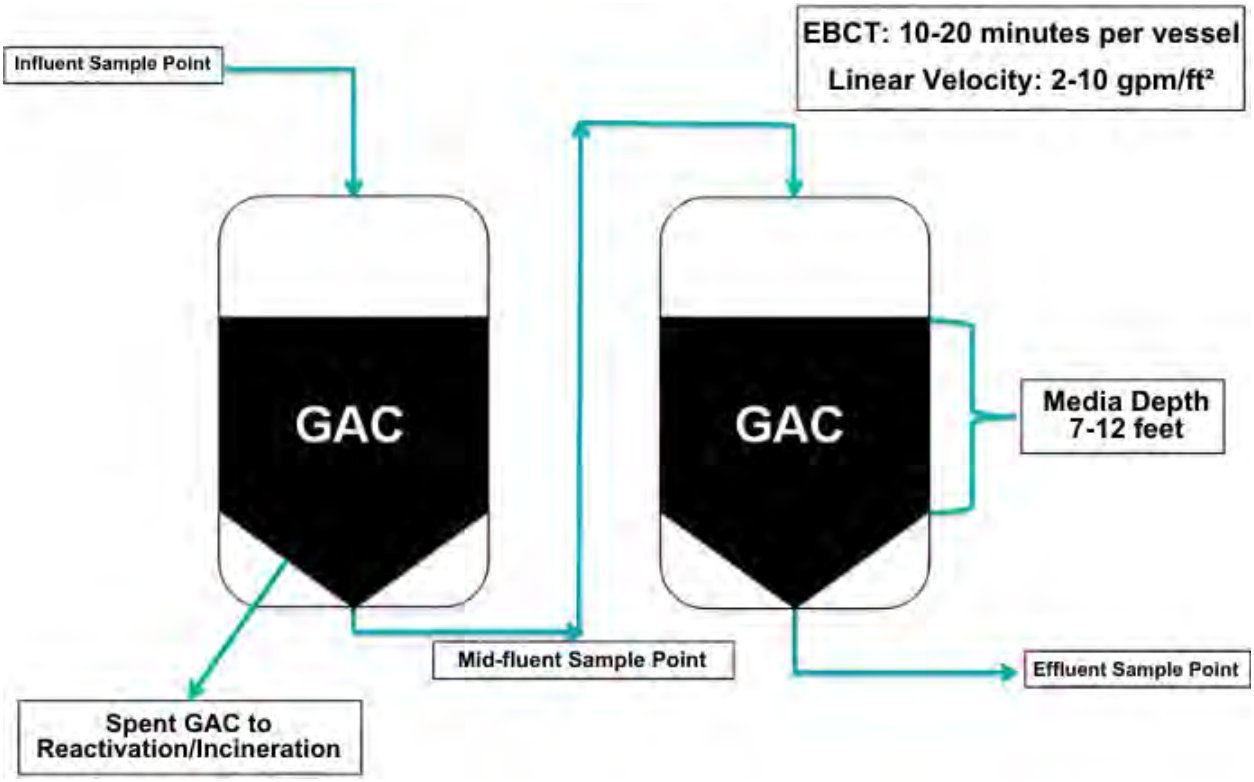

Figure 12-2. Typical GAC treatment system process flow diagram.

Source: Used with permission from Calgon Carbon Corporation.

Various GAC base materials (for example, bituminous coal, lignite coal, coconut shells) can be used for adsorption, though bituminous coal-based GAC has been used for the majority of existing sorption treatment systems for PFAS and current data show that bituminous-based products are more effective for PFAS removal (**McNamara et al. 2018**; **Westreich et al. 2018)**. Specialized GAC formulations and coconut-based GAC can also be effective. Media selection and life cycle cost will depend upon a number of factors, including PFAS and co-contaminant concentrations, media availability, and pricing.

GAC treatment applications will evolve as analytical methods improve and regulatory concerns encompass an increasing number of PFAS. Shorter chain PFAS exhibit faster breakthrough times (**Appleman et al. 2013**), so particular attention needs to be given to these compounds if their removal is

required. Alternative design optimization approaches or use of other technologies in combination with GAC (for example, ion exchange (IX) resins discussed in **Section 12.2.1.2**) can address high O&M costs that can be incurred for GAC treatment involving high influent PFAS concentrations, especially if shorter chain PFAS must be removed. As discussed in **Section 12.2.1.2**, specialty single-use and regenerable IX resins have been developed that have higher loading capacities for shorter chain PFAS. GAC and IX can also be used in series to optimize removal capacity and minimize O&M costs, generally with GAC ahead of IX to remove non-PFAS organics and longer carbon chain PFAS, followed by IX to remove the shorter carbon chain PFAS. This approach has been implemented in the field and is presented in a case study in **Section 15.2.2.1**.

Spent GAC that contains PFAS can be thermally reactivated and reused, which may result in a lower cost media replacement option versus new GAC. However, some regulatory agencies may not allow the use of reactivated GAC for drinking water systems. NSF/ANSI standards require that the use of reactivated GAC for drinking water systems involve only media generated by the treatment system owner/operator and cannot include a mixture of GAC that originated from other sources. The management of spent media should be planned during the life cycle assessment phase and be documented as the treatment system is executed. Commercial facilities are available for thermal reactivation of spent GAC, which currently are not available for other sorption media and can offer a potential life cycle cost benefit for spent media disposal. Based on vendor feedback (**Mimna 2017**), commercial thermal GAC reactivation is performed at higher operating temperatures than steam or nitrogen regeneration systems, and may be capable of complete desorption and destruction of PFAS from spent GAC (**Watanabe et al. 2016**; **Yamada et al. 2005**). However, similar to incineration, additional studies are needed to investigate the fate of PFAS in the GAC reactivation process.

Sustainability: GAC ex situ PFAS water treatment systems have unique sustainability considerations as well as considerations in common with other ex situ PFAS sorption media water treatment systems (treatment complex construction, utilities, water collection and pumping, and discharge infrastructure). Major sustainability considerations unique to GAC systems are associated with:

- raw material collection and transportation
- GAC manufacturing and transportation
- larger media vessels relative to IX due to longer EBCTs
- larger treatment complex size due to larger vessels
- spent media transportation followed by reactivation, destruction, or disposal.

Multiple resources are available for performing sustainability assessments for sorption remedial designs (**Amini et al. 2015**; **Choe et al. 2013**; **Choe et al. 2015**; **Dominguez-Ramos et al. 2014**; **Favara et al. 2016**; **Maul et al. 2014**; **Rahman et al. 2014**; **Ras and von Blottnitz 2012**). Additional information is included in **Section 12.9**.

12.2.1.2 Ion Exchange Resin

Treatment Description: Ion exchange (IX) resin is an effective sorbent for other contaminants and has historically been used for a variety of water treatment applications (for example, nitrate, perchlorate, arsenic). To date, IX for PFAS removal from water is limited to ex situ applications.
IX resin options for removal of PFAS include single-use and regenerable resins. Single-use anion exchange resins are used until breakthrough occurs at a pre-established threshold and are then removed from the vessel and currently disposed of by high temperature incineration or by landfilling, where permitted. Regenerable resins are used until breakthrough but are then regenerated on site using a regenerant solution capable of returning a reduced capacity to the resin. Temporary and permanent IX systems can be rapidly deployed.

Treatment Mechanism: Removal of PFAS by IX is a physical mass transfer process from the aqueous phase onto solid media that does not involve any form of chemical degradation or transformation. IX resins with positively charged functional groups remove negatively charged PFAS from water by forming ionic bonds (the sulfonic and carboxylic acid heads of PFOS and PFOA are negatively charged at the typical range of pH values found in natural water). Simultaneously, the hydrophobic end of the PFAS structures can adsorb onto the hydrophobic surfaces of the IX resins, leading to increased ion exchange affinity on resins with hydrophobic backbones. Some PFAS at high liquid-phase concentrations (for example, 1 g/L) have been shown to also exhibit nonexchange sorption onto IX resins (**Zaggia et al. 2016**). However, the specific conditions and underlying mechanisms leading to this nonexchange sorption are not yet fully understood.

State of Development: Ion exchange technology has been used since the late 1930 for common water treatment processes like softening, demineralization, and selective contaminant removal. The development and use of selective resins for PFAS removal is relatively new but already well established. Single-use resins are now widely used for PFAS removal from water due to their simplicity of use and effectiveness in reducing regulated PFAS to nondetect (ND) levels. As of 2019, a limited number of regenerable IX systems have been installed in full-scale applications after successful pilot testing. Collection of data on longer term treatment and on-site regeneration of the IX resin is ongoing at a case study site (**Section 15.2.2.2**). In general, the removal capacity of the single-use resin is higher than that of regenerable resin, and single-use resin can be more fully exhausted in a lead-lag vessel configuration than regenerable resin. The relative removal efficiency of regenerable and single-use resins depends upon PFAS and co-contaminant influent concentrations and treatment goals.

Effectiveness: Selective IX has been demonstrated to reduce concentrations for a broad suite of PFAS at the bench and field scale for influent concentrations as high as 100s of parts per billion (ppb) total PFAS to below analytical detection limits in effluent (**Kothawala et al. 2017**; **McCleaf et al. 2017**; **Woodard, Berry, and Newman 2017**; **Zeng et al. 2020**). The affinity of such resin for common subgroups of PFAS generally follows the order PFSA > PFCA. Within each subgroup, affinity increases with increasing carbon chain length, and are not necessarily sequential (that is, longer chain PFCA may be adsorbed better than shorter chain PFSA).

In general, IX resin systems being used for PFAS removal are not installed with the intention of removing co-contaminants. Co-contaminants (including organic and inorganic compounds) may significantly reduce the removal capacity of IX for PFAS, although this depends on the selectivity of the IX resin. Because of the variability in resin behavior, as well as site-specific chemistry and co-contaminants, influent characterization is needed to assess potential pretreatment options to remove co-contaminants. Pretreatment is necessary to prevent fouling (for instance, by iron or manganese) and preserve resin capacity for PFAS removal, particularly in the context of remediation where complex co-contaminant chemistry is expected. Pretreatment needs for drinking water applications may be simpler or not required. Another consideration for drinking water utilities is that, depending on the type of IX resin used, a freshly installed IX column may cause short-term disruptions in pH or corrosivity of effluent water,

which may necessitate mitigation strategies such as effluent blending or diverting initial effluent to waste (**Smith et al. 2023**).

Single-use PFAS-selective IX resins are well-suited to treat low-concentration PFAS such as is typically encountered in potable water treatment systems, where media change-out would be infrequent. **Figure 12-3** provides an example of removal curves and breakthrough information for a number of PFAS at the specified influent concentrations (in the legend) based on vendor-supplied data for a full-scale single-use system. Breakthrough is calculated as the ratio of the effluent concentration to the influent concentration (C/C_0). It is not uncommon to observe fluctuations in the breakthrough curve in some field pilot studies due to varied influent concentrations over time. For example, after a resin unit is in equilibrium with one PFAS at an initially higher influent concentration, a lower concentration influent can desorb PFAS from the resin, resulting in breakthrough higher than 100%. The typical breakthrough order observed in **Figure 12-3** is expected to be similar for various anion exchange resins, as relative ionic bond strengths and carbon chain lengths result in shorter chain PFCAs to longer chain PFCAs desorbing first, followed by shorter chain PFSAs to longer chain PFSAs. Similar responses also apply to GAC.

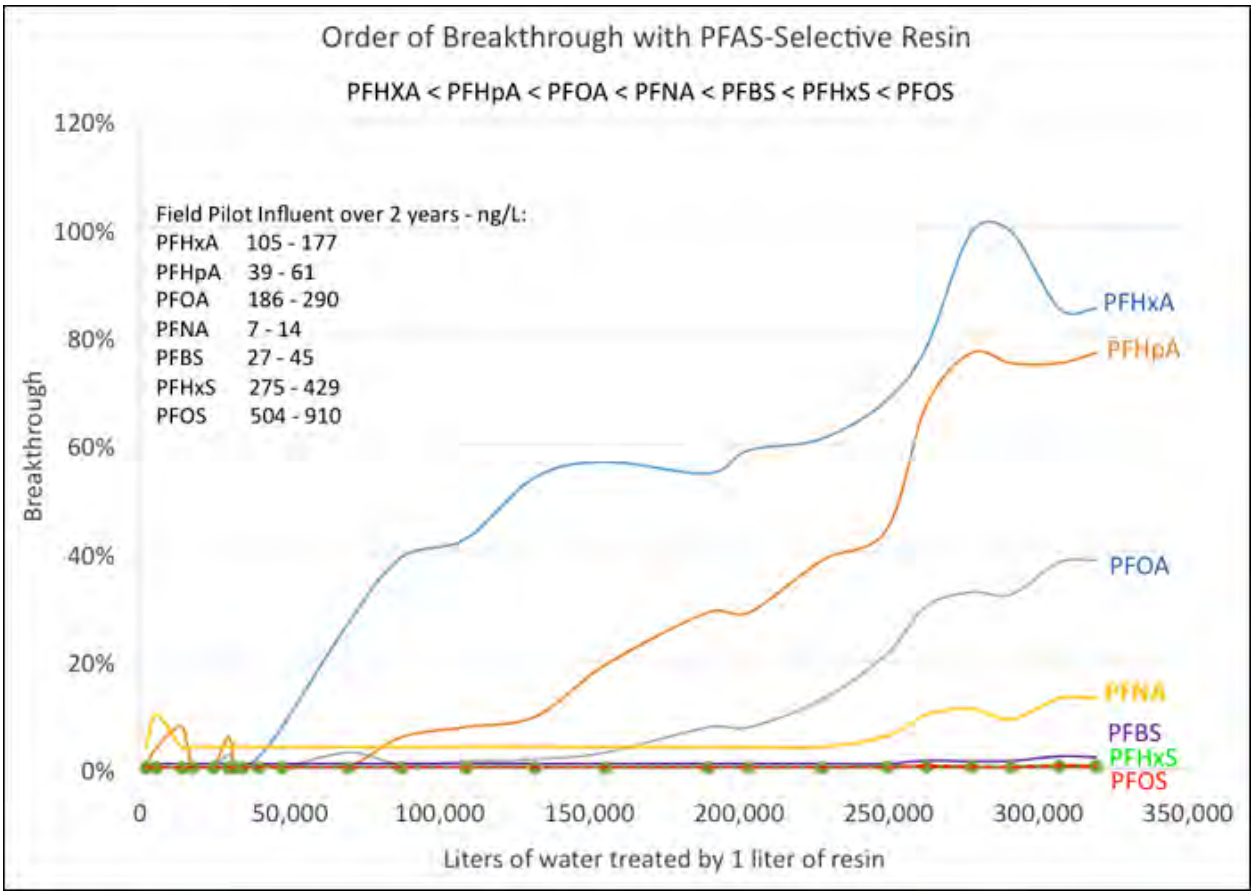

Figure 12-3. Example of IX removal curves from a field pilot study at specific influent concentrations (2.5-minute EBCT). (Note: Initial concentrations in ng/L or ppt.)

Source: Used with permission from Purolite Corporation.

Regenerable IX is not yet approved per NSF 61 for potable water treatment. Regenerable resins are better suited for removal of higher concentration PFAS where the savings realized from reusing the treatment media outweighs the cost of frequent replacement of nonregenerable media. Regenerable IX becomes more efficient than single-pass media when flow rate and concentration increase and RAOs go down,

because these factors increase the frequency and volume of media change-outs for single-pass media. These factors also increase the regeneration demand; however, regeneration frequency can be extended by using larger vessels. Cost efficiency and viability of regenerable IX relative to single-use IX and GAC media are evaluated in ESTCP ER18-5015.

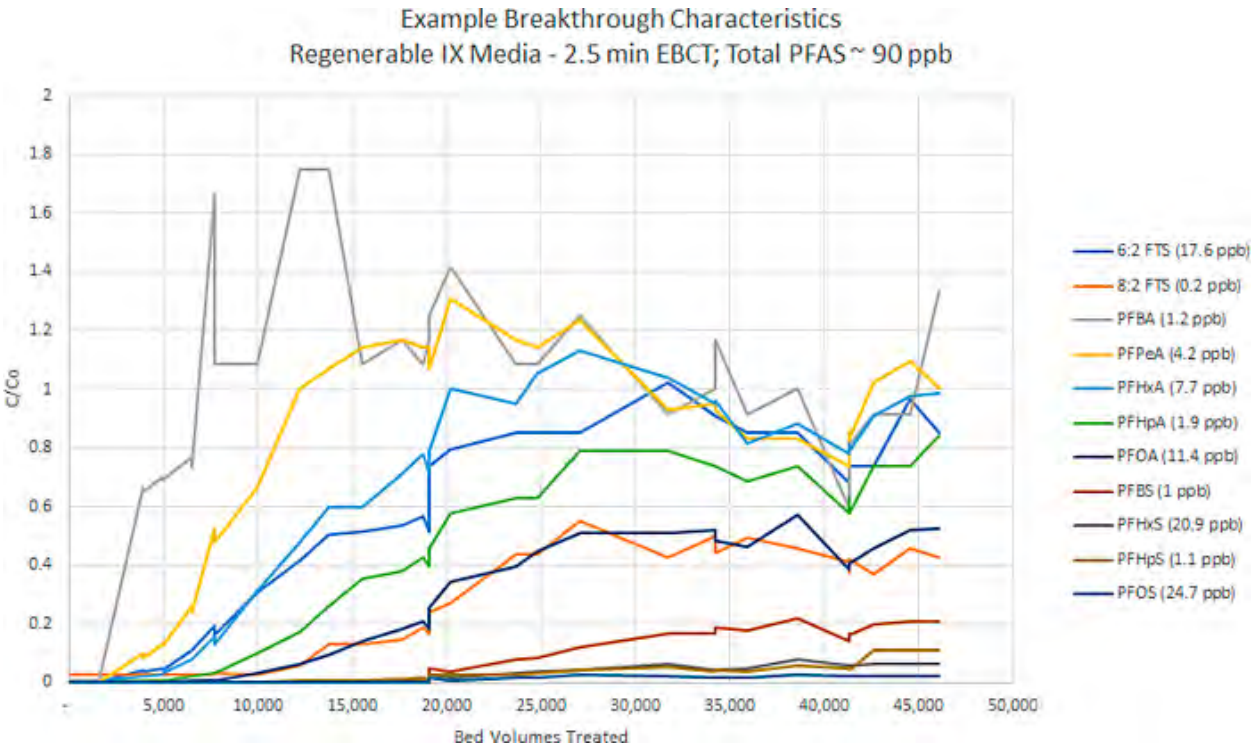

Figure 12-4. Example of regenerable IX removal curves from a field pilot study at specific influent concentrations (2.5-minute EBCT). (Note: Initial concentrations in µg/L or ppb.)

Source: Used with permission from ECT2.

An example of typical breakthrough curves for regenerable resin system is shown in **Figure 12-4**. On the graph the y-axis is sample concentration/original concentration (C/C_o), also note the influent PFAS concentrations (in the legend) in **Figure 12-4** are higher (reported in ppb) than presented in **Figure 12-3** (reported in ppt). Additional details on a regenerable resin system are provided in a case study in **Section 15.2.2.2**. The cost effectiveness for regenerable resin systems could increase significantly (and thus impact the system's practical implementability) when a central regeneration facility can be shared amongst multiple PFAS removal systems. The application of single-use versus regenerable resins must be evaluated on a site-specific basis.

Design/Operating Considerations: IX treatment systems are configured similarly to GAC systems. Refer to **Section 12.2.1** for a description of GAC systems that also applies to IX systems, and Section **12.2.1.2** for fouling considerations. **Figure 12-5** depicts a simple process flow diagram for a single-use IX treatment system.

Selective IX requires a relatively short EBCT of 1.5–3 minutes per vessel of resin (**AWWA 2025**), hence smaller resin volumes and smaller, less costly treatment vessels versus GAC, which requires EBCTs of about 10–20 minutes per vessel (**AWWA 2019**; **Brewer 2017**) and correspondingly larger volumes of media. Selective IX resins have shown high operating capacities when removing trace levels of PFAS (for example, 100,000–400,000 bed volumes; refer to **Figure 12-5**), resulting in fewer change-outs of spent IX

resin and reduced O&M costs. Capacity depends on the concentrations of competing anions, such as sulfate and nitrate, and on the specific PFAS breakpoint chosen for resin change-out. While lead-lag vessel design is standard, if space allows, it is possible to use a lead-lag-polisher design with three resin vessels in series. The addition of a polisher vessel provides a factor of safety for increasing the loading to the lead vessel, thereby reducing change-out frequency and cost. A lead-lag-polisher design will usually result in reduced operating expenses (OPEX) but higher capital expenses (CAPEX). Therefore, the decision to use it must be done on a case-by-case basis. Pretreatment may mitigate fouling and improve performance.

For drinking water supplies with relatively clean water, the industry is rapidly moving to rely more and more on vendor-provided modeling for common PFAS with such modeling including predicted breakthrough curves and resin capacities for specific PFAS breakpoints. Modeling can evaluate a variety of "what-if" scenarios, such as changing water chemistries and assessing the economics of operating to nondetectable levels or stricter regulatory limits for selected PFAS.

Pretreatment for several influent water parameters has been recommended (**Section 12.2.1**). Natural organic matter (NOM) is of particular importance because it occurs at concentrations that are three orders of magnitude higher than PFAS. Therefore, NOM can compete for the same ion exchange sites on the resin and can also blanket the surface of the resin beads, thereby blocking access for PFAS to the internal sites on the beads. The negative impact of NOM in groundwater on resin capacity can usually be factored in at the design stage if appropriate data and models are available, because NOM is usually present at less than 2 mg/L. However, when treating surface water with NOM concentrations that can

seasonally rise to 5–10 mg/L (and even higher), it is particularly important to consider negative impact on resin capacity. **Dixit et al. (2020)** evaluated the impact of various dosages of Suwanee River NOM on resin capacity for PFAS and showed decreases of 22%, 50%, and 68% in resin capacity when adding dosages of 5, 10, and 20 mg/L NOM and using an organic scavenger acrylic resin in isotherm test solutions.

Despite the growing adoption of modeling, pilot testing is still recommended when evaluating breakthroughs for multiple PFAS or when the impact of TOC or other contaminants such as iron and manganese must be known to determine pretreatment requirements. In such cases, a technique referred to as accelerated piloting may be used, in which monitoring ports in the pilot column are set at 25%, 50%, and 100% of the resin height. This allows results to be obtained more quickly, but it is with the understanding that the breakthrough profile for each of the ports will be somewhat different. There is also growing interest in using the rapid small-scale column testing (RSSCT) technique for resins. Originally developed for use with GAC, the RSSCT technique uses crushed GAC and shorter EBCTs to quickly predict operating capacity. At this time, it is too early to know if this technique will reliably work for spherical resin beads when crushed.

Selective IX resins show much higher selectivity for PFAS than for common anions in water such as sulfate (SO_4^{2-}), nitrate (NO_3^-), chloride (Cl^-), and bicarbonate (HCO_3^-). However, these common anions are generally present in water at about three orders of magnitude higher than PFAS and will be the main competitors for the ion exchange sites on the resin. As such, they will largely determine the operating capacity of such resins. The choice between single-use and regenerable resins will in part be determined by the expected service period before the resin must be either replaced (single-use) or total regeneration costs (including capital and transportation costs). As PFAS concentration increases or as effluent criteria decreases, the frequency of regeneration or media change-out increases. As regeneration or media change-out increases, regenerable IX becomes more long-term cost-effective, if indeed the cost of regeneration is less than the cost of media replacement.

Regenerable IX resin can be reused long term if protected from contact with strong oxidizing agents, foulants, and chemical/mechanical stresses. In recent years, both pilot-scale and full-scale regenerable IX systems have demonstrated long-term durability of the media. One study, ESTCP ER18-5015, demonstrated greater than 95% removal capacity for regenerated media as compared to new media over six loading and regeneration cycles. IX regeneration is a chemical process. Field-demonstrated regeneration uses a solvent-brine solution in which the brine dislodges the ionic head of the PFAS molecule and the solvent desorbs the fluorinated carbon chain (or "tail") from the IX resin (**Woodard, Berry, and Newman 2017**; **Amec Foster Wheeler 2017**). For a regenerable IX system, it is possible to concentrate the regenerant solution and reuse it by distillation (**Nickelsen and Woodard 2017**). The distillate residue then contains a concentrated PFAS waste that can be super-loaded onto specialized resin to create a small volume of solid waste that can be managed by off-site disposal or potentially through on-site destruction using other technologies currently under development and discussed in **Table 12-1 Treatment Methods Table** Excel File (for example, plasma or electrochemical destruction).

By combining various technologies in a treatment train approach, it may be possible to achieve better overall treatment at lower cost (**Section 12.8**).

Sustainability: Ex situ ion exchange water treatment systems have unique sustainability considerations in addition to those shared with other ex situ sorption media water treatment systems. Major sustainability considerations for ion exchange systems are associated with:

- raw materials, which are generally synthetic, petroleum derivatives
- resin manufacturing and transportation, including from overseas
- regeneration materials, energy, and labor for regenerable IX media
- disposal or destruction of regeneration residuals

- long-distance transportation of spent media to limited available disposal outlets
- energy-intensive destruction methods for spent media

12.2.2 High-Pressure Membranes

In the context of this document, high-pressure membranes are defined as those meeting the characteristic separation performance of nanofiltration (NF) and reverse osmosis (RO) membranes. Both the NF and RO membrane categories span a range of selectivity (for example, loose NF to tight RO) and may rely on different rejection mechanisms to support the separation of PFAS from impacted water. However, under the correct application, both technologies have been proven to effectively remove PFAS from a variety of feed water sources. This technology is generally considered more applicable to high volume, low concentration liquids than low volume, high concentration liquids.

12.2.2.1 Nanofiltration (NF)

NF is a form of membrane technology that is pressure-driven and shown to be effective in the removal of PFAS (**Tang et al. 2007**). This method of filtration provides high water flux at low operating pressure (**Izadpanah and Javidnia 2012**). Typically, NF membranes exhibit high rejection of polyvalent ions and other molecules of sufficient size, but are susceptible to permeation by monovalent ions (for example, sodium, chloride) and smaller molecules. The most common membrane module configurations are spiral-wound (consisting of flat sheet membrane material wrapped around a central collection tube); however, hollow fiber NF modules may also be available for applications with higher fouling potential.

Available data on the removal of PFAS via NF consist of laboratory-scale tests performed on flat sheet membrane coupons (laboratory-scale sections of the membranes to be tested) and one full-scale drinking water treatment plant using an NF treatment train. Therefore, variations in performance due to fouling, flux, and concentration distributions in standard spiral-wound membrane configurations have not been characterized (**Boo et al. 2018**).

NF membranes tested include the DuPont (formerly Dow FilmTec) membranes NF-270, NF-200, and NF-90, and the SUEZ (formerly GE Water & Process Technologies) DK membrane. Reported rejections were generally > 95% for PFAS with molecular weights ranging from 214 grams per mole (g/mol) to 713 g/mol, though some compounds had lower rejections (PFPeA at 70% and perfluorooctane sulfonamide at 90%) (**Steinle-Darling and Reinhard 2008**; **Appleman et al. 2013**). Effective full-scale removal of PFAS by NF

membranes was confirmed based on nondetectable PFAS concentrations (<4 ng/L) in NF permeate (**Boiteux 2017**). Salt passage for PFOS was reported to range from < 1% for the tighter NF-90 membrane to about 6% for the looser NF-270 and DK membranes (**Tang et al. 2007**). New research has focused on functionalizing membrane surfaces to improve PFAS selectivity (for example, **Johnson et al. 2019**). An appropriate disposal or treatment of the membrane concentrate stream needs to be considered, especially the application of high-pressure membranes for inland communities. Fluoropolymers may be used to manufacture membranes, which brings into consideration the need for PFAS-bearing reagents to manufacture the membranes, disposal of manufacturing byproducts, and disposal of spent filters.

12.2.2.2 Reverse Osmosis (RO)

RO is a technology used to remove a large majority of contaminants (including PFAS) from water by forcing water, under pressure, across a semipermeable membrane as described below. A typical RO system consists of three streams: the untreated water (feed), the treated water (permeate), and the residual reject water (concentrate). The most common membrane module configuration is spiral-wound, which consists of flat sheet membrane material wrapped around a central permeate collection tube. Like most treatment technologies, RO is seldom used alone, but rather as part of a treatment train. Most efficient RO performance may require pretreatment. RO-treated effluent (that is, permeate) may require supplemental management to mitigate the corrosivity of demineralized water.

Treatment Description: RO membranes are effective in removing most organic and inorganic compounds from water solutions. In recent years, new polymer chemistry and manufacturing processes have improved efficiency, lowering operating pressures and reducing operating costs (**Lau et al. 2012**). As a result, RO membranes are increasingly used by industry to concentrate or remove chemicals. RO is commonly used around the world in household drinking water purification systems, the production of bottled mineral water, self-contained water purification units (for example, for branches of the U.S. military), and industrial applications (for example, water supply to cooling towers, boilers, and deionized water). The largest application of RO is in desalination. In comparison, high-pressure membrane applications typically have higher capital and operating costs relative to GAC or IX systems designed for PFAS removal.

Treatment Mechanism: RO removes compounds from water solutions by forcing pressurized water across a semipermeable membrane. The driving pressure required in RO systems is a function of multiple factors, including the osmotic pressure of the feed water, the membrane type, and the system configuration. Typically, size exclusion is the prevailing mechanism for contaminant removal in RO membrane systems. The physical barrier (that is, semipermeable membrane) underlying the size exclusion removal mechanism provides additional assurance regarding the treatment of PFAS spanning a wide range of physical and chemical properties. Treated water (permeate) passes through the membrane and the rejected water (concentrate) is collected for disposal or discharge, depending on the nature of the compounds present.

State of Development: RO has been studied in bench-scale studies and pilot plants for wastewater and drinking water applications, offering the opportunity to compare both treatments operating simultaneously (**Tang et al. 2006**; **Tang et al. 2007**; **Flores 2013**; **Glover, Quiñones, and Dickenson 2018**; **Dickenson 2016**; **Merino et al. 2016**; **Appleman 2014**; **Snyder 2007**). This allows for an understanding of the effectiveness of traditional drinking and wastewater treatment methods alongside PFAS-specific technologies.

Effectiveness: Pretreatment is important when working with RO membranes. Membranes can be susceptible to fouling (loss of production capacity) because some accumulated material cannot be removed from the membrane surface during routine cleaning and maintenance procedures. Therefore, effective pretreatment to mitigate the formation of organic or inorganic foulants is a necessity for many RO systems. Pretreatment technologies would be specific to the RO feedwater quality.

RO removal of PFAS from various waters (for example, semiconductor wastewater, drinking water, surface water, and reclaimed water) has been studied and several studies have combined RO with nanofiltration (NF). PFOS removal > 99% was achieved using four different types of membranes over a wide range of feed concentrations (0.5–1,500 ppm [mg/L]) (**Tang et al. 2006**). Another study by **Tang et al. (2007)** tested five RO and three NF membranes at feed concentrations of 10 ppm PFOS over 4 days. The PFOS rejection and permeate flux performances were > 99% for RO and 90–99% for NF. The use of RO and NF as advanced drinking water treatments is still limited, but both technologies have been shown to be successful for the removal of longer chain (> C5) PFAAs (**Baudequin et al. 2011**; **Loi-Brügger et al. 2008**; **Tang et al. 2006**).

Thompson et al. (2011) studied the fate of perfluorinated sulfonic acids (PFSAs) and carboxylic acids (PFCAs) in two water reclamation plants that further treat water from wastewater treatment plants (WWTPs) in Australia. One plant (Plant A) used adsorption and filtration methods alongside ozonation; the other (Plant B) used membrane processes and an advanced oxidation process to produce purified recycled water. At both facilities, PFOS, perfluorohexane sulfonate (PFHxS), perfluorohexanoate (PFHxA), and PFOA were the most frequently detected PFAS. Comparing the two reclamation facilities, Plant A showed some removal during the adsorption/filtration stages. Overall, however, Plant A failed to completely remove PFOS and the PFCAs shorter than PFNA in chain length. All PFAS present were removed by RO at Plant B from the finished water to concentrations below detection and reporting limits (0.4–1.5 ng/L).

Design/Operating Considerations: This section refers to design and operating considerations for both RO and NF systems. Typical high-pressure membrane systems can achieve recoveries between 70% and 85%, with some high recovery applications able to achieve >95% recovery (**Bond and Veerapaneni 2008**; **Safulko et al. 2023**; **Stover 2013**). Recovery is defined as the ratio of treated effluent (permeate) to feed water. The feed water not accounted for in the permeate is the reject or concentrate. In conventional systems, the concentrate fraction may represent 15%–30% of the feed flow or <5% of the feed flow for high recovery applications. In conventional or high recovery high-pressure membrane systems, recovery is typically limited by the feed water quality.

In the process of planning and implementing a high-pressure membrane filtration system, there are several important issues that affect system design and operation and could impact system performance and thus PFAS removal. These issues include membrane flux, water quality, and temperature.

- **Membrane Flux:** One of the major challenges in the application of membrane technology is fouling (significant flux loss due to continuous accumulation of colloidal and organic matter, precipitation of inorganic salts, and/or microbial growth). There are several ways to mitigate fouling: (1) changing operating conditions, (2) modifying the membrane, and (3) modifying the feed by adding antifoulants prior to filtration system (pretreatment) (**Roux et al. 2005**). Adequate pretreatment and appropriate membrane selection can slow the fouling rate, but routine membrane cleaning is an essential step in maintaining the performance of the membrane process. Membrane replacement is a necessary part of plant operation to maintain the quality of the produced water (**Abdul-Kareem Al-Sofi 2001**). Although there are a number of cleaning techniques, such as physical or chemical or a combination of both, chemical cleaning methods are more widely used by NF and RO industries for membrane cleaning and regeneration. Spent cleaning solution may contain PFAS and would need to be managed properly.

- **Water Quality:** Because water quality can have a significant impact on membrane flux, feedwater quality is also a primary design consideration for membrane filtration systems. Poorer water quality (high suspended and dissolved solids, co-contaminants) will reduce flux, which in turn increase the necessary membrane area and required number of membrane modules, adding to both the cost and the size of the system. However, pretreatment can often improve feedwater quality at a lower cost than additional membrane area. Because RO is a relatively expensive

technology, efforts to improve water quality with pretreatment processes ahead of the RO membranes (filtration, precipitation; see **Section 12.7**) will result in reduced capital and operating costs.

- **Temperature:** Like other water quality parameters such as turbidity and total dissolved solids (TDS) (for NF/RO systems), the temperature of the feedwater also affects the flux of a membrane filtration system. Water becomes increasingly viscous at lower temperatures; thus, lower temperatures reduce the flux across the membrane at constant transmembrane pressure or alternatively require an increase in pressure to maintain constant flux. Because rejection decreases as membrane pores expand at higher temperatures, more permeation of PFAS across the membrane could occur at higher operating temperatures.

Sustainability: The environmental footprint for this technology includes energy source and consumption during treatment system operation, as well as manufacturing/disposal of pretreatment/treatment media (examples may include solids from upstream precipitation/coagulation or microfiltration, used cartridge filters, and worn RO membrane modules) and cleaning solutions to maintain the membrane. RO requires power for high-pressure pumps and the management of concentrate, which can be energy intensive.

An issue inherent to contaminant removal by membrane processes is the disposal of the PFAS-enriched concentrate, which must be carefully considered. Development of effective treatment methods for the concentrate entails evaluating significant parameters, such as volume generated, concentration, characteristics of the feedwater, and operational conditions, and using well-verified analytical methods to detect trace amounts of contaminants. Concentrate treatment and management alternatives remain an active area of research (**Joo and Tansel 2015**). **Tow et al. (2021)** documented treatment and management alternatives specifically focused on PFAS-impacted concentrates. **Tow et al. (2021)** reviewed 22 different PFAS-impacted concentrate treatment or management alternatives that included application of additional separation technologies (for example, adsorbents, foam fractionation), destructive technologies, and disposal/sequestration options. There are numerous options to consider for PFAS-impacted concentrate treatment and/or management, and identifying the best alternative will be a function of site-specific factors including location, volume of concentrate, PFAS concentrations, and presence of co-contaminants.

12.2.3 Foam Fractionation

Treatment Description: In the PFAS water treatment space, the term foam fractionation is used to encompass a larger set of adsorptive bubble separation technologies including foam, bubble, and aerosol fractionation. Foam fractionation is a physical separation process that traditionally uses air or other gases to generate bubbles rising through a water column to strip amphiphilic substances such as PFAS from the bulk liquid (**Lemlich and Lavi 1961**; **Lemlich 1972**). Foam fractionation technology has been used for decades in the commercial-scale aquarium business to clean water by separating and removing proteinaceous waste and has been advanced to multistage configurations for PFAS separation and concentration. Amphiphilic PFAS adsorb to the surface of the bubbles as they rise upwards. PFAS that accumulate at the top of the column as a concentrated foamate are then removed for further treatment or disposal. This process has been implemented for ex situ water treatment, and in situ, down-hole foam fractionation approaches have also been tested but are in less developed stages.

Treatment Mechanism: Air or other gaseous bubbles are introduced into a PFAS-containing liquid, which causes amphiphilic PFAS and other amphiphilic organic compounds to adsorb to the bubble surface, separating them from the bulk water. As the bubbles migrate upwards, PFAS are removed from the bulk liquid. The top foamate layer is concentrated in PFAS and can be removed passively via overflow or actively via vacuum suction for further treatment. The extent to and rate at which PFAS are removed depends on individual PFAS physical chemical properties, background water quality properties, and operational considerations discussed in the subsequent sections. **Buckley et al. (2021)** presented a

detailed review, including description of key separation mechanisms, of foam fractionation for water treatment. **Stevenson and Li (2014)** produced a monograph on the theory and practical implementation of foam fractionation.

State of Development: Foam fractionation has been studied at the bench scale and implemented at the pilot- and full-scale level to remove PFAS in groundwater (**Burns et al. 2021**) leachate (**Burns et al. 2022**; **Newman 2022**; **Smith et al. 2022**; **McCleaf et al. 2021**; **Robey et al. 2020**), and industrial water (**Smith et al. 2023**). The first application of foam fractionation for PFAS treatment was developed and built in Australia and is currently operating at full-scale in Queensland, Australia and at other sites around the world (see the case study in **Section 15.2.4.1** and **Burns et al. (2021)**. Foam fractionation systems have successfully removed PFOS and PFOA to low level parts per trillion levels (**Burns et al. 2021**; **Burns et al. 2022**; **Newman 2022**; **Smith et al. 2022**; **Smith et al. 2023**). Additional research is underway to promote removal of short-chain PFAS such as PFBA and PFBS in foam fractionation, which to date have not been effectively removed across all waters tested. Short-chain carboxylates have proven especially difficult to remove. Foam fractionation is provided by multiple commercial vendors in the United States, Europe, Canada, and Australia. Maximum flow rates implemented in the field are on the order of 50–150 gallons per minute in single fractionators. Scale up to larger foam fractionators is theoretically feasible, and multiple fractionators in parallel have been deployed to treat higher flow rates.

Effectiveness: Foam fractionation is highly effective at removing PFOS and PFOA and longer chain PFAS (**Burns et al. 2021**; **Newman 2022**; **Burns et al. 2022**; **Smith et al. 2022**) to single-digit parts per trillion levels, but its performance at removing PFAS with fewer than six perfluorinated carbons remains mixed. Removal of PFAS during foam fractionation is dependent upon individual PFAS adsorption coefficients (**Burns et al. 2022**), which are derived from the adsorption isotherm under specific conditions for each compound for uptake onto a gas/liquid interface. As with adsorptive media, perfluoroalkyl sulfonates of an equivalent perfluoroalkyl chain length are removed more effectively than perfluoroalkyl carboxylates (for example, PFHxS is removed more effectively than PFHpA). Researchers and practitioners have identified that chemical additions, often in the form of cationic surfactants, can improve the removal of PFBS, PFHxA, PFPeA, and PFBA (**Newman 2022**; **Buckley et al. 2023**; **Vo et al. 2023**). A cationic surfactant that successfully removed PFBA in a deionized solution of sodium chloride was unable to remove PFBA from landfill leachate under similar operating conditions (**Buckley et al. 2023**; **Vo et al. 2023**). Foam fractionation is also effective at removing a wide range of PFAS concentrations (for example, nanograms per liter to milligrams per liter); however, greater orders of magnitude removal require longer hydraulic retention times and/or additional stages of treatment.

Foam fractionation can also be effective for PFAS removal on a wide range of water quality types without the need for additional pretreatment. The complexity of the leachate matrix is likely one reason why foam fractionation has been trialed so extensively on leachate (**Burns et al. 2022**; **Newman 2022**; **Smith et al. 2022**; **McCleaf et al. 2021**; **Robey et al. 2020**). Compared to PFAS treatment with GAC, anion exchange resin, and reverse osmosis, foam fractionation performance is impacted in a much more limited way by background analytes such as TOC, dissolved metals, and hardness that foul adsorptive media and membranes. The primary constituents that concentrate into the foamate through a foam fractionation process are suspended solids, PFAS, and other surfactants, including any used to enhance the foaming process, while other water quality characteristics such as dissolved anions and cations remain similar in concentration to the source water. See the case study in **Section 15.2.4.2**.

Site-specific water chemistry does impact foam fractionation performance, so laboratory testing is recommended to optimize pilot design. Some researchers have reported a higher degree of removal during foam fractionation as TDS increases in the source water (**Buckley et al. 2023**).

Design/Operating Considerations: Design parameters that can affect the performance of ex situ foam fractionators include the following:

- The non-PFAS characteristics of the water, including constituents that can increase or diminish the natural foaming potential of the water
- The hydraulic retention time of the fractionator; hydraulic retention times reported in the literature for stripping fractionators have typically fallen within the range of 10–60 minutes (**Smith et al. 2022**; **Buckley et al. 2023**; **Newman 2022**)
- Countercurrent or co-current flow of gas and water
- The amount, speed, and bubble size of gas introduced per volume of water in the fractionator. The bubble size is partially related to the type of gas introduced, with ozone bubbles typically introduced with a smaller size than air.
- The amount of turbulence introduced along with the gas. More turbulence tends to increase foam generation and has an overall beneficial impact on PFAS removal
- The height of the water column relative to the foam collection point (that is, a weir or overflow)
- The mechanism of foamate removal, which can include traditional spillover or application of a vacuum process
- The number of treatment units operated in series
- Batch, semicontinuous batch, or continuous flow operation, which is discussed in more detail below
- The introduction of chemical agents to increase foaming or removal of particular PFAS

In ex situ foam fractionation processes, foam fractionation can be operated in either "stripping-wet" or "enriching-dry" modes (**Smith et al. 2023**). In stripping-wet mode, the top of the water column is located very close to the weir or overflow so that foamate may readily exit the fractionator. This mode of operation does not allow for significant foam drainage of interstitial liquid prior to foamate exiting the fractionator, so a relatively wet foam is generated. Under the enriching-dry mode, the fractionator fill volume is set at a larger distance from the weir or overflow to allow for a greater degree of drainage of excess interstitial liquid from the foamate. The enriching-dry mode produces a low volume of foamate, but typically results in target PFAS remaining in the treated water exceeding low-level PFAS treatment criteria, so the underflow or raffinate will require further treatment. Setting the fill volume too low in relation to the weir can result in poor treatment due to ineffective collection of foamate.

Practitioners may elect to adopt either a single-batch, multistage semicontinuous batch, or continuous flow-through design depending upon PFAS target treatment criteria, required throughput, and desire to further reduce the foamate volume prior to proceeding to additional treatment. Foam fractionation setup as a batch process typically configures the stripping-wet stage first, followed by one or multiple enriching-dry stages. Foam setup as a continuous flow-through process can configure the first stage to operate in either stripping-wet or enriching-dry mode, followed by one or more additional stages to be able to reach the treatment goals by the final stage, where water height in each successive stage will require careful management. Each of the configurations has relative benefits and drawbacks. For example, batch typically has lower flow-through capacity compared to flow-through designs, but has faster stripping times per fractionation column.

The stripping of PFAS from bulk phase liquid into a gaseous phase raises relevant concerns about worker exposure to PFAS and other compounds that may be stripped out of the aqueous phase via the operation of these systems. In the **Smith et al. (2023)** study, PFAS were measured in aerosols and air around a foam fractionator; the mean measured sum of PFAS was twenty-seven times higher than the concentration measured at a reference site, with the highest concentration measured closest to the outlet of the fractionator. The composition of PFAS measured was also similar to that measured in the foamate. Emissions control devices and enclosure of all foam fractionator components may be needed to mitigate gaseous PFAS releases from the foam fractionation process.

The ultimate disposition of the resulting PFAS-enriched foamate varies. Options include concentrating the foamate onto an adsorptive media or delivering it to an aqueous destruction process. The concentrated nature of PFAS in foamate makes it a good candidate for pairing with various PFAS destruction technologies, and it also promotes increased loading onto media. Electrochemical oxidation of foamate has been reported in the peer-reviewed literature with only partial ability to break down target PFAS (**Smith et al. 2023**). The TDS concentration in the final waste foamate created by foam fractionation is appreciably lower than that of residual waste material from the regenerable ion exchange resin treatment process, and may therefore have an advantage when paired with certain PFAS destruction processes.

Sustainability: The environmental footprint for this technology includes energy source and consumption during treatment system operation. One provider has reported a system energy consumption of 0.8 kWh/m3 in a semibatch system with a 250 m3 throughput that performs secondary and tertiary foam refractionation (**Burns et al. 2021**). As longer hydraulic retention times and more stages of refractionation/enrichment of foamate are introduced, energy consumption per volume of water treated increases. The PFAS-enriched foamate requires disposal, often via loading onto an adsorptive media. Destruction of PFAS in foamate is also under consideration, and research activities supporting PFAS destruction in foamate are identified in the ongoing research funded by SERDP/ESTCP. Unlike RO, the concentrate generated by foam fractionation offers an appreciable reduction in volume and is thus better suited for a low throughput, high energy consumption PFAS destruction technology.

12.2.4 In Situ Remediation with Colloidal Activated Carbon

Treatment Description: The primary function of injectable colloidal activated carbon (CAC) is to immobilize contaminants and prevent their further horizontal and vertical migration in groundwater. By flowing CAC into the flux zones of an aquifer, dissolved contaminants migrating in groundwater, as well as those contaminants back-diffusing from lower permeability zones, are captured and taken out of solution, thereby lowering the risk to downgradient receptors (for example, drinking water wells, surface water bodies). Long-term performance is subject to various parameters, such as contaminant flux and media saturation, similar to GAC.

CAC may be injected in situ using a grid pattern in source zones to immobilize contaminants, or it may be injected in a transect pattern perpendicular to the width of a plume to mitigate contaminant flux. Direct push or vertical wells can be used to inject CAC into the subsurface (**McGregor 2020**).

Treatment Mechanism: CAC consists of colloidal-sized particles of activated carbon (2 microns diameter on average) in aqueous suspension (the consistency of black-colored water), which can flow into aquifer flux zones upon gravity-feed or low-pressure injection. After injection, CAC particles will attach strongly to the aquifer matrix, where they can act as passive sorbents for organic contaminants, including PFAS. This sorption mechanism is detailed in **Section 12.2.1**. Due to the small size of the particles, the kinetics of

PFAS sorption on colloidal carbon are much faster than can be achieved with GAC, resulting in higher removal efficiencies (**Xiao et al. 2017**).

Unlike larger powdered activated carbon (PAC) particles (50+ micron diameter), CAC particles are small enough to move through most aquifer material pore throats under low pressure, allowing for relatively even distribution within aquifer materials. **McGregor (2020)** demonstrated that trying to inject PAC was not as successful as injecting CAC because higher injection pressures were required, resulting in preferential PAC distribution in more permeable lenses of sand. **McGregor (2020)** also observed preferential accumulation of PAC within the sand packs of monitoring wells that were present at the time of injection at four sites, which would lead to false positive treatment results. CAC accumulation was not observed in the sand packs of the monitoring wells.

State of Development: Over the past decade, in situ CAC treatment technology has been well established with project sites contaminated with hydrocarbon and chlorinated solvent contaminants. The application of the technology to treat PFAS contamination in groundwater has been successfully employed on >25 project sites in North America, Europe, the Middle East, and Asia (for example, **McGregor 2020**; **Carey et al. 2022**). A case study is included in **Section 15.2.3**, which details a full-scale CAC project site to predict the theoretical longevity and performance of the CAC to treat PFAS in groundwater in the presence of hydrocarbons. Results indicated an anticipated longevity of successful PFAS treatment on the order of decades. The study noted that longevity of performance could be extended by increasing the CAC dose, by increasing the thickness of the treatment zone perpendicular to flow, or by additional injection upon any future PFAS breakthrough.

Effectiveness: **McGregor (2018)** discussed the in situ injection of CAC at a site in central Canada to mitigate mass flux of PFOS and PFOA from a fire training area source zone. Prior to CAC injection, PFOS and PFOA were measured in groundwater monitoring wells at concentrations up to 1,450 ng/L and 3,260 ng/L, respectively. Monitoring wells at the site were screened in a shallow, thin silty sand overburden unit at depths of approximately 5–10 feet below ground surface. CAC was injected into the source zone at low pressure through temporary wells installed using direct push technology. Postinjection core sampling indicated that CAC was measured at distances of up to approximately 15–20 feet from the injection wells. **Carey et al. (2022)** discussed the performance of this project site where no detections of PFAS in the CAC adsorption zone were detected over the first 5 years (10 sampling events) except for a single well where low detection of PFOS and PFUnA at 533 days was seen (but not reproduced). The first five monitoring events included analysis for only PFOS and PFOA. The last six monitoring events included analysis for a full suite of PFAAs. At event 11 (the 6-year point), the detection limits were lowered to 1 ng/L and several PFAS were observed slightly above the new detection limits.

Carey et al. (2022) presented performance data on 16 field-scale projects employing CAC to treat PFAS in groundwater. On nine of the sites PFAS have been reduced to concentrations at or below detection levels, including five projects that analyzed for both short- and long-chain PFAS. Another five project sites showed >90% reduction in PFAS constituents, while one site showed >80% reduction. On a site where treatment of PFAS in groundwater was attempted near a landfill, initial results indicated >91% reduction but were not sustained, presumably due to the high dissolved organic load (>20 mg/L) associated with commingled landfill leachate.

Design Considerations: The focus of a CAC treatment is to target the actual vertical zone in the subsurface carrying the PFAS contamination rather than simply treating a broad vertical section of aquifer, as is often the case with pumping systems. This targeting of the vertical PFAS flux zone allows for a more accurate interception of the PFAS mass requiring treatment and usually results in a much lower cost of treatment. The use of direct-push injection or dedicated injection wells targeting these flux zones allows for accurate application of the CAC suspension.

The longevity of any CAC treatment performance will be dependent upon PFAS composition, rates of PFAS mass discharge, presence of co-contaminants, CAC dosing, and CAC application design. **Carey et al. (2019)** performed modeling with respect to an actual full-scale CAC project site to predict the theoretical longevity and performance of the CAC to treat PFAS in groundwater in the presence of hydrocarbons. Results indicated an anticipated longevity of successful PFAS treatment on the order of decades. The study noted that longevity of performance could be extended by increasing the CAC dose, by increasing the thickness of the treatment zone perpendicular to flow, or by additional injection upon any future PFAS breakthrough.

Sustainability: The environmental footprint of in situ CAC treatment is relatively small when compared to treatment technologies requiring pumping of groundwater and aboveground separation of contaminants, hauling of waste, and then destruction of collected waste. CAC operates passively. Use of CAC avoids on-going energy requirements and greenhouse gas associated with operation and maintenance of pump and treat systems.

The **Danish EPA (2022)** performed a sustainable remediation methodology assessment (**ISO 2017**) generating a comparative full life cycle analysis (LCA) on the use of a commercially available CAC product, and pump and treat technology for treating groundwater contaminants. Results showed that over a 30-year operating period, the CAC treatment generated less than 5% of the greenhouse gases generated using the pump and treat approach. Although the actual site chosen for comparison in the study was treating trichloroethylene contamination, the comparative LCA results may provide information about the sustainability of the CAC treatment approach relative to pump and treat approaches for carbon-sorptive dissolved organic contaminants.

12.2.5 Supercritical Water Oxidation

The Priority Topics for Treatment Technologies include updated information for supercritical water oxidation (see **Section 1.6.2**).

12.3 Field-Implemented Solids Treatment Technologies

Field-implemented technologies are those that have been implemented in the field by multiple parties at multiple sites and have widespread regulatory approval, and the results have been documented well in the peer-reviewed literature. The technologies in this section may be applied to a variety of PFAS-impacted solid media, including soil, sediments, or sludge. The Priority Topics for Treatment Technologies include updated information about treatment of PFAS-contaminated sediment (see **Section 1.6.4**).

One unique class of solid waste that may require treatment is biosolids generated by wastewater treatment plants, which have been historically managed through land application, use or disposal at landfills, or incineration. These technology options have not been fully evaluated to determine their effectiveness for PFAS in field-implemented examples. The regulatory landscape for management of biosolids is evolving, and some states have started to require testing. A few prohibit land application if concentrations of certain PFAS are greater than specific levels. (see **Section 12.1.4.3**)

Site-specific evaluation is always needed to identify the best technology for a given treatment scenario. As with water treatment, solids treatment can be performed ex situ (for example, excavation or dredging) or in situ (for example, injection or reactive capping). At present, field-implemented solids treatment has been performed almost entirely ex situ. There are currently three known field-implemented technologies for treating soil contaminated with PFAS: sorption/stabilization, excavation/disposal, and soil washing.

12.3.1 Sorption and Stabilization

Treatment Description: Amendments are added to the soil and sediment to reduce the potential for PFAS to mobilize from soil and sediment to groundwater and surface water. For sorption purposes, PFAS-adsorbing materials (for example, activated carbon) can be applied through in situ soil mixing or ex situ stabilization (for example, pug mill mixing) to reduce the leachability of PFAS from contaminated soil/sediment through physical and/or chemical bonding.
Sorption and stabilization (considered "immobilization" or "chemical fixation" technologies) is a relatively quick, simple, and low-cost (relative to off-site disposal) way to reduce ongoing PFAS contamination transport to waterways and groundwater from source zones. The main disadvantage is that these technologies do not destroy the contaminants, but rather bind or immobilize them. For some amendments, established test methods have shown the binding to be stable over the long-term (see below).

Stabilizing PFAS in situ may reduce the effectiveness of future in situ soil treatments and thus limit future remediation to excavation and disposal to landfill or in situ remediation employing strong chemicals and/or high energy inputs to overcome stabilization bonds. Long-term project objectives should be carefully evaluated before implementing any technology that could limit future options. Additionally, in flood-prone areas, immobilized/stabilized soils with PFAS could be eroded and transported off site.

Treatment Mechanism: Amendments adsorb or stabilize PFAS to reduce their release from soil. This occurs primarily through electrostatic interactions between charges on the PFAS functional group and charges on the sorbent, as well as hydrophobic interactions between the amendment and the carbon-fluorine chain on the PFAS. "Principal component analysis" has shown "that electrostatic sorption dominates for shorter chained PFAS and that hydrophobic sorption dominates for longer chained PFAS" (**Sörengård et al. 2020**). Typical amendments that have been demonstrated in the field include activated carbon and activated carbon-composite materials, such as activated carbon blended with aluminum hydroxide, kaolin, and carbon. Some of these blends are said to be specifically designed to treat anionic, cationic, and zwitterionic long- and short-chain PFAS (**Kempisty, Xing, and Racz 2018**).

State of Development: Sorption and stabilization techniques using carbon-based amendments are considered field-implemented technologies. Various amendments have been applied to soil/sediment both in situ and ex situ. Different delivery methods for amendments, such as injection or in situ mixing, may provide different results depending on geology and objectives. Proprietary formulations of activated carbon with inorganic amendments have been developed with the intent of increasing their sorption of PFAS. One such product was used on a large-scale project involving the ex situ treatment of 900 tons of PFAS-impacted soil from an airport site in Australia (**Stewart 2017**). However, controlled third-party laboratory studies (**Sörengård et al. 2020**) and field tests (**USEPA 2017**) have shown little advantage to these formulations when compared to powdered activated carbon alone. Additional studies have been performed looking at biochar (**Zhang and Liang 2022**) and fly ash (**Sörengård et al. 2022**), with mixed results.

Effectiveness: Sorption and stabilization techniques vary in their effectiveness according to site conditions, PFAS types, mixing approaches, and amendments chosen.

The effectiveness of 44 different sorption amendments to treat a wide range of PFAS was studied and summarized in a detailed and controlled series of experiments (**Sörengård et al. 2020**). The study

included three forms of powdered activated carbon, a commercial proprietary blend of carbon and minerals, granular activated carbon, biochars, and a number of other sorbents. Results showed the powdered activated carbon amendments outperformed all other amendments in sorbing PFAS in all PFAS groups measured (short-chain C3–C7 PFCAs, long-chain C8–C17 PFCAs, and PFSAs, FTSAs, and FOSA).

A study conducted with an activated carbon-based blend amended with inorganic minerals showed that at average addition rates of around 2.5–5% (wt/wt), PFOS and PFOA in soil leachates were reduced by 95% to >99% following a 48-hour treatment process (**Stewart and MacFarland 2017**).

The charge on the PFAS affects sorption (for example, cations sorb more readily than zwitterions and anions). Aquifer and soil chemistry also affect the sorptive ability of PFAS onto the amendments. High organic content in soil can reduce effectiveness (**NGWA 2017**). Low pH, the presence of polyvalent cations in the soil, or treatment amendment also increases sorption, retardation, and metals precipitation. An independent study at the University of Adelaide, Australia, showed that environmental ranges of pH and ionic strength did not adversely affect the binding of a specialized amendment to PFOA (**Lath et al. 2018**). Co-contaminants also play a role in the effectiveness of PFAS sorption. A recent review article (**Li, Oliver, and Kookana 2018**) showed that the organic carbon component of natural soils and sediments plays less of a role in PFAS sorption than once thought; the mineral component of the soil/sediment and the pH conditions play a more important role in PFAS adsorption.

In independent studies, the Multiple Extraction Procedure (MEP; USEPA Method 1320; **USEPA 1986**) has been used to successfully demonstrate the simulated long-term stability of immobilized PFAS in amended soils (**Stewart and MacFarland 2017**). The MEP is designed to simulate 1,000 years of acid rain conditions in an improperly designed sanitary landfill. In another independent study, the accumulation of PFAS in earthworms and plants was reduced by >90% in soil treated by carbon-based immobilization compared to untreated soils (**Bräunig 2016**; **Kempisty, Xing, and Racz 2018**). The amended soil can be mixed with concrete and other stabilizers to improve performance; however, the concrete increases pH and may influence binder performance (**Ross et al. 2018**).

Design/Operating Considerations: To establish design and application parameters for implementation of sorption and stabilization technology in soils, it is necessary to perform site-specific laboratory and/or pilot treatability tests. Information and quantity of amendment material required (dose rates) for materials can be determined with either simple beaker or jar-type lab treatability tests. These studies are most applicable if site soils and water are used to ensure that the effects of site-specific geochemical characteristics are assessed. Once the dose of amendment material is determined, field pilot studies are often conducted to validate lab data and design for full-scale implementation.

For in situ soil mixing, the amendments are added to soils at the design dose or application rate under controlled conditions with specific types of equipment designed to perform mixing. In situ soil mixing can be performed on soils in place with a wide range of standard construction equipment, including excavators, large diameter augers, and in situ blenders. In addition to in situ soil mixing, soils can be removed and mixed in equipment such as a pug mill or other similar mixing systems. As for other contaminants that have been stabilized in projects executed over the past 30 years, the thoroughness of the mixing can impact performance of PFAS-specific stabilizing agents.

After implementation of in situ soil mixing, it is important to perform postconstruction quality assurance and quality control to verify design endpoints. This may include leachability (Toxicity Characteristic Leaching Procedure (TCLP), USEPA Method 1311(**USEPA 2021**); Synthetic Precipitation Leaching Procedure (SPLP), USEPA Method 1312(**USEPA 2021**); or Multiple Extraction Procedure (MEP), USEPA Method 1320(**USEPA 2021**)), hydraulic conductivity (ASTM D5084, **ASTM 2016**), and strength tests (various). ITRC has prepared a technical and regulatory guidance document on the development of

performance specifications for solidification/stabilization (**ITRC 2011**) that may prove useful in planning a PFAS soil stabilization/solidification project.

Sustainability: The environmental footprint for sorption and stabilization includes emissions from earthwork equipment, manufacturing, and transporting amendment material. This footprint can be smaller than excavation if the treated soil is reused on site. Community impacts include hindrance of redevelopment due to land use restrictions. However, if the land use is not expected to change, such as on active government-owned aviation or military sites, stabilization with amendments and reuse of the soil may be a viable and cost-effective approach. If PFAS regulations change in the future, which is likely, reusing the PFAS-impacted soil could expose a facility owner to future liability.

Resources are available for performing a sustainability assessment for sorption and stabilization remedial design, relating to other contaminants (**Goldenberg and Reddy 2014**; **Hou et al. 2016**; **Kuykendall and McMullan 2014**).

12.3.2 Excavation and Disposal

Treatment Description: This approach involves removing contaminated soil/sediment for off-site disposal. The contaminated material is disposed of at a permitted landfill, then the excavated area is filled with clean backfill. Treatment with stabilizing agents can reduce PFAS leachability from excavated soils and should be considered prior to landfilling. Sometimes, excavated soil/sediment can be treated on site using the sorption and stability approach or thermal treatment (as discussed in the Sections **12.4** and **12.7.2**) followed by soil reuse or off-site disposal.

Treatment Mechanism: This method is intended to remove PFAS from the source location. Transportation and disposal in a lined landfill is an option for excavated soil; however, leachate management should be a consideration at these facilities (see **Section 12.1.4.2**).

State of Development: Soil excavation and disposal is a well-demonstrated, proven technology. However, PFAS have been reported in landfill leachate (**Lang et al. 2017**), although the source for PFAS in leachate may be consumer product waste containing fluorochemicals. In some states, the leachate is not analyzed or regulated for PFAS. Disposal of PFAS waste to landfills potentially adds to the PFAS contaminant load in the landfill leachate. Some nonhazardous waste landfills do not accept PFAS waste.

Effectiveness: Excavation and disposal of PFAS-contaminated soil effectively removes a source area that may otherwise serve as a continuing source of groundwater contamination but does not result in destruction of the PFAS. Disposal of PFAS-impacted soils or wastes into unlined landfills should be avoided as unlined or improperly lined landfills can be sources of PFAS to the environment.

***Design/Operating Considerations*:** Difficulties in finding landfills willing to accept the waste, coupled with rapidly changing regulations regarding whether PFAS are hazardous or not, make this option less straightforward than one would expect. Case-by-case inquiries to landfill facility owners is likely the best course of action. Overall, issues related to disposal of PFAS in landfills are similar to issues commonly encountered with other contaminants. See **Section 2.6.3**, Solid Waste Management, for additional discussion on this topic.

Sustainability: The environmental footprint for excavation and disposal includes earth-moving equipment emissions, transporting contaminated soil and backfill, and resource extraction (such as borrow area fill material) of backfill material.

Truck hauling traffic affects the local community by creating additional traffic congestion, noise, and particulate matter emissions. The cost for this approach is high, but the solution is generally permanent and for smaller treatment volumes may be cost-competitive. Guidance is available for performing a sustainability assessment for an excavation and disposal remedial design (**Cappuyns and Kessen 2013**; **Goldenberg and Reddy 2014**; **Söderqvist et al. 2015**; **Song et al. 2018**).

12.3.3 Soil Washing

Treatment Description: Soil washing is generally considered a media transfer technology. It is an on-site, ex situ treatment process that uses physical separation and chemical desorption/extraction techniques to remove adsorbed PFAS mass from soil. Fundamentally, the application of soil washing systems relies on the principle that most environmental contaminants, with the propensity to interact with soil, will preferentially bind to the finer soil fraction (for example, clays and silts) versus the coarser grained soil fraction (for example, sands and gravels) (**USEPA 1996**). Soil washing systems use a wash solution usually consisting of water, but surfactant and/or an extraction solvent can also be used to dissolve and concentrate PFAS (**ESTCP 2022**). Physical size separation techniques are used to separate the finer grained from the coarser grained soil particles, thereby concentrating and reducing the PFAS-impacted soil volume that must be further treated or disposed. Refer to **Figure 12-6** for a typical soil washing process schematic.

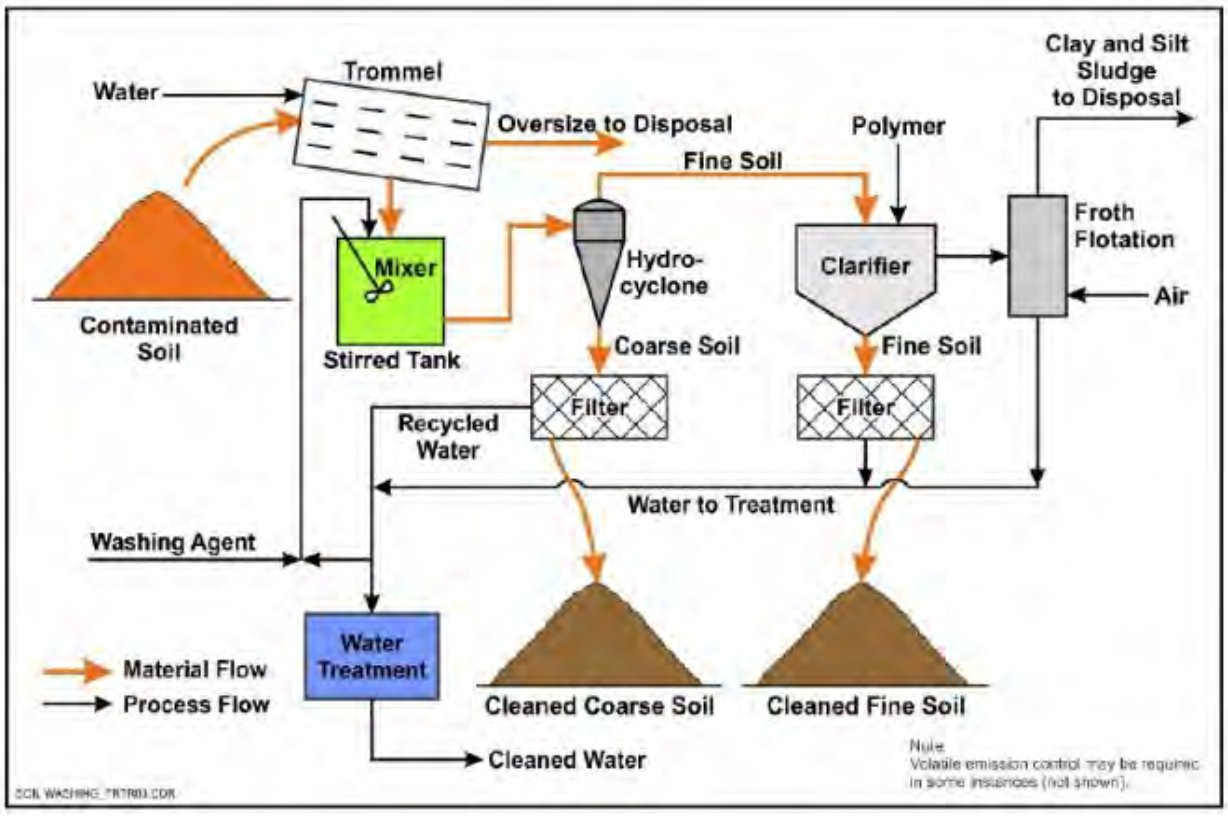

Figure 12-6. Soil washing process schematic.

*Source: Federal Remediation Technologies Roundtable (**https://www.frtr.gov/matrix/Soil-Washing/**).*

Treatment Mechanism: The concept of reducing PFAS soil contamination via particle size separation is underpinned by the preference of PFAS to sorb to soil fractions with high organic carbon content, promoting stronger hydrophobic interactions. Typically, finer soil fractions (for example, clays and silts) are enriched in organic carbon relative to coarser grained soil fractions (for example, sands and gravels). Therefore, using a fluid, such as water, to promote particle size separation can effectively segregate the soil fraction containing the highest PFAS impact. The PFAS impacted fine grained soil fraction can be further processed to minimize volume and managed separately for treatment or disposal from the coarser grained soil fraction. Several mechanical approaches can be implemented to facilitate the particle size separation process, including vibratory screens, trommels, hydrocylcones, and spiral classifiers (**USEPA 1999**).

During the soil washing process, the sorbed PFAS mass may transfer from the solid phase to the liquid phase through diffusion processes. Additionally, PFAS mass removal from impacted soil may be enhanced by promoting both desorption and dissolution into the liquid phase by flushing with water or an extraction solvent. PFAS extracted into the aqueous phase is then treated by other technologies (for example, GAC and/or IX) or staged for off-site disposal (**ESTCP 2022**). Leveraging desorption for PFAS mass reduction in impacted soil during the soil washing process is most effective for PFAS with lower distribution coefficients (i.e., less preference for the solid phase) and higher solubility in the wash solution.

State of Development: Soil washing is considered a field-implemented technology based on its history with other contaminants and has been evaluated for PFAS treatment efficacy in multiple field tests. The technology grew out of mining industry operations and was modified for environmental applications during the 1990s. It has historically been applied to soils contaminated with metals, semivolatile organics, and PCBs/pesticides (**USEPA 1999**; **USEPA 1993**). The same soil particle size separation and dissolution wash processes employed for these historical contaminants have been transitioned for application to PFAS-impacted soils based on similar physical and mass transfer properties. The transference of these separation and removal processes has been verified for PFAS-impacted soils by field demonstration projects performed to date. PFAS soil washing pilot/field demonstration projects have been performed at multiple Australian and U.S. sites (**Quinnan et al. 2022**; **ESTCP 2022**; **Becker 2022**). There are currently only a small number of vendors offering ex situ soil washing for full-scale applications. Further research and field studies are still required for alternative surfactants/extraction solutions that can be employed to remove PFAS more effectively from the finer grained soil fraction.

Effectiveness: A general guideline for contaminant reductions by soil washing is 90%–95% for the coarser grained soil fraction, assuming particle size separation of the coarser grained soils and mass transfer to the liquid phase for follow-up treatment/removal.

Results from an ESTCP pilot test confirmed that coarser grained sand and gravel fractions met performance goals, while the finer grained fraction was segregated for later treatment or disposal. The grain size composition was approximately 30% gravel, 40% sands, and 30% fines. Approximately 180 tons of PFAS-impacted soil was treated. Baseline PFOS concentrations detected in composite samples representing combined particle sizes ranged between 3.9 and 740 µg/kg, while detected baseline total PFAS concentrations ranged between 5.38 and 874 µg/kg. PFOS removal efficiencies were generally highest in the gravel fraction (94.6%–98.1%), followed by the sand fraction (88.6%–96.1%), and the finer grained fraction (-7.7%–61.8%, where variability in the PFAS concentrations in the finer grained fraction is thought to have caused the negative removal efficiency). The removal efficiencies for total PFAS for the coarser grained fraction were generally higher than PFOS for each stockpile, indicating that the soil washing process was effective at removing other PFAS (**Quinnan et al. 2022**; **ESTCP 2022**).

Another field-scale soil washing demonstration investigated the treatment of approximately 573 cubic yards of PFAS-impacted loamy sandy soil and sediments. Baseline stockpile characterization for PFOS concentrations ranged between approximately 3,000 µg/kg and 12,000 µg/kg for the coarser and finer

soil fractions, respectively. Following two rounds of soil washing treatment, the coarser grained soil fraction showed a PFOS reduction of 99% while the finer grain soils PFOS reduction was 89%. Because of the particle size separation, the total soil volume requiring off-site disposal was reduced by more than 90% (**Becker 2022**; **ESTCP 2022**).

Design/Operating Considerations: Determining the soil grain size distribution, as well as PFAS concentrations within the various grain size types, are the key design/operating considerations. Since soil particle size separation represents the primary PFAS removal/soil volume reduction mechanisms, soil washing is less cost-effective as the percentage of finer grained soils increases. A particle size distribution of 0.25–2 millimeters is considered optimal for soil washing, while <0.063 millimeters may not be viable, which correlates to <25% silts and clays considered optimal and >50% may not be viable (**USEPA 1990**; **1997**). High clay content with corresponding high moisture levels poses a material handling and feed challenge. Heterogeneity and inconsistent feed conditions can also impact PFAS removal efficiency, which can require preprocessing for homogenization. Soils may need to be segregated by order of magnitude concentrations and treated using different process conditions to optimize treatment throughput and minimize treatment costs. Other key process parameters include soil throughput, retention time, contaminant solubility, wash solution to soil ratios, soil cation exchange capacity, and design parameters associated with the wash solution treatment and soil dewatering processes.

Sustainability: Intensive energy usage is required for the various material handling, separation, and liquids treatment operations. The generated wash solution requires treatment but can be recycled for continuous reuse. Treated soils can potentially be redeposited on site if applicable regulatory criteria are met, which avoids off-site disposal. Separated finer grained soils that do not meet regulatory criteria require off-site disposal.

Related Ongoing Research Funded by SERDP

- ER20-5258 Ex Situ Soil Washing to Remove PFAS Adsorbed to Soils from Source Zones

12.4 Incineration

Because of the increasing interest in incineration from the public, press, and regulatory community, and the potential application of incineration to liquids or solids, the following information is being provided as a separate section. The Priority Topics for Treatment Technologies include updated information for incineration, pyrolysis/gasification, and thermal desorption (see **Section 1.6.1**).

Treatment Description: Incineration is defined as "burning hazardous materials at temperatures high enough to destroy the contaminants" (**USEPA 2012**). Incineration is destruction (mineralization) using combustion, which requires heat and oxygen. Heat is applied directly to the PFAS-contaminated solids (soil/sediment/spent adsorbents/waste) or liquids (AFFF/water/wastewater/leachate/chemicals). Vaporized combustion products can be captured (precipitation, wet scrubbing) and/or further oxidized at elevated temperature. Pyrolysis and gasification are related thermal treatment technologies. Some additional information about pyrolysis and gasification is discussed in **Section 12.5**, thermal treatment for air sources and in **12.7.2** thermal treatment for solids.

State of Development: Incineration is a mature technology that has been used for various solid and liquid wastes, but its ability to remove PFAS from waste streams is a topic of study. The USEPA has compiled a PFAS Thermal Treatment Database (**USEPA 2022**) to help synthesize the current body of research.

Effectiveness: Incineration is one of only a few technologies that can potentially destroy PFAS, though the conditions required to destroy PFAS are not well understood (**USEPA 2024**). In December 2020,

USEPA released a draft interim guidance on destruction and disposal of PFAS (**USEPA 2020**) and Version 2 was released in April 2024 (**USEPA 2024**). Recent testing and reporting of PFAS destruction by incineration has documented destruction efficiencies of greater than 99 percent for some PFAS (**Barr Engineering 2022**; **Chemours 2023**; **EA Engineering 2021**).

There are multiple areas of active research to evaluate the effectiveness of incineration which initially focused on destruction temperatures and treatment times. Ongoing research is also assessing the potential of incineration to generate byproducts of incomplete combustion, to analyze stack gas, to understand deposition onto land, and to manage incinerator wastes, along with other potential risk factors.

In April 2022, in response to a congressional requirement in the National Defense Authorization Act (NDAA), the Department of Defense (DOD) placed a temporary ban on incineration of PFAS-containing materials generated by the DOD up until such time as a PFAS disposal policy was developed consistent with **USEPA (2020)** and Section 343 of the 2022 NDAA. The DOD published a memo with interim guidance about destruction or disposal of materials containing PFAS, including AFFF that has been taken out of service, on July 11, 2023 (**USDOD 2023**). The DOD interim PFAS disposal guidance supersedes the previous temporary moratorium and is expected to be updated annually. **USDOD (2023)** identifies the following PFAS disposal options in order of prioritization: 1) Spent GAC reactivation at a RCRA permitted facility; 2) landfilling at a permitted RCRA Subtitle C hazardous waste facility; 3) landfilling at a permitted RCRA Subtitle D non-hazardous solid waste facility with an appropriate leachate and gas collection and management system; and 4) incineration at a permitted RCRA Subtitle C hazardous waste facility. Publicly available air testing results for PFAS incineration destruction efficiency and byproducts of incomplete combustion were considered in the development of the DOD interim PFAS disposal guidance, while ongoing PFAS incineration research and updates to **USEPA (2020)** will be incorporated into the future annual updates. A follow-up statement was published on July 17, 2023 about additional planning and coordination that is needed before incineration is implemented (**USDOD 2023**).

Design/Operating Considerations: Waste incinerators are fixed facilities. Federal and state permits dictate the materials processed, core incinerator operations (for example, temperature and time, turbulence), and control of process air, liquid, and solid wastes. Permit and design/construction similarities reduce the operational and performance differences between individual incinerators.

When considering waste disposal options, transportation costs, energy costs, regulatory approvals, and final disposition of process waste residues should be evaluated, as these differ among incineration facilities.

Sustainability: The environmental footprint for incineration includes transportation and supplemental fuel for the incineration process. Incineration of contaminated soil, liquid wastes, and IDW is energy-intensive and PFAS emissions, including potential PFAS combustion byproducts, from incinerators are currently not well understood (**USEPA 2020**). Truck hauling traffic affects the local community by creating additional traffic congestion, noise, and particulate matter emissions. The cost for this approach is high, but the solution may be cost-competitive for smaller treatment volumes.

12.5 Air Treatment Technologies

PFAS vapors or particles can be generated during any activity that involves PFAS or materials containing PFAS. The multitude of sources for PFAS-containing vapors and particles, some of which are unique due to their specific function (for example, industrial or commercial processes), is complicated by a lack of basic understanding of the chemical and physical properties for PFAS that are not used as widely. Additionally, air emissions should be considered as part of any PFAS-related activity, regardless of whether it is the primary media being treated. For example, during landfill leachate treatment, air emissions could be generated, requiring treatment.

PFAS vapors or particulates may be captured by conventional air pollution control (APC) equipment that has been historically developed to control vapors, particles, and fine dusts emitted from permanent industrial sources or temporary environmental or construction sites. Though the effectiveness of conventional APC technologies in removing PFAS from air streams is not well understood, current practice is to apply these methods and practices of vapor and dust control that are presently used or required for similar equipment and processes. The performance of these technologies should continue to be researched and documented with a focus on those PFAS that can be reliably quantified. Specific research needs for the emissions from thermal treatment technologies, including those related to APC equipment, are discussed in USEPA (**2024**, section 3.a).

A standardized method for stack testing for PFAS emissions has only recently been developed (see **Section 11.1.7.12**), and stack testing to date has primarily focused on the overall removal efficiency for the destruction technology being evaluated (for example, see **Barr 2022**). Sampling stack emissions and performing adequate analysis is an active area of research and will need to be a part of assessing adequate treatment of any stack emissions thought to contain PFAS. Additional information on the effectiveness of thermal treatment technologies is included in **Section 12.7.2**.

12.5.1 Conventional Air Pollution Control (APC) Technologies

PFAS vapors may be captured by conventional APC equipment. However, this does not mean that older methods do not need to be tested to document their performance, nor does it mean the older methods should not be modified or entirely redesigned to account for PFAS. Rather, it means that conventional APC technologies that can treat vapors and particles containing PFAS may have some level of removal efficiency and should be evaluated to ensure appropriate capture or destruction is taking place.

Thermal treatment technologies for PFAS contained in emissions are an area of focus in the research community. A limited number of these technologies have been implemented and are currently being evaluated for their efficiency.

Technologies and equipment for control of potential emissions can be placed in four groups: 1) those that capture PFAS-containing particles; 2) those that capture PFAS-containing vapors, 3) those that capture PFAS in both vapors or particles, and 4) those that destroy PFAS in the air stream being emitted from the process. Destruction of PFAS through thermal oxidation and incineration is briefly covered here and is also covered in **Section 12.4**. Particle capture and vapor capture are further described below. More information about specific air pollution control technologies is available from **USEPA (2022)**, which is a web site with links to individual technology fact sheets.

12.5.1.1 Particle Capture

PFAS that are fully partitioned to particulate matter in the air stream could be removed by particle capture mechanisms:

- Bag houses and similar units rely on filter media whose pore openings are smaller than the smallest targeted particle or particulate. The nature of the targeted material is less important than its overall size and smallest dimension. The filter material may be configured as a bag or a sheet. Either may be flat or pleated to increase its surface area within a specific area perpendicular to the air flow.

- Cyclones accelerate the speed of a particle as it travels a circular path that continually decreases in diameter. As the same amount of air is forced through a smaller cross section, its velocity increases. The weight of a particle or particulate becomes the force that pushes it to the outer diameter of the spiral. A collection point in the design diverts the slice of total air flow containing all particles traveling along the outer wall to a collection vessel. This method generally works best when the air is relatively dry so that the solids do not adhere to the walls of the cyclone.

- Wet scrubbers add a liquid (typically water) to the air stream being treated. They are used to control airborne vapor and particles. There are two main reasons for the addition of water:
    - Water adsorbs to the particle to increase its weight and accelerate its settling under the force of gravity. The air flow is often horizontal to the unit, and the cross-section of the wet scrubber increases greatly (at least an order of magnitude) immediately after the point where the liquid is introduced.
    - Water in the liquid droplets, mist, or fine spray provides enormous area through which water-soluble or miscible vapors may dissolve. The rapidity of this transformation is important because the time the air stream is exposed to water droplets or vapors are in contact with the air stream is typically very limited.
        - Wet-scrubber air often flows horizontally to allow more volume or area for the particles to fall or settle.
        - Wet scrubbers (or scrubber towers) through which air travels vertically and is discharged at the top often employs a greater mass or volume of water to a given mass of particles or vapors than a horizontal configuration. This provides more water particle surface area and higher humidity, which improves capture of vapors and/or particles.

- Electrostatic precipitators (ESPs) contain one or more grids of fine wires perpendicular to the air flow. Electrical current applied to the grids creates a small, opposite charge on particles in the air or changes the charge on individual particles. These charges are intended to enhance the capture of particles on the charged grids and potentially other surfaces of the unit. Low humidity in the air to be treated is desirable.

12.5.1.2 Vapor Capture

APC technologies that specifically target vapors are few, though the use of various media allows capture of specific contaminants or mixtures of contaminants better than on one medium. The most common vapor treatment technique is adsorption of vapors, which may contain PFAS, from the treated airstream onto media. Media may include granular activated carbon, raw or coated clays, or synthetic resin. Some media may capture numerous PFAS while others perform better for groups (for example, short- or long-chain compounds or those with specific subgroups). The evaluation of the efficiency of these technologies depends on important operating conditions such as the empty-bed contact time (EBCT),

which can vary for each media type. Typical vapor control EBCTs range from seconds to a minute. Very fine (powdered) dry media can be injected into the air stream in special cases. However, the practice is unusual in environmental remediation and creates an additional waste stream (that is, the powdered media) that must be managed. These technologies will require continued evaluation and ongoing research to ensure that the objectives for PFAS removal in the air stream are adequate.

12.5.1.3 Thermal Treatment

The use of thermal treatment for PFAS destruction in stack emissions is a topic of current research and is dependent on having reliable methods for sample collection and analysis of PFAS contained in those emissions. Pyrolysis, gasification (see **Section 12.7.2**), and thermal oxidation are being investigated for their use and efficiency on PFAS-laden air streams. Some investigations have shown significant levels of PFAS removal using these methods (**Winchell 2022**; **Chemours 2020**; **Barr 2022**). Continued data collection on the efficiency of these systems will guide this important management option to control PFAS in stack emissions in the future. The Priority Topics for Treatment Technologies include updated information for incineration, pyrolysis/gasification, and thermal desorption (see **Section 1.6.1**).

12.6 Limited Application and Developing Liquids Treatment Technologies

The treatment technologies presented in this document are provided in a hierarchy defined in **Section 12.1**, which is based on level of implementation and confidence derived from widespread, well documented examples. The three development levels are: field-implemented technologies, limited application technologies, and developing technologies. Both in situ and ex situ technologies are included in this section. It is not always clear if a limited application or developing technology may be effective in situ, ex situ, or both; therefore, further distinction is not made in this section.
The field-implemented technologies described in the preceding sections have been applied at multiple sites and are well documented in the available literature. In addition to these well-demonstrated technologies, many technology approaches have been tested in academic and other research laboratories at the bench scale or have progressed as far as field pilot tests or limited field applications. These limited application technologies are briefly summarized in the **Table 12-1 Treatment Methods Table** Excel File. Additional information is provided in the following sections.

Not all of these limited or developing technologies have been demonstrated as suitable or effective under multiple treatment scenarios. For instance, destructive technologies, such as electrochemical oxidation, nonthermal plasma, hydrothermal alkaline treatment, and supercritical water oxidation, have been shown to be effective for treatment of high concentration, low volume liquids but may be less suitable for high volume, low concentration liquids.

12.6.1 Sorption Technologies

12.6.1.1 Coated Sand

Polymer-coated sand is an adsorbent material that has high affinity for organic contaminants. Cyclodextrin molecules are polymerized by a cross-linking agent and form inclusion complexes with many organics. The adsorbent material has two components: (a) polymer coat (active component that removes the contaminants) and (b) support base (inactive component); the combination of both provides an adsorbent with high selectivity and mechanical stability.

The adsorbent showed similar performance in removing PFOA and PFOS as GAC, but one of the key features of this technology is the high regenerability of the adsorbent (filter) for reuse (**Bhattarai, Manickavachagam, and Suri 2014**). Another important feature of the technology is that it can remove other organic pollutants such as chlorinated solvents (for example, trichloroethene (TCE), perchloroethylene (PCE), hexavalent chromium, and others (**Badruddoza, Bhattarai, and Suri 2017**). Surface modification has been shown to improve the adsorption of PFOS (**Zhou, Pan, and Zhang 2013**) by using organic polymeric surfactants.

12.6.1.2 Zeolites/Clay Minerals (Natural or Surface-Modified)

Zeolites are naturally occurring aluminosilicate compounds that are widely used in chemical separation and purification due to their high surface area and small uniform pore size among other properties (**Tao et al. 2006**). Zeolites are also being increasingly considered as a medium for the sorption of various pollutants, including cationic heavy metals, ammonium, and some volatile organic compounds, due to the aforementioned properties, as well as their high ion exchange capacity and low cost (**Delkash, Ebrazi Bakhshayesh, and Kazemian 2015**). Clay minerals, including natural and surface-modified (see below), are also used as adsorbents and are similar to zeolites in composition but have different crystalline or chemical structure. Surface-modified clays have been reported to have enhanced adsorption performance for a variety of organic and inorganic constituents (**Han et al. 2019**), as well as for PFAS (**Zhou et al. 2010**, **2013**).

Both zeolites and clay minerals can be used ex situ (that is, pump and treat) by being placed in packed-bed flow-through vessels or in situ via injection into aquifers. In situ applications of these materials are lacking in study or field application. Most available literature is limited to academic laboratory experiments (**Ochoa-Herrera and Sierra-Alvarez 2008**; **Punyapalakul et al. 2013**; **Zhou, Pan, and Zhang 2013**; **Zhou et al. 2010**). **Du et al. (2014)** and **Arias Espana, Mallavarapu, and Naidu (2015)** provided comprehensive literature reviews. Zeolite and clay minerals use both ion exchange and adsorption mechanisms to remove PFAS from water. These materials exhibit widely varying PFOS and PFOA adsorption capacities (**Du et al. 2014**), so PFAS adsorption performance should be assessed for each specific zeolite or clay-based media. However, synthetic processing of zeolite can create highly siliceous material (**Baerlocher 2007**) or can incorporate cationic surfactants into the surface structure (aka surface-modified zeolites–SMZ) (**Jiménez-Castañeda and Medina 2017**). One study indicated that engineered zeolites with a high Si/Al ratio were effective at adsorption of PFOS, presumably due to hydrophobic interactions rather than ion exchange (**Ochoa-Herrera and Sierra-Alvarez 2008**).

Surface-modified clays are made by intercalating a modification agent into the clay that has a high affinity for specific classes of contaminants. For PFAS adsorption, the modification agent is attached to

the clay via cation exchange sites and includes electrostatic and hydrophobic moieties that are highly specific for PFAS. Mechanistically, PFAS molecules diffuse into the interlayer space of the surface-modified clay and then are bound through ionic and van der Waals forces with the fixed modification agent (**Yan et al. 2021**).

Two modified clay-based adsorbent products are identified as being used in field pilots or small-scale field trial applications (**Arias et al. 2013**; **Arias Espana, Mallavarapu, and Naidu 2015**) to treat PFOA and/or PFOS.

A commercially available surface-modified clay was successful at adsorbing a variety of PFAS from AFFF-impacted groundwater. The media was resistant to fouling by groundwater constituents, such as natural organic matter, and common co-contaminants (diesel, TCE, and 1,4-dioxane) (**Yan et al. 2020**). Laboratory and pilot-scale column testing of surface-modified clay for PFAS removal from contaminated groundwater that is to be used for drinking water showed PFOS and PFOA removal to the treatment target (2 ng/L). This media demonstrated a shorter empty bed contact time (EBCT) and longer media bed life than 13 other adsorbents (**Pannu and Plumlee 2021**; **Hwang and Grieco 2021**). PFAS adsorption (short- and long-chain) by using surface-modified clay with a variety of water types was examined in **Grieco et al. (2021)** and **Najm et al. (2021)**.

High silica materials, such as H-form synthetic mordenite (HSM) and Y-form sodium zeolite (NA-Y80), and hydrotalcite clay provided adsorption capacities that were equivalent or exceeded powdered activated carbon (PAC). Surfactant-modified clays also performed as well as or better than PAC. It should be noted that none of these studies were conducted in flow-through column experiments, so applicability to ex situ treatment systems cannot be assessed. **Arias Espana, Mallavarapu, and Naidu (2015)** stated that organoclays, clay minerals, and highly siliceous materials have fast kinetics (0.4–3 hr to reach equilibrium), making them suitable for remediation applications.

12.6.1.3 Biochar

Biochar is a hybrid word rooted in the words “biomass” and “charcoal.” Biochar is a carbon-rich porous solid that is synthesized by heating biomass, such as wood or manure, in a low oxygen environment (**Ahmad et al. 2014**). Biochar may be produced by pyrolysis of PFAS-impacted media (**Thoma et al. 2021**). This material has primary applications for carbon sequestration, improvement of soil fertility, and most recently as an adsorbent for pollutant removal. Biochar is characterized to have high affinity for organic contaminants, which is dependent on both the pore structure and the surface functional groups of the biochar material (**Guo et al. 2017**).Some of the key factors controlling the properties of biochar (for example, pore size composition and hydrophobicity) include the temperature of pyrolysis and biomass feedstock, among others. In many respects, the properties of biochar are similar to but generally lower than those of GAC for sorptive purposes.The variability of biochar with regard to performance parameters and quality control makes it challenging to implement on a large scale, and procuring large volumes of consistent materials and meeting design specifications can be challenging at large scales.

The available literature is limited to academic laboratory batch experiments on the bench-scale (**Chen et al. 2011**; **Inyang and Dickenson 2017**; **Kupryianchyk et al. 2016**; **Rahman et al. 2014**; **Xiao, Ulrich, et al. 2017**), with one published study reporting pilot-scale column operation (**Inyang and Dickenson 2017**).

12.6.1.4 Hydrogels and Fluorogels

Efficient removal of short-chain PFAS from water can be achieved using hydrogels and fluorogels because of their high selectivity and affinity for these compounds (**Ateia et al. 2019**; **Kumarasamy et al. 2020**). For example, **Ateia et al. (2019)** demonstrated selective, rapid removal of 16 PFAS using cationic polymer (hydrogel) poly (N-[3-(dimethylamino)propyl] acrylamide, methyl chloride quaternary (DMAPPAA-Q). While adsorption was not reversed in a standard environmental matrix, regeneration was possible using a simple solvent/salt matrix. Performance was maintained in six consecutive sorption/regeneration cycles.

12.6.2 Precipitation/Coagulation/Flocculation

Precipitation/coagulation/flocculation is a common pretreatment approach used in wastewater treatment plants for removing various particles and dissolved constituents. Coagulants, either commodity or proprietary chemicals, can be added to water (conventional technology) or generated by anode-cathode reactions of metal plates inserted into the water (electrocoagulation). Common examples include:

- inorganic cationic coagulants (for example, alum, iron-based)
- commodity (for example, polyDADMAC) and specialty (for example, Perfluorad) polymers
- electrochemical precipitation

Coagulants assist in the formation of solids. Flocculation is typically conducted by adding a soluble polymer and slowly mixing to allow the particles to agglomerate and grow. Upon solid formation, constituents such as PFAS can be physically incorporated into, or sorbed onto, the flocculated particulate (which is known as co-precipitation). The precipitated solids are then separated from the water by sedimentation and/or filtration processes. The solid material containing the PFAS requires disposal, see the **Table 12-1 Treatment Methods Table** Excel File and **Section 12.3.2**.

Literature documents only bench-scale study results on treating PFAS via precipitation, flocculation, or coagulation; therefore, this is considered a partially developed technology. Evaluations have focused on conventional commodity chemical coagulation (for example, aluminum or ferric salts) and nonconventional coagulation (for example, proprietary chemical coagulants or electrocoagulation). Pilot- and full-scale applications have not been documented in the United States (**Birk 2017**), and specialty materials for PFAS applications will require strict quality control to ensure that performance characteristics are consistent.

Nonconventional precipitation (for example, electrocoagulation or advanced chemical precipitants) has shown more potential for direct PFAS treatment, but has very limited data. High-affinity cyclodextrin polymer has been tested in bench-scale reactors and was found to have superior removal capacity to GAC (**Xiao, Ling, et al. 2017**).

Electrocoagulation reactors, which range from basic to very sophisticated designs, have been reported to be highly efficient, compact, relatively low cost, and completely automatable (**Baudequin et al. 2011**; **Lin et al. 2015**). Recent studies have found that PFAAs, such as PFOA and PFOS, can be quickly sorbed on the surface of zinc hydroxide particulates generated by electrocoagulation (**Lin et al. 2015**).

12.6.3 Redox Manipulation

Redox manipulation includes chemical oxidation and reduction technologies. These have been summarized in more detail in **Nzeribe et al. (2019)**. Chemical oxidation for PFAS is a technology approach that is achieved via the delivery of liquid, slurry, or gaseous oxidants to transfer electrons from a reactive oxidant species to a target (PFAS) and affect the cleavage of atoms in the PFAS molecular structure. Carboxylic or sulfonic group "heads" (functional groups) of PFAS are commonly more susceptible to redox transformation than the fluorinated carbon chain "tails." There is a lack of robust evidence of defluorination via chemical oxidation processes. The mechanisms involving multiple species of free radicals that trigger PFAS oxidation are not well understood. PFAA precursors are also known to be oxidized to form persistent and terminal PFAAs without further oxidation (**Houtz and Sedlak 2012**; **Anumol et al. 2016**). Consequently, care should be taken to monitor site and plume conditions and understand potential formation and transport of transformation products.

Additional mechanistic studies are needed to develop chemical oxidation as a feasible PFAS remediation approach and to further assess factors that may promote or limit this technology. Common oxidants that have been documented to treat PFAS and other organic contaminants (for example, chlorinated solvents) include ozone, catalyzed hydrogen peroxide, and persulfate, as discussed further below. The impacts of co-contaminants, quenching reactions, and metals mobilization are also considerations for redox-based remedies (for example, **ITRC 2005**, **2011**).

12.6.3.1 Ozone-Based Systems

Ozone can be coupled with other oxidants such as hydrogen peroxide and persulfate to promote the generation of a suite of aggressive free radicals capable of degrading PFAS. An ozone-based system was implemented for the treatment of PFAS in a single field-scale test by **Eberle, Ball, and Boving (2017)** using combined ozone and activated persulfate.

The main pathway and mechanism behind the ozone-based system tested by **Eberle, Ball, and Boving (2017)** is unknown, as detailed mechanistic studies have not been performed. However, they suggested that PFAS reduction in groundwater after treatment was not limited to partial degradation, but it is possible that sorption also had a role to play in the declining aqueous PFAS concentration. They

postulated that activated persulfate could lead to a decline in pH, thereby increasing sorption of PFAS to soil due to increased protonation.

This approach has been partially demonstrated in one field-scale setting, and results are encouraging for application using ex situ or in situ approaches. However, because there is an absence of supporting mechanistic data, it is likely that other factors could come into play that may promote or limit this technology.

The application of the ozone-based system for the treatment of PFAS has also been evaluated in bench studies (**Lin et al. 2012**; **Kerfoot 2014**; **Huang et al. 2016**; **Eberle, Ball, and Boving 2017**; **Thomas et al. 2020**). **Lin et al. (2012)** and **Thomas et al. (2020)** tested ozone systems without and inclusive of hydrogen peroxide addition in alkaline environments, and **Kerfoot (2014)** used hydrogen peroxide and ozone bubbles for a bench-scale test of groundwater from a monitoring well foam firefighting site in Canada. **Huang et al. (2016)** combined ozone with photolysis to produce hydroxyl radicals and photogenerated electrons. **Dai et al. (2019)** tested combinations of ultraviolet light, ozone, and air fractionation, and reported that ozonated air fractionation provided more than 95% reduction in PFAS concentrations.

In the field demonstration, PFAS concentrations in groundwater were reduced by 21–79% after treatment. Also, an initial pilot test at a fire training area using ozone and peroxide has shown removal of 98.5% and 92.3% for PFOS and PFOA, respectively, in groundwater and over 80% for PFOS on saturated soil with proportional release of fluoride (**Kerfoot 2016**).

In bench-scale studies, **Eberle, Ball, and Boving (2017)** decreased PFAS by 99.9% using PFAS-contaminated site groundwater and spiked deionized water. **Eberle, Ball, and Boving (2017)** also reported that the system was not sensitive to other groundwater organics. **Kerfoot (2014)** reported 89.8% removal of PFOS and > 80% for other PFAS (PFPeA 89.8%, PFHxA 86.2%n and PFHxS 98.1%). These studies, however, do not confirm destruction through mass balance and analysis of byproducts.

Each of these approaches and test conditions used different water matrices and starting concentrations. It is difficult to state whether published regulatory levels can be achieved in practice with these technologies, but in general they appear to be effective as a polishing technology to achieve low part-per-trillion treatment requirements.

- ER18-1545 Enhanced Oxidative Destruction of PFAS in Investigation-Derived Waste Soil and Water

12.6.3.2 Catalyzed Hydrogen Peroxide (CHP)–Based Systems

CHP is one of the strongest oxidant systems used in environmental remediation. It involves reaction of hydrogen peroxide with a catalyst to predominantly generate hydroxyl radicals. Some CHP systems produce nucleophiles and reductants, including superoxide and hydroperoxide (**Mitchell et al. 2014**). Common catalysts include transition metals such as iron (Fenton and Fenton-like reaction) or manganese, chelated metals, and naturally occurring minerals, for example, **Watts et al. (2005)** and **Teel et al. (2007)**.

Hydroxyl radicals attack the alkyl groups of both PFCAs and PFSAs, but do not attack the perfluoroalkyl chain. As a result, PFCA and PFSA precursors are transformed to PFCAs of related perfluorinated chain length (**Bruton and Sedlak 2017**). **Mitchell et al. (2014)** demonstrated that superoxide and hydroperoxide (which are nucleophiles and reductants generated as a reaction in CHP but are not chemical oxidants) generated in alkaline pH CHP systems mineralize PFOA but did not elucidate a mechanism.

Bench-scale testing has been successfully demonstrated. Field deployment of hydroxyl radical-based CHP systems may be limited due to decomposition of PFAS precursors to PFOA and other PFCAs as unreactive transformation products (**Bruton and Sedlak 2017**).

CHP systems that predominantly generate hydroxyl radicals partially transform PFAAs to their PFCAs of related perfluorinated chain length, which are not further transformed (**Houtz and Sedlak 2012**; **Bruton and Sedlak 2017**). Systems that generate superoxide and hydroperoxide have been demonstrated at the bench test level to mineralize PFOA (**Mitchell et al. 2014**), but effectiveness with other PFAS is unknown.

12.6.3.3 Activated Persulfate

Persulfate anion ($S_2O_8^{2-}$) is activated to generate reactive radical species, primarily sulfate radicals (2.6 volts, or V) and hydroxyl radicals (2.7 V). Methods to activate persulfate include transition metals, high pH, and heat activation (**Siegrist, Crimi, and Simpkin 2011**). Hydroxyl radicals are the predominant radicals formed at high pH conditions (**Furman et al. 2011**), while at acidic pH there is greater yield of sulfate radicals (**Siegrist, Crimi, and Simpkin 2011**).

PFCAs are attacked by sulfate radicals under acidic conditions, initiating a decarboxylation reaction, where cleavage of the carbon-to-carbon (C-C) bonds occurs between PFCAs and the carboxyl group (-COOH), forming unstable perfluoroalkyl radicals (C_nF_{2n+1}) (**Hori et al. 2010**; **Lee et al. 2012**; **Yin et al. 2016**). A stepwise series of decarboxylation and hydrogen fluoride (HF) elimination reactions continues to form shorter chain PFCAs until all PFCAs are mineralized to fluoride and carbon dioxide. PFSAs such as PFOS are unreactive with sulfate radicals (**Park et al. 2016**; **Bruton and Sedlak 2017**). Hydroxyl radicals attack the alkyl groups of both PFCAs and PFSAs, but do not attack the perfluoroalkyl chain. As a result, PFCA and PFSA precursors are transformed to PFCAs of related perfluorinated chain length (**Bruton and Sedlak 2017**). Under alkaline pH conditions the sulfate and hydroxyl radicals are reactive with the alkyl groups but similarly unreactive with the perfluoroalkyl chain, which is the basis of the TOP method (**Houtz and Sedlak 2012**).

Activated persulfate under acidic conditions has proven effective for PFOA (PFCAs) with nominal 100% degradation, but PFOS is not transformed. Sulfate radicals and hydroxyl radicals generated by alkaline persulfate activation transform PFCA and PFSA precursors to PFCAs of related perfluorinated chain length (**Bruton and Sedlak 2017**).

12.6.3.4 Sonochemical Oxidation/Ultrasound

The sonochemical process relies on the propagation of acoustic waves in liquids at frequencies ranging between 20 kHz and 1,000 kHz (**Furuta et al. 2004**), which results in cavitation. Operating parameters such as frequency (**Campbell and Hoffmann 2015**), power density (**Hao et al. 2014**), solution temperature, sparge gas, and initial concentration of PFAS (**Rodriguez-Freire et al. 2015**) play a significant role in the sonochemical degradation and defluorination rate of PFAS (**Cao et al. 2020**).

Sonochemical degradation occurs via two mechanisms: localized thermal treatment and free radical destruction (**Rayaroth, Aravind, and Aravindakumar 2016**). During cavitation, cyclic formation, growth,

and collapse of micro/nano bubbles result in an intense increase in temperature and pressure (5000 Kelvin (K) and 2000 atmosphere (atm)), along with the generation of free radicals (**Furuta et al. 2004**; **Chowdhury and Viraraghavan 2009**).

Sonochemical oxidation has been successfully applied for rapid degradation of PFAS to fluoride (F^-), sulfate (SO_4^{2-}) and carbon dioxide (CO_2). **Vecitis et al. (2008)** reported a complete recovery of SO_4^{2-} and >90% defluorination of PFOA and PFOS with initial concentrations of 0.24 µM and 0.20 µM, respectively, for a field-scale application to treat groundwater from below a landfill. At bench scale, sonolysis has been reported in the literature as one of the most effective treatment processes for PFAS-contaminated water, because they almost immediately mineralize to SO_4^{2-}, CO_2, carbon monoxide (CO), and F^- after cleavage of their C-C/C-S bond. Studies have reported >90 percent degradation and defluorination for PFOA and PFOS (**Moriwaki et al. 2005**; **Vecitis et al. 2008**; **Cheng et al. 2008**, **2010**). **Gole et al. (2018)** demonstrated removal and defluorination of AFFF in a 91-L sonolytic reactor. **Lei et al. (2020)** showed a synergistic treatment effect of a combined persulfate/ultrasound approach.

12.6.3.5 Photolysis/Photochemical Oxidation

A thorough review of photolysis/photochemical oxidation technology for PFAS decomposition is reported in **Wang et al. (2017)**. **Chen, Zhang, and Liu (2007)** and **Giri et al. (2011)** reported removal of PFAS by direct photolysis at 185 nm. **Hori et al. (2004)** and **Chen, Zhang, and Liu (2007)** reported that direct photolysis at 254 nm alone is not very effective because PFAS do not absorb light at wavelengths >220 nm due to their chemical structure. Chemical reagents/catalysts such as Fe^{3+}, $S_2O_8^{2-}$, TiO_2, heteropolyacid photocatalyst ($H_3PW_{12}O_{40}$), CO_3^{2-}, and IO_4^- when combined with ultraviolet (UV) (>220 nm) light can effectively decompose PFAS (**Hori et al. 2005**; **Chen and Zhang 2006**; **Zhang, Pan, and Zhou 2016**; **Hori et al. 2007**; **Wang et al. 2008**; **Cao et al. 2010**; **Gomez-Ruiz et al. 2018**; **Xu et al. 2020**). This is due to generation of strong and reactive oxidative species such as $OH^•$, $H^•$, $CO_3^{•-}$ and PFAS-Fe complexes. Photochemical oxidation of PFAS is said to be dependent on the light source (UV or vacuum ultraviolet), initial concentration of PFAS, environmental matrix, temperature, pH, and type of reagent used (**Lin et al. 2012**; **Giri et al. 2012**; **Lyu et al. 2015**, **2015**; **Xu et al. 2017**). Use of non-traditional photocatalytic methods such as fixating a photocatalyst within a porous media (**McIntyre et al. 2023**; **McIntyre et al. 2022**; **McIntyre et al. 2021**; **McIntyre and Hart 2021**) or the use of boron nitride may enhance destructive performance (**Qanbarzade et al. 2023**).

The major degradation pathways involved in the photochemical oxidation of PFAS are direct photolysis and free radical reactions. The C-C bond between PFAS is cleaved with the COOH group to form perfluoroalkyl radicals (**Hori et al. 2003**; **Hori et al. 2008**), which then react with water and undergoes hydrogen fluoride elimination to form shorter chain compounds (**Liu et al. 2017**). These then undergo hydrolysis to form subsequent shorter PFAS (losing CF2 units). During direct photolysis, the C-C and C-S bonds of PFAS are broken by photoelectrons to generate perfluoroalkyl radicals and carbon dioxide (**Wang et al. 2017**).

12.6.3.6 Electrochemical Treatment

Electrochemical treatment occurs via anodic oxidation; a variety of materials have been used as anodes. The treatment effectiveness of PFOS and PFOA using different anodes can vary significantly. Most research on PFAS, particularly PFOS and PFOA removal, has been conducted using a boron-doped diamond (BDD) electrode due to its mechanical, chemical, and thermal stability (**Trautmann et al. 2015**; **Schaefer et al. 2017**; **Schaefer et al. 2019**; **Wang et al. 2019**; **Smith et al. 2023**). Some other electrodes, such as lead dioxide (PbO_2), titanium oxide (TiO_2), titanium suboxide ($Ti4O_7$), and tin oxide (SnO_2), also have the ability to treat PFAS-contaminated water (**Ochiai et al. 2011**; **Zhou et al. 2012**; **Zhao, Gao, et al. 2013**; **Liang 2017**; **Liang et al. 2018**). Operating conditions and parameters such as pH (**Lin et al. 2012**; **Zhou et al. 2012**), current density, electrolyte type (**Song et al. 2010**; **Zhuo et al. 2012**), electrode distance (**Lin et al. 2012**), initial PFAS concentration, and temperature are important factors that influence electrochemical oxidation of PFAS (**Niu et al. 2016**).

Electrochemical treatment proceeds via direct and indirect anodic oxidation (**Radjenovic and Sedlak 2015**; **Niu et al. 2016**; **Schaefer et al. 2018**). In direct electrolysis, contaminants are adsorbed onto and degraded directly at the electrode, while in indirect electrolysis, contaminants are degraded in the bulk liquid in reactions with oxidizing agents (that is, hydroxyl radicals) formed at the electrode (**Radjenovic and Sedlak 2015**).

Bench-scale studies have shown success in the degradation and defluorination of PFAS, including short-chain, long-chain PFAAs as well as PFAA precursors (**Chiang 2018**). Electrochemical oxidation of precursors may lead to the transient generation of perfluorinated carboxylates (**Schaefer et al. 2018**). Ultimately, fluoride is released, with typical recoveries ranging from 60 to 80%; the fate of the remaining fluoride is unknown, but studies have suggested that losses due to volatile perfluorinated alkanes may occur.

Electrochemical treatment has been tested as a stand-alone technology for PFAS concentrations at ppb levels and as a destruction technology to destroy concentrated PFAS waste streams generated from other treatment technologies such as ion exchange and foam fractionation (**Liang et al. 2018**; **Chiang 2018**). It has been partially demonstrated as an ex situ treatment of PFAS. But in situ application is also being considered and funded in the SERDP program. The issue of perchlorate formation as a byproduct during electrochemical oxidation of PFAS has been addressed by **Schaefer et al. (2017)** using a biological treatment polishing step. The issue can also be minimized by not using sodium chloride as the electrolyte (**Chiang 2018**).

The technology has been demonstrated via bench studies and pilot-scale reactor to be very effective for treatment of short-chain, long-chain PFAAs, as well as most commonly detected PFAA precursors in spike water systems and several remediation-derived waste streams laden with high PFAS concentrations.

12.6.3.7 Solvated Electrons (Advanced Reduction Processes)

Advanced reduction processes (ARP) has been investigated for the reductive degradation of groundwater contaminants. ARP involves the combination of activation methods such as ultrasound, ultraviolet, microwaves, catalysis, and electron beam with reducing agents (reductants) such as ferrous iron, sulfide, sulfite, iodide, titanium (III) citrate and dithionite to generate very reactive reducing radicals and the hydrated electrons (e–aq) that mineralize contaminants to less toxic products (**Vellanki, Batchelor, and Abdel-Wahab 2013**; **Ochoa-Herrera et al. 2008**). The reducing hydrogen radical ($H^{\bullet}$) and the hydrated electron are strong reductants that react easily with halogenated organic compounds (**Buxton et al. 1988**). ARP-induced degradation rates depend on initial solution pH and reductant concentration (**Vellanki, Batchelor, and Abdel-Wahab 2013**). **Bentel et al. (2019)** described insights gained from a structure-activity relationship analysis of the mechanisms involved in the reaction of solvated electrons with PFAS. **Cui et al. (2020)** offered a detailed critical review focused on mechanisms of reductive PFAS destruction by solvated electrons.

The degradation pathway of PFAS using ARP differs from that of oxidizing agents in that the hydrated electron (**Song et al. 2013**) cleaves the C-F bond adjacent to the functional group of the PFAS rather than the C-C or C-S bond. **Qu et al. (2014)** proposed that hydrated electrons lead to the reductive cleavage of the C-F bonds, resulting in fluorine elimination from PFOA. Furthermore, they proposed that under UV irradiation, cleavage of the C-C bond between the COOH group and the perfluoroalkyl group occurred as shorter chain intermediates were detected in solution. **Qu et al. (2014)** therefore concluded that two reactions are responsible for the reductive defluorination of PFOA: (1) direct photolysis by UV irradiation, and (2) photoreduction by hydrated electrons. **Tenorio et al. (2020)** showed that PFAS treatment by solvated electrons varies widely among compounds.

Reductive processes have proven feasible for degradation of most PFAS, especially PFOS. It should be recognized that electrons will be scavenged by oxygen, nitrate, and chlorides, and this should be considered for treatment application. Recent research using UV-activated sulfite demonstrated effective generation of hydrated (aka solvated) electrons. Laboratory tests showed >50% defluorination of both PFOS and PFOA within 24 hours (**Strathmann 2018**).

12.6.3.8 Plasma Technology

Plasma technology is a promising destructive PFAS treatment technology. Plasma is formed as a result of an electrical discharge from the addition of sufficient energy to gas (**Jiang et al. 2014**) and is classified into two major groups based on temperature and electronic density: thermal plasma (local thermal equilibrium) and nonthermal plasma (nonequilibrium plasma) (**Bogaerts 2002**). Due to lower energy requirements and selectivity, nonthermal plasma is most often used in water treatment processes (**Jiang et al. 2014**). In water treatment plasma applications, electrical discharges can be discharged above the liquid surface, directly to the liquid, or in the form of bubbles in liquids (**Locke, Lukes, and Brisset 2012**) (**Stratton et al. 2017**). These electrical discharges diffuse in liquids to initiate various chemical and physical effects, including high electric fields, intense UV radiation, shock waves, and formation of strong oxidative and reductive reactive species ($H^{\bullet}$, $O^{\bullet}$, $OH^{\bullet}$, H_2O_2 aqueous electrons, H_2, O_2, O_3), which are effective for the treatment and removal of contaminants (**Lukes, Appleton, and Locke 2004**; **Lukes et al. 2005**; **Stratton et al. 2017**; **Singh et al. 2019**).

- ER21-3564 Non-thermal Treatment of Unused AFFF Concentrate by Liquid-phase Plasma Discharge Process

Determination of plasma treatment mechanisms and degradation pathways for PFAS is a research focus, and several mechanisms and pathways have been proposed. **Takeuchi et al. (2013)** proposed that the main reaction pathway for PFOA by plasma treatment is by thermal cleavage of the C-C bonds resulting in direct decomposition to gaseous products without formation of shorter chain PFCAs. Others have proposed that PFAS decomposition is due to conversion to unstable radicals during interaction of PFAS with the most energized ions in the plasma (**Hayashi et al. 2015**; **Obo, Takeuchi, and Yasuoka 2015**), or with positive ion(s) generated by the plasma (**Yasuoka, Sasaki, and Hayashi 2011**) at the bubble gas-

liquid interface. The unstable radicals produced during PFAS decomposition can result in a sequential loss of one carbon within the chain.

Plasma effectively degrades PFAS in a relatively short period of time (30-minute treatment) in both synthetic water and groundwater. It has been reported that plasma treatment provided 90% degradation of PFOA and PFOS, with only about 10% of the destroyed PFOA and PFOS being converted to shorter chain PFAAs (**Stratton et al. 2017**). The degradation rate is not affected by the presence of co-contaminants. This is an environment-friendly technology, because there is no demand on pressure or temperature and it does not require significant input of chemicals. Plasma also generates a broad range of reactive species.

12.6.3.9 Zero-Valent Iron (ZVI)/Doped-ZVI

ZVI is an inexpensive groundwater remediation technology. It is the most commonly used reductant for in situ groundwater remediation. It is a strong reducing agent capable of successfully reducing major groundwater contaminants such as chlorinated solvents. Recently nanoscale zero-valent iron (nZVI) has had increased attention due to its higher reactivity, surface area, and potential in situ injectability compared to the micro-sized ZVI.

In general, the removal of PFAS by ZVI in reductive processes involves the mass transfer of contaminants to the ZVI surface, and their adsorption and reaction (transformation of contaminants into less toxic/nontoxic species) on the ZVI surface, followed by the desorption and mass transfer of byproducts into solution (**Arvaniti et al. 2015**). Because the reduction of contaminants by ZVI is a surface-mediated electron transfer process, the surface properties of ZVI influence contaminant reactivity. (**Arvaniti et al. 2015)** found that PFOS removal using Mg-aminoclay-coated nZVI occurred via adsorption of PFOS to the ZVI surface followed by reduction. A similar decomposition mechanism for PFOS using ZVI in subcritical water was reported by **Hori et al. (2006)**, who suggested that adsorption of PFOS onto ZVI played a major role in PFOS decomposition, as fluoride was detected in the treatment solution after treatment.

This technology is highly effective for the removal of PFOS, reacts relatively quickly, and has proven feasible for degradation of most PFAS.

12.6.3.10 Alkaline Metal Reduction

Alkaline metal reduction involves the use of alkali metals (that is, the reductant) to reduce organic compounds to their anion radical. Reductive degradation of branched PFOS has been reported with vitamin B_{12} as a catalyst and Ti(III)-citrate or nanosized zero-valent zinc as a bulk reductant (**Ochoa-Herrera et al. 2008**; **Park, de Perre, and Lee 2017**) where degradation rates increase with increasing solution pH, bulk reductant dose, and temperature.

The degradation pathway of PFAS by alkali metal reduction as postulated by **Ochoa-Herrera et al. (2008)** suggests that destruction of branched PFOS isomers occurs via chemical reductive dehalogenation. **Park, de Perre, and Lee (2017)** suggested that the ability of vitamin B_{12} to reduce branched PFOS isomer

and not linear is because the branched PFOS isomers possess greater electron density differences that are absent in linear PFOS isomers. Bench-scale studies have shown success for branched PFOS isomers and have proven to be efficient (greater than 70% removal; see **Ochoa-Herrera et al. (2008)**). In situ applications have not been tested. Removal and defluorination are lower for PFHxS relative to PFOS. Polyfluorinated sulfonate intermediates (C_5-C_8) are the final products (**Park, de Perre, and Lee 2017**).

Bimetallic $nNiFe_0$ particles supported on activated carbon have demonstrated transformation of both linear- and branched-PFOS isomers, achieving 94% PFOS transformation at 50°C (**Zenobio et al. 2020**). Transformation byproducts detected in the particle extracts indicate defluorination and desulfonation pathways.

12.6.3.11 High-Energy Electron Beam (eBeam)

High-energy electron beam (eBeam) is a high efficiency, flow-through, nonthermal, chemical-free technology that utilizes electron accelerators to generate large numbers of highly energetic electrons from electricity (**Cleland 2011**; **Pillai and Shayanfar 2016**). The technology has been commercialized globally for pasteurizing foods, sterilizing medical devices, cross-linking polymers, and eliminating insects and pests from fresh produce (**Cleland 2011**; **Pillai 2016**; **Pillai and Shayanfar 2016**; **Zembouai et al. 2016**). It provides a form of ionizing irradiation that does not involve the use of radioactive isotopes. The amount of energy from eBeam that is absorbed by an irradiated material per unit mass is called dose. The absorbed dose during eBeam treatment depends on the type and thickness of the material, the beam power, and the length of time the material is exposed to the electron beam (**Waite 1998**).

eBeam is applicable for use on soil and liquid matrices for many purposes: disinfection of sewage sludge (**Praveen et al. 2013**; **Waite 1998**); remediation of heavy hydrocarbon-contaminated soils (**Briggs 2015**); and remediation of volatile organic compounds (VOCs) and semivolatile organic compounds in liquid wastes such as groundwater, wastewater, and landfill leachate (**USEPA 1997**). During irradiation of water, three primary reactive species are formed: solvated electrons and hydrogen radicals, which are strong reducing species, and hydroxyl radicals, which are strong oxidizing species. This creates both advanced reduction and oxidation processes without the addition of any chemicals. The absolute concentration of radicals formed during irradiation is dose- and water quality-dependent, but it has been measured at greater than millimolar (mM) levels in potable, raw, and secondary wastewater effluent (**Waite 1998**).

Researchers at Texas A&M University recently demonstrated defluorination of PFOA in aqueous samples by eBeam technology (**Wang et al. 2016**). The study measured defluorination efficiency as a function of molar concentration of free fluoride ions and initial molar concentration of PFOA to be treated. Final defluorination efficiencies ranged from 34.6 to 95% under various increasing concentrations of nitrate, alkalinity, and fluvic acid. The defluorination is possibly due to the formation of aqueous electrons and the formation of secondary radicals (**Wang et al. 2016**). **Kim et al. (2019)** demonstrated eBeam defluorination of PFOS when used in combination with chemical oxidants.

An additional study further demonstrated eBeam-mediated defluorination of PFOS and PFOA with decomposition efficiencies of 95.7% for PFOA and 85.9% for PFOS in an anoxic alkaline solution (pH = 13). Radical scavenging experiments indicated that the aqueous electron and hydrogen radical were important in the eBeam degradation of PFOA and PFOS (**Ma et al. 2017**). Further evaluation of this technology for treating other PFAS (polyfluorinated precursors and other long- and short-chain PFAAs) in soil and water, as well as testing over a range of concentrations, will be necessary to further understand treatment performance potential and to identify any deleterious byproducts.

12.6.3.12 Supercritical Water Oxidation

The content in this section has been replaced with the Priority Topic for Supercritical Water Oxidation (see **Section 1.6.2**).

12.6.4 Biodegradation

A limited number of studies have tested microbial degradation of PFAS and many conflicting reports exist, all suggesting that more work needs to be performed to fully understand the biotic transformations of these compounds.

Microbial degradation of PFAS has been observed to occur with polyfluoroalkyl substances (**Butt, Muir, and Mabury 2014**), which contain some carbon-hydrogen bonds instead of C-F bonds (**Buck et al. 2011**). Recent research documented the aerobic biotransformation of fluorotelomer thioether amido sulfonate (FtTAoS) over a 40-day period to produce 4:2, 6:2, and 8:2 fluorotelomer sulfonate (FTS), 6:2 fluorotelomer unsaturated carboxylic acid (FTUCA), 5:3 fluorotelomer carboxylic acid (FTCA), and C4 to C8 perfluorinated carboxylic acids (**Harding-Marjanovic et al. 2015**). An unintended consequence of biologically mediated transformations is the conversion of precursors (polyfluorinated) to perfluorinated compounds.

PFOA and PFOS have been shown to be resistant to microbial biotransformation under a variety of growth conditions (**Liu and Mejia Avendaño 2013**). However, other PFAS, including chemicals in AFFF with nonfluorinated alkyl groups (polyfluorinated substances), are likely amenable to biotransformation. Most recently, defluorination of PFOA and PFOS were observed using an ammonium oxidizing autotroph (**Huang and Jaffé 2019**). Upon addition of PFOA or PFOS (0.1 mg/L and 100 mg/L, respectively) to the A6 culture, shorter chain perfluorinated products and acetate were observed. Incubations with hydrogen as a sole electron donor also resulted in the defluorination of up to 60% of PFOA and PFOS during 100-day incubations, while total fluorine (organic plus fluoride) remained constant. Reductive defluorination of perfluoroalkyl substances may be possible, as observed when using vitamin B12 and Ti(III)-citrate (**Ochoa-Herrera et al. 2008**).

- ER22-3312 Cometabolic Transformation and Treatment of PFAS Precursors in PFAS-Impacted Soils and Aquifer Sediments

Research on the fungal degradation of PFAS has been ongoing due to the wide spectrum of substrate reduction catalyzed by extracellular ligninolytic enzymes. Experiments with white-rot fungus showed limited degradation of PFOA in microcosm studies under certain conditions (**Tseng 2012**). The innovative delivery of fungal enzymes for PFAS treatment requires further research.

The biodegradation of PFAS has been reported in a few studies as described above and in the following: 8:2 FTOH (**Wang et al. 2009**), 6:2 FTOH (**Liu et al. 2010**), 6:2 FTS (**Wang et al. 2011**), and N-ethyl perfluorooctane sulfonamidoethanol (**Rhoads et al. 2008**; **Rhoads et al. 2013**). Recently the PFOA-degrading strain YAB1 was isolated from soil that had been impacted by perfluorinated compounds through acclimation and enrichment culture, where perfluorooctanoic acid (PFOA) was amended as the sole carbon source (**Yi et al. 2016**). "This strain was preliminarily identified as Pseudomonas parafulva based on colony morphology, physiological and biochemical features, and 16S rRNA gene sequencing. Using shaking flask fermentation, the maximum tolerable concentration of YAB1 on PFOA was found to be 1,000 mg/L" (**Yi et al. 2016**), and the optimal PFOA concentration for the growth of YAB1 was 500 mg/L. After 96 hours of culture, the PFOA degradation rate was "32.4%. When 1 g/L glucose was added to the inorganic salt culture medium, the degradation rate increased to 48.1%. Glucose was the best exogenous carbon source for the degradation of PFOA" (**Yi et al. 2016**).

12.6.5 Alkaline Hydrothermal Reaction

Alkaline hydrothermal treatment involves degradation of PFAS under high pressure, high temperature, and high pH conditions. **Wu et al. (2019)** demonstrate rapid destruction of particularly recalcitrant PFOS during hydrothermal treatment of a solution amended with NaOH. They propose an initial cleavage of the functional group catalyzed by OH-, followed by sequential chain-shortening and decarboxylation to produce carbonate and fluoride salts. Other researchers (**Li et al. 2022**; **Hao et al. 2021**, **2022**) have demonstrated PFAS degradation in a variety of matrices, but generally long residence times (> 30 minutes) have been required for high degrees of PFAS degradation (for example, > 90%). **Pinkard et al. (2023)** demonstrated greater than 99% degradation in a continuous flow system.

12.6.6 Deep Well Injection

A potential alternative to treatment may be the use of on-site or off-site underground injection waste disposal wells for liquids containing PFAS. The **USEPA (2024)** considered deep well injection as one of three viable, commercially available disposal options. This approach eliminates discharges to surface water and groundwater, which could be a consideration given the present climate of varying discharge limitations for PFAS. However, deep well injection is not a destruction technology.

Class I wells, as defined by USEPA, are acceptable for both hazardous and nonhazardous liquid wastes (**USEPA 2019**). The USEPA has published guidance on the requirements for the use of injection wells, which include siting, construction, operation, monitoring, testing, record keeping, reporting, and closure (**USEPA 2019**). The USEPA has also studied the risks associated with underground injection wells (**USEPA 2001**), and these risks should be considered for the use of underground injection wells for PFAS-laden water. This option may be most attractive as a disposal option for high concentration liquids, such as RO reject water, anion exchange regeneration fluids, wastewater from manufacturing sites, and landfill leachate.

12.6.7 Monitored Natural Attenuation

Definition of MNA "The term "monitored natural attenuation," refers to the reliance on natural attenuation processes (within the context of a carefully controlled and monitored site cleanup approach) to achieve site-specific remediation objectives within a time frame that is reasonable compared to that offered by other more active methods" (**USEPA 1999**).

12.6.7.1 Introduction

Monitored natural attenuation (MNA) is fundamentally a risk management strategy. MNA is not a "presumptive" or "default" remedy—it represents a remedy component option that should be evaluated alongside other applicable remedy component options, including in combination with active treatment (for example, active treatment of "hot spots" and MNA for distal segments of a plume or as part of a treatment train). MNA is not considered a "no action" or "walk-away" approach but is rather considered "an alternative means of achieving remediation objectives that may be appropriate for specific, well-documented site circumstances where [the implementation of MNA] meets the applicable statutory and regulatory requirements" (**USEPA 1999**). In its guidance for the cleanup of contaminated soil and groundwater in the Superfund, RCRA Corrective Action, and Underground Storage Tank Programs, USEPA noted that "...there is often a variety of methods available for achieving remediation objectives at any given site, MNA may be evaluated and compared to other viable remediation methods (including innovative technologies) during the study phases" (**USEPA 1999**) informing remedy selection and periodically thereafter. A comprehensive long-term monitoring program is critical to any MNA remedy component to verify its continued viability. If plume migration trend data suggest a potential threat to receptors or lack of progress toward remediation objectives, additional contingency measures are likely to be to be required.

Attenuation Processes The "natural attenuation processes" include a variety of physical, chemical, or biological processes that, under favorable conditions, act without human intervention to reduce the mass, toxicity, mobility, volume, or concentration of contaminants in soil or groundwater. These in situ processes include biodegradation; dispersion; dilution; sorption; volatilization; radioactive decay; and chemical or biological stabilization, transformation, or destruction of contaminants." (**USEPA 1999**).

MNA has been proposed as a strategic component to manage PFAS impacts at some sites (**Newell et al. 2021**, **2021**). MNA is an established management approach for a variety of contaminant classes that are subject to natural attenuation processes when released to the environment, including petroleum hydrocarbons and chlorinated solvents (**USEPA 1999**). In addition, MNA is an established management approach for certain metals and other inorganic constituents that do not degrade but are attenuated through various nondestructive processes (**ITRC 2010**; **USEPA 2015**), which can be considered analogous to PFAS. Although there are currently no recognized destructive attenuation mechanisms for PFAAs, numerous biotic and abiotic transformation pathways have been documented for several polyfluorinated PFAS (see **Section 5.4**). As research regarding natural attenuation mechanisms for PFAS continues, it is possible that additional biotic and abiotic attenuation pathways (including transformation, destruction, or mineralization) may be identified.

The predominant known processes for PFAS natural attenuation are those that contribute to plume stability resulting from natural retardation of PFAS transport and promote retention of PFAS mass in the subsurface away from potential receptors. These include solid phase partitioning (**Section 5.2.3**), partitioning at the air-water interface (**Section 5.2.4.1**), natural advection mechanisms, and matrix diffusion (**Section 5.3.1**).

In the subsurface, physical and geochemical processes can result in a stable plume by slowing PFAS migration through the unsaturated zone, reducing or preventing the mass discharge from the unsaturated zone to an underlying aquifer, and slowing the rate of PFAS migration within the saturated zone. The

preferential sorption characteristics of polyfluorinated compounds with cationic or zwitterionic head groups can also promote attenuation (refer to **Section 10.4.6**). This represents a form of "chemical retention" (**Newell et al. 2021**) because if naturally retained in the untransformed, cationic, or zwitterionic precursor state these compounds are anticipated to move more slowly than if they were transformed to more mobile anionic PFAAs.

12.6.7.2 Considerations for an MNA Remedy Component

MNA may be most applicable to PFAS sites with some combination of a stable plume, a long travel time to the nearest receptor, and low and/or decreasing mass discharge rates. A stable plume may be demonstrated if the attenuation rate offsets the migration rate (that is, steady state condition) (see **Section 10.4.7**). Practitioners may rely on multiple strategies, including concentration trend analysis, to demonstrate the degree to which PFAS plumes may be attenuating and/or stabilizing.

For documented stable plumes, and in the absence of immediate risk receptors or where exposures can be controlled, MNA may be considered as an effective management approach for the following scenarios: 1) as a final remedy component for plume segments where a comprehensive data set demonstrates natural attenuation trends that can achieve comparable reduction rates and time frames to attain the remediation objectives for PFAS groundwater concentrations versus active treatment technologies (for example, lower parts per trillion plumes or distal plume segments; scatter/random PFAS detections that do not represent a defined plume); or 2) as a final treatment train step to reach low parts per trillion cleanup levels once active treatment has reached a defined interim treatment objective or plateau condition/point of diminishing returns (assuming lines of evidence supporting MNA has been established).

Given the evolving state of understanding and associated uncertainties regarding the behavior of PFAS in the environment, development of reliable PFAS fate and transport models that are rigorous and include the derivation of site-specific parameters that govern PFAS fate and transport will be needed. High-resolution site characterization methods (including tracer studies) and fate and transport modeling may be beneficial in evaluating natural attenuation of PFAS. Consideration of MNA as a potential element of a remedial strategy may require implementation of source control measures (that is, hydraulic modifications, in situ injections, removals, etc.) and/or demonstration of stable conditions.

Comprehensive PFAS fate and transport modeling is further complicated by the uncertainties of precursor PFAS transformation in the environment. For more information regarding PFAS fate and transport modeling and assessing plume stability, see Assessing Plume Stability in **Section 10.4.8**.

Until a more thorough understanding of PFAS attenuation is developed, consideration of MNA should be evaluated cautiously, whether as the primary or complimentary technology at PFAS contaminated sites.

12.7 Limited Application and Developing Solids Treatment Technologies

The treatment technologies presented in this document are provided in a hierarchy defined in **Section 12.1**, based on level of implementation and level of confidence in the technology from peer-reviewed literature and extent of documented performance. The three development levels include field-implemented technologies, limited application technologies, and developing technologies. Where appropriate in the text both in situ and ex situ technologies are discussed. However, it is not always clear

if a limited application or developing technology may be effective in situ, ex situ, or both, thus further distinction between in situ and ex situ is not made in this section. Table 12-1 Treatment Methods Table Excel File presents limited application and developing technologies for solids, which may be applicable to soil, sediments, biosolids, or other solid media, including PFAS-laden materials (for example, GAC, resin, scrubbers, filters). Thermal treatment warrants further discussion as a limited application technology because it has been field-demonstrated at multiple sites by multiple practitioners but has not been well documented in peer-reviewed literature.

12.7.1 Sorption and Stabilization/Solidification

Limited application and developing materials being demonstrated or developed for sorption and stabilization include minerals (for example, organically modified clays) or stabilization agents (for example, Portland cement). Stabilization/solidification through mixing with cementitious materials (for example, Portland cement or other amendments) can be applied to encapsulate PFAS-impacted soil/sediment to restrict PFAS leaching or migration. In situ solidification is always performed with soils in place, and it is necessary to use specialized equipment and maintain careful control over the addition of amendments and water content. In batch experiments, a reduction of 95-99% of leachable anionic PFAS, including PFOS and PFOA, was achieved with amending contaminated soil with 0.5% to 5% by weight of a commercially-available surface-modified clay (**Wang et al. 2021**). Other laboratory (**Willett and Geary 2021**) and in situ field studies (**McDonough et al. 2021**) on soils mixed with up to 10% by weight of this surface-modified clay showed reduction in leaching of a number of PFAS. In situ solidification is intended to yield a high-compressive-strength monolith that has low permeability. A bench-scale study (**Sörengård, Kleja, and Ahrens 2019**) indicated that solidification using a binder (combination of Portland cement, fly ash, and ground granulated blast-furnace base slag) at a ratio of 9:1 reduced leaching for 13 out of 14 PFAS (except for PFBS). Introducing additional additives (for example, activated carbon, surface-modified clays) at a 2% concentration can further reduce leaching of PFAS in solidification-treated soil.

12.7.2 Thermal Treatment

Thermal treatment is defined as mobilization or destruction, or both, of chemicals using heat. This can be accomplished by thermal desorption or thermal destruction. Heat is applied directly or indirectly to the PFAS-contaminated soil/sediment. The Priority Topics for Treatment Technologies include updated information for incineration, pyrolysis/gasification, and thermal desorption (see **Section 1.6.1**).

Ex situ thermal treatment has been demonstrated (450–954°C) at field pilot-scale studies by a few technology vendors and is considered a partially demonstrated technology (**Endpoint Consulting 2016**; **Enviropacific 2017**; **Colgan et al. 2018**; **Grieco and Edwards 2019**). The effectiveness depends upon the ability to deliver heat to achieve sufficient and evenly distributed temperature at field scale cost-effectively. The pilot studies conducted have reported >90% removal of PFAS from soil when high heat has been applied.

In addition, lower temperature thermal desorption has been demonstrated to be effective for PFAS at 350–400°C on the bench scale. During a recent proof of concept laboratory bench test, 99.99% removal of PFAS from soils was demonstrated while heating the target volume to 400°C (**Crownover et al. 2019**; **DiGuiseppi, Richter, and Riggle 2019**).

No documented examples of in situ thermal treatment for PFAS-impacted soil have been identified. However, the ex situ testing at 350–400°C suggests that these temperatures are sufficient for desorption of PFAS and therefore in situ treatment is potentially feasible for PFAS.

At bench, pilot, and field scales, limited data sets are available and data gaps still exist mainly regarding fate of volatilized PFAS and air emissions (**Lassen et al. 2013**; **USEPA 2020**; **Yamada et al. 2005**). Another concern is the volatilization of hydrogen fluoride, which could pose serious health and safety issues and could compromise equipment components. Hydrofluoric acid and other non-PFAS off-gas concerns can be managed through conventional off-gas treatment systems (scrubbers), as is further described in **Section 12.5** (Air Treatment). Although air emissions from the thermal treatment of PFAS have not been thoroughly studied at the field scale to date, some limited field-implemented air emission

studies from the thermal treatment of PFAS have been completed (**Barr Engineering 2022**; **Chemours 2023**). PFAS treatment via high temperature air incineration and subsequent acid-gas scrubbing is a common practice during carbon reactivation (**Mimna 2017**).

Pyrolysis and gasification are often described as heat-induced thermal decomposition processes, though these processes are not solely focused on treatment and are typically used to convert a waste product into a useful feedstock for another product, such as energy, fuels, and chemical commodities. These technologies have only recently been evaluated with respect to treating PFAS (**Winchell et al. 2022**; **Thoma et al. 2022**; **Bamdad et al. 2022**; **DiStefano et al. 2022**).

12.8 Integrated Water Treatment Solutions

This section provides guidance on the development and selection of treatment solutions for water containing PFAS in combination with other constituents. It is often necessary to combine treatment technologies into integrated solutions to achieve project objectives for co-contaminants. While PFAS can affect multiple media, the focus of this section is on treatment of water and the water treatment processes. The water matrix may contain constituents such as TOC, TSS, and TDS at levels that may require pretreatment because they could interfere with and reduce the effectiveness of the PFAS treatment technologies. Regulated organic and inorganic co-contaminants require treatment to meet their respective remedial objectives. An integrated solution can include a combination of treatment mechanisms (separation, sorption, and destruction) and development stages (for example, field-implemented, limited application, and developing). **Section 18** provides guidance for sorption-based technologies for separation and concentration of PFAS from water including considerations for pretreatment and co-occurring constituents.

12.8.1 Development of Alternative Water Treatment Trains

Many factors play into the development and selection of integrated treatment solutions and the considerations and examples provided here are intended to assist in the selection process. The remedial action or treatment objectives are key drivers in selecting treatment technologies and waste disposal methods. Liquid and solid waste stream generation is another critical factor in the selection process as waste may be subject to PFAS regulations. While the focus of this section is on water treatment, the treatment technologies applicable to solid wastes are discussed in **Sections 12.3**, **12.4**, and **12.6**. Factors affecting pre-treatment, primary treatment, and post-treatment selection are presented in **Section 12.1.1**. Selection of an integrated treatment solution may be an iterative process to select a primary treatment technology that best meets project objectives while minimizing the associated pre-treatment, post-treatment, and generated waste streams.

Figure 12-7 (provided as a separate PDF) shows a sample flow chart that includes a variety of options for integrated treatment solutions based on different water and process waste matrices. The water matrix column in the flow chart, which represents the composition of the water to be treated, includes examples of naturally occurring substances and inorganic and organic co-contaminants. The pre-treatment stage provides examples of technologies that can be used as standalone or in combination for treating different co-contaminants. The PFAS treatment system can also include multiple treatment technologies (treatment train) that each generate waste that must be subsequently treated or disposed of. The sample flow chart provides examples of wastes generated by different treatment technologies and corresponding potential disposition options. Factors in selecting PFAS treatment methods are presented in Sections **12.2**, **12.3**, **12.4**, **12.5**, **12.6** and **12.7**.

Every water source is different, so proper characterization is important for developing and selecting the proper integrated solution. The following questions may help guide the selection process:

1. What are the remedial action objectives and discharge criteria for all contaminants?
2. What information is available on geochemistry, natural organic matter, and potential inorganic constituents, and what are the remaining data needs for adequate characterization?
    a. What are the pre-treatment options for the identified matrix?
    b. What wastes are generated through pretreatment?
3. What other non-PFAS organic constituents (for example, volatile and semi-volatile organic co-contaminants) are present at levels that require treatment?
    a. What types of treatment technologies or combinations of technologies apply?

   b. What wastes are generated by application of each treatment technology?
   c. Can the co-contaminants be effectively treated by the same technology as PFAS, and, if so, could this adversely affect PFAS removal? Do the technologies compete with each other, and does this reduce effectiveness and efficiency of PFAS removal?

4. Are field-implemented treatment technologies available for the treatment or destruction of waste streams; if not, consider limited application and developing technologies and possibly pilot testing?

Lu et al. (2020) provided a critical review of PFAS treatment train approaches. Additional recent work is focusing on simultaneous coupling of technologies, where PFAS are sorbed onto reactive particles, which are then destroyed in the presence of catalyst (for example, **Zhang, Zhang, and Liang 2019**; **Xu et al. 2020**). **Pica et al. (2019)**; **Soriano, Gorri, and Urtiaga (2017)**; and **Soriano, Schaefer, and Urtiaga (2020)** described and evaluated combined filtration followed by electrochemical oxidation approaches.

12.9 Sustainability of PFAS Treatment

Federal and state environmental protection agencies have published myriad green remediation best management practice fact sheets and guidance documents covering a variety of remediation topics and emphasizing the minimization of environmental cleanup footprints (**USEPA 2012**, **2018**), including methods to quantify the environmental footprint (**USEPA 2019**). The best management practice fact sheets for excavation and surface restoration, implementing in situ thermal technologies, and (more generally) materials and waste management may offer supplemental sustainability information to that already included alongside the remediation technologies presented within this section (**USEPA 2008**, **2012**, **2013**).

Applying such a framework for PFAS cleanup projects, the environmental impact drivers for PFAS cleanup technologies that should be considered include the life cycle environmental footprint of all facets of the cleanup, including project site preparation; installation of the remedy; materials, equipment, and energy used to operate the remedy; waste materials generated by the cleanup technology; and demolition and deconstruction of the remedy. In alignment with greener cleanups, green and sustainable remediation recommends the "the site-specific employment of products, processes, technologies, and procedures that mitigate contaminant risk to receptors while making decisions that are cognizant of balancing community goals, economic impacts, and environmental effects" (**ITRC 2011, 2011, p. 3**). Economic and quality of life impacts to the community can be alleviated by early incorporation of green and sustainable remediation best management practices, including meaningful stakeholder engagement, creation of employment opportunities, and advancement of the local community's skill set to help manage treatment systems and public outreach (**USEPA 2012**). Lastly, climate change vulnerability and adaptation measures of remedial technologies should also be considered to ensure resiliency in the implemented remedial action (**USEPA 2013**, **2014**).

In alignment with sustainability principles, performance of early and meaningful risk communication can assist professionals in raising the community's awareness of environmental hazards, empowering community participation in risk reduction measures, and increasing the quality of life for the community impacted by contamination and related risk management activities (**USEPA 2007**). Several environmental and public health regulatory agencies have prepared information documents to assist professionals in performing effective risk communication for PFAS sites, for example, see **ATSDR (2018)**.

In addition, a communication plan can be developed to assist with information dissemination and stakeholder engagement (**Emmett et al. 2009**). **Section 14** provides further in-depth guidance on risk communication planning and performance. A risk communication toolbox is also being developed to help decision makers through the planning process and provide tools to assist with meeting performance

metrics at each planning step. Additional guidance on stakeholder concerns and engagement is provided within this document in **Section 13**.

12.10 Improving Evaluation of PFAS Treatment Technologies

Significant effort has been completed with respect to reviewing and compiling comparative information on PFAS treatment technologies. In a number of instances, proponents of innovative treatment technologies have claimed success in removing or destroying PFAS with limited confirmation of performance. For example, removal mechanisms may not have been proven, byproducts may not have been measured, and the effect of the technology in actual environmental matrices, at environmentally relevant concentrations, on PFAS mixtures, or with co-contaminants present may be unknown.

To guide future assessments and investments in developing PFAS treatment technologies, a SERDP project has prepared suggested lines of evidence, recommended metrics, and decision tools to assess the effectiveness of PFAS treatment technologies. These lines of evidence and decision-making tools can be used to identify priorities and next steps to advance a given technology, assess whether a technology is ready for field demonstration, and identify key areas of uncertainty regarding technology performance.

Further SERDP-funded work (ER18-5053) is focused on developing a comprehensive assessment framework for ex situ PFAS treatment technologies and generating data to compare established and emerging approaches on a life cycle assessment and costing basis.

13 STAKEHOLDER PERSPECTIVES

This section identifies the concerns of stakeholders who have been or may be affected by PFAS contamination. In this section, we summarize many of the concerns that have been expressed by local communities, tribes, and environmental groups. Evaluation of exposure levels and potential human health consequences are of paramount concern to stakeholders.

Section Number	Topic
13.1	**Stakeholder Concerns**
13.2	**Specific Tribal Stakeholder Concerns**
13.3	**Stakeholder Resources**

The term "stakeholder" is defined broadly by ITRC as members of environmental organizations, community advocacy groups, tribal entities or other citizens' groups that deal with environmental issues, or a concerned citizen who is not a member of any organization or group. Public stakeholders, such as advocacy groups, often speak for the communities that are affected by environmental issues. In this document, a differentiation is made between public stakeholders and interested parties (responsible parties, state regulators, and owners and operators of contaminated sites).

Stakeholders share greater ownership of outcomes when they have the opportunity to influence site characterization, remedy selection, and long-term site management. Because PFAS are so abundant in consumer products, stakeholders are also concerned with the production and eventual use of these products and are seeking safer alternatives and sometimes outright bans (see **Section 2.5** for information about PFAS Uses and information about certifications related to reduction or elimination of PFAS in products). Environmental regulators and responsible parties also benefit from informed, constructive stakeholder involvement because it can help them make better decisions, reduce the likelihood of costly, time-consuming repeated work, and allow those in affected communities to have a voice in governing the long-term use of land, water, and other resources. Often, stakeholders such as long-time residents have unique site knowledge as well as a major stake in the remedial outcome. In the case of PFAS, many national environmental organizations have made community outreach a major focus. Local grassroots organizations and one, the National PFAS Contamination Coalition (**https://pfasproject.net**), have led a major effort to inform the public and influence policy. In addition, ATDSR studies (for example, **ATSDR 2022**) and National Academy of Science (**NAS 2022**) studies have included community outreach efforts.

Developing site-specific characterization and remediation strategies for communities and tribal organizations can be challenging, because there are many misconceptions about PFAS. The lack of scientific knowledge about many of these PFAS further enhances the need to educate the public. Therefore, early and effective community engagement emphasizing timely access to test data, transparency, and responsiveness is imperative. Community engagement may be able to address many stakeholder concerns and help to communicate risks. The **ITRC Risk Communication Toolkit for Environmental Issues and Concerns** includes information about stakeholder engagement and is published as a separate document. **Section 14** addresses tools for PFAS-specific risk communication challenges, and provides some examples of PFAS risk communication issues.

This section identifies the concerns of stakeholders who have been or may be affected by PFAS contamination. Because PFAS are emerging contaminants and have been detected in ecological receptors (animals and plants, see sections **5.5** and **5.6**) and blood serum in many humans (**Section 7.1**), there are many individuals who are potentially affected worldwide.

In this section, we summarize many of the concerns that have been expressed by local communities, tribes, and environmental groups. Evaluation of exposure levels and potential human health consequences are of paramount concern to stakeholders. The list of concerns below is not all inclusive, as developments in science and identification of contaminants in the environment are likely to lead to additional concerns. This list was developed from general research on PFAS, direct communication and involvement with environmental and community groups, a consultant for one of the tribes, and extensive review of news reports. **This section is intended to highlight the concerns that have been expressed by various groups. It is not intended to be a definitive statement of the technical merits of those concerns.**

USEPA conducted five community engagement events and one event with tribal representatives during the summer of 2018. Meeting materials, information, and summaries of each event are provided on USEPA's website: **https://www.epa.gov/pfas/pfas-community-engagement**. Series-specific lists of concern and associated social factors identified from presentations by public and community stakeholders during the USEPA PFAS community meetings held in 2018 are provided in the **ITRC Risk Communication Toolkit for Environmental Issues and Concerns** which is published as a separate document, and are discussed in **Section 14.3.4.** See also **https://pfascommunityengagement.org** for information about EPA virtual listening sessions in Spring 2023.

The following concerns were identified during preparation of this document, with details of these concerns in the following sections.

• Lack of comprehensive regulatory standards or advisories for thousands of PFAS for the following (**13.1.1**): Drinking water (**13.1.1.1**) Environmental media other than drinking water (**13.1.1.2**) Human consumption of food (**13.1.1.3**) Ecological risk (**13.1.1.4**)	• Limited availability of information on the health effects of PFAS (**13.1.15**)
• Desire for one standard or screening level for PFAS (**13.1.2**)	• Responsibility for sampling and treatment on private property (**13.1.16**)
• Lack of Occupational standards (**13.1.3**)	• The potential for PFAS emissions from cleanup methods (**13.1.17**)
• Lack of comprehensive monitoring information (**13.1.4**)	• Lack of scientific evidence that current PFAS treatment and disposal methods and remedies are fully protective of human and ecological health and prevent toxic emissions (**13.1.18**)
• Need to apply a precautionary approach in decision making (**13.1.5**)	• Stormwater and PFAS manufacturing discharges that may contain PFAS (**13.1.19**)
• Safety of short-chain substitutes (**13.1.6**)	• Psychological effects (**13.1.20**)
• Contamination from AFFF release sites (**13.1.7**) and unused AFFF disposal (**13.1.8**)	• Economic consequences of local PFAS contamination (**13.1.21**)
• Duty to warn AFFF responders (**13.1.9**)	• Remediation of PFAS with other contaminants, especially chlorinated solvents (**13.1.22**)
• Limitations in sampling and analysis methods (**13.1.10**)	• Pesticides containing PFAS (**13.1.23**)
• Limited programs for health monitoring and blood testing (**13.1.11**)	• Artificial turf (**13.1.24**)
• PFAS in food packaging (**13.1.12**)	• Semiconductor manufacturing (**13.1.25**)
• Potential PFAS contamination in recycling, compost, and fertilizer (**13.1.13**)	• Remediation using monitored natural attenuation (MNA) (**13.1.26**)
• Lack of disclosure by product manufacturers (**13.1.14**)	

Stakeholders who use this document should consider that much of the information is very technical. Nevertheless, it aims to lay a framework by which to understand this set of compounds, the foundational nature of the science, and many of the uncertainties.

13.1 Stakeholder Concerns

13.1.1 Lack of Comprehensive Regulatory Standards or Advisories for Thousands of PFAS

This section discusses the lack of advisory standards or screening values for various environmental media and exposure pathways.

13.1.1.1 PFAS in Drinking Water

The USEPA published National Primary Drinking Water Regulations (NPDWR) for six PFAS (**USEPA 2024**).

Several states have regulatory values for some specific PFAS, but the majority of PFAS are not included in any of the states' regulations. Information about available current regulatory standards and guidance values for PFAS in drinking water are provided in **Section 8**, with a summary table linked on the **PFAS fact sheet page**.

Stakeholders are concerned because the health consequences of these other compounds remain uncertain. Firm conclusions relating individual PFAS to specific health outcomes remain elusive (**Guelfo et al. 2018**). Information about health impacts for other PFAS is provided in **Section 7.1**.

13.1.1.2 PFAS in Environmental Media Other than Drinking Water

With the exception of regional soil screening levels for a limited number of PFAS (**USEPA 2023**), there are no federal standards or screening levels for evaluating environmental media (air, soil, and surface water and groundwater not used for drinking) and limited federal requirements that compel such monitoring at the time of publication.

USEPA has developed interim recommendations for screening and remediation of groundwater for PFOS and PFOA at CERCLA and RCRA regulated sites (**USEPA 2019**). **Section 8** includes information about regulations, guidance, and advisories for PFAS. In addition, the **Environmental Media Values Table** Excel file is available.

There are few limits by the federal and most state governments on PFAS in biosolids being applied to land for food and/or nonfood crops. PFAS, such as PFOA and PFOS, have been detected in biosolids produced at wastewater treatment plants (WWTPs), and in soil, surface waters, and leachate from landfills. WWTP biosolids are commonly applied to land as a soil amendment, and can remobilize PFAS to other migration and exposure pathways. Stakeholders are concerned about uptake by crops eaten by humans and animals. **Section 2.6** introduces PFAS sources at landfills and WWTPs, and **Section 5.6** and **Section 6.5.1** discuss plant uptake of PFAS. USEPA will be performing a risk assessment of biosolids as part of the PFAS Strategic Roadmap (**USEPA 2021**).

There are few regulatory or guidance limits for PFAS in surface water that may affect fish and consumers of fish. In addition, PFAS in surface water also creates an exposure pathway that potentially affects ecological and human health. For more information on PFAS in surface water, see **Section 16**.

While recognizing that drinking water is the dominant exposure pathway, **Vestergren and Cousins (2009)** identified that PFAS impacts to other media need to be considered because "there is a clear need

of investigations of how to remediate the hotspot areas with focus on the unsaturated zone," because "PFAS that are pooled in the unsaturated zone will continue to infiltrate and spread from contaminated areas as long as the source is not removed, or infiltration of precipitation is inhibited."

13.1.1.3 Human Consumption of Food

Many stakeholders want clear advisories or standards on PFAS in food due to the occurrence of PFAS in a variety of food. In Europe important sources of human exposure to PFOA and PFOS have been found to include the consumption of fish, meat, and eggs (**EFSA 2018**). The US Food and Drug Administration (FDA) has published information on their PFAS studies on their website (**USFDA 2019[1768]**). Few screening levels or advisories have been posted; for example, Maine has developed screening levels for fish for PFBS, PFOS, and PFOA, and for milk and beef for PFOS (**ME DEP 2021**). Further information about development of standards for food consumption is found in **Section 8.2.2.11**. PFAS are found in a variety of foods, including homegrown produce and wildlife. Some areas of concern regarding foods include the following:

- PFAS have been found in food purchased at stores. Some occurrence information for foods collected as part of the FDA's Total Diet Study is published in **Genualdi et al. (2021)**.

- Some states have issued fish consumption advisories for specific lakes and rivers after tests confirmed the presence of PFAS in surface water. **Section 15.3** includes a case study example about a recently enacted fish consumption advisory by the New Jersey Department of Environmental Protection.

- In February 2018, the Environmental Protection Authority of Victoria, Australia, "assessed waterfowl from three wetlands to better understand the extent and distribution of PFAS contamination ahead of the duck hunting season. PFAS was detected in waterfowl from all three wetlands." As a result, health risk assessments were undertaken and human health advisories were issued (**Environmental Protection Authority Victoria 2019**), p.1).

- In Wisconsin, the Department of Natural Resources (DNR) recommended not consuming the liver of deer killed within a 5-mile radius of an industrial site where elevated levels of PFOS were found. "DNR And DHS Issue Do Not Eat Advisory for Deer Liver In Five-Mile Area Surrounding JCI/Tyco Site In Marinette", September 15, 2020, https://dnr.wisconsin.gov/newsroom/release/37921.

- Alaska Community Action on Toxics (ACAT) (**Byrne 2009**) reported that "A study by **Martin et al. (2004)** on the presence of PFOS in the livers of arctic animals revealed elevated PFOS levels in almost all species studied." Furthermore, it reported that "In a recent study (Ostertag et al. 2009[2119]) of foods consumed by a Canadian Inuit population, traditional foods were more widely contaminated and contained higher concentrations of PFCs [PFAS] than nontraditional foods. Caribou had the highest concentrations of perfluorinated compounds (PFCs), including PFOS." At the request of the Yupik people of St. Lawrence Island, the ACAT is conducting a study to determine the safety of the traditional foods they eat for subsistence (**Byrne 2009**).

13.1.1.4 Ecological Risk

There is wide stakeholder concern that ecological receptors have been or will be harmed by releases of PFAS to the environment (**Section 7.2**). Currently, there are no federal risk-based ecological guidelines or thresholds for environmental media. Ecotoxicity studies are generally limited to a relatively small number of PFAS (typically PFOA and PFOS). Stakeholders are asking for expanded studies in this field to evaluate additional PFAS, including short-chain precursor compounds as well as "next-generation" substitute

compounds. Several states have established some criteria that are intended to protect aquatic organisms in their respective surface waters (see **Section 16.3**).

13.1.2 Desire for One Standard or Screening Level for PFAS

Among stakeholders there is a difference of opinion regarding how standards for PFAS should be established. Many stakeholders believe that PFAS should be treated as a class of chemicals (**Kwiatkowski et al. 2020**), similar to how PCBs or dioxin are currently regulated. In 2021, Vermont concluded that further information is needed to evaluate the feasibility of regulating PFAS in drinking water as a class (**VT ANR 2021**,**2021**). **Section 7.1** includes information about approaches for assessing toxicity of PFAS mixtures.

Given the lack of toxicological information for the vast majority of PFAS, when even less is known about the potential additive and synergistic effects associated with PFAS mixtures (see **Section 7.1.5**), many stakeholders support evaluating the mass of total PFAS as a preferred screening method, rather than limited compound-specific testing using target analyte lists (**CSWAB 2018**). However, it is noted that given the lack of a method to test for total PFAS (see **Section 13.1.10**), screening might need to be completed using a method such as the TOP assay, total organic fluorine, or non-target analysis as descried in **Section 11**. For example, the Conservation Law Foundation in New England put forth a petition requesting that PFAS in drinking water be regulated as a group with a treatment technique drinking water standard. See https://www.nhpr.org/post/activists-ask-new-england-states-regulate-pfas-chemicals-class#stream/0 and https://www.mass.gov/lists/pfas-information-a-petition-for-rulemaking-to-establish-a-treatment-technique-drinking-water. However, some interested parties do not support treating PFAS as a class of chemicals, because some PFAS, such as certain fluoropolymers, like PTFE, might need less toxicological information because they are unable to enter cells, they are not mobile in the environment, they do not bioaccumulate, and they are therefore not available to cause adverse health effects (**Henry et al. 2018**), although this issue needs further study (**Lohmann et al. 2020[1821]**). See also **Section 2.2.2.1**.

13.1.3 Lack of Occupational Standards

There are few standards or guidance values for occupational exposure for PFAS. NIOSH identified occupations that might have a higher potential exposure to PFAS, and identified occupational exposure studies and other research (**NIOSH 2021**). Stakeholders are concerned that paper mills and wastewater treatment plants where PFAS have been documented in indoor air, and manufacturers and industrial users of PFAS, do not have specific occupational standards for all of the PFAS that the workers might be exposed to during workplace activities.

13.1.4 Lack of Comprehensive Monitoring Information

Many stakeholders are concerned that most individuals and communities do not have any testing for PFAS. Moreover, there is no comprehensive federal requirement for PFAS testing of all drinking water systems and private wells. Based on publicly available data, there is an estimate that up to 80 million people in the United States might have drinking water with PFOA and/or PFOS concentrations greater than 1 nanogram per liter (**Andrews and Naidenko 2020**).

Limited testing has occurred in some public water systems, and USEPA's Unregulated Contaminant Monitoring Rule (UCMR) and other regulatory programs have provided more (see **Section 8**). Some significant points regarding the status of a comprehensive monitoring effort follows:

- As described in **Section 8.2.2.4**, the third round of USEPA's required monitoring program (UCMR3), which occurred between 2013 and 2015, sampled for only six of

the thousands of PFAS. UCMR3 was limited to public water systems (PWS) serving more than 10,000 people and a nationally representative subset of smaller PWSs, but private wells and many smaller PWSs were not included. More information about the UCMR3 data is included in **Section 8.2.2.4**. From this data set, it was estimated that approximately 6 million residents of the United States have drinking water that exceeds the 2016 health advisory for PFOA or PFOS, or both (**APHA 2016**).

- Sampling for UCMR4 (**USEPA 2016**), which occurred between 2018 and 2020, did not include any PFAS in its analyte list (**USEPA 2020**). Many stakeholders are concerned that an opportunity to better understand the magnitude of PFAS contamination on PWSs was not taken.

- Summarizing information about the UCMR, **Siros (2018)** stated, "America's Water Infrastructure Act of 2018 … requires drinking water systems serving more than 3,300 people to test for unregulated contaminants pursuant to USEPA's [UCMR]. Prior to this new law, only drinking water systems that served more than 10,000 people were required to monitor for unregulated contaminants. …Th[e] new testing requirement, which goes into effect in 2021, is expected to add more than 5,000 drinking water systems to the list of systems that are required to test for these unregulated contaminants." UCMR5 testing, scheduled for 2023–2025, will analyze for 29 PFAS chemicals (for which there is a validated USEPA testing method) in systems serving more than 3,300 people using lower detection limits than previous UCMRs. UCMR5 will also include monitoring at a nationally representative subset of PWSs (approximately 800) serving fewer than 3,300 people, contingent on appropriations, (**USEPA 2023**). UCMR5 does not mandate sampling of private water wells (**USEPA 2023**).

- Some states (for example, New Hampshire, Massachusetts and Vermont) have initiated testing of private wells in certain locations where there is a high potential for PFAS contamination, and require testing of public water systems subject to maximum contaminant level (MCL) regulations. The Washington State Department of Health announced that it will be conducting additional testing for PFAS at several hundred untested water systems. The state of Michigan is also testing all public community water systems for PFAS (see https://www.michigan.gov/pfasresponse/drinking-water/statewide-survey). New Jersey requires that sellers of private homes must test the wells prior to the sale of a home, and requires that landlords test private wells every 5 years (https://dep.nj.gov/pfas/drinking-water/#is-testing-for-pfas-required-under-new-jerseys-pwta).

13.1.5 Need to Apply a Precautionary Approach in Decision Making

Given the lack of toxicological data for the great majority of PFAS and PFAS mixtures, many stakeholders want a precautionary approach to the use, treatment, and analysis of PFAS-containing chemicals. This precautionary approach presumes compounds of similar structure may be expected to have similar modes of action and pose a similar risk to human health and the environment, lacking evidence to the contrary. This is particularly true because there are many nonessential uses of PFAS in consumer products (see **Section 2.5**) that receive no regulatory scrutiny.

13.1.6 Safety of Short-chain Substitutes

Many stakeholders are concerned with the use of substitute short-chain PFAS. After concerns arose that PFOA and PFOS (both long-chain PFAS) have health risks at very low concentrations, industry began to substitute them with shorter chain PFAS (see **Section 2.4**). Although some short-chain PFAS appear to be less bioaccumulative, the publicly available data are limited. Some short-chain PFAS can be persistent, and tend to be more water–soluble and more mobile than long-chain PFAS. Because of their greater water solubility, studies indicate short-chain substitutes are more readily taken up by plants than longer chain PFAS, including food crops (**Higgins 2017**). In their Interim Chemical Action Plan for PFAS,

the **Washington State Department of Ecology and Washington State Department of Health (2019 p. 1)** states that short-chain PFAS are difficult to remove from water, noting further, "Without additional health and safety data, it is impossible for us to evaluate whether short-chain replacements are safe substitutes. If environmental exposures to short-chain PFAS are found to pose health risks to people or the environment, mitigation will be difficult and expensive." Precursor compounds for some short–chain PFAS are also of interest in future monitoring studies; for example, perfluoro-1-butane-sulfonamide (FBSA, a precursor to PFBS), has been documented with high detection frequency (32 out of 33 samples) in fish from North America (**Chu et al. 2016**; **Ericson, Jogsten, and Yeung 2017**). Finally, in the Helsingør Statement (**Scheringer et al. 2014**) and the Madrid Statement on Poly- and Perfluoroalkyl Substances (**Blum et al. 2015**), scientists and other professionals expressed concerns about the embrace of short-chain PFAS as preferable replacements for long-chain PFAS.

13.1.7 Contamination from AFFF Release Sites

Many stakeholders believe that all potential AFFF release sites should be investigated, and where necessary, potential exposure should be mitigated. Investigations to date have identified the use of AFFF as one of the main sources of PFAS releases to the environment, and AFFF releases have been responsible for PFAS contamination of multiple drinking water sources. Although AFFF foams typically contain less than 2% total PFAS, thousands of gallons of foam mixture may be applied during a given event, and the concentrations of concern for PFAS are very low (below 100 parts per trillion (ppt)). Typical locations where AFFF is stored and used include civilian airports, military bases, chemical plants, municipal fire departments, oil refineries, bulk fuel storage facilities and terminals, and crash sites. AFFF was used abundantly for training purposes at military bases with flight operations and at civilian airports. Additional information is presented in the ITRC **AFFF fact sheet** and in **Section 3**.

13.1.8 Contamination from Unused AFFF Disposal

Stakeholders are concerned that incineration of unused AFFF is not always specifically regulated with PFAS-specific emission conditions and limits, and that incineration may generate dangerous byproducts (see **Section 3.10** on AFFF Disposal; **USEPA 2020**; **Earthjustice 2020**). The U.S. military indicated plans to collect and destroy unused firefighting foam that contains PFOS and PFOA (**USDOD 2018**). In a 2017 request for AFFF disposal research project proposals (**U.S. Air Force 2017**), the Air Force acknowledged that the foam, which was designed to resist extremely high temperatures, is difficult to burn and that "the high-temperature chemistry of PFOS and PFOA has not been characterized, so there is no precedent to predict products of pyrolysis or combustion, temperatures at which these will occur, or the extent of destruction that will be realized." Stakeholders are concerned that there are no federally mandated protocols that require incineration to reach certain temperatures to specifically target PFAS. (See **https://theintercept.com/2019/01/27/toxic-firefighting-foam-pfas-pfoa/**)

The National PFAS Contamination Coalition (an assembly of stakeholder groups from across the U.S.) opposes incineration (and similar thermal treatment technologies) for disposal of PFAS-contaminated wastes and collected PFAS products because stakeholders are concerned that thermal treatment technologies may not be specifically permitted to treat PFAS, and that demonstration is needed that treatment will fully destroy PFAS, that is, reduce the molecules to carbon, fluoride salts, and/or other constituents (**National PFAS Contamination Coalition Statement on Incineration of PFAS – National PFAS Contamination Coalition (pfasproject.net)**). **See Section 13.1.18** below.

The USEPA's Interim Guidance, Version 2 (**USEPA 2024**) indicates that thermal treatment (which includes incineration) is commercially available and potentially has the capability to destroy PFAS or manage the migration of PFAS in PFAS-containing materials, but that further research activities are needed. Some facilities in the United States have been permitted by state regulatory agencies for the thermal treatment of PFAS.

The Foam Exposure Committee (FEC), a subgroup of the Fire Department Safety Officers Association (**FDSOA 2021**), whose objective is to reduce firefighter/first responder exposures to PFAS in firefighting foams, reports that the absence of federal and state regulations addressing disposal provides more opportunities for fire departments to expose their firefighters and contaminate their own communities with AFFF products. Current regulatory programs that address use and disposal of AFFF are provided in **Section 8.2**.

13.1.9 Duty to Warn AFFF First Responders

Aside from standard workplace safety requirements regarding hazardous materials right-to-know, stakeholders are concerned that there has been no legal duty to warn or to require notice of hazards to first responders who handle AFFF. Several studies have concluded that some PFAS were elevated in the blood of first responders.

- The New Hampshire Department of Health and Human Services PFC Blood Testing Program (**NH DHHS 2016**) results indicate the geometric mean levels of PFOS and PFHxS in the blood serum of firefighters were elevated versus the geometric mean levels of those who had not worked as firefighters. Numerous other studies indicated that blood serum levels were elevated in firefighters (**LeMasters et al. 2006**; **Jin et al. 2006**; **Dobraca et al. 2015**). It is difficult to tease out whether these higher levels are related to exposures to AFFF, PFAS in firefighter gear (clothing), consumption of water from PFAS-contaminated drinking-water wells in affected communities, especially those that may be located near training facilities that have used AFFF, or other sources.

- IPEN (International Pollutants Elimination Network) released a report that presents information from recent studies that firefighters using AFFF have elevated blood levels of both PFHxS and PFOS; see also **NIOSH (2021)** for links to additional research. Earlier IPEN reports describe fluorine-free firefighting foam alternatives that can replace uses of toxic fluorinated firefighting foams (**IPEN 2018**, **2019**). The FEC recommends replacing older stocks of AFFF with fluorine-free foam solutions (**FDSA 2021**).

13.1.10 Limitations in Sampling and Analysis Methods

Stakeholders are concerned that current PFAS site investigations may not adequately define the types and total mass of PFAS present, due to limitations in analytical methods (**see Section 11**) that are still evolving. Moreover, the PFAS family of compounds contains thousands of chemicals, but standard analytical methods can identify only a fraction of these chemicals.

A related concern is that the specification for shorter chain AFFF published by the Department of Defense (**USDOD 2018**; **NAVSEA 2017**) still allows concentrations of PFOA and PFOS up to 800 ppb in AFFF concentrate, because that is the lowest concentration of either PFOA or PFOS that can be measured in the concentrate with current analytical methods. This is because the overall high concentrations of the many chemicals in the AFFF concentrate "swamp" the lab instrument, interfering with its ability to detect any individual compound except when it is present at high concentrations. The DOD has recently published a draft analytical method, DOD AFFF01, to quantify PFOA and PFOS with a limit of quantitation of less than 25 ppb (**Willey 2021**). The modern short-chain AFFF formulations are fluorotelomer-based, so PFOS (and other PFSAs) should not be present and PFOA may be present only as contamination from the production process (as discussed in **Section 3.1**), but without analytical methods to prove this, users cannot know for certain if the new AFFF products are PFOS- and PFOA-free. The ITRC **AFFF fact sheet** and **Section 3** include more information about AFFF specifications.

13.1.11 Limited Programs for Health Monitoring and Blood Testing

Some PFAS (for example, PFOA, PFOS) bind to proteins in the blood, making blood testing a means of investigating human exposure to PFAS (see **Section 7**). Many communities where PFAS have been detected have asked that the government establish a program for blood serum testing and long-term health monitoring so that they can better understand any health risks associated with PFAS exposure. ATSDR established a multi-site study with seven partners across the country to better understand the connection between PFAS exposures and health effects (**ATSDR 2020**).

Some states have provided limited testing on people in high-impact areas. For example, New Hampshire provided blood serum testing for people who worked on, lived on, or attended childcare on an AFFF-impacted site and were exposed to contaminated drinking water (**NH DHHS 2016**). New Hampshire also performed blood tests in selected towns where people used private wells that tested above the 2016 health advisories for PFOA and PFOS. However, many state and local governments are wary of blood testing programs because there is no correlation between the PFAS level in blood serum and any definitive health effects. People who participate in such tests are usually informed of their results and provided context about how they compare with national and location-specific averages. Only limited long-term programs have been established to monitor the health outcomes of exposed populations (for example, C8 Science Panel (**C8 Science Panel 2020**). If there is no assistance from the government, many community members cannot afford to have their blood tested.

13.1.12 PFAS in Food Packaging

Many stakeholders are concerned that food packaging containing PFAS leaches into food. Food packaging, such as bowls, plates, clamshells, trays, and pizza boxes, often includes PFAS for anti-grease resistance, and PFAS is sometimes used in the molding process to manufacture paper plates and containers. A 2008 FDA study found that "fluorochemical paper additives do migrate to food during actual package use," and oil and grease "can significantly enhance migration of a fluorochemical from paper" (**Begley et al. 2008**).

There is only limited peer-reviewed information regarding PFAS transfer to food. One study documented that 6:2 FTOH moves from dishware or containers into food (**Yuan et al. 2016**). A Canadian analytical lab found that PFBA moves from cupcake liners into cupcakes (**CEH 2018**).

The FDA has approved 20 next-generation, short-chain PFAS for coating paper and paperboard used to serve food. The FDA Effective Food Contact Substance Notifications database is available online (**FDA 2018**). Concerns have been raised that these compounds have not been adequately tested for human impact. Because of trade secrecy laws with regard to patents, the government does not publicly disclose the identity of the specific chemicals in food packaging. However, according to The Intercept (**Lerner 2016**), in documents filed with the USEPA, under TSCA section 8(e) requirements, **DuPont (2010)** reported that substitute PFAS used to produce food contact paper could pose a "substantial risk of injury," including cancerous tumors in the pancreas and testicles, liver damage, kidney disease, and reproductive harm. For more information about FDA's PFAS activities and food contact materials (FCM) PFAS phaseouts, please see **Section 8.2**.

Although there are no enforceable PFAS limits in food or water at the federal level as presented above in **Section 13.1.1.3**, some states and cities are moving forward with bans. Several states, including Washington, Minnesota, Maine, New York, and Vermont, have enacted laws to ban PFAS use in some food packaging. See **Section 8.2** and the **Regulatory Programs Summary** Excel file for information about regulatory programs. Stakeholders are concerned because not only does PFAS in food packaging pose potential risks to consumers of the food, but the used packaging may end up in compost or landfills. Compost is eventually applied to soil and PFAS are potentially transferred to certain food

crops, and may leach to groundwater. If compost goes to a landfill, PFAS potentially ends up in the landfill's leachate.

13.1.13 Potential PFAS Contamination in Recycling, Compost, and Fertilizer

Carpeting, furniture, and numerous other items containing PFAS are often recycled. There is concern that the recycled materials are often used in products where the consumer has no way of knowing whether it is has PFAS contamination. Biosolids from wastewater treatment plants are used in some composts and fertilizers and PFAS sampling may not be part of the screening process for these products. However, this is changing; New Hampshire and Maine both require testing. Additionally, stakeholders are calling for more testing and regulation for land-applied or disposed paper mill waste due to potential PFAS impacts. Stakeholders are concerned that composting of paper mill waste to make fertilizer, which, for example, is still done in Michigan, should get more attention. It is difficult to know which mills make "waterproof" or food contact papers that contain PFAS.

13.1.14 Lack of Disclosure by Product Manufacturers

Some stakeholders are concerned that chemical and product manufacturers are not required to disclose when they sell, make, or use PFAS in their products because some formulations are proprietary and may not be listed on a Safety Data Sheet. For example, many sturdy, waterproof, and heat-resistant products containing PFAS are produced for the construction industry, including polished granite countertops. Additionally, there is lack of disclosure and transparency concerning the composition of AFFF, because AFFF suppliers claim that formulations are proprietary.

13.1.15 Limited Availability on Information on the Health Effects of PFAS

Some stakeholders are concerned that politics may delay or even prevent the full disclosure of PFAS toxicity information. For example, the 2018 release of ATSDR's Draft Toxicological Profile for PFAS was reportedly delayed because of concerns about the public response. This example, if replicated, may lead to distrust and reduce the efficacy of risk communication. Additionally, collected health data may not be clearly and fully shared or explained to stakeholders.

13.1.16 Responsibility for Sampling and Treatment on Private Property

When off-site contamination is suspected or discovered, stakeholders believe that the responsible parties should be accountable for establishing an entire program to deal with the problem. This includes sampling and analysis, disclosure of PFAS content, health monitoring, and if appropriate, remediation and mitigation. Upon detection of PFAS above state or USEPA limits, stakeholders maintain that responsible parties should be required to provide affected residents with alternative water supplies. Additionally, stakeholders believe that the cost of the program, including long-term treatment and monitoring, should be borne by responsible parties.

13.1.17 Potential PFAS Emissions from Cleanup Methods

Stakeholders believe that treatment systems (from large public water treatment systems to small private point-of-use systems) should be monitored for effectiveness, as the type and frequency of monitoring may vary for all systems. There is also concern that disposal or regeneration of GAC canisters, resins, and byproducts will add contaminant loads of PFAS to the air, land, and water. Stakeholders are concerned that companies that thermally treat spent carbon filters that contain PFAS do not

provide publicly accessible information that documents full destruction of all PFAS; some companies claim all PFAS are destroyed, yet the research appears to be focused on targeted PFAS (for example, PFOS and PFOA) destruction. More concerns about thermal treatment are discussed in **Section 13.1.8**, with further information provided in **Section 12.4**.

13.1.18 Lack of Scientific Evidence that Some PFAS Treatment and Disposal Methods and Remedies Are Fully Protective of Human and Ecological Health and Prevent Toxic Emissions

Historically, the three standard practices for PFAS waste management are landfilling, wastewater treatment, and incineration. Stakeholders' concerns with these disposal practices are highlighted in a study sponsored by the Environmental Working Group (EWG) (**https://www.ewg.org/news-insights/news-release/study-disposal-pfas-waste-increases-contamination**). One of the conclusions of that study is that all three methods have been found to not effectively contain or destroy PFAS. Tasha Stoiber, EWG senior scientist and primary author of the study, found that "The three common 'disposal' options for getting rid of PFAS do not eliminate these contaminants but rather end up just returning either the same chemicals or their byproducts back into the environment." Additionally, USEPA has confirmed that while "Thermal treatment technologies are common remediation approaches for contaminated media and waste, limited information exists on the efficacy, potential atmospheric emissions, operational conditions, costs, etc. for thermal treatment technologies specifically targeted for PFAS" (**Mills et al. 2020**).

Additionally, USEPA stated that "Research on thermal stability of PFAS compounds, the ability to fully capture and identify PFAS compounds and their thermal decomposition byproducts, and the efficacy of emission control technologies are areas of targeted research. These efforts, in cooperation with states and industries, [are] aimed at proper disposal of PFAS-laden wastes without media-to-media transfer or environmental release" (**USEPA 2019**). In USEPA's Interim Guidance, Version 2 (**USEPA 2024**), they identified areas for further study to assess the efficacy of destruction and disposal of PFAS-containing materials (that are not consumer products) to help protect public exposure to PFAS. Recent testing and reporting of PFAS destruction by incineration has been documented (see **Section 12.4**).

Additionally, it should be noted that other technologies besides the three methods can be used in remediation. These include ion exchange, granulated activated carbon (GAC), and reverse osmosis (see **Section 12**).

An example that demonstrates the stakeholders' concerns about adequate protection provided by disposal options is the Holston Army Ammunition Plant (Holston) in Tennessee. In a July 16, 2019, letter to USEPA Region 4 Administrator (**https://cswab.org/wp-content/uploads/2019/07/Holston-Citizen-Petition-Region-4-PFAS-July-2019.pdf**), several environmental groups stated that Holston will present a risk to human health and the environment by burning polymer-bonded explosives (PBXs) containing PFAS. The groups cited a recent decision by the neighboring State of Kentucky to prohibit the Blue Grass Army Depot from open-air burning or detonation (OB/OD) of "munitions wastes that are a potential source of Per- and polyfluoroalkyl substances (PFAS), including Teflon, Viton, and Viton-A. This includes both short and long chain PFAS." Both bases are located in USEPA Region 4. The groups stated: "Open air burning and detonation do not provide either sufficient or sustained temperatures times to achieve destruction. OB/OD activities at Holston are very likely resulting in the ongoing release and dispersion of PFAS to the environment, posing a potentially substantial health risk to workers and residents."

13.1.19 Stormwater and PFAS Manufacturing Discharges that May Contain PFAS

PFAS, including PFOA, have been detected at the storm drain outfalls at active facilities. Stakeholders are concerned that most NPDES effluent permits do not require PFAS sampling and the magnitude of PFAS concentrations in such discharges remains unknown. Older and inactive facilities' discharge areas, many of which have not been sampled for PFAS, may also act as long-term sources of stormwater and/or groundwater contamination due to residual PFAS in soil at stormwater discharge areas.

13.1.20 Psychological Effects

It was reported at one Superfund community (Tuscon AZ) that children in some communities are scared to drink water (**Strauss 2024**) where contaminated drinking water supplies have the effect of deterring children from drinking clean water. Additionally, blood level values have become an identity, and there are pictures of people holding up signs identifying their blood levels.

In addition, the Agency for Toxic Substances Disease Registry (ATSDR) has identified that studies "suggest that the experience of exposure to hazardous substances and the resulting psychosocial changes can result in adverse physical and psychological health effects" (**ATSDR 1995**).

13.1.21 Economic Consequences of Local PFAS Contamination

Individuals have voiced concerns about significant economic consequences on property values and businesses. See the USEPA community meetings information provided on USEPA's website: **https://www.epa.gov/pfas/pfas-community-engagement**. In one case in Massachusetts, the Board of Health added PFAS to the list of substances homeowners with private wells in certain areas of town must test for before selling their homes (**Town of Harvard, MA 2020**). In New Jersey, PFOA, PFOS, and PFNA were added to a list of chemicals that private well owners must test for prior to selling their homes under the NJ Private Well Testing Act. This also applies to landlords who rent homes with private wells (see **https://www.nj.gov/dep/rules/adoptions/adopt_20200601a.pdf**). In another instance, because PFAS was detected in water used by dairy cattle, the farmer had difficulty selling the milk products. Stakeholders are particularly concerned about facilities located in economically disadvantaged communities. These communities need the economic benefits of a facility but have few resources to demand enough testing of air emissions and of potential health impacts on the community.

13.1.22 Remediation of PFAS With Other Contaminants Especially Chlorinated Solvents

At many sites where PFAS has been found, especially military sites that are contaminated with AFFF, there is concern that past cleanup efforts have spread PFAS. Many military sites have been listed as Superfund sites because they are contaminated with chlorinated solvents (**https://www.epa.gov/fedfac**). The early remedy for removal of solvents from groundwater was pump and treat with air strippers. Since air stripping doesn't remove PFAS, groundwater contaminated with PFAS was, and in some cases continues to be, discharged into streams and rivers, through reinjection, discharge to wastewater treatment plants, or reuse such as irrigation or make-up water for recycling.

Even if remediation systems use GAC or other techniques to clean up chlorinated solvents (for example, PCE and TCE), these systems are not typically optimized for PFAS capture. If they are optimized for PFAS capture, it is unclear if they will be as effective for solvent capture. Additionally, it is not clear whether in the past PFAS was released during the regeneration process for solvent-laden GAC, thus spreading some

PFAS through air during the heating process. More information about treatment systems and co-contaminants is included in **Section 12.8**.

13.1.23 Pesticides containing PFAS

Some pesticides contain PFAS. PFAS have been used as an active and inert (or inactive) pesticide ingredient. PFAS can be used as herbicidal dispersants and wetting agents and to aid wetting and penetration in insecticides. A patent has been issued for insecticides and fungicides having branches composed of perfluoroalkyl chain molecules. Other pest control patents refer to compounds with some of the side chains composed of perfluoroalkyl (**Gaines 2022**). This creates a number of problems, including low levels residing in soil, uptake in food, and "masking" other sources of the PFAS in areas that have been historically sprayed with insecticides. Some pesticides have received new USEPA guidance, including https://www.epa.gov/pesticides/epa-stops-use-12-pfas-pesticide-products and https://www.epa.gov/pesticides/pfas-packaging. More information about PFAS uses is included in **Section 2.5**.

13.1.24 Artificial Turf

Many stakeholders are concerned that plastic grass blade and/or "rubber crumb" backing in artificial turf contains PFAS. Artificial grass blades are plastic and were found by one nonprofit organization to contain PFAS. This issue was investigated by the Connecticut Department of Energy & Environmental Protection (**CH DPH 2022**), which analyzed "grass" blades from a previous study and suggested that the PFAS had a different origin (see **Table 2-6**). While this may be true for the product analyzed, artificial turf in parks and schools is from many different manufacturers. Additionally, "[a]rtificial turf infill is often made from recycled tires, which may be another source of PFAS. Polymeric pellets manufactured specifically as infill are also available, and patents indicate that these materials may contain PFAS as well" (**Fernandez, Kwiatkowski, and Bruton 2021**). The City of Boston has recently banned all new artificial turf in city parks. (https://www.theguardian.com/environment/2022/sep/30/boston-bans-artificial-turf-toxic-forever-chemicals-pfas)

13.1.25 Semiconductor Manufacturing

There is concern that the semiconductor industry has long been a source of PFAS that has been overlooked. A recent survey of the technical literature by researchers from Cornell University "revealed that there are several specific examples of fluorocompounds that are currently in use by the semiconductor industry in the lithography process" (**Ober, Florian, and Deng 2022**). More information about PFAS use is available in reports from the Semiconductor Industry Association (**SIA 2023**; **SIA 2023**). As with the concern about remediation of PFAS with other contaminants, the manufacture of semiconductors has also seen releases of chlorinated solvents. In the remediation process, the industry used pump and treat with air stripping, which does not remove PFAS from contaminated water; thus, PFAS remained in the discharge waters. In one case (Moffett Field), the site was contaminated by a plume of chlorinated solvents that spread from a center for semiconductor development that is now commingled with the VOCs and other PFAS used at Moffett Field. Recently, NASA, which is the steward of the site, found PFAS from past use of AFFF and from the semiconductor industry adjacent to Moffett (**Tetra Tech 2022**).

13.1.26 Monitored Natural Attenuation (MNA) for PFAS

Although early in the research stages, using remediation techniques that employ MNA for PFAS presents a range of problems and concerns for community and tribal stakeholders. As this document points out in its discussion of these still unproven processes to remediate PFAS (see **Section 12.6.7**), there are no currently recognized destructive attenuation pathways for PFAAs (a class of PFAS) in natural settings.

Communities generally do not favor prolonged cleanup approaches with uncertain funding, with a commensurate degree of risk, and a shift of the burden for environmental cleanup to another generation. A related stakeholder concern is that the strictest cleanup standards be applied. Cleanup standards may differ from site to site based on risk assessments, site conditions, or state regulations Additionally, many community members perceive MNA as a "do-nothing" approach.

MNA for PFAS is similar to nondestructive retention processes for metals and radionuclides, thus leaving diluted PFAS in the environment (**ITRC 2010**, section 5 Stakeholder and Tribal Issues). This referenced document details major concerns that are specific to leaving contamination in place, including requirements for enhanced community participation; need for long-term monitoring and maintenance; future use considerations; and long-term health and safety, as well as many tribal concerns. The framework from ITRC (**2010**, section 5), is used here to address stakeholder perspectives and concerns about using MNA for PFAS.

- Enhanced Community Participation

Attenuation-based restoration projects require the community to coexist with some residual level of contamination for an extended period. Attenuation-based projects should always include communicating this temporal component. Prior to beginning attenuation projects, the public must be fully informed of planned activities and potential consequences. Afterwards, stakeholders must be informed about the progress in retaining chemicals "safely" in place and the risks of long-term environmental changes that may affect the retention capability of the subsurface, such as geochemical changes in the subsurface, earth movement, and a host of natural phenomena.

- Need for Long-Term Monitoring and Maintenance

Stakeholders may be concerned that attenuation-based restoration of PFAS will require extensive long-term monitoring and maintenance to ensure that public health and ecological parameters are met. Significant uncertainties in attenuation cleanup efficacy and timelines may conflict with stakeholder expectations. Consequently, stakeholders should receive additional communication of technical information, results of monitoring, and prognoses. Stakeholders will also be concerned about what will happen if attenuation does not proceed at the projected rate. Stakeholders may expect that target contamination levels be set for future dates and for reassessment of the cleanup strategy if monitoring shows that targets are not being met by natural attenuation. As an important precept, the responsible party must commit that the remedy will be revisited (for Superfund sites, this occurs every 5 years) and selection of attenuation will not hinder future investigations and consideration of other means to remove the contaminants.

- Future Use Considerations

Generally, the public favors site cleanup that leads to unrestricted use. If unrestricted use is not possible, the smallest area possible should be set aside, and institutional and engineering controls should be incorporated into the activity (see also **Section 14**). If the future use does lead to unrestricted use, a long-term stewardship program must be developed to ensure that the contaminants are reduced to acceptable levels or eliminated. While MNA may be less costly than other remediation techniques, the public generally is not concerned with simply reducing the overall restoration costs; they may be more concerned with removing the contamination quickly and gaining access to the land—or lifestyle—as before the contamination occurred. As such, the public should be full partners in future land-use decisions. If MNA is selected, the site should be visibly marked and documented for long-term identification.

13.2 Specific Tribal Stakeholder Concerns

Tribes share many concerns with other stakeholders; however, they differ from other stakeholders in several key aspects. The 573 federally recognized tribes are each culturally, governmentally, and socially unique. Some tribes view any level of contamination of their lands and natural and cultural resources as unacceptable. Many tribes have culturally significant or sacred areas, which may include springs, mountains, hunting areas, plant-gathering areas, or burial sites. When culturally significant or sacred areas are affected, traditional methodologies that nontribal environmental professionals rely on (such as the applicable exposure scenarios or factors for a risk assessment) may not be sufficient to portray the effect to a tribe. For example, some plants and animals can have tremendous cultural or religious importance to a tribe, including birds and feathers, game animals, and herbs. Many tribes sustain themselves through hunting, fishing, and gathering of foodstuffs. Additionally, many tribal cultural ceremonies include the use of water. Other areas of difference include diet (for example, some tribes consume more fish per capita) and growing crops or grazing animals on areas fertilized by biosolids from wastewater treatment facilities.

Tribes are sovereign entities that have established government-to-government relationships with federal, state, and local governments—relationships that must be recognized in the decision-making process. When a PFAS-contaminated site affects a tribe, the project timeline must include tribal approvals in addition to other typical agency approvals. Sampling, research, and services on tribal lands generally require institutional review board or tribal council approval. Each sovereign nation operates differently, ranging from tribes that have no research capacity to tribes that have a full review board with a formal application process. The initial steps in the approval process may include drafting a proposal, preparing a poster or podium presentation, and presenting to the tribal government.

Once tribal approval is granted and the project commences, the practitioner must obey tribal protocol with respect to cultural practices. The tribe may reserve the right to retain the findings in the case of exploratory research and restrict publication. Regulatory findings for water and soil concentration, level of treatment, and monitoring are first reported to the tribe's department of environmental quality or natural resources and then forwarded to state environmental organizations and USEPA.

A Tribal PFAS Working Group was formed in 2020 to "help address and reduce PFAS in Indian Country." The working group is comprised of members of the National Tribal Water Council, Tribal Science Council, National Tribal Toxics Council, Tribal Waste and Response Steering Committee, and Tribal Pesticide Program Council (**National Tribal Water Council 2023**).

Most of the concerns that tribes have are listed in **Section 13.1**. However, as mentioned above, there may be some distinctions that are important to tribes:

- PFAS in surface waters and lakes may have a higher level of concern when they are used for fishing, given that tribal members rely on these water bodies.
- Drinking water and irrigation water in the arid Southwest are limited, and there is heightened concern that tribes will be unduly impacted if drinking or irrigation water is contaminated. Stakeholders are concerned with lack of PFAS sampling of tribal PWSs. USEPA performed limited sampling of tribal PWS during the 2022–2023 timeframe with no PFAS results above the detection limit (**USEPA 2022**; **Mok et al. 2022**).
- Tribal lands are often close to installations that used AFFF (notably DOD) or other industrial sources of PFAS (manufacturers, leather tanneries).
- Tribal lands are often close to installations that used AFFF (notably DOD) or other industrial sources of PFAS (manufacturers, leather tanneries).

- Where biosolids have been applied to tribal farmlands or grazing lands, there is a need to sample these tribal lands for PFAS contamination. In some cases, cities may have paid tribal communities to spread biosolids from WWTPs that may have been unknowingly contaminated with PFAS.

- Activities on and near tribal lands may have involved use of PFAS-containing chemicals that could impact tribal members working in these facilities through inhalation and dermal exposure.

- Landfills on tribal lands that accepted outside waste need to be sampled for PFAS contamination, which may be in the landfill leachate. Companies that paid a fee to the tribes to use their land managed many of these landfills. Although most required sampling, often the sampling plans did not include sampling landfill leachate for PFAS.

- A big issue facing tribes is that tribal environmental offices and budgets are typically small, and they do not have the people or money to perform appropriate site investigations to determine if they have PFAS in their community.

13.3 Stakeholder Resources

Below are a number of resources for communities available at the time of publication. These resources are websites of major environmental organizations and projects that specifically deal with PFAS. These groups aim to help environmental and community groups to better understand the issues and science around PFAS. These websites have not been reviewed for accuracy or to determine if they are up to date.

14 RISK COMMUNICATION

The ability to communicate potential risks to human health and the environment is a vital skill to facilitate community participation and decision-making. The process of informing people about potential hazards to their person, property, or community (**Hance, Chess, and Sandman 1991**; **USEPA 2022**) is called risk communication. Risk communication can be particularly challenging when dealing with science that is rapidly evolving, as in the case with PFAS. Communicators must grapple with competing interpretations of uncertain science and risk management strategies, while earning community trust and promoting meaningful engagement. This section addresses PFAS risk communication challenges and risk communication tools with PFAS-specific examples.

Section Number	Topic
14.1	**Role of Risk Perception**
14.2	**Risk Communication Challenges**
14.3	**Risk Communication Planning and Engagement Tools**
15.4	**Risk Communication Case Studies**

According to USEPA's Risk Communication in Action: The Risk Communication Workbook (**USEPA 2007, p.1**), the overall purpose of risk communication is *to assist affected communities [to]* ***understand*** *the processes of risk assessment and management, to* ***form*** *[scientifically valid]* ***perceptions*** *of the likely hazards, and to* ***participate*** *in making decisions about how risk should be managed*. Risk is the relationship between the probability of harm associated with an activity and vulnerability of exposed elements (**Slovic 1987**; **Slovic 2003**).

The **ITRC Risk Communication Toolkit for Environmental Issues and Concerns** is published as a separate document. In addition, guidance on general performance of risk communication for contaminated sites is provided in *Risk Communication in Action, the Risk Communication Handbook,* (**USEPA 2007**); *Decision Making at Contaminated Sites: Issues and Options in Human Health Risk Assessment,* (**ITRC 2015**); and *Improving Dialogue with Communities: A Risk Communication Manual for Government,* New Jersey Department of Environmental Protection, (**Hance 1991**).

The following subsections present risk communication challenges of PFAS and provide PFAS-specific risk communication information for components of risk communication planning.

14.1 Role of Risk Perception: Public Stakeholders and Decision Makers

It is essential for decision makers to understand stakeholders' risk perceptions of the hazard. Risk perception is the disposition that individuals or communities adopt toward hazards and is the product of their knowledge, beliefs, attitudes, judgments, and feelings, as well as wider cultural and social factors. Stakeholders include, but are not limited to, the community, public entities, potential responsible parties, regulatory agencies, and municipal and state officials. Risk perception for PFAS is challenging to address because the science is rapidly evolving, the exposure is perceived as involuntary, the risk mangagement strategies are a moving target, and health impacts are greatest for the most sensitive populations. The risk management strategies can be a moving target because of these challenges.

The environmental management community is acting largely based on growing evidence of health risks and general precaution as our understanding of PFAS exposure and associated risk is continuously redefined. In this context, risk amplification (heightened perception of risk) and attenuation (diminished perception of risk) can serve as guiding principles to better understand stakeholder context and site-

specific factors contributing to stakeholders' perceived risk to proposed risk management strategies. Risk amplification occurs when stakeholders perceive more risk from a hazard than the decision maker's perceived risk. Conversely, risk attenuation describes scenarios where decision makers perceive heightened risk from a hazard while stakeholders perceive less risk from the same hazard. For more information on factors that influence risk amplification and attenuation, see **section 2.8** of the Risk Communication Toolkit.

14.1.1 Role of Risk Perception and Public Stakeholders

In a scenario of risk amplification, stakeholders perceive their risk to a hazard as a major concern while experts assess the hazard as carrying a lesser degree of risk (for example, low or moderate) (**Kasperson and Kasperson 1996**). In the context of PFAS, risk perception is heightened by uncertainties and variability among policies and standards due to developing sampling methodologies and analytical procedures; new scientific information on health effects, risk assessment evaluations, and treatment technologies (**NGWA 2017**); and overall confidence/trust in the proponent or lead organization that is communicating risk. Additional human health and exposure factors that heighten risk perception for PFAS are summarized in **Section 14.2**. **Section 13** includes information about stakeholder perspectives on PFAS concerns.

This heightened sense of risk may result in opposition to proposed risk management strategies, such as source control (in which there is scientific uncertainty pertaining to the "safe" level of exposure, if any, without risk).

To address risk amplification challenges, it is important to build trust among the community by maintaining transparent communication of these uncertainties and variabilities early in the project life cycle (**USEPA 2005**, **2007**). New data findings and research on PFAS should be regularly shared with impacted stakeholders. Current knowledge, including uncertainties and information about variability of potential susceptibility to health effects in individuals with the same exposures, should be conveyed accurately in an understandable manner.

Uncertainties in individual causation and variability in regulatory guidance can cause the affected individuals to lack confidence in current scientific knowledge. Therefore, a risk communication project team should communicate these uncertainties to the affected individuals in collaboration with risk assessors, community involvement coordinators, and community members to develop site-specific messaging. It is important to understand that standards for the same chemical often differ depending on the entity setting them. This is not unexpected, because standard-setting guidance is not simply a mathematical formula. Risk assessment approaches used in standard-setting processes include best professional judgment in the selection of the factors involved. In addition, a collaborative effort can be made to develop performance metrics, supplemental to cleanup standards, that evaluate how the action will lead to measurable increased protection for public health and the environment, thus leading to the development of targets or objectives (**Hadley, Arulanantham, and Gandhi 2015**) that offer reductions in risk. These metrics are referred to as secondary risk management performance metrics and can be used to communicate and evaluate success of a proposed PFAS risk management strategy, as well as assist with alleviating stakeholder concerns associated with uncertainty. Examples of applicable secondary risk management performance metrics in the context of PFAS are reduction in contaminant bioavailability/loading, source control/removal, and mitigation of exposure pathways (**NGWA 2017**; **Harclerode et al. 2016**).

Furthermore, risk amplification can be heightened when a community perceives that they have limited control over risk. Explicit efforts to share control reduce outrage and risk amplification (**Sandman 2013**). Therefore, it is essential to create an atmosphere of collaboration. In situations where an open public forum is met by public outrage, it important to be compassionate and lend a listening ear. Acknowledgment and documentation of questions that cannot be answered communicates transparency

and can be a first step toward building trust. Effective participation is presented in the **ITRC Risk Communication Toolkit for Environmental Issues and Concerns**.

In contrast, in a risk attenuation scenario, experts judge hazards as relatively serious while stakeholders do not pay attention or pay comparatively little attention to that risk event (**Kasperson and Kasperson 1996**). This diminished sense of risk results in challenges in stakeholder participation in risk mitigation activities ("Why do we need to spend money/do testing, etc., for this?"). In the context of PFAS, risk mitigation and monitoring measures include participation in blood testing, installation of a water treatment system, and use of an alternate water source. To address risk attenuation challenges, site-specific risk perception factors related to inaction can be identified via stakeholder engagement and integrated into a communication plan (**NGWA 2017**; **Harclerode et al. 2015**; **Harclerode et al. 2016**).

14.1.2 Role of Risk Perception and Decision Makers

Due to the evolving science of PFAS, project managers, risk assessors, and risk communicators can also become caught in between those who amplify risk and those who deny risk. As noted, uncertainty in the toxicity and risk can lead to lack of consensus on how to evaluate risk and proposed risk management strategies. Due to risk amplification, there may be an elevated demand to take action to reduce potential risks beyond what is even technically and/or financially feasible. The underlying uncertainty feeding this risk amplification may also lead to opposition to proposed risk management strategies from some decision makers prior to establishment of the "right number" to dictate such action. When communicating with the public, it is essential to mitigate downplaying or embellishing risk due to lack of consensus on risk among decision makers.

Strategies should be implemented by the lead organization to navigate this rift to craft an approach and communicate a plan that is most likely to be reasonable and protective. One strategy is to incorporate the community's needs and values to place a greater weight on how risk management is considered. A second strategy is to develop secondary risk management objectives to help evaluate how interim and long-term action will lead to measurable increased protection for public health and the environment (**Hadley, Arulanantham, and Gandhi 2015**; **Harclerode et al. 2016**). These complexities highlight the importance of formulating a robust risk communication plan and team, including community and third-party involvement, as needed, as well as considering the dimension of perception as part of the risk communication process.

Case studies that showcase implementation of meaningful and effective community participation and inclusion of a third, neutral party to facilitate implementation of a successful risk communication strategy for PFAS-impacted communities are included in **Section 15.4**.

14.2 Risk Communication Challenges

There are many general challenges to risk communication about any environmental situation, including diversity of audience backgrounds, importance of establishing trust among the parties, and clearly communicating about the scientific and regulatory requirements. ITRC's Risk Communication Toolkit for Environmental Issues and Concerns includes a more detailed discussion of these challenges.

Emerging contaminants, and more specifically PFAS, pose unique challenges to achieving meaningful and effective risk communication. There is often divergent information available from different sources about the potential severity and uncertainty associated with exposure and adverse health impacts that may result from exposure, and the need for treatment or response actions. For example, people will do their own research, which may result in conflicting information. Communicators need to be prepared to explain the choices and decisions made regardless of the conflicting information. Some of the risk communication challenges for PFAS are discussed in the following sections.

14.2.1 Regulatory

There are regulatory challenges for emerging contaminants, see **Section 8**.

- PFAS are emerging contaminants, which means that they are the subject of intensive investigation, so new information, and thus our understanding of hazard, exposure, and risk, are emerging and evolving. This can challenge us to rethink determinations of protectiveness within very short time scales. More information is available from USEPA (**2023**, **2022**) about PFAS and emerging contaminants.

- Federal and state standards, guidance, and policies for PFAS are not uniform and are available for only a handful of compounds. This is also challenging given the recent expansion of additional PFAS analytes added to the USEPA Fifth Unregulated Contaminant Monitoring Rule (UCMR5) (**USEPA 2023**), the federal maximum contaminant levels (MCLs) (**USEPA 2024**), and the lack of consensus-based toxicity values for all PFAS analytes (see **Section 7.1** for information about human health effects).

- Regulatory standards and health advisories are in the parts per trillion range (or parts per quadrillion range), and it is difficult to explain to general audiences what these levels mean in terms of risk, how they were derived, or that, with current analytical methods, may not be detected.

- Most people have little to no understanding of risk assessment, risk management, and existing rules and legislation associated with chemical use and release. Risk communicators often need to provide this context before even discussing site or chemical specifics.

14.2.2 Fate and Transport

There are technical and scientific challenges and uncertainties around fate and transport of PFAS in the environment, see **Section 5**.

- There are many sources for PFAS and many of them have multiple release mechanisms, so simply explaining where the PFAS came from, including personal/lifestyle-based choices of individuals, and how PFAS got into the environment can be complicated.

- Most people have only a very basic understanding of (and lots of misconceptions about) chemistry, geology, environmental systems, and groundwater. Risk communicators often need to provide this context before even discussing site or chemical specifics.

- Fate and transport behaviors differ among individual PFAS (although broad generalizations may be appropriate based on chain length and functional groups).

- The environmental persistence, solubility, and mobility of PFAAs can result in:
    - very large impacted areas encompassing a wide range of environmental settings and potential transport pathways
    - complex transport pathways between interconnected environmental systems (groundwater-surface water; air-soil-groundwater; etc.).
    - bioaccumulation of PFAS into the food chain from impacted media, such as from contaminated sludges and/or biosolids.

- The multiplicity of sources and pathways (combined with the wide range of potential toxicity values discussed below) can create a sense that everything is equally contaminated and dangerous. Communicators need to help people understand the variability in the degree of contamination and relative risk related to each pathway.

- We are still identifying new PFAS sources (for example, PFAS from compost sites).

- Precursor transformation can affect how a PFAS site will evolve, but this is not well understood.

- Knowledge about uptake by plants and animals is increasing, but it is often difficult to answer questions about specific species.

14.2.3 Toxicological/Epidemiological Information and Risk Assessment

There are challenges and unknowns for toxicological and epidemiological information about PFAS, see Sections **7.1** and **17.2**.

- One of the greatest challenges to risk communicators is having to craft messaging in the face of often intense disagreements over the interpretation of available science and the magnitude of uncertainty; we are communicating health risks when the risks are not fully known or characterized.

- There is reliable toxicological information for only a small subset of PFAS.

- A select subset of PFAS has been studied in sufficient detail to support risk assessment and remedial decision-making.

- While human studies may conclude that there is evidence that elevated exposure to PFAS increases the risk of certain health effects, regulatory risk assessment focuses on populations. This means that it is not possible to relate a current health effect in a specific individual to PFAS exposure or to use risk assessment results to predict whether future health effects will occur on an individual basis.

- Although most people have some detectable level of PFAS in their blood serum from consumer products and diet (anthropogenic background), certain populations may have elevated exposure due to localized sources, such as aqueous firefighting foam (AFFF) and industrial discharge, which can contaminate environmental media, particularly drinking water, leading to increased blood serum PFAS to levels that may increase the risk to human health.

- Communities often learn that they have been unknowingly exposed to PFAS for up to several decades prior to the discovery of their presence.

- Community members may want to compare PFAS blood/serum concentrations to PFAS levels in drinking water or other environmental media. A limited number of public-facing tools are available for estimating blood/serum concentrations based on drinking water concentrations, including ATSDR's Estimator Tool (**ATSDR 2022**) and Silent Spring Institute's Digital Exposure Report-Back Interface (DERBI) (**Silent Spring Institute 2022**).

- Blood serum levels of certain PFAS can remain elevated for many years post-exposure, while levels of other PFAS decrease more rapidly, and currently there is no accepted method to hasten the reduction of PFAS blood levels.

- Individuals may be part of PFAS biomonitoring studies or can obtain their individual blood serum levels on their own. These individuals have access to information for comparison to regional and national reported levels, and thus may be more informed on their personal exposure than the medical practitioner.

- There is a need to provide understandable and informative public health advice to exposed individuals, including woman of childbearing age and pregnant woman who are making decisions about whether to nurse and/or use water known to be contaminated with PFAS to prepare formula (**Section 7.1**).

14.2.4 Technical

There are technical challenges in the areas of site characterization and treatment technologies, see Section **10** and **12**.

- There may be issues in the identification of responsible parties due to the difficulty in distinguishing between low levels of PFAS from use of consumer products (anthropogenic background) and PFAS contamination resulting from discrete sources, such as industrial uses.

- Although a subset of PFAS can be effectively removed by established treatment technologies, effective methods for the remaining compounds are in development.

14.2.5 Analytical Ability

There are technical challenges in laboratory analytical methods and field sampling, see **Section 11**.

- There are numerous PFAS in existence, yet not all can be measured. Sampling methodologies and analytical procedures to measure PFAS concentrations are still being developed and refined.

- Units used for reporting PFAS concentrations in environmental media and clinical tests are not uniform, and there are differences between blood and serum testing that are not standardized. For environmental professionals, converting and contextualizing these unit differences are routine practice for understanding risks. However, use of varying units may contribute to confusion for general audiences trying to compare and interpret testing results. There are difficulties in clearly and concisely communicating unknowns and limitations of analytical technologies related to the understanding of the extent of PFAS present in the environment, exposure pathways, and magnitude of the potential risk.

14.2.6 Challenges to Risk Communication around Health Risks

When performing risk communication, it is essential to acknowledge that individuals may receive their information from a variety of sources, which may provide conflicting or inconsistent messaging. As presented in **Section 7.1**, there is a growing body of research pertaining the adverse health impacts of PFAS in humans and laboratory animals. The discussion potential human health risks from PFAS exposure has been taken up in multiple venues, including peer-reviewed scientific studies, news media, and public comments on draft government documents and proposed regulations. The severity and uncertainty of adverse health impacts that may be associated with PFAS and the need for subsequent action has been communicated in an inconsistent manner. Because of the seriousness of potential health effects such as cancer, developmental delays and altered immune system response, as well as the persistence of PFAS in the human body, there is a case for prudence and precautionary mitigation practices to reduce exposures even in the absence of unequivocal human health consequences.

The risk communication challenge around health risks lends itself to a scenario in which stakeholders, including potential responsible parties and federal and state regulatory agencies, are not in consensus on the risk assessment and management strategy. Consistent messaging about uncertainties is essential for risk communication to be successful and to best help those in need. If stakeholders are in debate about the level of risk, then communicate by informing the public that all parties are striving to get the risk evaluation "right" but that there may be a delay in taking action. Communities that may be impacted may request an interim measure, such as an alternate water source, to alleviate concerns with potential exposure. Interim measures coupled with public outreach and community involvement can be a cost-effective risk management strategy in the short term. Public outreach should include measures being taken as well as associated milestones for future actions toward making a more informed risk management decision that utilizes limited resources efficiently, while integrating stakeholder values and community needs.

14.3 Risk Communication Planning and Engagement Tools

Prior to preparing risk communication materials and performing outreach, a project team should develop a risk communication plan to ensure there is a robust risk communication process in place from the outset. A risk communication plan is critical to guide decision makers to determine modes of information transfer as well as stakeholder engagement methods and tools that are appropriate and applicable for identified target stakeholders and site-specific characteristics. As stakeholder concerns and site characteristics are further defined, the communication team will need to continuously revisit the steps of communication planning. The **ERIS PFAS Risk Communications Hub** is a resource for risk communication information such as state FAQs, case studies and other resources.

In the case of PFAS, many national environmental organizations have made community outreach a major focus. Local grassroots organizations and one, the National PFAS Contamination Coalition (**https://pfasproject.net**), have led a major effort to inform the public and influence policy. In addition, ATSDR studies (for example, **ATSDR 2022**) as well as the National Academy of Science (**NAS 2022**) have included community outreach efforts.

14.3.1 Risk Communication Planning Model

The **ITRC Risk Communication Toolkit for Environmental Issues and Concerns** presents a risk communication planning model that has eight components, as shown in Figure 14-1. At the center of this model is a step to review and evaluate. This step indicates that communication planning with stakeholders is two-way, ongoing, and continuous, allowing for review of where you are in your outreach efforts and where you may need to go.

This planning model, adapted from the work of **NJDEP (2014)**, facilitates development of project-specific communication plans to be developed at each stakeholder engagement and/or outreach phase of a project. Of note, the NJDEP 2014 document relied on the work of Caron Chess, Billie Jo Hance, and Peter Sandman, Environmental Communication Research Program, Cook College, Rutgers University, as published by the New Jersey Department of Environmental Protection. The model is interactive, which allows for new information to be incorporated into the plan so that the outreach can be modified accordingly. This approach encourages establishing ongoing dialogue between the lead organization and all stakeholders so that the resulting outreach plan reflects the priorities and concerns from all parties. This will help you develop a robust risk communication plan. **Section 4** of the Risk Communication Toolkit provides detailed discussion of each of the communication planning model steps. The key aspects of the risk communication planning model are briefly summarized here.

- Issue identification helps you to clearly understand what the situation is in order to develop a responsive and effective risk communication plan.

- Goals are the big picture or ultimate impact that is desired for a project, issue or situation.
- Identification of communities with whom you need to establish a dialogue and those who wish to talk with your organization is important.
- Community assessment is needed to gain a deeper insight into stakeholder concerns and values that facilitate the development of a dialogue. **Section 13** addresses stakeholder perspectives for PFAS.
- Messages are the information you want/need to share with audiences about the issue or case, a question that you need them to answer, or both.
- A communication method is the means by which you communicate with your audiences.
- Once you have a clear goal, understand stakeholder concerns, know your message and have selected your method, it is time to lay out the strategy in order to implement the plan.
- Evaluation is the systematic collection of information about activities, characteristics, and outcomes of projects to make judgments about the project, improve effectiveness, or inform decisions about future programming. Many risk communication efforts require an ongoing presence or outreach to stakeholders. A debrief meeting is an opportunity for you to review the results of the evaluation and will identify what follow-up, if any is needed.

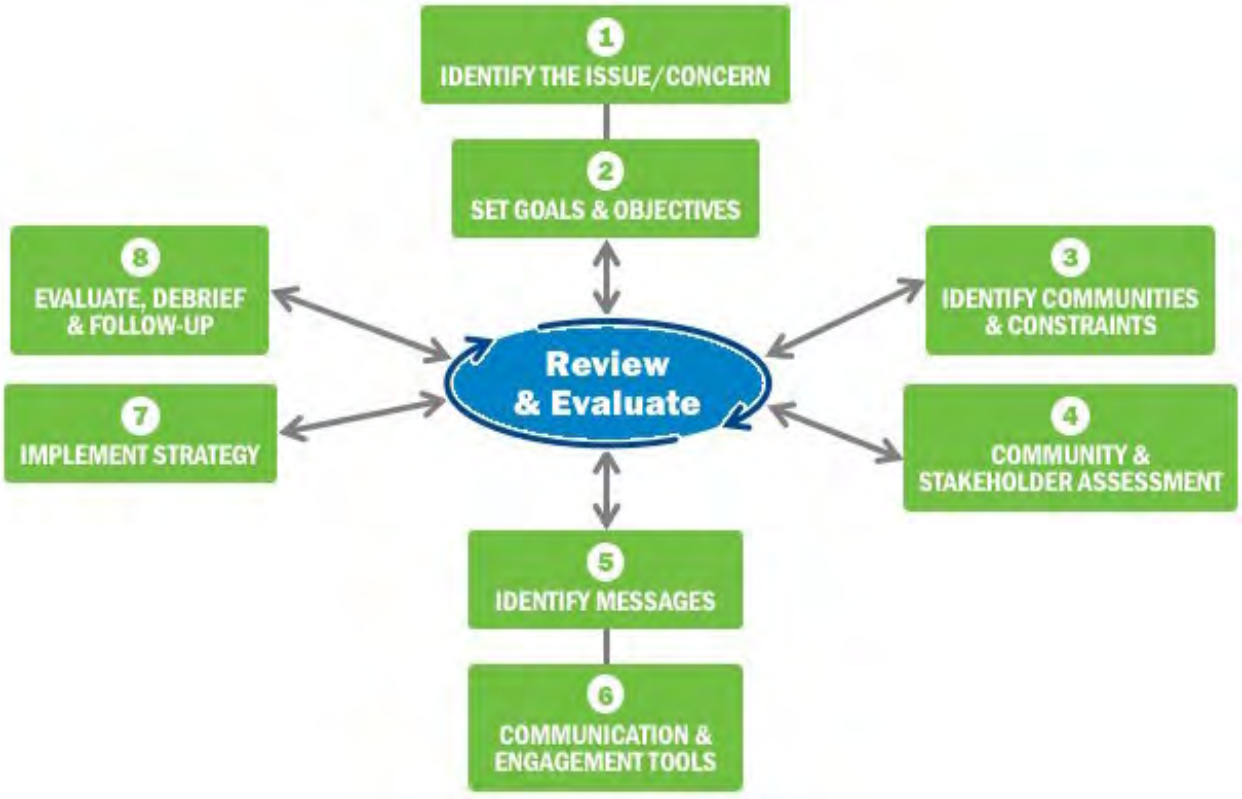

Figure 14-1. Communication plan process diagram.

Source: Modified from NJDEP 2014.

General information about risk communication planning is included in the **ITRC Risk Communication Toolkit for Environmental Issues and Concerns** document. This toolkit is a good resource for information about risk communication basics and tools. The toolkit can aid decision makers using this process and provide tools to assist with meeting performance metrics at each planning step. In addition, Minnesota Department of Health has developed the *Drinking Water Risk Communication Toolkit*, which can be accessed at **https://www.health.state.mn.us/communities/environment/water/toolkit/index.html**.

The following subsections are risk communication resources and tools with PFAS examples. The PFAS case studies in **Section 15.4** offer examples of community and stakeholder assessment strategies.

14.3.2 PFAS Risk Communication SMART Goals and Objectives

This section includes some examples of SMART (specific, measurable, attainable, relevant, and timely) goals for PFAS. In addition, example messages are included.

Example SMART Goals

Example of Communication of Goals

Issue: The governor established an independent PFAS science advisory panel of national experts to provide guidance to the state on protectiveness of criteria and develop science-based recommendations that will guide the administration and legislature on the best regulatory policy moving forward.

Goal: The PFAS Science Advisory Panel will complete a report within 6 months that will provide a general understanding of human health risks associated with PFAS in the environment. These science-based data will be used to develop a regulatory response that the administration and legislature will take and implement by (date).

Example of Assessing Stakeholder Concerns

Issue: Due to public health concerns, the state agency will conduct a statewide study of PFAS levels in X public water supplies at X schools that operate their own (private) wells by (date.)

Goal: By (date), the environmental agency will develop an inventory and location map of sites where PFAS has been used or disposed; prioritize sites for further investigation based upon the potential to impact drinking water supplies (based upon state groundwater maps, site history, and site ownership); incorporate data into a GIS-based data management system; and develop and implement a plan to sample private and or public water wells to assess potential impacts to drinking water supplies from prioritized sites.

For this example:

- specific: develop an inventory and location map
- measurable: testing
- attainable: implement a plan to sample private and public water supplies
- relevant: testing at prioritized sites will define impact
- timely: by X date

Example of a short-term SMART goal (from the Little Hocking Water Association case study, **Section 15.4.1**).

- By (date), the community is informed via the municipal website, flyers, and canvassing that bottled water is available as an alternate water source and utilized by 85% of the population.

- After (months), the extent of the impacted water supply is known via well testing and communicated to the community via a public meeting, municipal website, and newsletter.

Example of a long-term SMART goal (from the Little Hocking Water Association case study).

- By (date) and after (months), using a community-first strategy that includes the establishment of a community advisory committee and using multiple methods of communication—media, social media, internet, and meetings—determine whether the study area residents' blood PFOA levels are elevated and provide actions that 12,000 residents can take to produce a measurable reduction of PFOA blood levels.

14.3.3 Community Identification and Mapping Tools

Due to the persistent and recalcitrant nature of PFAS and its presence in the public drinking water supply, numerous and variant federal, state, private, and public stakeholders can be impacted. Actor mapping is a tool to help guide a communication team to lay out, track, and update stakeholder roles and relationships. During this exercise, practitioners learn who is the most affected by site information and decisions, as well as their level of interest and influence.

The outcome of the tool will assist in identification of unengaged/disinterested stakeholder populations, identify needs for relationship and/or capacity building, develop a site-specific communication team, and target outreach resources toward affected and unengaged/disinterested stakeholder populations. In the context of PFAS, this is of particular importance to identify and address affected groups who may not be participating in preventive and mitigation measures (such as an interim drinking water supply and a fishing ban) and/or at sites in which stakeholder groups are facing conflict resolution.

Simplified **examples** of an actor-linkage matrix and interest-influence matrix are presented, followed by resources to perform complex actor mapping, such as social network analysis. The examples provided are not representative of an existing project; stakeholder roles and relationships vary on a project-specific basis. Different types of mapping approaches can be used based on what visual communication method(s) work best for your organization and stakeholders. The examples provided here (actor-linkage matrix and interest influence matrix) are for demonstration purposes only and are not prescriptive.

Example Context: A PFAS site consisting of a groundwater plume that has impacted drinking water supply wells and has identified contaminants in the local fish population.

Example 1: Actor-Linkage Matrix: A tool that assist practitioners in describing relationships among stakeholders through codes (**Reed et al. 2009**) (**Figure 14-2**).

Example 1: Actor-Linkage Matrix Evaluation

- *Identify unengaged stakeholder populations*: potentially anglers and tourism business operators

- *Facilitate relationship/capacity building*: utilize the relationship between the responsible party and water purveyor to restore relationship between the responsible party and water users

- *Identify and develop the communication team*: team consists of a representative for the lead organization and for each regulatory agency, responsible party, water purveyor, and each low-power stakeholder group

- *Target communication strategy resources*: increase information transfer to unengaged stakeholder populations and rebuild intermittent and conflicted relationships with water users in alignment with risk communication strategy SMART goals

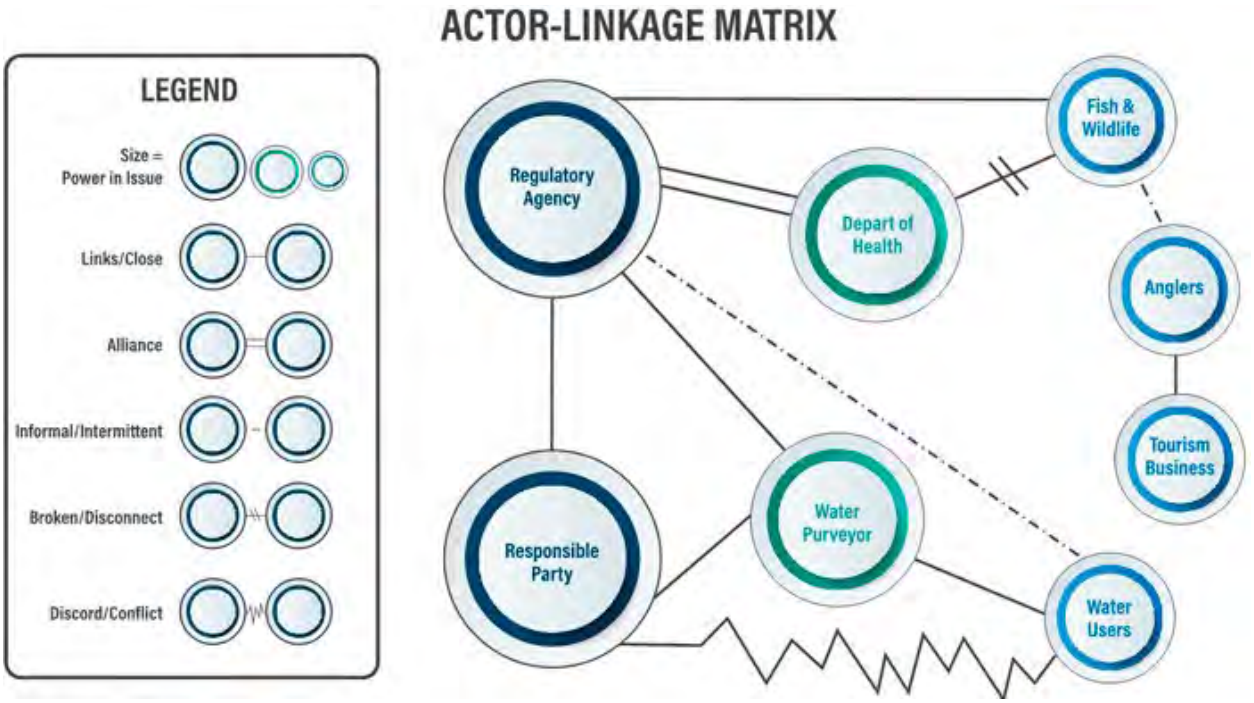

Figure 14-2. Example actor-linkage matrix.

The same example is used for the interest-influence matrix.

Example Context: A PFAS site consisting of a groundwater plume that has impacted drinking water supply wells and has identified contaminants in the local fish population.

Example 2: Interest-Influence Matrix: A tool that assist practitioners in identifying the stakes that social actors (stakeholders) have in a cleanup project. Identified stakeholders are placed in a matrix according to their relative interest and influence (**Reed et al. 2009**) (**Figure 14-3**).

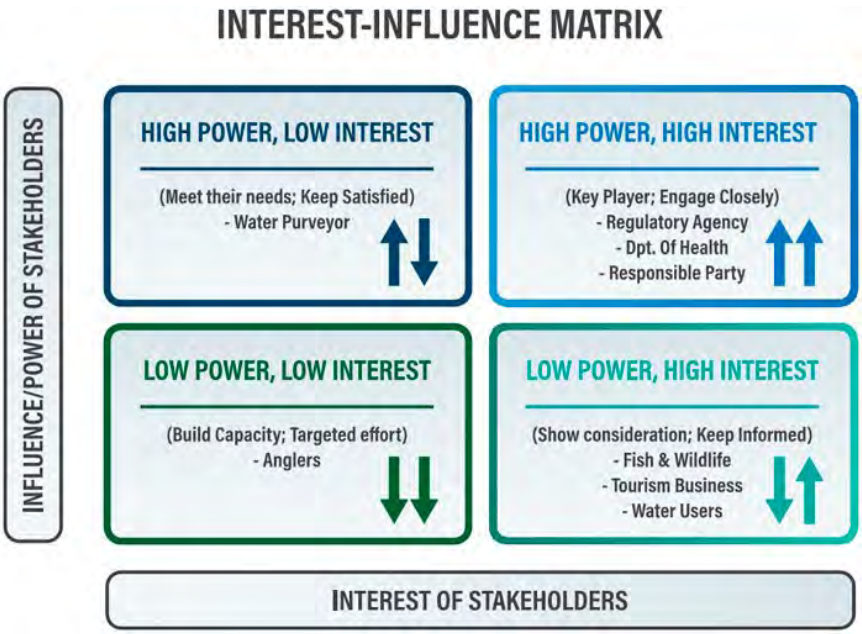

Figure 14-3. Example interest-influence matrix.

Example 2: Interest-Influence Matrix Evaluation

- *Identify unengaged stakeholder populations:* lead organization (for example, state agency or responsible party) (high-power) stakeholders have the role to engage lower power stakeholders who may not be currently engaged or are disengaged

- *Facilitate relationship/capacity building:* utilize high-interest stakeholders to build relationships with lower interest stakeholders, particularly ones with low power (such as the anglers)

- *Identify and develop the communication team:* team comprised of the lead organization and each regulatory agency, responsible party, water purveyor, and a representative of each low power stakeholder group

- *Target communication strategy resources:* increase information transfer to unengaged stakeholder populations and rebuild relationships with low-interest stakeholders in alignment with risk communication strategy SMART goals.

14.3.4 Social Factors Vision Board Tool

Stakeholder risk perception and associated social factors shape individuals' attitudes toward management of hazards that affect personal safety and public health, and play an important role in supporting legitimacy and compliance with policies and protection measures. Due to the evolving state of the science of PFAS, including appropriate risk management strategies and relevant public policy, the present public attitude toward legitimacy and acceptance of proposed policies and strategies is hindered.

The success of public outreach in terms of exerting a positive influence on community stakeholders and in preventing and mitigating their exposure to a risk is based on site-specific physical, psychological, sociological, and demographic characteristics or "social factors." Identification of these social factors among individual stakeholder groups can assist practitioners in refining engagement methods and outreach materials to maximize benefits to the community and meet specific needs of the targeted public sector.

A vision board can be used as a medium for stakeholders to rate their level of importance and/or interest on applicable social factors. Identified factors can then be used to further develop SMART goals and key messages, develop public outreach materials, and select engagement methods. The overall objective is to gain deeper insight into stakeholder concerns, values, and preferred communication method to facilitate a two-way street knowledge transfer and capacity building towards a successful risk management strategy. A social factors vision board tool can be used as starting materials for an engagement survey and interview. The target audience for this tool is an established community advisory group or a periodic outreach meeting, focus group, or decision maker stakeholders' group.

The vision boards (see **ITRC RC Social Factors Vision Board attachment**) developed for this toolkit are focused on a specific topic of concern and associated social factors identified from presentations by public and community stakeholders during the USEPA **PFAS community meetings** held in 2018.

Note that the vision boards for a specific project are living documents. The statements/questions and social factors should be updated to represent project-specific conditions and stakeholder concerns. Social factors presented on the toolkit vision boards are representative of affected communities' perceptions as opposed to expert opinion based on scientific studies. This toolkit was prepared as an example to provide a starting point for practitioners to understand the present needs and concerns of a PFAS-affected community. In addition, the rating system presented in each board is interchangeable to any social factor topic. More information on using the social vision board are provided in the **ITRC Risk Communication Toolkit for Environmental Issues and Concerns** document.

14.3.5 PFAS Key Messages

A message is information you want/need to share with communities about the issue or concern, a question that you need them to answer, or both. It is linked to the case specific goal and addresses key points about the issue that were learned through the community assessment. You start with the community and their concerns. Effective messages reflect what your target group needs are as well as what you need to communicate. In the case of emerging contaminants, elements of a message are likely to include: what is known and unknown about a contaminant, acknowledgement of uncertainty; commitment to share new information when it is learned; explanation of how decisions will be made with respect to protecting public health and remediating the problem, etc.

Message mapping is a process for developing your information so that it is concise and includes the information that is critical to convey. The objective is that the message is simple, yet comprehensive enough, and includes the most pertinent information relevant to your issue. A mapped message starts with a question, responds with three key ideas, is no more than twenty-seven words, and takes no longer than nine seconds to deliver. An example of key messages developed for a PFAS site is provided in **Table 14-1**. Additional resources on key messaging and mapping is provided in the **ITRC Risk Communication Toolkit for Environmental Issues and Concerns** document.

Table 14-1. Message Mapping Worksheet.

Stakeholder: Community member	**Question/Concern/Issue:** What are PFAS and why is the state concerned about them?	
Key Message/Fact 1: PFAS are a family of human-made chemicals in many products used by consumers and industry.	**Key Message/Fact 2:** PFAS are emerging contaminants of concern.	**Key Message/Fact 3:** Some PFAS may adversely impact human health.
Keywords: Supporting Facts 1.1 PFAS are a large group of thousands of manufactured compounds, produced and used for over 60 years. Some PFAS are still in use, some are not.	**Keywords:** Supporting Facts 2.1 PFAS are a contaminant of active scientific research. Scientific knowledge is changing rapidly.	**Keywords:** Supporting Facts 3.1 PFAS can build up in the body (bioaccumulate) and take a long time to leave the body.
Keywords: Supporting Facts 1.2 PFAS have been used in coatings for textiles, paper products, and cookware and to formulate some firefighting foams, and have a range of applications in the aerospace, photographic imaging, semiconductor, automotive, construction, electronics, and aviation industries.	**Keywords:** Supporting Facts 2.2 Laboratory methods may or may not exist to detect all the PFAS contaminants that we know about; methods are developing and evolving with the emerging science.	**Keywords:** Supporting Facts 3.2 Some PFAS, such as PFOA, have been found to impact fetal development and are passed to babies through nursing and bottles.
Keywords: Supporting Facts 1.3 PFAS are found throughout the environment, in people, and in animals and fish.	**Keywords:** Supporting Facts 2.3 Federal and state regulations are changing as the scientific knowledge evolves; this leads to guidance and recommendations that may vary across the country.	**Keywords:** Supporting Facts 3.3 Studies in exposed humans suggest that some PFAS may cause high cholesterol, higher liver enzymes in blood, decreased response to vaccines, decreased birth weight, and testicular and kidney cancer.

*Source: (**Covello, Minamyer, and Clayton 2007**).*

A template of the message mapping worksheet is included in **Covello, Minamyer and Clayton (2007)**.

14.3.6 Communication and Engagement Tools

14.3.6.1 Public Outreach

Public health and regulatory agencies have developed several public outreach materials to inform stakeholders about PFAS, from the compounds' origins and environmental distribution to exposure pathways, associated health effects, and management strategies. Outreach tools include community education classes to inform and support high school teachers, medical professionals, journalists, and municipal water managers. The following provides a summary of available resources for accessing and developing public education materials for PFAS-impacted communities. Although printed public education materials are effective at communicating information, techniques that include face-to-face communication, such as open house meetings, focus groups, and door-to-door canvassing, are often more effective at addressing fears and building trust. Additionally, face-to-face communication provides an opportunity for practitioners to learn from the public and other impacted stakeholders.

The **ITRC Risk Communication Toolkit for Environmental Issues and Concerns** document includes Guidance for Writing Analytical Results Letter, Guidance for Writing Press Releases.

14.3.6.2 Fact Sheets and Frequently Asked Questions (FAQs)

To achieve effective risk communication, it is essential for public education materials to be presented in a clear and simple manner that is understandable by nonscientists and speaks to a broad audience. Common rules of thumb include writing at a sixth-grade comprehension level, using simple terminology, and providing materials in multiple languages for nonnative speakers. Over the past few years, environmental and public health agencies, nonprofit advisory groups, trade associations, and regulatory agencies have prepared numerous fact sheets and FAQ documents on PFAS-related topics to inform stakeholders, including concerned residents, agricultural and recreational entities, water purveyors, end users, public health professionals, and others. These public education materials developed specifically for PFAS-impacted communities are typically available on the organization's website.

Fact sheets, FAQs, and other public outreach material should be distributed in multiple modes to maximize audience reach and increase opportunity for engagement. Recommended modes of distribution include mailings, websites, local municipal health departments, public health professional offices, public libraries, and information booths at community events.

The **ITRC Risk Communication Toolkit for Environmental Issues and Concerns** document includes additional information about FAQs.

- **Compilation of PFAS Fact Sheets, Frequently Asked Questions (FAQs)** and other resources developed by the Association of State and Territorial Health Officials (ASTHO) and the Environmental Council of the States (ECOS) are available:
    - https://www.astho.org/PFAS/
    - https://www.eristates.org/projects/pfas-risk-communications-hub/

14.3.6.3 Active Centralized Information Repository

Unlike a "passive" repository of site documentation at a central location, an "active" repository refers to a platform that remains up to date on site findings and enables two-way exchange of information among decision makers and the impacted community. A common platform for an active repository is a centralized website that contains a complete compilation of site documentation (among all agencies);

frequent updates on site activities, health information and regulatory policy; and a depiction of the CSM (such as a source-exposure pathway graphic and geologic maps). The website should also contain a platform to facilitate stakeholder involvement by providing an opportunity for them to ask questions, submit information, and join a listserv (an application that distributes messages to subscribers on an electronic mailing list).

Examples of centralized websites can be found at the following web links:

- Michigan Department of Environmental Quality, *Michigan PFAS Action Response Team (MPART):* **https://www.michigan.gov/pfasresponse/**

Michigan agencies representing health, environment, and other branches of state government have joined together to investigate sources and locations of PFAS contamination, to take action to protect people's drinking water, and to keep the public informed as we learn more about this emerging contaminant.

- New Hampshire Department of Environmental Services (NHDES), *NH PFAS Investigation*: **https://www4.des.state.nh.us/nh-pfas-investigation/**

NHDES maintains a website to update interested parties on NHDES's investigation into the presence of PFAS in New Hampshire. The website includes a map that shows PFOA and PFOS data from water samples collected around the state.

- Vermont Department of Environmental Conservation (VDEC), *Vermont PFOA Contamination Response*: **https://dec.vermont.gov/pfas/pfoa**

Numerous Vermont agencies, including VDEC, Department of Health (VDH), Emergency Management, Agency of Agriculture, and Agency of Education have joined together to investigate and address PFAS contamination in Vermont. VDEC and VDH have created and maintained web pages to push information out to the public as it becomes available to keep the public informed of the PFAS issue.

Not all stakeholders have access to the internet, and depending upon the seriousness of the site's situation, it may be appropriate to hold regular meetings and/or office hours to provide more than one mode for stakeholders to obtain information and engage with decision makers.

14.3.6.4 Community Education

Individual stakeholder groups and individuals themselves process information in a variety of modes and media. An effective risk communication strategy takes this factor into consideration and encompasses multiple forms of outreach. In addition to informative materials, such as fact sheets, stakeholder meetings and interactive sessions (such as poster presentations, question and answer sessions) can be held to involve individuals in the learning and understanding process. Prior to selection of a method, an audience assessment should be conducted to determine how a community communicates and to learn what tool is the most effective to use.

Community Education Example—Bennington College Community Education Strategy, Vermont

In 2016, PFAS were discovered in the public water system of Hoosick Falls, New York, and in hundreds of private residential wells in Petersburgh, NY, and North Bennington, Vermont. In response to this nearby problem, Bennington College asked how the scientific resources of a college or university might become a civic resource in times of environmental uncertainty. After some discussion about how to maintain the scientific and educational integrity of the college while also being a good neighbor to impacted communities, Bennington College decided to open the doors of its science classrooms to the problem of PFAS contamination. This was done primarily in two ways: (1) a new introductory class on PFOA was

offered to local communities free of charge, and (2) students in more advanced science classes in chemistry and geology worked to produce independent data on PFAS contamination in the region. More information about both of these strategies is below.

Many residents impacted by PFAS voiced a desire to learn about the science of the problem even as there was a recognition that much of that science was currently quite difficult for residents to grasp. Indeed, many of the risks and ramifications of PFAS contamination are currently published in daunting regulatory reports and peer-reviewed research articles (often behind paywalls). Addressing these concerns, Bennington College designed a new class to review the chemical properties, environmental pathways, and policy concerns of PFOA, entitled "Understanding PFOA." This class also taught residents how to collect water samples for PFAS analysis at a commercial lab and how to interpret laboratory results from PFAS analysis. Bennington College has offered this class every spring to local residents since 2016, free of charge. A number of local teachers, journalists, nurses, elected officials, parents, and students enrolled, and the class has become a vehicle for the community to get up to speed on the science of PFAS so they can engage the issue more productively.

Bennington College also put together faculty-led research teams to produce independent data on PFAS contamination in conversation with community questions. Bennington College realized that impacted communities often had interesting questions about PFAS that fell outside of the urgent protocols of state agencies, which rightfully focused on safeguarding public health. These community questions, however, provided useful pathways to educate residents about the problem and to encourage local participation in research into PFAS contamination. Working with residents of Hoosick Falls, Petersburgh, and North Bennington, the college helped investigate a number of community concerns, such as:

- "Is there any PFOA in my maple syrup?"
    - Bennington College tapped two maple trees in the spring and analyzed the sap, finding 8.8 parts per trillion (ppt) of PFOA in the sap of a maple tree about 1,000 feet from a plastics plant and 2.3 ppt of PFOA in the sap of a maple tree about a mile from the plant.
- "My well had high levels of PFOA but now I have a filtration system in my basement. If my well was contaminated for years, I wonder if there might be any residual PFOA in my water pipes. Could any built-up PFOA still be contaminating the water coming out of my kitchen faucet?"
    - Bennington College analyzed water from the kitchen faucet from three homes with high levels of PFOA in their well and a point of entry treatment filtration system (Hoosick Falls house, 2,100 ppt of PFOA in well; Petersburgh house, 1,800 ppt of PFOA in well; North Bennington house, 3,000 ppt of PFOA in well). In all three homes, PFAS were nondetectable in water from the kitchen sink.
- "When the state tested my well, they found PFOA levels just below the health guidance level and thus we did not get a filtration system. How stable are detected levels of PFOA in the groundwater?"
    - Bennington College reviewed data from over 200 residential wells that had been sampled and analyzed for PFOA at least twice in one year. They found an average variation of 24% in individual wells. PFOA levels increased in about half of the wells and decreased in about half the wells. This increase and decrease did not have an obvious spatial pattern (for example, a plume moving in one direction) but appeared to be fairly randomly scattered across the sampling area.

More information about Bennington College's ongoing engagement with PFAS can be found at **www.bennington.edu/pfoa**.

15 CASE STUDIES

The following case studies have been compiled from 2020 to 2025. Each case study has a date in the title indicating when it was added to this section. The case studies are provided for illustrative purposes and general reference. They demonstrate examples of methods and results from selected sites that may be applicable at other locations, depending on site specific conditions. The information is provided for general reference. Please see the ITRC disclaimer.

Section Number	Topic
15.1	**Site Characterization Case Studies**
15.2	**Treatment Case Studies**
15.3	**Risk Assessment Case Study**
15.4	**Risk Communication Case Studies**
15.5	**Surface Water Quality Case Studies**

The PFAS team has identified and included case studies supporting the following sections:

- **Section 10** Site Characterization
- **Section 12** Treatment Technologies
- **Section 9** Risk Assessment
- **Section 14** Risk Communication
- **Section 16** Surface Water Quality

15.1 Site Characterization Case Studies

15.1.1 Data Visualization at an AFFF Release Site (2020)

McGuire et al. (2014) and **McGuire (2013)** presented a detailed characterization of a subset of PFAS soil and groundwater concentrations, focused on PFAAs in the vicinity of a former unlined burn pit where fire training activities were conducted up to 1990. Data presented in **McGuire et al. (2014)** were used for this visualization example. For brevity, this example shows relative concentration trends between shallow and deep soil samples collected at six borings where total PFAA concentrations exceeded 5,000 ug/Kg in shallow soil. The inset map in the top left of **Figure 15-1** shows the former burn pit location, as well as the locations of these six borings (S-2, S-4, S-5, S-6, S-7, and S-10). Shallow soil samples were collected at a depth of approximately 2 ft below ground surface (ft bgs) (0.61 m), and the deep soil samples were collected at the water table, which is approximately 15–20 ft bgs (4.6–6.1 m) on average.

The bar chart in Figure 15-1a compares concentrations of shallow and deep soil concentrations for total PFAAs at these six boreholes and clearly demonstrates that shallow PFAA soil concentrations are much higher than deeper soil concentrations at the water table. This figure indicates that there is likely attenuation that limits vertical migration of PFAAs. **McGuire (2013)** attributed this to the high clay content of vadose zone soils, and high VOCs and TOC in this area, which may enhance retardation.

A different type of bar chart is shown in Figure 15-1b to illustrate the composition of the main PFAA constituents in shallow soil samples (PFHxS, PFOS, PFHxA, PFOA). Review of Figure 15-1b reveals the following trends:

- In three of the six boring locations, PFOS is greater than 95% of total PFAA concentrations in shallow soil.
- In the other three borings, PFOS is less than 50% of total PFAAs. These borings have higher relative concentrations of PFHxS, PFHxA, and PFOA.
- PFHxS, PFOS, PFHxA, and PFOA combined represent at least 80% of total PFAA concentrations in shallow soil.

The difference in PFOS composition shown in Figure 15-1b suggests that some borings were drilled in an area that was influenced by a mixture of different AFFF products, whereas other borings with a high proportion of PFOS may be influenced primarily by AFFF produced using electrochemical fluorination.

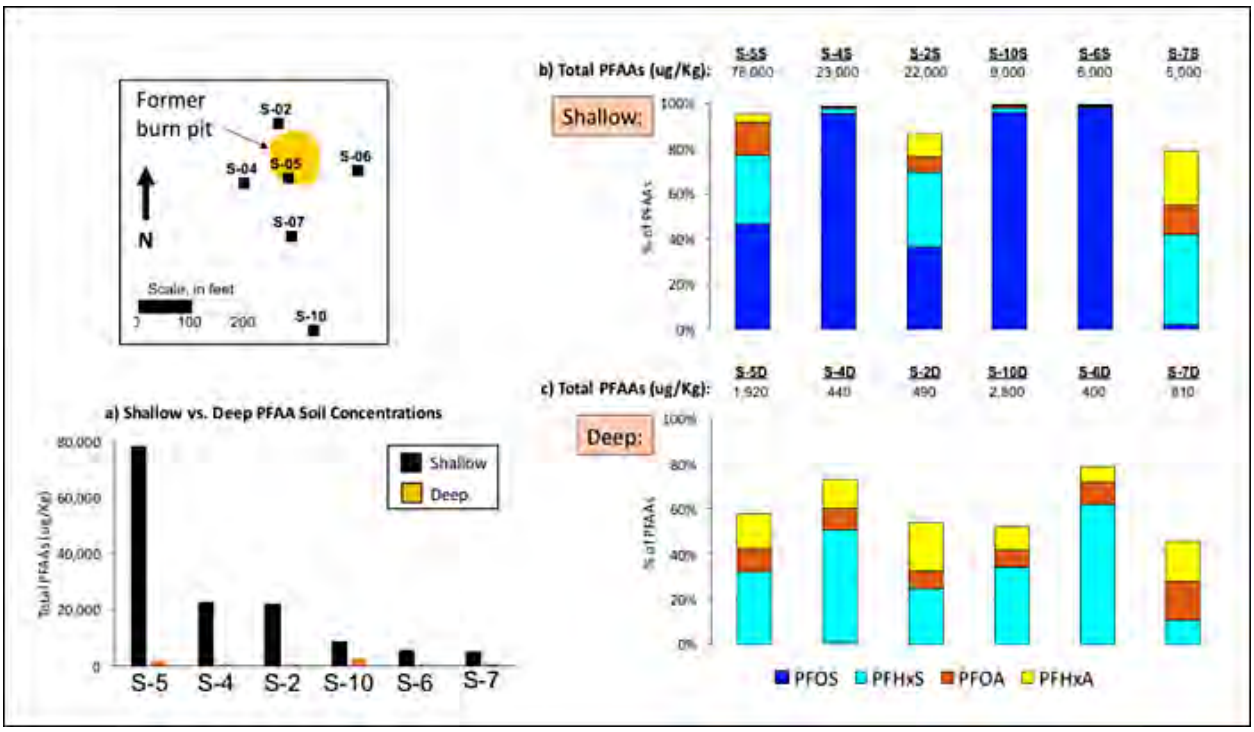

Figure 15-1. Comparison of shallow and deep soil samples at an AFFF release site.

Source: G. Carey, Porewater Solutions. Used with permission.

Figure 15-1c shows the same type of bar chart with relative percent of total PFAA concentrations for the deeper soil samples collected at the water table. Comparison of Figures 15-1b and 15-1c indicates that there is a clear difference in PFAA composition between the shallow and deep soil samples. PFOS is very low in terms of relative concentrations in deep soil samples, compared to the shallow soil samples where PFOS makes up a higher proportion of the total PFAA concentration. This may be due to enhanced retardation of PFOS in the vadose zone relative to the other compounds (PFHxS, PFHxA, and PFOA), which is consistent with the relative site-specific K_{oc} values determined by **McGuire et al. (2014)**. In addition, Figure 15-1c shows that these four compounds typically represent only around 50% of total

PFAA concentrations in the deep samples, which suggests that shorter chain compounds are more prevalent at the water table and in underlying groundwater, most likely due to precursor transformations.

Radial diagrams may also be used as visual aids to illustrate spatial and/or temporal trends for individual PFAS constituents or total concentrations for various PFAS groups. As an example, **Figure 15-2** presents a radial diagram map showing trends for various PFSAs (PFOS, PFHxS, PFBS) as well as perfluorohexane sulfonamide FHxSA, which is a precursor to PFHxS. The radial diagram legend in the top right portion of Figure 15-2 shows that the four axes are arranged in order of FHxSA, PFOS, PFHxS, and PFBS. There are two data series shown on the radial diagram legend: (1) the blue-filled data series, which represents PFAS constituent concentrations at monitoring well location; and (2) a darker blue outline that represents maximum source concentrations at well GW13, which is situated directly adjacent to the former burn pit area. This latter data series is a reference and is the same at all monitoring well radial diagrams. Including this reference data series makes it easier to visualize changes in concentrations throughout the plume. The radial diagram legend also shows how symbols may be plotted to represent where constituents were not detected in a groundwater sample. Another option for radial diagram symbols is to indicate where concentrations are above groundwater cleanup criteria at each well location (not shown). The compound axes are logarithmic in this example, to allow for visualization of order of magnitude concentrations between wells, or between compounds at any one well location.

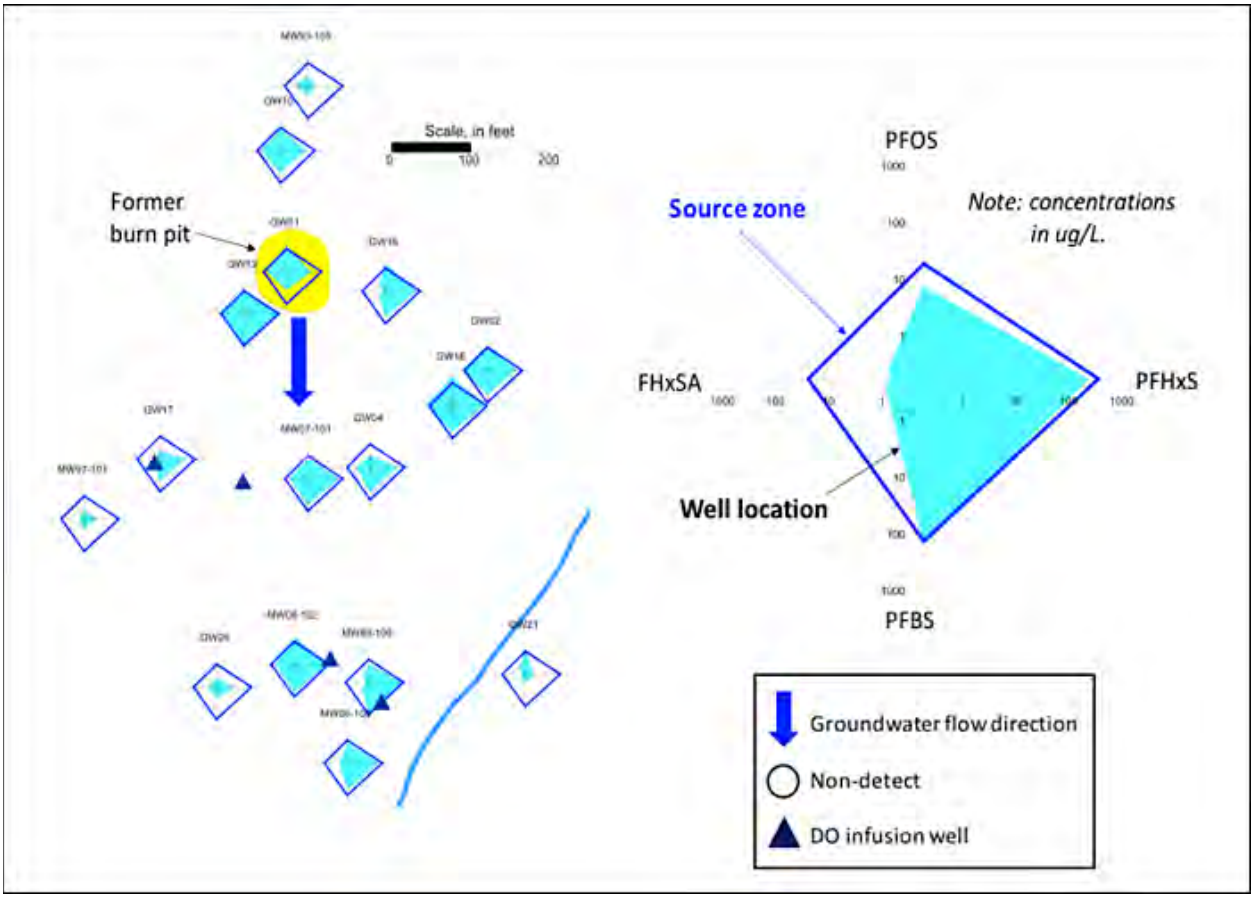

Figure 15-2. Radial diagrams illustrating PFSA trends at an AFFF release site.

Source: G. Carey, Porewater Solutions. Used with permission.

Groundwater flow in this area is generally to the south/southeast. The main radial diagram map shown in Figure 15-2 facilitates an analysis of how concentrations for these four constituents vary along the

groundwater flow path downgradient from the former burn pit area, and how concentrations vary across the width of the plume. For example, the radial diagram shown at GW01, which is located inside the footprint of the former burn pit, indicates that concentrations of the longer chain compounds (FHxSA and PFOS) are similar to those in the nearby well at GW13, whereas PFHxS and PFBS are about an order of magnitude lower at GW01 then GW13. The radial diagrams also clearly show that groundwater downgradient of the DO infusion wells (triangle symbols) has low to non-detect FHxSA, indicating that aerobic transformation of this precursor has occurred downgradient of these infusion wells (**Section 10.4.4**).

Although not shown with this case study, radial diagrams are also helpful for visualizing redox indicator trends, to confirm whether redox conditions are favorable for the transformation of precursors to PFAAs. Examples of a modified radial diagram method used for redox zone delineation are presented in **Carey et al. (1999)** and **Carey et al. (2003)**.

15.1.2 Application of Radial Diagrams (2020)

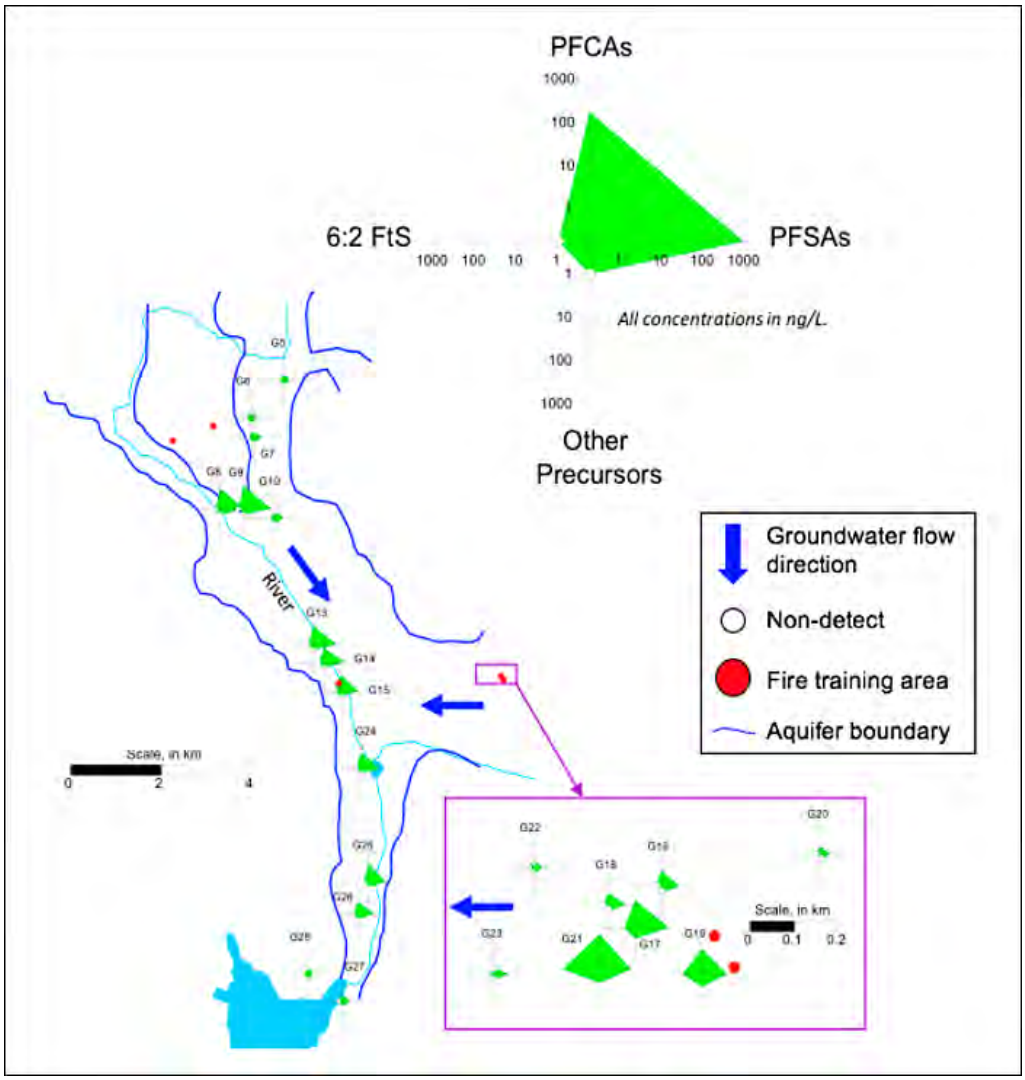

Figure 15-3. PFAS composition in groundwater.

Source: G. Carey, Porewater Solutions. Used with permission.

Figure 15-3 presents another type of application of radial diagrams for visualizing certain PFAS trends, in this case for an aquifer contaminated with PFAS from several fire training areas in the vicinity of Uppsala, Sweden. The blue outlines shown in Figure 15-3 represent the boundaries of eskers (deposits formed by streams flowing beneath a glacier), which essentially act to channel groundwater flow in the aquifer. The legend shown on Figure 15-3 indicates that the four axes of the radial diagram now represent concentrations of 6:2 FTS (which dominates the other FTSs), total PFCAs, total PFSAs, and total concentrations of other chemical-specific precursors. Symbols are shown to represent non-detects at each well location. Groundwater flow in the main aquifer channel is from northwest to southeast (parallel to the river channel) and is to the west in the inset box shown in the bottom center of **Figure 15-3**.

Examples of trends that are evident based on the radial diagram map (Figure 15-3) include:

- All chemical-specific precursors are nondetect in the main aquifer channel, indicating that precursors were effectively attenuated closer to the fire training areas.
- PFSA and PFCA concentrations appear to be declining along the main flow channel (for example, downgradient of G8 and G9.
- Concentrations of precursors in the vicinity of the fire training areas shown in the inset map are much higher than in the main groundwater flow channel. This indicates that precursors may be attenuating prior to reaching the main flow channel in this area, due to sorption, biotransformation, and/or possibly discharge to the nearby creek.
- The combination of elevated PFCAs and PFSAs, as well as high 6:2 FtS near at least two of the fire training areas, indicates that AFFFs produced using telomerization were used at one point at some of these fire training areas.

15.1.3 Application of Environmental Sequence Stratigraphy (ESS) (2023)

Due to the high mobility and persistence of PFAS, groundwater plumes may extend to greater distances than those observed for conventional contaminants such as hydrocarbons and chlorinated solvents. Consequently, PFAS plumes may be more susceptible to unusual groundwater plume flow patterns. For example, site geology may cause groundwater plumes to diverge from directions predicted based on evaluation of a groundwater potentiometric surface (hydraulic gradient). Furthermore, longer groundwater plumes experienced by PFAS may result in groundwater/surface-water interaction to a greater extent. The case study presents an example where environmental sequence stratigraphy (ESS) is used to update a conceptual site model (CSM) for a PFAS-impacted site.

ESS (**USEPA 2017**) is a data analysis technique designed to improve CSMs through enhanced understanding of interaction between site geology, groundwater flow patterns, and preferential contaminant transport pathways. ESS provides a framework for interpretation of data generated via high-resolution site characterization (HRSC), existing subsurface data, such as geologic boring logs, and (potentially) geophysical data. The data evaluation focuses on site depositional/erosion history to identify geologic sequences and patterns (geologic heterogeneity and anisotropy in hydraulic conductivity) that explain contaminant migration pathways. ESS is useful to identify patterns in sedimentary deposits (consolidated or unconsolidated) comprising clays, silts, sands, and gravels. ESS techniques are designed for sedimentary deposits and are not applicable to metamorphic/crystalline rock or glacial till; however, adjusted ESS techniques can also be applied to glacial outwash deposits, which have similar characteristics to nonglacial sedimentary deposits.

This case study describes a site where ESS predicted a groundwater plume that did not follow the direction expected via simple hydraulic gradient analysis.

15.1.3.1 Sequence Stratigraphy

Sequence stratigraphy involves the study of geologic heterogeneity in sedimentary deposits in the context of their depositional environments and is applicable to sites underlain by sedimentary aquifers (for example, intermixed gravels, sands, silts, and clays). Subtle geologic heterogeneities can have significant effects on groundwater and contaminant transport. The ESS framework is designed to evaluate and incorporate these heterogeneities into a CSM to improve understanding of contaminant fate and transport. ESS techniques involve three-dimensional evaluation of geologic data, with an experienced geologist looking for detailed patterns and trends in the depositional framework (for example, lateral and/or vertical continuity of geologic strata).

ESS implementation generally involves a three-step process. The first step involves review and understanding of the regional geology and depositional environment. The second step involves a detailed review of existing lithology data, to assess both vertical and horizontal grain-size sedimentary patterns. Additional information may also be incorporated at this step, such as geophysical data and/or manmade site features (for example, drainage pathways). The third step involves development of a CSM integrating the detailed geologic data collected during the preceding steps to develop a hydrostratigraphic understanding of what controls migration of groundwater and contaminants. During this third step, three-dimensional data-modeling tools may be used to interpret the lateral continuity of subsurface strata, identify trends and/or lithologic sequences, and integrate geology and geochemical data sets.

This method can identify preferential groundwater and contaminant flow pathways associated with the geology and hydrogeology that may not be apparent in conventional/engineering-focused investigations, and may not necessarily follow the general groundwater gradient. Furthermore, ESS techniques can be useful to map and predict contaminant mass transport, identify data gaps, and identify target locations for focused investigation and/or remediation.

15.1.3.2 Site Background

An updated CSM (**Trihydro 2019**) was prepared for Ellsworth Air Force Base, where previous training and incident response involving aqueous film-forming foam (AFFF) resulted in groundwater impacted by PFAS as documented in a PFAS site inspection report of aqueous film forming foam areas (**Aerostar 2019**). Historical site investigations were typically focused on specific operable units (OUs) in a piecemeal fashion. As a result, geologic and hydrogeologic connections between some OUs were not apparent. Furthermore, previous investigations focused on contaminants of concern such as trichloroethene (TCE).

A detailed evaluation of regional and site geology was conducted in accordance with the ESS framework and is summarized herein. Briefly, regional geology consists of confined and unconfined aquifers. The shallow, unconfined aquifer comprises unconsolidated sediments (terrace alluvium) overlying the Pierre Shale formation, which covers a large segment of the plains surrounding the Black Hills and is reported to be up to 860 feet thick at the site. The Pierre Shale is a low-permeability formation that functions as a barrier to vertical groundwater flow, and as a confining unit to deeper aquifers. Deeper, confined aquifers exist at depth beneath the Pierre Shale. The Pierre Shale is considered the bedrock surface at the site and is encountered between 0 and 40 feet below ground surface.

The CSM focused on the shallow aquifer, defined as a terrace alluvium, which includes a combination of paleochannel deposits, modern channel deposits, and undifferentiated sediments (see geologic cross-section shown in **Figure 15-4**). The undifferentiated sediments are poorly graded deposits associated with floodplains, wind, or other weathering, which are generally more fine-grained and lower permeability than the channel deposits. The paleochannel deposits consist of sand and gravel, deposited by ancient surface-water streams, with characteristics including high permeability and fining-upwards sequences. The paleochannel deposits underlying Ellsworth AFB provide preferred pathways for groundwater and

contaminants with unpredictable orientations that are not discernable from the direction of modern drainages.

For the updated CSM, the site depositional history was evaluated, along with historical geologic and hydrogeologic data sets. The project involved "synthesizing decades of lithology data, from over 1,100 boreholes [within a site area of approximately 4,800 acres] with varying geologic interpretation" (**Trihydro 2021**). Site depositional history was evaluated and lithology logs were compiled and integrated with manmade infrastructure features to map out fine-scale geologic features and identify trends and pathways that affect contaminant migration. The large number of existing boreholes provided a rich data set for ESS evaluation, and a multimonth effort was required to review the existing logs and convert the logs into digital format.

As part of the ESS evaluation, the project team "looked at fine scale stratigraphic patterns in the contaminant transport pathways to predict where additional remedial solutions should be located" (**Trihydro 2021**). One of the questions posed midproject was to figure out how the shallow groundwater, outside of the base boundary, had become impacted by PFOA/PFAS. The area was approximately 0.5 miles from any known release or storage area.

15.1.3.3 Results

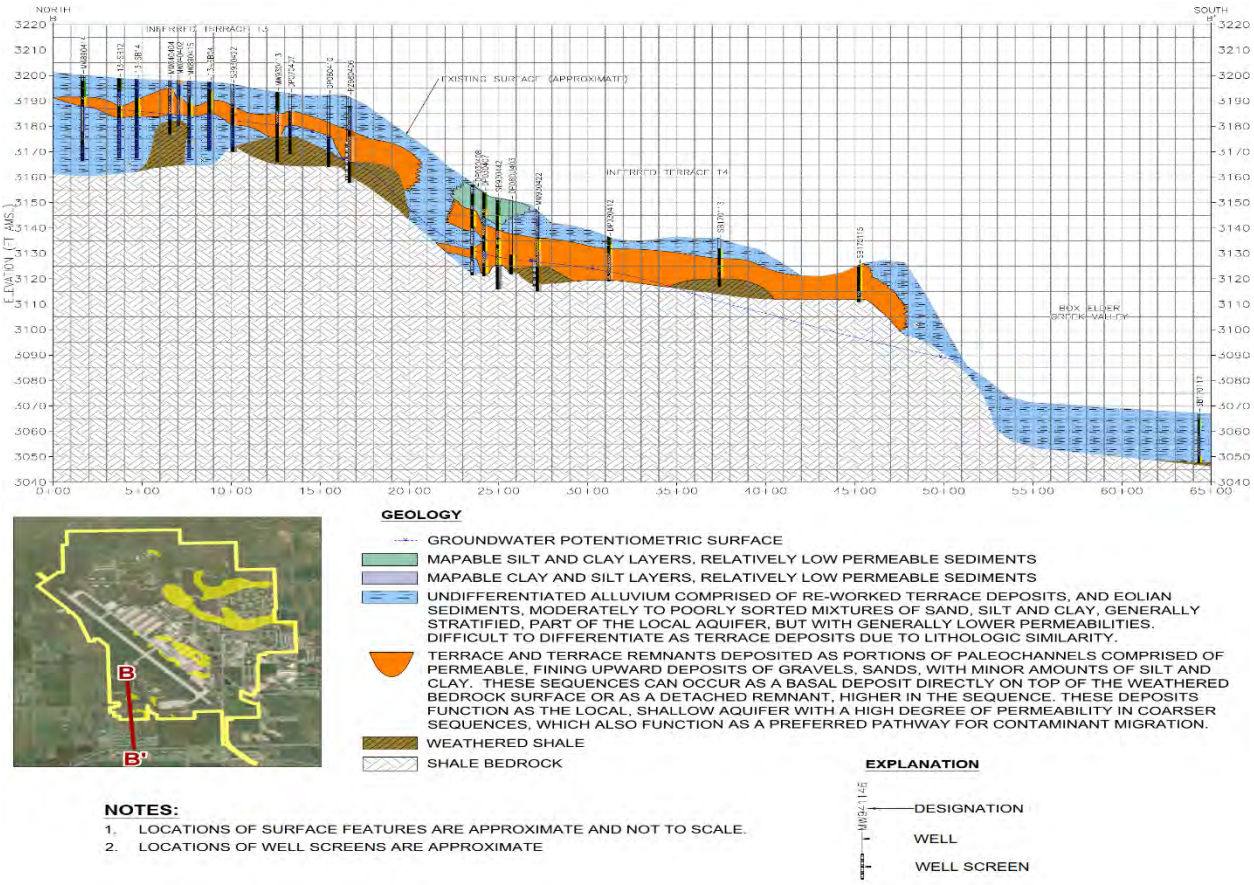

Figure 15-4. Geologic cross-section generated from ESS evaluation (Trihydro 2019).

Source: M. Olson, Trihydro. Used with permission.

The CSM developed for Ellsworth AFB used ESS techniques to show how geologic heterogeneity and anisotropy, resulting from site depositional history, caused multiple PFAS groundwater plumes to diverge from the direction predicted using simple potentiometric surface maps. The ESS evaluation identified several course-grained channel structures throughout the site. "More specifically, the CSM showed how buried paleochannel structures and a subtle weathered bedrock surface controlled contaminant migration pathways" (**Trihydro 2021**). In addition, subsurface stormwater structures were identified as high-permeability conduits, potentially providing secondary migration pathways for contaminants off site.

As illustrated in **Figure 15-5**, the groundwater plume (the TCE plume is shown in yellow) diverges from the prevailing groundwater flow direction (blue arrows) after encountering a course-grained paleochannel (shown in dark pink). The TCE plume is illustrated on **Figure 15-5** due to the extensive historical data set for TCE that is amenable to detailed plume mapping, better than would be the case for PFAS; the PFAS data set remains relatively limited (but growing) at the site. Detailed geologic cross-sections generated through the ESS evaluation (**Figure 15-4**) provide further insights into the structure of the paleochannels that influence the plume behavior. "Through ESS techniques, portions of previously unidentified plumes were found" (**Trihydro 2021**), and subsequent PFAS site characterization and/or remediation activities will rely on the new understanding moving forward to provide a more accurate remedial strategy.

15.1.4 Case Study: PFAS in Drinking Water Aquifer from Residential Septic Systems—A Conceptual Site Model (2025)

Contributed by Jenna Raup, TRC Engineers Inc., used with permission.

Multiple lines of evidence suggest that septic systems are contributing PFAS to overburden groundwater and fractured bedrock supply wells in a densely developed residential area lacking municipal water and sewer. As part of New York State's emerging contaminant sampling initiative, TRC Engineers Inc. (New York, NY), on behalf of the New York State Department of Environmental Conservation, sampled groundwater at a dry-cleaning State Superfund Site, and PFAS were detected above comparison criteria. The surrounding area was surveyed for sensitive receptors, and private water supply wells were tested to evaluate potential exposure. The presence of PFAS in groundwater at and near the State Superfund Site led to an investigation to determine the source(s) of PFAS in groundwater. A stepwise approach was implemented to identify potential sources via desktop review, followed by scoping and implementing targeted sampling at suspected source sites. Desktop sources reviewed included environmental reports, site and surrounding area history, environmental databases, historical documentation and maps, infrastructure construction records and maps, and numerous other publicly available records, including news reports and social media pages. Two hundred eighteen private water supply wells, which draw from the bedrock aquifer, are the domestic water source for approximately 50% of the properties within a ½-mile radius of the site (the Assessment Area). They are in locations that lack municipal water and sewer and were tested for PFAS. The results of the private well sampling were considered when searching for potential PFAS source sites.

Based on the desktop review and private water supply data, 12 potential PFAS source locations were identified for further investigation. These locations were associated with potential on-site use and release of PFAS-containing products, nearby private well sampling results indicative of a potential source, or geologic setting that represented a potential pathway to the bedrock water supply aquifer. The sampling program was designed to target potential release points, and minimize the number of samples collected. It was anticipated that concentrations of PFAS at a release point would suggest a potential source, and a subsequent remedial investigation may be warranted to define the nature and extent of the PFAS contamination. The targeted investigation program included soil or overburden groundwater sampling, or both, at each potential point source, access permitting, sediment and surface water sampling in the adjacent lake and at the discharge point of the publicly owned treatment works (POTW). In addition, the investigation program used the septic tracers, acesulfame potassium, sucralose, nitrate, and nitrite, in select bedrock water supply wells, and acesulfame potassium and sucralose in select overburden groundwater sampling locations. Though not used in this study, other common tracers such as surfactant metabolites, pharmaceuticals, antimicrobials, caffeine, boron, and others could have provided additional lines of evidence that the PFAS-rich groundwater did, in fact, co-occur with common wastewater (that is, septic) indicators. The lines of evidence presented below indicated that septic systems are the main source of PFAS in the Assessment Area bedrock water supply. Additional discussion of septic systems is included in **Section 1.3.2**.

- Other potential sources in the area were ruled out by the data. These included a firehouse that uses and stores aqueous film-forming foam; an oil recycling company which experienced a documented fire; a domestic septic pump out facility; boat detailing facilities; an apartment complex with on-site laundry and potential carpet cleaning; and potential sewer line inflow and exfiltration.

- PFAS concentrations in private wells were of similar order of magnitude throughout the Assessment Area. PFAS concentrations in overburden groundwater samples were of similar order of magnitude to PFAS concentrations in bedrock aquifer samples collected from private wells, and in many cases, were slightly higher.

- There is a connection between overburden and bedrock hydrogeologic units.
    - Prior studies identified a downward vertical groundwater gradient in the vicinity of the Superfund site.
    - Septic tracers were detected in overburden groundwater and private well–derived drinking water in every instance.

- The PFAS signatures of areawide wastewater and bedrock water supply closely match, with few exceptions.
    - Approximately 50% of the Assessment Area is served by municipal water and sanitary sewers. The effluent at the POTW that receives sanitary wastewater from approximately 50% of the Assessment Area was sampled, and the PFAS signature was used as a proxy for wastewater discharges in the area. There are clear similarities among the PFAS signatures of the POTW effluent, the bedrock water supply, and overburden groundwater (relative PFAS ratios included approximately 30%–40% perfluorooctanoic acid (PFOA) and 30%–40% perfluorooctane sulfonic acid (PFOS)), followed in lesser concentrations primarily by perfluorobutane sulfonate (PFBS) and perfluoroheptanoic acid (PFHpA). **Table 15-1-1** presents a statistical summary of PFAS analytical results for private wells in two discrete neighborhoods of the Assessment Area and for the POTW effluent.

- PFAS signatures in groundwater throughout the Assessment Area exhibited low variability (**Table 15-1-1**). In addition, in locations where both overburden groundwater and private water supply samples were analyzed, PFAS signatures matched (same predominant, secondary, tertiary PFAS).

Table 15-1-1. Statistical summary: PFAS analytical results.

	Composite Private Well Results for 91 Homes		Composite Private Well Results for 23 Homes		POTW Discharge Effluent
	Average	SDσ	Average	SDσ	Grab Sample Result

SD**σ**=standard deviation

Source: **Raup et al. 2024**, https://onlinelibrary.wiley.com/doi/10.1002/rem.70001. *Used with permission.*

The use of forensics and PFAS signature analysis was relatively limited due to the suite of PFAS reported for drinking water samples (6 PFAS) and the limited scope of environmental investigation (absence of upgradient, downgradient, and bedrock monitoring wells). However, based on multiple lines of evidence, the data did not substantiate the need for further investigation into any of the suspected sources. Taken together, the findings above support the following conceptual site model: consumer product use and discharge to domestic septic systems in a densely developed residential area have resulted in widespread presence of PFAS in shallow bedrock groundwater. **Figure 15-1-6** depicts this using pie charts to represent PFAS in domestic products, wastewater, and overburden and bedrock groundwater. More information about data visualization is included in **Section 1.3.7**. Downward vertical groundwater

gradients in the area and long-term supply well pumping have contributed to these impacts. It was concluded that the source of areawide PFAS impacts was unrelated to historic dry-cleaning operations at the site. A full case study is provided in **Raup, J., M. Eberle, E. Denly, D. Glass, S. Stefansky, J. Dyber, B. Scharf, S. Saucier. 2024. "A Conceptual Site Model for Per- and Polyfluoroalkyl Substances Water Supply Impacts in a Residential Community." Remediation Journal 35:e70001**.

15.2 Treatment Case Studies

Several well-developed technology case studies are presented in the following sections. Additional information on other water treatment case studies is summarized in Table 15-1 provided as a separate Excel file.

15.2.1 Granular Activated Carbon (GAC) (2020)

Case Study: Granular Activated Carbon System—Oakdale, Minnesota (Contributed by Virginia Yingling, Minnesota Department of Health, used with permission)

Background

Oakdale is a suburban community located east of St. Paul, Minnesota, with a population of approximately 28,000. Prior to state or federal laws regulating such waste disposal, industrial wastes from a PFAS manufacturer were disposed of in a privately operated 55-acre unlined dumpsite (Oakdale Disposal Site, 1940–1960) and in the Washington County Landfill, a permitted 40-acre unlined municipal landfill in Lake Elmo, Minnesota (1969–1975). In 2005, PFAS were detected in six of the eight operating Oakdale city drinking water supply wells.

Eight PFAS have been detected in groundwater associated with these sites, with PFBA, PFHxS, PFOA, and PFOS being present at the highest concentrations. PFAS have also contaminated a stream that drains the wetlands that comprise part of the Oakdale Disposal Site and PFAS re-infiltration has contributed to groundwater contamination in areas not immediately downgradient of the waste disposal sites. Both sites underwent remedial activities in the 1980 to address industrial solvents and in 2009–2011 to address PFAS. These actions included soil and waste excavation with on- and off-site encapsulation, and groundwater pump and treat (GAC) for hydraulic containment.

The regional groundwater flow direction at both sites is to the south-southwest toward the Mississippi River, approximately 8 miles away. The primary source for PFAS impacts to groundwater appears to be the Oakdale Disposal Site, but the Washington County Landfill may have contributed to the contamination in the easternmost city wells.

Water Characteristics

The maximum concentrations detected to date in the city wells are shown in **Table 15-2** along with the relevant Minnesota health-based guidance values for PFAS in drinking water.

Table 15-2. Maximum concentrations of PFAS in drinking water from Oakdale city wells.

Chemical	Maximum Concentration Detected in Any Oakdale City Well (µg/L)	Minnesota Department of Health's Health-Based Guidance Value (µg/L)
PFBA	2.15	7
PFBS	0.136	3 (acute), 2 (chronic, subchronic)
PFPeA	0.176	None established
PFHxA	0.382	None established
PFHxS	0.142	0.047
PFOA	0.871	0.035
PFOS	1.38	0.015
NOTE: All concentrations reported as of August 2019 and guidance values reported are as of December 2019.		

The Minnesota Pollution Control Agency (MPCA), Minnesota Department of Health (MDH), City of Oakdale, and the chemical manufacturer agreed to address the situation by constructing a GAC treatment plant to treat the water from the two most highly contaminated wells. In addition, the city shut off one well and drilled a replacement well north of the contaminated area. Other wells with PFAS detections are used seasonally and to maintain pressure throughout the distribution system, but the pumping schedule is managed to ensure PFAS remain below MDH guidance values in the water delivered to the community. This includes meeting the MDH's Health Risk Index, which is a toxic equivalency quotient (TEQ)-like assessment of the additive toxicity of multiple PFAS.

Treatment Technology Design Details

The GAC treatment facility (**Figure 15-6**) began operations in October 2006. It consists of ten filter vessels (each containing 20,000 lbs. of GAC) set up in five parallel lead-lag pairs (shown below) housed in a 7,000 ft^2 facility. The system treats 2,500 gallons per minute with a minimum empty bed contact time (EBCT) of 10 minutes per vessel. The water is combined back into one stream, chlorinated and fluoridated to meet state and federal standards, and then piped to the distribution system.

Figure 15-6. GAC treatment system, Oakdale, MN.

Source: Courtesy of the Minnesota Department of Health.

System Performance

The city and MDH monitor the PFAS concentrations in the influent, lead vessel effluent (that is, between vessels), and post–treatment facility effluent (Figures **15-7** and **15-8**). Monitoring currently occurs quarterly for the first three quarters following GAC change-out and monthly in the final quarter prior to change-out.

The GAC is changed out approximately every 12 months to prevent breakthrough of any PFAS above MDH guidance values. GAC change-out may involve a complete replacement of all GAC or just the lead vessel GAC and change of flow to make the former lag vessel the new lead vessel. This will depend on the effluent concentrations at the time of change-out. Initial removal rates are 100% (below analytical limit of detection) for all seven PFAS analyzed (PFBA, PFPeA, PFHxA, PFOA, PFBS, PFHxS, PFOS).

Breakthrough order follows the expected sequence of shorter chain and PFCAs preceding longer chain and PFSAs. PFBA breakthrough of the full system typically occurs within 2 months after a complete GAC replacement, but because the influent PFBA does not exceed its health-based guidance value of 7 µg/L, this does not pose a health risk and does not trigger any response actions. Interestingly, PFBA effluent concentrations eventually exceed influent concentrations, presumably due to PFBA desorbing in the presence of more readily sorbed, longer chain PFAS. As shown in the graphs below, PFOS has broken through the full system only once (2012; max effluent concentration = 0.019 µg/L) and PFOA has broken through only four times (2010, 2012, 2015, 2018; max effluent concentration = 0.086 µg/L). At no time did any PFAS exceed the then-current health-based guidance values.

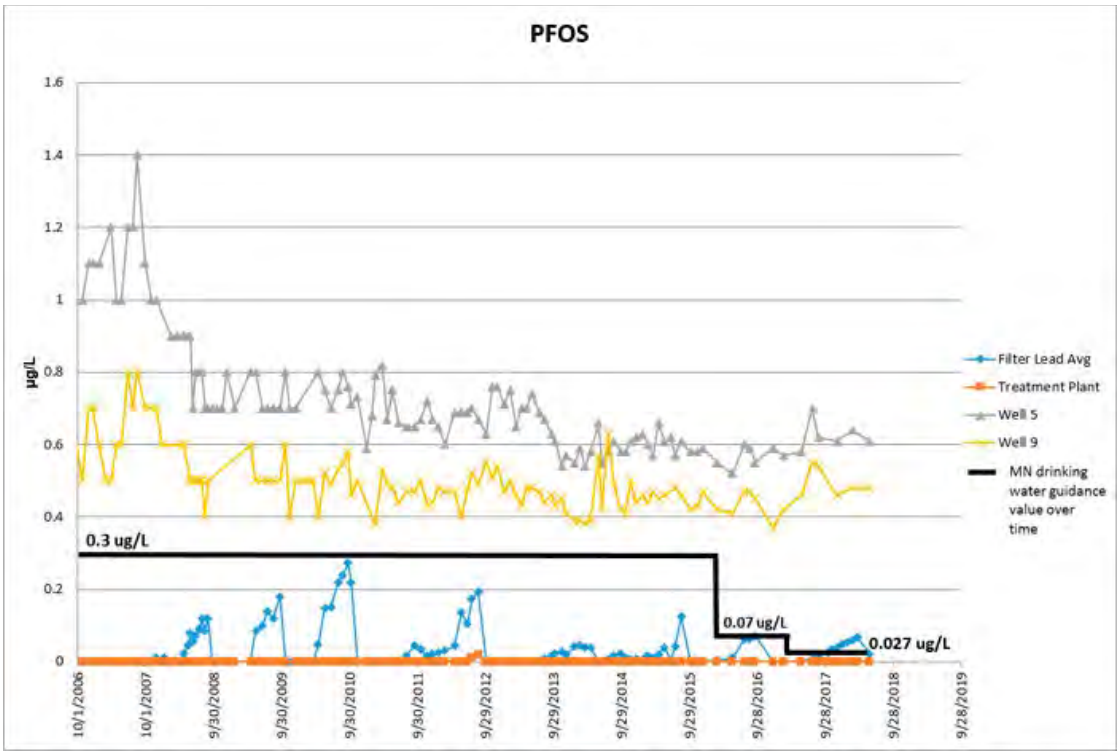

Figure 15-7. Influent and effluent concentrations for PFOS.

Source: Courtesy of the Minnesota Department of Health.

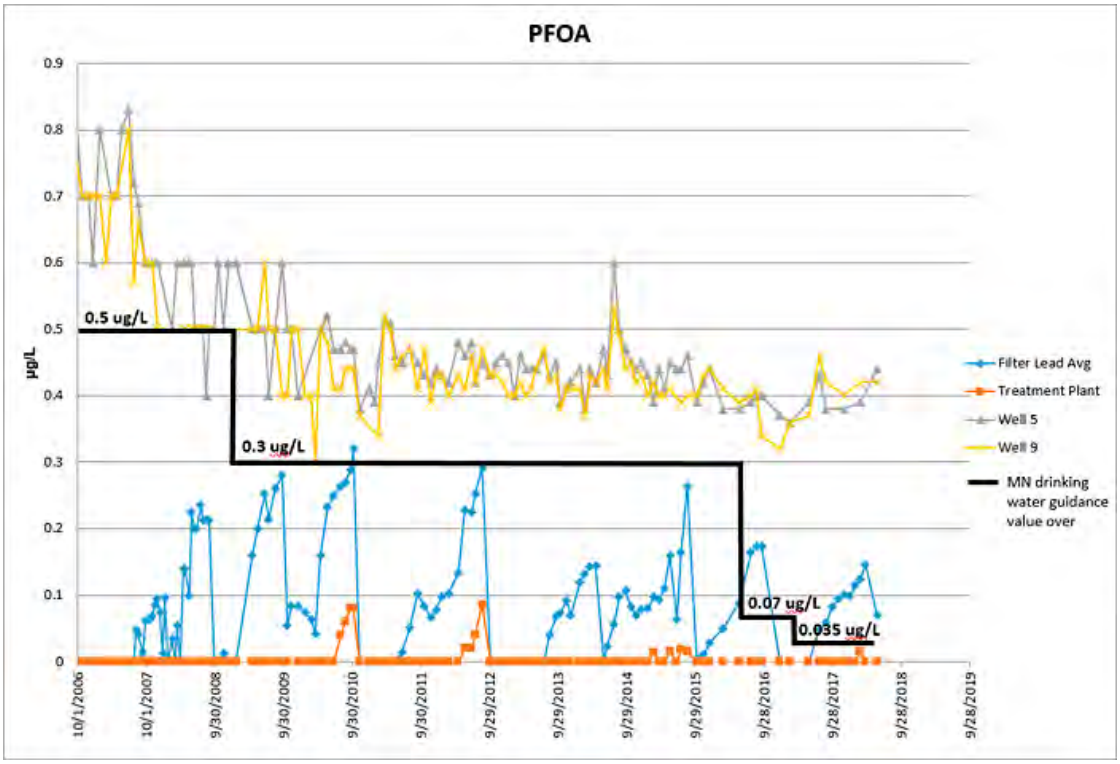

Figure 15-8. Influent and effluent concentrations for PFOS.

Source: Courtesy of the Minnesota Department of Health.

Costs

Capital costs for the GAC treatment facility were approximately $2.5 million. Annual operation and maintenance (O&M) costs, including sampling and GAC change-out, are approximately $250,000.

15.2.2 Ion Exchange (IX) Resins

Ion exchange resins can be utilized as single-use, where the media is disposed when it has reached the limit of its sorptive capacity, or regenerable, where the resin is regenerated and reused indefinitely (theoretically). The following two case studies outline field applications for these two related technologies.

15.2.2.1 Single-Use IX (2020)

Case Study: Horsham Township, Pennsylvania (Contributed by Francis Boodoo, Purolite Corporation, used with permission)

Background

The township of Horsham, Pennsylvania, located close to an AFFF release site, supplies drinking water to 7,800 residential, commercial, and industrial customers using 15 deep water wells. In 2014, five of the wells were confirmed to be impacted with PFAS. PFOS and PFOA were found in two wells at concentrations approaching the USEPA 2009 provisional health advisories (HAs) of 200 ppt and 400 ppt, respectively. These wells were immediately taken out of service. In June 2016, one month after EPA issued final HAs of 70 ppt for the combined concentrations of PFOS and PFOA, three more wells were removed from service due to elevated concentrations. The township began purchasing supplemental water from a nearby water supplier and began installing GAC filters to remediate and return the five impacted wells to service. Responding to consumer concerns, the township adopted an aggressive removal plan to reduce average PFOS/PFOA concentrations to less than 1 ppt (essentially to nondetect levels) in its entire water system by the end of 2016.

In addition to GAC filtration, the township started up a 50-gallon-per-minute selective ion exchange (IX) resin pilot in November 2016 on Well 10 to evaluate the performance of the resin in consistently reducing PFOS/PFOA to nondetect levels. A temporary 1-year permit was obtained from Pennsylvania Department of Environmental Protection (PA DEP) to install the resin pilot downstream of an existing GAC pilot that had been started up 20 days earlier. This was the first permit issued by the state of Pennsylvania for treating PFAS in drinking water using ion exchange resin.

Influent Water Characteristics

Influent concentration of a total of seven PFAS during the test period from November 2016 to August 2018 was an average of 103 ppt, a minimum of 78 ppt, and a maximum of 147 ppt. Individual PFAS concentrations are shown in **Table 15-3**. Average influent values for PFOS and PFOA were 34.1 and 20 ppt, respectively, somewhat lower than USEPA's 70 ppt combined 2016 HA. Other influent geochemical parameters included sulfate at 8–23 ppm, nitrate at 10–11 ppm, alkalinity at 148–232 ppm, chloride at 35–50 ppm, pH at approximately 7.5, TDS at 296–358 ppm, suspended solids at 0.5–0.6 ppm, TOC at 0.2 ppm, and one sample detection for 1,1-dichloroethane at 37 ppt.

Table 15-3. Influent PFAS Characteristics of Well 10*.

nanograms per liter (ng/L) (or parts per trillion (ppt))								
	PFBS	PFHpA	PFHxS	PFHxA	PFNA	PFOS	PFOA	Total PFAS
Lab Detection Level	1	1	2	1	2	2	1	
Minimum	6	4	17	6		27	13	78
Average	9	5	28	9		34	20	103
Maximum	14	8	41	13	2	48	40	147
* PFBS =perfluorobutanesulfonate; PFHpA = perfluoroheptanoate; PFHxA = perfluorohexanesulfonate; PFHxA = perfluorohexanoate; PFNA = perfluorononanoate, PFOS = perfluorooctanesulfonate, PFOA = perfluorooctanoate, PFAS = total poly- and perfluoroalkyl substances								

Treatment Technology Design Details: GAC and Ion Exchange System

Well 10, with a peak design flow rate of 100 gpm, was used for large-scale piloting at a reduced flow rate of 50 gpm under the terms of the permit from PA DEP. The water was first passed through a 20-micron suspended solids filter, then in series through two 2.5-ft diameter stainless steel vessels, each vessel containing 20 cubic feet of bituminous GAC. EBCT for each charge of GAC amounted to 2.8 minutes or a total of 5.6 minutes for the two GAC vessels; linear velocity was approximately 10 gpm/ft^2. The township recognized that EBCT was lower than the 10–20 minutes specified in the PA Public Water Supply design manual and that linear velocity, even though it complied with the PWS, was higher than the typical 4 gpm/ft^2 used for GAC; however, the township and PA DEP considered the design acceptable for the low levels of PFAS measured and for the temporary nature of the pilot. After initial treatment by the GAC pilot, the water was passed through a 2.5-ft diameter vessel containing 20 cubic feet of Purolite Purofine PFA694E selective resin. Bed depths for both the GAC and resin media were approximately 34 inches. Sampling points were installed on the outlet of each vessel. An extra sampling point was installed in the resin polishing vessel at two-thirds of the resin bed depth. This allowed monitoring corresponding to EBCT of 1.8 minutes at the two-thirds sampling point and 2.8 minutes EBCT for the entire resin bed. The two-thirds sampling point would provide advanced notice of PFAS breakthrough.

System Performance

The entire system became operational on November 29, 2016. PFOS and PFOA sampled at the two-thirds point of the resin bed remained consistently at nondetect levels until rising to 2.6 ppt on day 394 and 4 ppt on day 472 (see Figure 15-9). For reporting purposes, the township decided to use a minimum reporting level of 2.5 ppt for each of PFOS and PFOA; values below the minimum reporting level would be considered nondetect. Once the PFOA concentration reached 2.6 ppt at the two-thirds sampling point for the resin, the treated water was diverted to the local sanitary sewer in keeping with the PA DEP permit. PA DEP has since granted permission to bypass the GAC system to enable performance evaluation of just the resin.

On day 514, with permission from PA DEP, the two GAC vessels were taken out of service while the raw water was routed directly to the resin vessel, which continued to operate. In this way, the performance of the resin could be evaluated without pretreating with the GAC. The resin operated for 639 days before PFOA was detected at a concentration of 2 ng/L of PFOA in an effluent sample from the resin bed. At that point the concentrations of PFBS, PFHxS, and PFOS were still at nondetect levels. Operating capacity of the resin at that point was equivalent to treating 511,000 bed volumes (BVs) of water based on two-thirds of the resin volume, or 329,000 BV based on the entire volume of resin.

Following successful and consistent performance of the resin-only system, PA DEP has issued an operating permit for use of resin only in a pair of lead-lag ion exchange vessels. Similar permits have also been issued at neighboring townships.

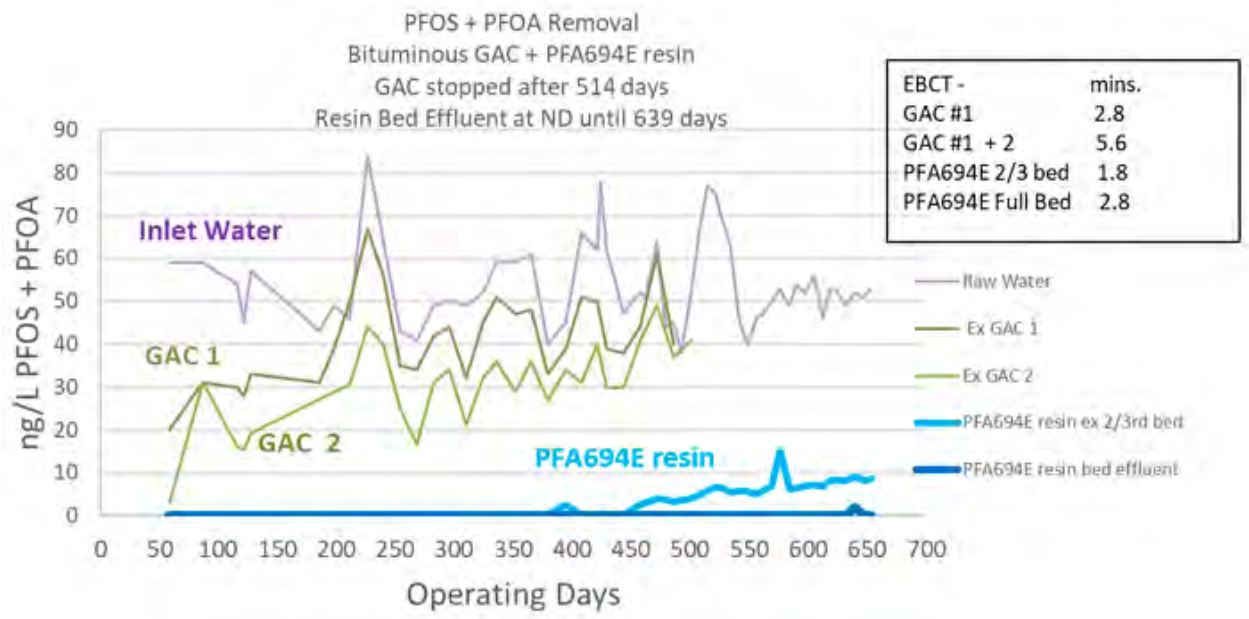

Figure 15-9. Combined PFOS/PFOA breakthrough.

Source: F. Boodoo, Purolite Corporation. Used with permission.

Even though PFOS and PFOA were the initial targets for reduction, consistent reduction of other short- and long-chain PFAS to nondetect levels was also achieved after passage through the resin. For conciseness, only total PFAS breakthrough graphs are shown in **Figure 15-10**, but the order of breakthrough observed was PFHxA < PFHpA < PFOA < PFNA < PFBS < PFHxS < PFOS.

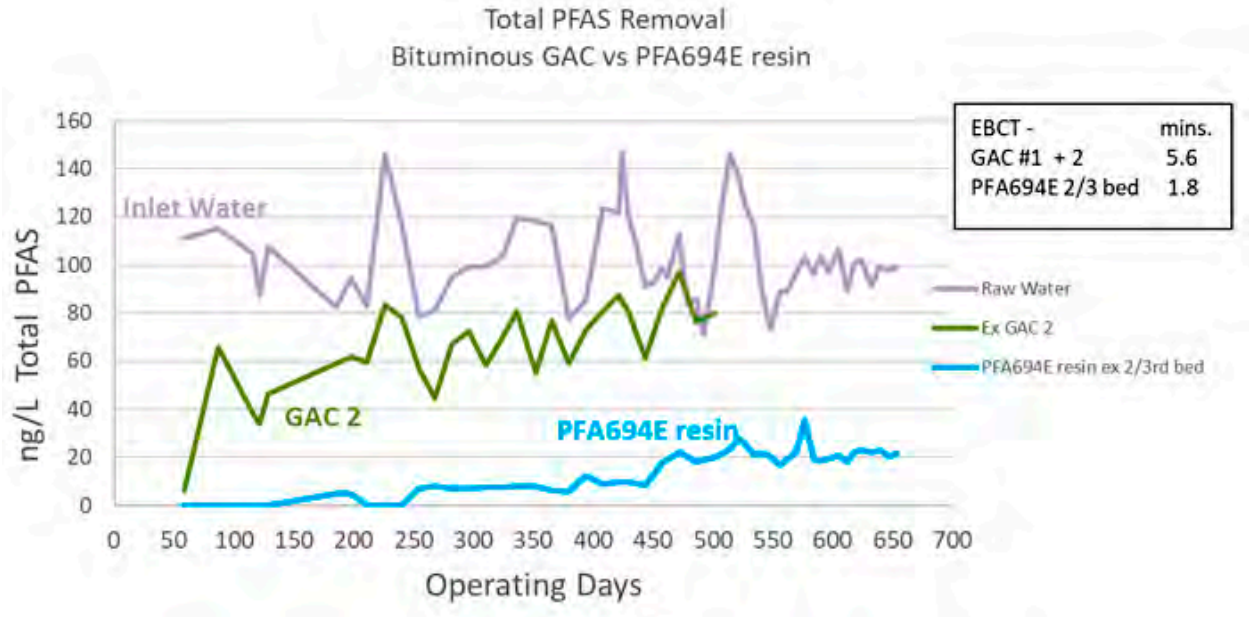

Figure 15-10. Combined breakthrough of total PFAS.

Source: F. Boodoo, Purolite Corporation. Used with permission.

Costs

The proposed permanent full-scale system is designed for a peak flow rate of 100 gpm with a pair of lead-lag vessels for the media. Design for ion exchange will include one 20-micron cartridge filter followed by two 4-ft diameter vessels with resin bed depth of 36 inches and EBCT of 2.8 minutes. Design for GAC will be one 20-micron cartridge filter followed by two 6-ft diameter vessels with GAC bed depth of 60 inches and EBCT of 10.6 minutes.

Annual operating cost, including replacement media, labor, trucking, spent media profiling, and incineration, is estimated at approximately $8,000 and $15,000, respectively, for ion exchange and GAC. These estimates are based on a very conservative operating capacity estimate of 350,000 BVs for a lead-lag pair of resin vessels; a generous capacity of 34,000 BVs is assumed for the GAC system. Operating costs are estimated at $0.16 and $0.29 per 1,000 gallons of water treated by the resin and GAC systems, respectively. Larger vessels needed for the GAC system will further add to the cost of using GAC versus the PFAS-selective resin.

15.2.2.2 Regenerable IX (2020)

Case Study: Regenerable Ion Exchange Resin Pilot Test and Full-Scale Application (Contributed by Steve Woodard, ECT2, and Nathan Hagelin, Wood Group, used with permission)

Background

The Air Force Civil Engineering Center (AFCEC) is conducting ongoing response activities to remove and remediate groundwater impacted by poly- and perfluoroalkyl substances (PFAS) at the former air force base in New Hampshire. The two primary PFAS found at the site are perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), at combined concentrations (PFOA+PFOS) above the 2016 USEPA lifetime health advisory (LHA) of 0.07 micrograms per liter (µg/l). In 2015, the USEPA issued an administrative order to establish maximum hydraulic containment of PFAS compounds to reduce source zone mass and mitigate migration of PFAS compounds to off-site receptors.

AFCEC responded by contracting with Wood Group, PLC, to conduct a side-by-side pilot test in 2016, comparing the performance of Emerging Compound Treatment Technologies' (ECT2) regenerable ion exchange (IX) resin and bituminous GAC. The resin outperformed GAC and was selected for full-scale implementation, mainly on its life cycle cost advantages, as determined by the results of the pilot study.

To evaluate the resin's ability to be regenerated, regeneration trials were conducted throughout the pilot test using a proprietary regeneration procedure with a solution of organic solvent and brine. Overall, PFAS removal results for the regenerated resin were consistent with new resin, as shown in **Figure 15-11**. Extended follow-on pilot testing utilized multicycling to confirm the effectiveness of the regeneration procedure to restore the resin's

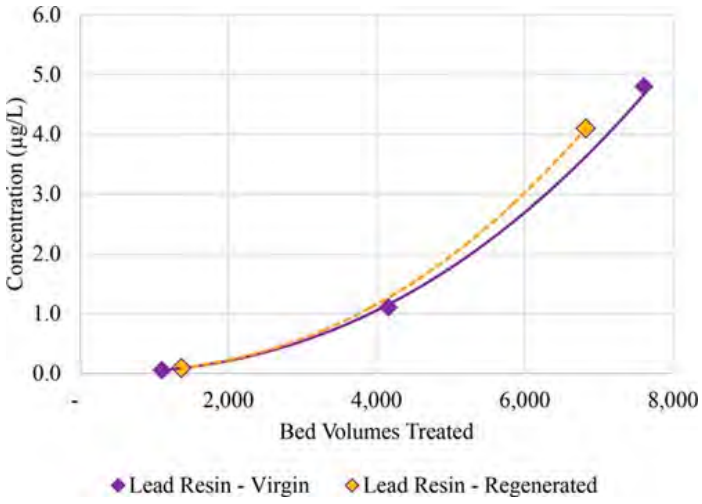

Figure 15-1. Postregeneration breakthrough curve (total PFAS).

Source: Steve Woodard, ECT2, and Nathan Hagelin, Wood Group, PLC. Used with permission.

PFAS removal capacity. The regenerable resin system was selected for full-scale application, based on system performance and a favorable life cycle cost comparison.

Influent Water Characteristics

Table 15-4 provides a summary of influent PFAS concentrations observed throughout the pilot test. Total PFAS concentrations ranged from 65 to 112 µg/l, with an average of 94 µg/l. Average influent concentrations for PFOS and PFOA were 26 and 12 µg/l, respectively. Influent general chemistry parameters included pH of 6.8, alkalinity of 115 milligrams per liter (mg/l), TDS of 230 mg/l, total suspended solids of less than 2 to 5.6 mg/l, sulfate of 17 mg/l, TOC of 4.5 mg/l, and chloride ranging from 30 to 250 mg/l.

Table 15-4. Influent PFAS Concentrations.

		Influent Concentration Observed During Pilot Test (µg/L)		
Analyte	**Analyte Acronym**	**Low**	**High**	**Average**
6:2 Fluorotelemer sulfonate	6:2 FTS	15	22	18
8:2 Fluorotelemer sulfonate	8:2 FTS	0.055	0.3	0.23
Perfluorobutane sulfonate	PFBS	0.81	1.3	1.1
Perfluorobutanoic acid	PFBA	0.89	2.1	1.3
Perfluoroheptane sulfonate	PFHpS	0.85	1.4	1.1
Perfluoroheptanoic acid	PFHpA	1.6	2.2	1.9
Perfluorohexane sulfonate	PFHxS	18	25	22
Perfluorohexanoic acid	PFHxA	5.9	8.9	7.7
Perfluorooctanoic acid	PFOA	9.1	13	12
Perfluorononanoic acid	PFNA	0.046	0.082	0.054
Perfluorooctane sulfonate	PFOS	4.2	32	26
Perfluoropentanoic acid	PFPeA	3.1	5.1	4.2
Sum of PFAS	-	65	112	94

Treatment Technology Design Details for Full-Scale System

The permanent full-scale resin system was designed for a maximum flow rate of 200 gpm (0.76 m^3/min), with influent total PFAS concentrations of approximately 90 µg/l. The primary project objective was to consistently produce treated water with combined PFOS plus PFOA concentrations below the 2016 USEPA lifetime health advisory (LHA) of 0.07 micrograms per liter (µg/l). The full-scale IX resin system was installed between fall 2017 and spring 2018, and the system officially commenced operation in April 2018.

Figure 15-12 shows a process flow diagram of the treatment system. The pretreatment portion includes bag filters to remove suspended solids and 6000-lb backwashable liquid GAC pretreatment filter to remove iron. The PFAS removal system consists of two parallel trains of lead-lag regenerable IX resin vessels, each 86" tall x 36" diameter, packed with 49 cubic feet of ECT's SORBIX A3F regenerable resin. These vessels are designed to operate up-flow during normal operation, and down-flow during regeneration. Two parallel, 86" tall x 36" diameter polish vessels are filled with IX resin for PFAS polishing, including short chains. The polish vessels operate in the down-flow mode and contain a blend of IX resins tailored to the general water chemistry and PFAS species and their relative concentrations.

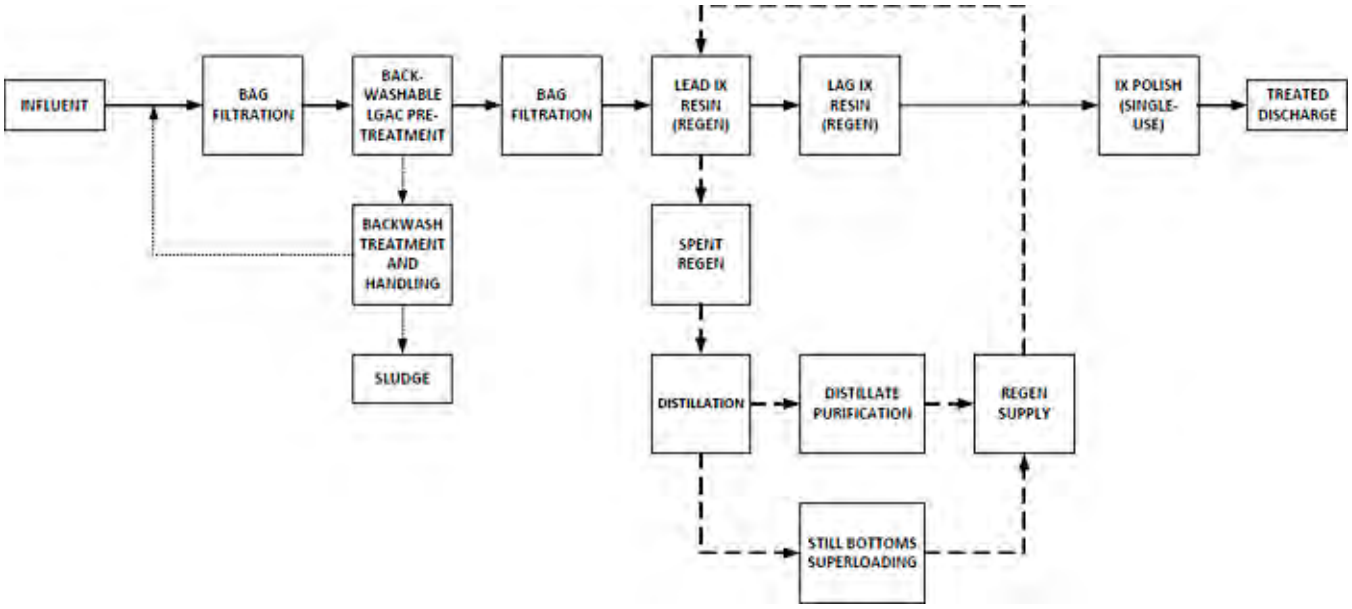

Figure 15-12. Block flow diagram of full-scale treatment system.

Source: Steve Woodard, ECT2, and Nathan Hagelin, Wood Group, PLC. Used with permission.

The in-vessel regeneration system (Figures **15-13** and **15-14**) consists of a regenerant solution holding tank and pump skid. The regenerant solution is a mixture of organic solvent and brine, which effectively strips PFAS from the IX resin and then flows into a spent regenerant holding tank. The spent regenerant is recycled for reuse in the next regeneration cycle by using a distillation and super-loading process. First, the spent regenerant is transferred to a solvent recovery unit. Solvent makes up the majority of the regenerant solution and is recovered through distillation, given its low boiling point relative to water, and transferred to the regenerant supply tank for reuse in the next regeneration cycle. The remaining distillate residue, known as the "still bottoms," is a low-volume, high PFAS concentration brine solution. The still bottoms are pumped through super-loader vessels that contain a proprietary resin blend, transferring the PFAS mass onto the super-loaded media. Super-loading is the process by which a relatively small volume of highly concentrated PFAS solution is passed very slowly through a small volume of media. The long EBCT approaches equilibrium (isotherm) conditions, thereby maximizing PFAS mass transfer onto the media and minimizing the amount of solid waste requiring disposal or incineration.

System Performance

The PFAS remediation system has been successfully treating the groundwater since system start-up in April (**Figure 15-15**). Through December 2018, the effluent water quality from the IX resin system has been consistently nondetect for the monitored PFAS compounds, including the short-chain species, readily achieving compliance with the treatment objective of 0.70 µg/l LHA target for PFOS and PFOA. Although 6:2 FTS has not been detected in samples collected from the IX vessel effluent, it has been detected in the system effluent and is believed to be the result of transformation processes that are not yet understood.

The system has been operated in the 35- to 70-gpm range since start-up, somewhat less than the design flow rate. This has been done to accommodate higher than anticipated influent iron concentrations that have resulted in the requirement for frequent bag filter change-outs. The resulting extended EBCTs in both the backwashable GAC pretreatment vessel and the IX resin vessels have resulted in better than projected PFAS removals. Also, the resin regeneration schedule has been modified to accommodate the lower flow rate by removing one of the two parallel trains from service. This has allowed the resin vessels to be loaded closer to design values. Four resin regenerations have been performed successfully through December 2018; however, the IX media regenerated through December 2018 was not loaded to the full design capacity due to the reduced flow during early operation. Operational modifications have been made to address and correct minor challenges with the distillation system, and regenerant recovery and

super-loading processes have proven successful. The original super-loading media is still operational, having removed and concentrated greater than 99.99% of the recovered PFAS mass; therefore, no PFAS waste has needed to be hauled off site to date.

Costs

The capital cost for the regenerable IX was $2.9M for *all* treatment equipment, process piping, pumps, instrumentation, and system electrical. It does not include project management, construction management, the extraction network and field piping, or the building and building mechanical or electrical systems.

15.2.3 Colloidal Activated Carbon (2023)

Case Study: In Situ Colloidal Activated Carbon—PFAS in Groundwater in Crawford County, Michigan (Contributed by Scott Wilson, Regenesis, used with permission)

Background

Since the late 1980s, the Michigan Department of Military and Veterans Affairs (DMVA) has been implementing a range of technologies to remediate groundwater impacted by chlorinated solvents at Camp Grayling in Crawford County, Michigan, a year-round training center for the Michigan Army National Guard (MIARNG). In 2016, the DMVA became aware of the potential contamination of PFAS from past operations such as on-site firefighting training at Grayling Army Airfield (GAAF). Groundwater testing

revealed PFAS commingled with chlorinated solvents migrating toward the property boundary. The impacted groundwater was shallow at 15 feet below ground surface (bgs) and was shown to be moving at a velocity of about 250 ft/yr through a sandy gravel aquifer. Sensitive downgradient receptors included numerous residences and surface water bodies. See also Regenesis (**2020**) for more information.

Contaminant Characteristics

Target groundwater contaminants at the GAAF site included PFAS (PFOS and PFHxS) at a combined concentration of about 130 ng/L commingled with perchloroethylene (PCE), which was present at a concentration of about 10 ug/L. Data from dedicated passive flux samplers deployed at the project site indicated that groundwater contamination was primarily existing in a sandy contaminant flux zone located between 15 and 27 feet bgs.

Regulatory Involvement

The DMVA decided to perform a demonstration of in situ colloidal activated carbon (CAC) technology to treat the PFAS and PCE contamination at the GAAF site. This demonstration consisted of injecting CAC into a zone of the contaminated aquifer and actively monitoring groundwater moving through the treatment area. The primary reason DMVA chose this approach was its proven performance on other project sites where it rapidly removed PFAS from the dissolved phase and was expected to perform for decades with a single application. “Additionally, the project life-cycle cost was a consideration for the DMVA in their selection. The projected cost for installing” an in situ CAC treatment zone in the subsurface was significantly lower than installing and “operating a mechanical system over a similar timeframe” (**Regenesis 2020**).

Treatment Technology

CAC is composed of very fine particles of activated carbon (1–2 µm) suspended in water using organic polymer dispersion chemistry. When the CAC material is injected into the subsurface, the carbon particles bind to the aquifer matrix but do not obstruct pore throats. Groundwater flows through the treatment zone. Organic compounds such as PFAS sorb on to the carbon particles, removing them from groundwater.

To determine the amount of CAC required for the demonstration, a proprietary finite-difference model was used to determine dosing of carbon, expected contaminant retardation/competitive sorption, and expected performance longevity. The model accounts for site-specific factors such as hydrogeology and contaminant flux while considering competitive sorption and biodegradation (in the case of PCE) to determine the quantity of CAC required.

Ultimately “the application design consisted of a single row of nine direct push injection points positioned upgradient of a previously installed monitoring well, MW-29” (**Regenesis 2020**). The total amount of CAC injected was 2,400 lbs of a 4% (w/w) suspension and 2,400 lbs of a 20% (w/w) suspension. “The injection line was configured as an arc to account for temporal and spatial variability in the groundwater flow direction. Initially two downgradient well pairs (MW-29/29C and MW-29D/29E) were placed 6 feet and 16 feet downgradient of the barrier, respectively, to monitor the pilot test performance. Each well of a well pair was installed with a 5-feet screened section to monitor the upper and lower treatment interval sections” (**Regenesis 2020**). **Figure 15-16** shows the monitoring well layout.

“The vertical injection interval was specified from 15 to 27 feet below the ground surface (bgs) to match the PFAS flux zone and accommodate seasonal water table fluctuations. In the pilot test area, this PFAS flux zone predominantly comprised of sand and gravel overlying a clay layer” (**Regenesis 2020**).

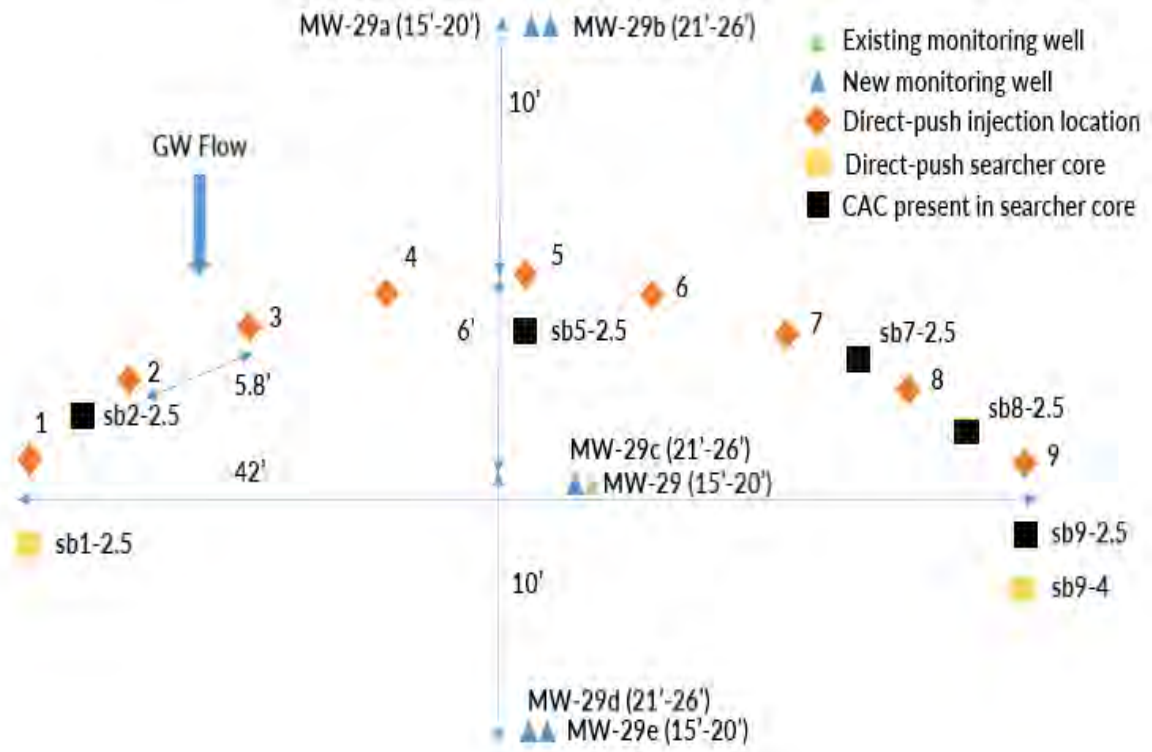

Figure 15-16. Wells used for the CAC demonstration project. Note that the values after the dash in the "sb" points are the distance from the injection point.

Source: Scott Wilson, Regenesis, used with permission.

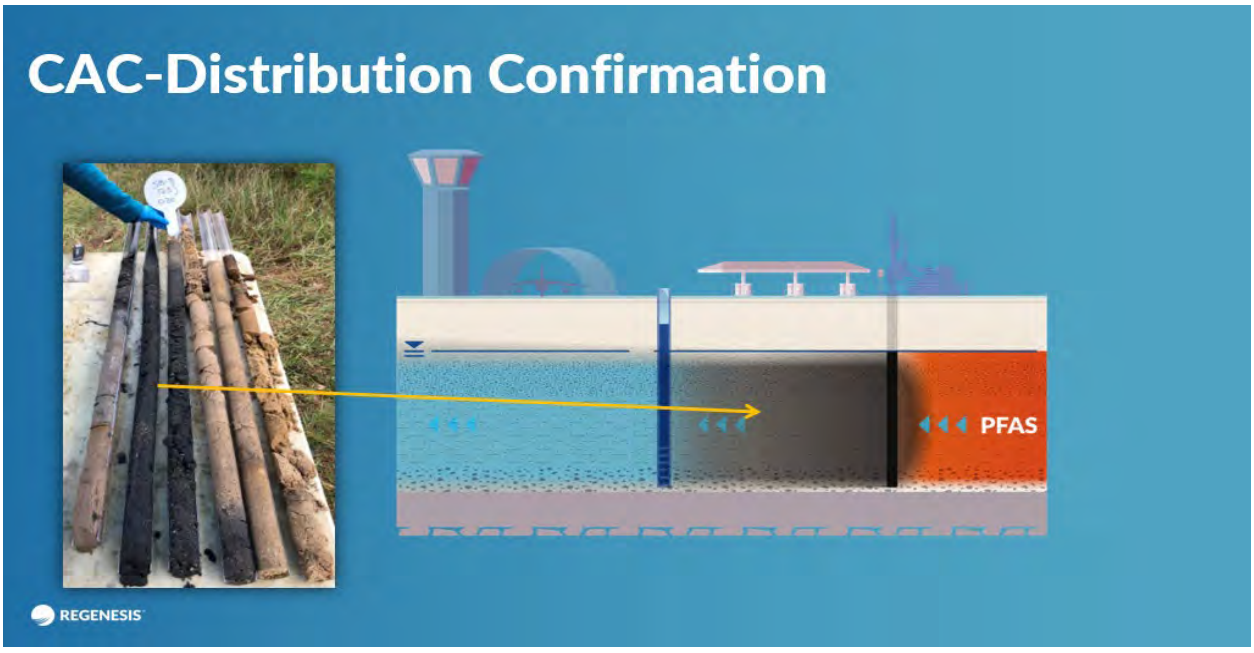

Figure 15-17. Vertical sections of a "searcher core" verifying the presence of CAC at the interval between 15 and 28 feet bgs.

Source: Scott Wilson, Regenesis, used with permission.

Injection of the CAC zone commenced in October 2018. Subsurface CAC distribution was optimized during injection by "adjusting injection variables including flow rate, screen size, injection volume, and injection point positioning" (**Regenesis 2020**). Verification of required CAC distribution was achieved "by collecting soil cores and groundwater samples from temporary piezometers placed between injection points. The soil cores revealed consistent CAC distribution over the target interval, while the groundwater samples collected from the piezometers indicated" (**Regenesis 2020**) required CAC presence in groundwater (**Figure 15-17**).

System Performance

By the first sampling event, approximately one month after injection, the CAC zone treatment had reduced PFAS "to concentrations below the standard method detection limit of 10 nanograms per liter (ng/L) in downgradient wells. Initial reductions were also observed in upgradient well-pair (MW-29A/B), indicating potential injection influence. However, by the second event, approximately two months after injection, concentrations in these upgradient wells had begun to rebound while the downgradient wells remained at non-detect" (**Regenesis 2020**). Since then, the CAC treatment has maintained PFAS concentrations below 10 ng/L in the downgradient wells for 3.5 years. **Figure 15-18** includes PFAS concentration data for upgradient and downgradient well pairs.

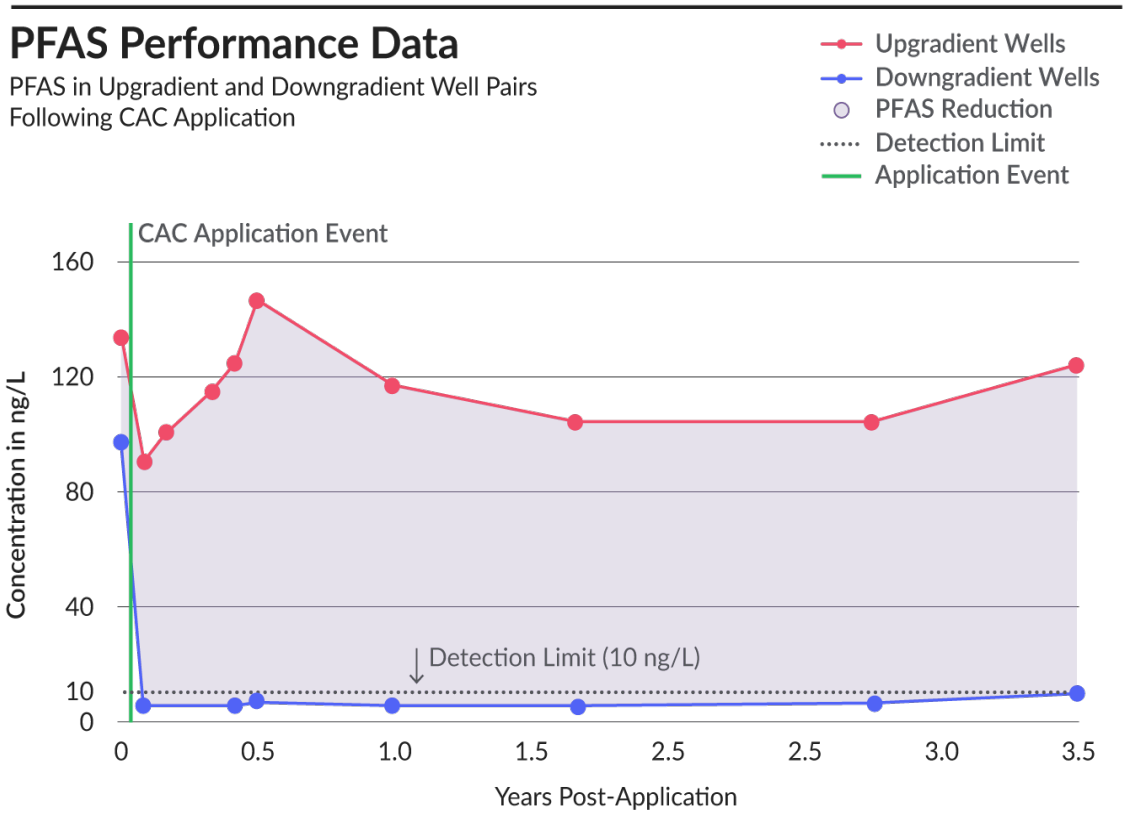

Figure 15-18. PFAS reductions as an average of monitoring well concentrations downgradient of CAC-treated zone.

Source: Scott Wilson, Regenesis, used with permission.

PCE concentrations followed a similar pattern as PFAS: reduction to nondetect (1 microgram per liter) by the first month, followed by sustained nondetect levels. **Figure 15-19** includes PCE concentration data for upgradient and downgradient well pairs.

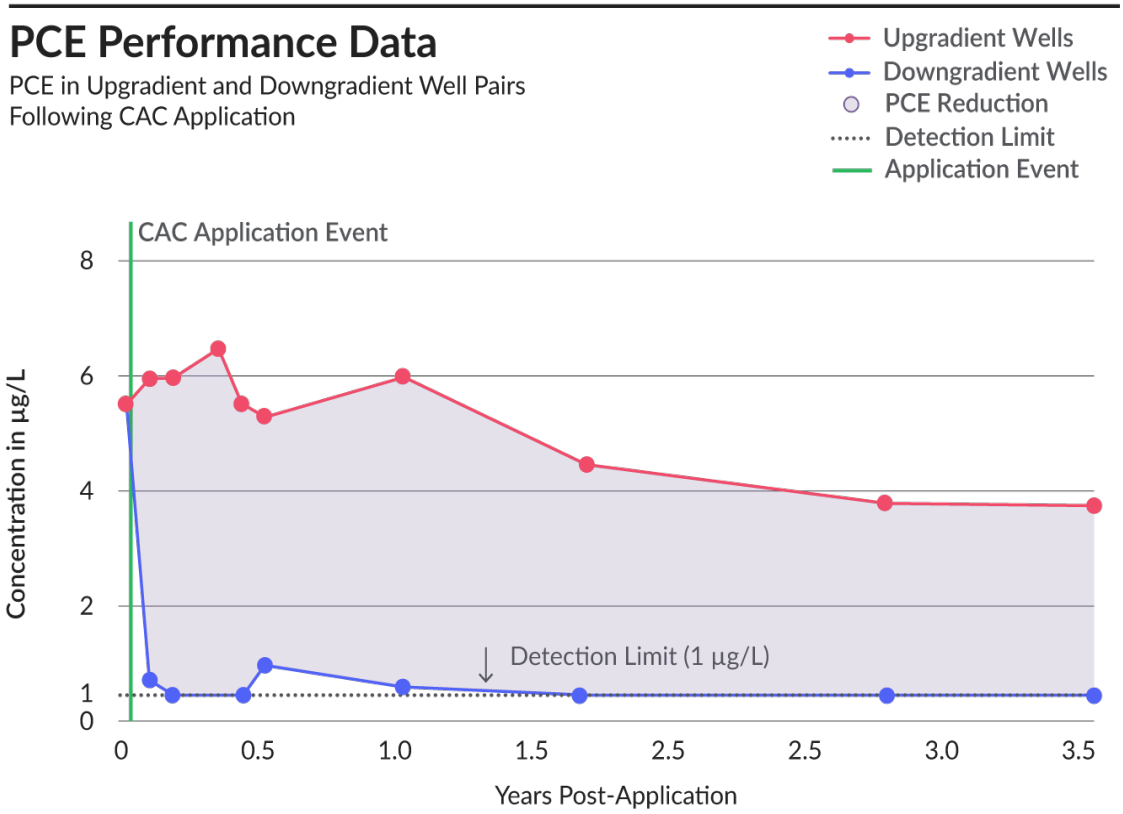

Figure 15-19. PCE reductions as an average of monitoring well concentrations downgradient of CAC-treated zone.

Source: Scott Wilson, Regenesis, used with permission.

The CAC demonstration has achieved all the remedial objectives to date (3.5 years) while modeling predictions suggest that the CAC installed will continue to remove PFAS and PCE for decades. Based on this demonstration project, the Michigan DMVA is considering expanded use of in situ CAC technology at other sites.

Cost

The total installation cost of the demonstration project was about $55,000, including the CAC material cost of $28,000 and field labor/subcontracting cost of about $27,000. There is no operation or maintenance cost. Sampling and analysis totals about $6,200 per year.

15.2.4 Foam Fractionation

15.2.4.1 Ex situ Groundwater Treatment (2023)

Case Study: Field Trial Conducted for the Australian Department of Defence (2019-2021) in Queensland, Australia (Contributed by David Burns, EPOC Systems)

EPOC Enviro LLC (USA), a subsidiary of OPEC Systems (Australia), was contracted by the Australian Department of Defence to provide a groundwater treatment field trial plant at the Army Aviation Centre

Oakey in Queensland, Australia. The field trial project was managed by WSP with project management and contract administration provided by GHD. The field trial plant required a design capacity to treat 250 m3/day (2.9l/sec or 46 gpm) to remove PFAS from groundwater, which included the primary treatment technology known as Surface-Active Foam Fractionation (SAFF®) and paired with an anion exchange (AIX) resin polishing treatment to ensure compliance with Australian and New Zealand Heads of EPAs (HEPA) drinking water guideline criteria prescribed by the PFAS National Environmental Management Plan (**NEMP, V2, Jan. 2020**). Groundwater had historically been contaminated by AFFF discharges from 1977 to 2005. Following the 3-year field trial, the Australian Department of Defence subsequently awarded a continuation of the groundwater treatment plant contract with increased treatment capacity of 345 m3/day (4.0l/sec or 63 gpm) and an expanded irrigation network.
A full case study is provided in the **Burns et al. (2021)** article, "PFAS Removal from Groundwaters using Surface-Active Foam Fractionation." https://onlinelibrary.wiley.com/doi/10.1002/rem.21694.

15.2.4.2 Ex situ Landfill Leachate Treatment (2023)

Case Study: Field Trial Conducted for Telge Återvinning AB, Sweden (2021–2022) (Contributed by David Burns, EPOC Systems)

EPOC Enviro LLC (USA), a subsidiary of OPEC Systems (Australia), was contracted by Telge Återvinning AB to provide a containerized treatment plant to treat leachate at the Telge Recycling Plant in Sweden. The initial field trial and project management were provided by EnvyTech Solutions AB. The treatment plant required a design capacity to treat 500 m3/day (5.8l/sec or 92gpm) to remove PFOS from landfill leachate water using Surface-Active Foam Fractionation (SAFF®) without any pretreatment or polishing treatments. The leachate, which exhibited a complex background chemistry including algal/zooplankton content, suspended solids, total organic carbon, and other organic and inorganic contaminants, was contained in a catchment pond with a volume of approximately 15,000 m3. A direct feed line drew water from the leachate pond to the SAFF® treatment plant using a submerged pump located approximately 1.5 m below the surface. The system achieved average treatment results for PFOS ≤2.34 ng/L, PFHxS ≤1.00 ng/L, and PFOA ≤1.28 ng/L, corresponding to removal percentages of ≥98.7%, ≥98.8%, & ≥99.7%, respectively. The mean concentration of PFOS was below 50 ng/L, which is defined by the voluntary Scandinavian REVAQ guideline.

A full case study is provided in the **Burns et al. (2022)** article, "Commercial-scale remediation of per- and polyfluoroalkyl substances from a landfill leachate catchment using Surface-Active Foam Fractionation (SAFF®): https://doi.org/10.1002/rem.21720.

15.2.4.3 PFAS Treatment Train Processing Using Surface-Active Foam Fractionation (SAFF®) and Eight Different PFAS Destruction Technologies—Lake Elmo, Minnesota (2025)

Contributed by Rebecca Higgins, AECOM, and Andri Dahlmeier, MPCA, used with permission.

The purpose of this case study is to present an example of a PFAS treatment train. While conditions at other locations will vary from the case study here, the results below are encouraging for application at other remediation sites. The full details of these results can be found in the final Project 1007 Feasibility Study report upon completion (**MPCA 2023**). Additional information about foam fractionation is included in **Section 12.2.3** of the Guidance Document. A surface water quality case study that describes PFAS-containing foam for Project 1007 is included in **Section 15.5.1**.

Background

The Project 1007 Corridor is in the Twin Cities East Metro Area of St. Paul, Minnesota, and is a large flood control project constructed by the Valley Branch Watershed District to mitigate flooding in the landlocked

subwatershed of the Tri-Lakes area. The conveyance system, consisting of open channels, pipes, dams, storm sewers, and existing surface water bodies, directs water from the Tri-Lakes area in Washington County to the St. Croix River. Within the drainage area of Project 1007, two PFAS source areas were identified as the former Oakdale Disposal Site and the closed Washington County Landfill. In addition to groundwater impacts resulting from two disposal areas, Project 1007 also facilitated a direct surface water to groundwater pathway along the corridor. This has resulted in widespread impacts extending approximately 120 square miles within six groundwater aquifers, including those used for drinking water in the Twin Cities East Metro. Impacts span multiple watersheds, groundwater divides, and drinking water supply aquifers. To read the full extent of investigation, including characterization and initial findings, please refer to the Source Assessment Progress Reports located on the Project 1007 website (**MPCA 2023**).

While the extent of the problem is still being defined, potential remedial options have been defined. Initial concepts of a remedial treatment train involved several steps. First, a concentration/separation step (for example, foam fractionation, reverse osmosis, filtration via granular activated carbon (GAC) or ion exchange resin (IX) for bulk PFAS removal from the source water. While these methods are typically effective at achieving applicable standards, it may be advantageous for the PFAS to be concentrated in an aqueous form. This may reduce operation and maintenance costs by reducing or eliminating the need for filtration media. This also allows for more options to destroy the PFAS removed from the bulk liquid.

This case study evaluated the treatment train of using foam fractionate to separate and concentrate PFAS prior to the testing of multiple PFAS destruction vendors.

SAFF® Process

SAFF® is a proprietary foam fractionation process that uses the foaming properties of PFAS to capture and concentrate PFAS in water. This technology takes advantage of the fact that PFAS are generally both hydrophobic and hydrophilic. The process effectively concentrates PFAS in foam at the water surface, which can be skimmed or vacuumed off the top. The SAFF® specifically uses a two-step process to remove and then concentrate the PFAS into a smaller volume for further processing or disposal. A third concentration step can also be used to additionally concentrate the PFAS to reduce costs associated with destruction. This was manually attempted as part of this pilot study. Additional information about foam fractionation can be found in **Section 12.2.3** and **Section 18.4**. More information about this pilot study can be found in the Project 1007 Feasibility Study (**MPCA 2023**).

Environmental Site Description and Results

The foam fractionation system was located in Tablyn Park (City of Lake Elmo) because of the ease of access to - impacted surface water (Raleigh Creek) and the two impacted aquifers (Shakopee and Jordan). These three water sources were treated separately by the foam fractionation system to better evaluate the treatment efficiency with different PFAS concentrations and water chemistries. A SAFF20 was deployed, which contains two primary fractionation vessels that remove PFAS from the bulk water, and a single secondary fractionation vessel which further concentrates the PFAS.

Treatment of water from Raleigh Creek showed a typical response in that foam readily formed during aeration, allowing PFAS to be removed from surface water. This foaming was a result of both PFAS and naturally occurring organic matter. With foam formation, PFOS and PFOA were readily removed from the bulk water treated at a treatment capacity of approximately 25,000–30,000 gallons per day (gpd) for the lowest effluent concentrations as shown in **Table 15-2-5**. Higher treatment capacities of up to 45,000 gpd could be achieved with PFOS and PFOA removal still above 95%. Other PFAS were also monitored. Longer chain PFAS, including perfluorohexanoic acid (PFHxS), were also removed; however, short-chain PFAS such as perfluorobutanoic acid (PFBA) had significantly limited removal efficiencies (less than 50%). Secondary fractionation treatment was tuned to limit the volume of water removed with the foam

to reduce the PFAS concentrate to a volume of less than 0.5 gpd with attempts to meter the concentrate at small volumes back into the secondary fractionation step. This mimics tertiary fractionation.

Table 15-2-5. Removal efficiencies for PFOS and PFOA in the Tablyn Park study.

	PFOS (ng/L)			PFOA (ng/L)		
Water Source	**Influent**	**Effluent**	**Concentrate^**	**Influent**	**Effluent**	**Concentrate^**
Raleigh Creek	2,940	2.9 (99.9)*	4,530,000	903	0.836 (99.9)*	1,780,000
Shakopee Aquifer	1,340	1.42 (99.9)*	19,100,000	392	3.57 (99.1)*	6,360,000
Jordan Aquifer	0.92	Below Detection	Not Available^	26.5	4.95 (81.3)*	Not Available^

Notes: All analytical results were completed by USEPA Method 1633.
^Concentrate was mixed with concentrate from other water samples in system holding tank.
*Percent removal

The system responded differently during the groundwater treatment from both aquifers due to a lack of organic matter which limited the foam formation. . To achieve higher removal efficiencies without the addition of a surfactant, the aeration amount was oscillated between high and low air injection to promote removal. These results indicate high PFOS and PFOA removal regardless of the surface water chemistry and PFAS concentrations of the influent water. The effluent was discharged under Minnesota Pollution Control Agency (MPCA)–approved discharge to nearby Raleigh Creek.

Higher concentrations were achieved in the concentrate from the Shakopee Aquifer because of recirculation of the collected concentrate back into secondary fractionation by manually metering in the concentrate. This is similar to what is done during tertiary fractionation. This was not achieved with concentrate formed during Raleigh Creek treatment because the higher organic matter resulted in too much foaming during manual metering. The resultant concentrate from the treatment of Raleigh Creek and the Shakopee Aquifer was used for the PFAS destruction testing.

Destruction Technologies Descriptions

The next phase of the treatment train was to evaluate currently identified destruction technologies for further PFAS treatment. For the purposes of this case study, destruction is defined as the process of transformation and reduction of targeted PFAS, focused on PFOA and PFOS. Total organofluorine, often measured as adsorbable organofluorine, was also used to measure reductions in total PFAS. The definition of destruction may differ among various technology vendors, and the reader is encouraged to specifically define destruction within pilot studies to establish a common reference and goal for varied technologies.

The MPCA posted a request for proposals for bench-scale testing of destruction technologies with the surface water foam fractionation concentrate. Responses were received for four categories of destructive technologies, some with multiple vendors that were considered for further testing. These included plasma, (1 vendor), UV-activated photoreduction (2 vendors), supercritical water oxidation (3 vendors), and electrochemical oxidation (1 vendor) (**Table 15-2-6**). See **Section 12.2** and **Section 12.6** for more information about water treatment technologies. A second electrochemical oxidation vendor was also tested in a pilot-scale demonstration with the concentrate from treatment of the Shakopee Aquifer. As bench-scale and pilot-scale results are difficult to compare, the pilot-scale results are not presented in this case study. A recent peer-reviewed publication includes detailed explanations of these processes (**Meegoda et al. 2022**).

The destruction technology evaluation project was large, and considered many variables, including PFAS using multiple analytical methods. For brevity, here we present abbreviated results for two of the most studied PFAS, PFOA and PFOS.

Destruction Testing Results

The PFAS concentrate from the foam fractionation system in Tablyn Park was sent to the vendors for processing through their PFAS destruction systems. Note that the initial PFAS values in **Table 15-2-6** and **Table 15-2-7** do not match those seen in **Table 15-2-5**, as some vendors performed dilutions to either increase the volume of waste for processing to accommodate the treatment capacity of their pilot unit (Vendor E) or to increase the transmittance (decrease natural organic matter concentration) of a sample (Vendor B). These variations in influent concentrations for Vendors B and E and the resulting final concentrations are shown in the tables below. While dilutions would not be required in the first instance in a field application, they would likely still be required in the second instance.

For the bench-scale results, the vendors targeted high destruction efficiencies. Multiple vendors noted that energy efficiencies may be achieved through reconcentration of the effluent from their systems. Instead of treating the concentrate to reach a discharge criteria, energy savings can be achieved by only treating waste with high PFAS concentrations. This may also reduce the number of systems required to treat the concentrate volume produced in a full-scale system.

Table 15-2-6. PFAS destruction technology results for Tablyn Park foam fractionation concentrate, PFOA*.

Technology	Vendor	Initial	Final
Plasma	Vendor A	1,700,000	290
Photochemical	Vendor B	338,100	20
	Vendor B	314,600	70
	Vendor C	1,500,000	86
Supercritical Water Oxidation	Vendor D	971,000	Not reported
	Vendor E	33,000	29
	Vendor E	34,000	12
	Vendor E	36,000	7.2
	Vendor E	132,146	7.3
	Vendor F	1,670,000	Not reported
Electrochemical Oxidation**	Vendor G	11,380,000	3.8

Notes: *Values in ng/L
**Pilot testing was also performed using another electrochemical oxidation method. These tests were performed using equipment in the field, and preliminary results have shown promise in significant PFOS and PFOA destruction. Additional studies are in progress.

Some vendors included other evidence of destruction. This is recommended in PFAS destruction testing. This included analysis of shorter chain PFAS, which results from sequential defluorination as is observed with photochemical reduction, electrochemical oxidation, and plasma. Increases in fluoride concentrations were also observed, but mass balances were not achieved. Some of the vendors also performed adsorbable organofluorine (AOF) and total oxidizable precursor (TOP) assay analysis, and this is recommended in the evaluation of destruction technologies. At this site, precursors are not found at high concentrations in the surface water and groundwater, so this was not of particular concern in the evaluation; however, elsewhere precursor analysis is important in understanding the destruction of all PFAS present. Additionally, AOF can provide insight into total PFAS destruction, including those compounds that are not included in USEPA Method 1633A. It should be noted that AOF does not capture ultra-short-chain PFAS (ultrashort PFAS). **See Section 11.2**, **Section 1.5.3**, and **Section 1.5.4** for more information about PFAS analysis.

Table 15-2-7. PFAS destruction technology results for Tablyn Park foam fractionation concentrate, PFOS*.

Technology	Vendor	Initial	Final
Plasma	Vendor A	3,200,000	2,100
Photochemical	Vendor B	930,700	230
	Vendor B	1,072,900	2,400
	Vendor C	2,400,000	220
Supercritical Water Oxidation	Vendor D	3,660,000	Not reported
	Vendor E	120,000	44
	Vendor E	130,000	7.4
	Vendor E	150,000	7.6
	Vendor E	341,070	4.9
	Vendor F	3,510,000	Not reported
Electrochemical Oxidation**	Vendor G	4,160,000	3.8

Notes: *Values in ng/L
**Pilot testing was also performed using another electrochemical oxidation method. These tests were performed using equipment in the field, and preliminary results have shown promise in significant PFOS and PFOA destruction. Additional studies are in progress.

In addition to the destruction capabilities, other factors should be considered when evaluating destruction technologies. These include potential byproducts, the destruction (or potential production) of short-chain and ultrashort PFAS, air emissions, energy consumption, operating conditions, and operation and maintenance needs. Electrochemical oxidation, photochemical reduction, and plasma are all known to sequentially defluorinate longer PFAS, resulting in increases in shorter chain PFAS. Issues with high detection limits in the starting concentrate limited the analysis of the production of these PFAS. These items were evaluated as part of the larger study but are not discussed here, because these items often require larger pilot studies to fully evaluate. Cost information was provided by some of the vendors, but those that included full-scale systems did caution that the costs were high-level estimates and that additional testing at the pilot scale would be required to better complete cost estimations. The treatment cost is also highly dependent on the treatment goals. Treatment for longer times or at higher energies can result in lower effluent concentrations, but this can also greatly increase energy demands and decrease treatment capacity, requiring larger systems to be installed.

Conclusions

Results suggest the four types of destruction technologies examined all provide a significant level of PFOA and PFOS reductions. Additionally, results indicate a treatment train approach using foam fractionation can be an effective method of decreasing the volume of PFAS-contaminated water that requires treatment, making PFAS destruction technologies more implementable and cost-effective. Many of the technologies also operate more efficiently at higher PFAS concentrations. Selection of a destructive technology depends on site-specific water chemistry, and multiple destruction technologies should be considered to evaluate potential interferences. For example, foam fractionation can concentrate natural organic matter, which decreases transmittance and decreases efficiency of one of the UV-activated photoreduction technologies. While some of the technologies had higher effluent concentrations, the effluent from destruction can be cycled back through the foam fractionation system to reconcentrate the remaining PFAS, further supporting a treatment train approach. Filtration with granular activated carbon or ion exchange could also be employed as a polishing step to further treat the effluent of the foam fractionation system if needed to meet the applicable regulatory criteria or site-specific goals.

For Project 1007, additional testing of the PFAS concentrate and subsequent destruction technologies may be conducted to determine the effectiveness with different PFAS mixtures and water chemistries. This will likely not occur until the location of the potential full-scale system is selected, as this may impact the PFAS mixture and concentration in the resulting PFAS concentrate treated by the destruction technologies. The results of this pilot study have been incorporated into a feasibility study to assess remedial options to reduce the migration of PFAS impacts within the East Metro.

15.2.5 Soil Washing

15.2.5.1 Full-scale Soil Washing of PFAS-contaminated Soil Stockpiles, Alaska (2025)

Case Study: Full-scale Soil Washing of PFAS-contaminated Soil Stockpiles, Alaska. Contributed by Toni Mehraban, Brice Engineering, LLC, Used with permission.

Background

During construction of new facilities and infrastructure at a military installation in Alaska, potentially PFAS-impacted soil was excavated during building foundations, site grading, and utility installation. To avoid construction delays, 145,793 cubic yards (cu yd) of soil was stockpiled on the installation. Through characterization in 2021, approximately 139,098 cu yds were determined to be impacted with PFAS and co-contaminants above Alaska Department of Environmental Conservation (AK DEC) cleanup levels (CULs). The installation disposed of 11,972 cu yds of PFAS-impacted soil off-site and in 2022 Brice Engineering, LLC (Brice) and their soil washing technology was selected to treat the remaining 127,126 cu yds in 42 stockpiles through a patented soil washing process with an objective to reduce levels below AK DEC CULs.

Treatment Technology Design

As described in **Section 12.3.3**, soil washing uses particle size separation of soil fractions through aggressive contact with wash water that encourages PFAS to desorb from the soil phase into the water phase where treatment is more readily available through a closed-loop water treatment system. Unlike many destructive soil treatment technologies that have high energy/electricity demands, soil washing is a very effective and efficient solution to bulk treatment, providing an opportunity for full-scale implementation at a high throughput to significantly reduce the volume requiring further treatment. Washed soils meeting the CULs can be beneficially reused on-site, while the reduced volume not meeting CULs after the first wash can be rewashed to meet CULs, disposed off-site, or treated through subsequent destructive treatment technologies. In the end, the vast reduction in PFAS-impacted soil quantities that remain after soil washing makes destructive soil treatment technologies that will eliminate off-site disposal more viable. For this case study, water from a nearby surface water body was used (with no amendments) as the wash fluid.

Soil Characteristics

In 2021, the stockpiled soils were characterized to determine in-place volume (bank cu yds), bulk density, gradation, total organic carbon (TOC), and bulk concentrations of PFAS and co-contaminants. The stockpiles processed via soil washing in 2023 and 2024 were labeled EIE365-1, EIE378-4, EIE405-1, EIE405-2, and EIE-405-3 and consisted primarily of silty sand with gravel or silty gravel with sand. Particle size distribution and TOC concentrations for the four stockpiles are presented in **Table 15-2-8** and initial bulk soil concentrations of PFAS and co-contaminants are presented in **Table 15-2-9** and **Table 15-2-10**, respectively (**USACE 2021**).

Table 15-2-8. Geotechnical and TOC characteristics[1].

Stockpile	% Gravel		% Sands			% Fines	Density (ton/cu yd)	TOC (mg/kg)
	Coarse	Fine	Coarse	Medium	Fine	Silt

System Performance

During the 2023 and 2024 operational seasons (approximately 6 months of cumulative soil washing operations due to the winter conditions in Alaska) 32,431 loose cu yds of impacted soils (soils containing PFAS, diesel range organics ([DRO], polycyclic aromatic hydrocarbons [PAHs], and pesticides) were processed through the soil washing plant (**Table 15-2-11**). The effectiveness and quality of data for treatment were verified through 43 incremental sampling methodology soil samples (500 cu yd decision units [DUs], 30 soil increments per DU), 16 field triplicate incremental sampling methodology soil samples, 6 pretreatment discrete soil samples, 3 field duplicate pretreatment discrete soil samples, 71 field blank samples, 4 process water samples, and 1 processed water field duplicate sample. It should be noted that, based on contract payment schedule and equipment used, measurements of soil entering the soil washing plant were recorded in volume (loose cu yds via 2 cu yd industry standard excavator bucket loads) and measurements of processed soil exiting the soil washing plant were recorded in weight (tons via calibrated loader scale).

Table 15-2-11. Summary of preprocessed soil treated in 2023 and 2024.

TASK/F35 Project	EIE405			EIE365	EIE378
Associated Stockpile(s)	EIE405-3	EIE405-1	EIE405-2	EIE365-1	EIE378-4
Preprocessed Volumes (cu yd)	1,975	3,835	815	6,430	19,376
TOTAL PREPROCESSED VOLUME (cu yd)	**32,431**				

Notes: cu yd—cubic yard

Through soil washing, 30,768 tons of oversize and coarse-grained fractions were treated to below AK DEC CULs, of which 5,219 tons were also below May 2024 U.S. Environmental Protection Agency (USEPA) residential soil Regional Screening Levels (RSLs) used at the time and were reused by the installation for backfill and winter road maintenance (**Table 15-2-12**). Of the 6,398 tons of postprocessed fines not meeting the AK DEC CULs, 266 tons were rewashed at the end of the 2024 operational season to evaluate the effectiveness and efficiency of a second wash; these materials were successfully treated to below AK DEC CULs. Therefore, approximately 6,132 tons of postprocessed fines remain on-site for second wash, disposal, or possible future consideration of treatment with a destructive technology. As such, soil washing was able to reduce the volume of PFAS-impacted soils by 83%, representing a total of 31,034 tons of soils meeting AK DEC CULs out of 37,166 tons of postprocessed soils. **Table 15-2-13** and **Table 15-2-14** summarize the PFAS and co-contaminant concentrations for the postprocessed coarse and fines fraction from the first DU for each stockpile. It should be noted that the elevated concentration of postprocessed fines during processing of EIE405-1 and EIE365-1 soils is not indicative of PFAS concentrating on the fines fraction but an ineffective operating procedure that was corrected during treatment of EIE378-4.

Table 15-2-12. Summary of postprocessed soil treated in 2023 and 2024.

Stockpile(s)	Oversize (tons)	Coarse (tons)	fines (tons)	Total (tons)

In addition to soil, 314 one-cu-yd sacks of vegetation were also generated as a result of soil washing operations and are being temporarily stockpiled on-site until waste characterization is complete, and disposition options are finalized.

The capacity of wash water in the soil washing plant is approximately 71,500 gallons, which is circulated in a closed loop through the soil washing plant for soil processing and treated through a water treatment plant consisting of two trains of pretreatment sand media, lead-lag granular activated carbon vessels, and lead-lag ion exchange resin vessels. During soil washing operations, this water capacity is circulated 20 times through the soil washing plant per day, resulting in the equivalent of approximately 1.4 million gallons of water per day processed through the water treatment system. Treatment system media is backwashed several times per day. Over the course of the operating season, a total of 86,000 gallons of process water was used (additional water was necessary above 71,500 gallons of the plant capacity due

to evaporation and accumulated water content in postprocessed materials). PFAS and co-contaminants of concern were treated to less than their respective AK DEC CULs and discharged on-site.

This project is ongoing with opportunities for process optimization to reduce the volume requiring rewash or disposal off-site, or both. Destructive technologies are also being considered for incorporation into the project, resulting in a complete treatment train that will provide a total on-site treatment and management solution.

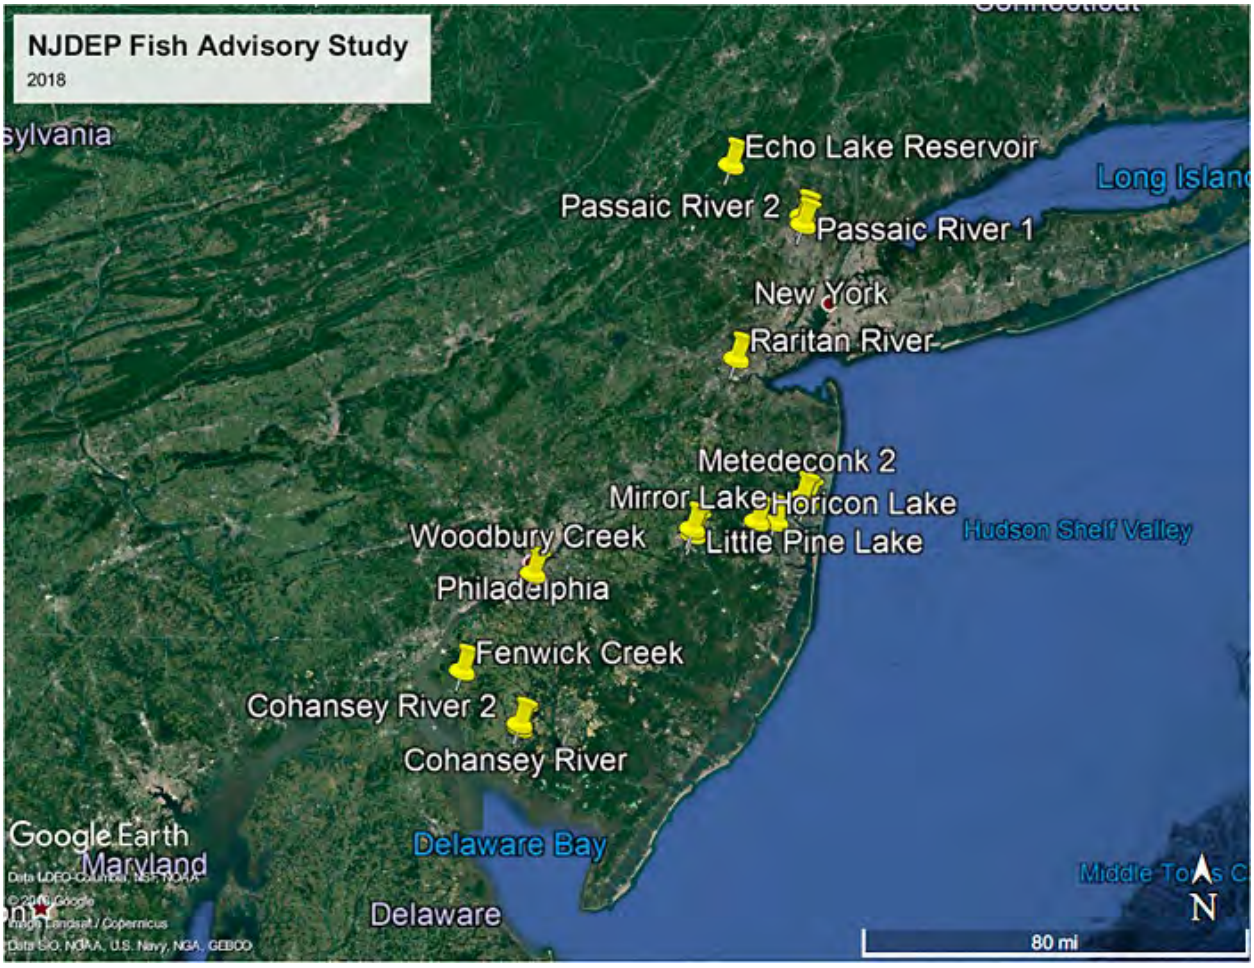
Costs

The cost to implement soil washing is based on two main factors: 1) the total amount of soil to be processed and 2) the percentage of fines in the soil. The less soil to be treated and the higher the percentage of fines, the higher the unit cost. This is because mobilization/demobilization of labor and equipment does not vary substantially, as the same equipment and labor is needed regardless of the amount of soils to be treated on-site. Additionally, as the percentage of fines increases, treatment throughput decreases. Based on experience, the cost of soil washing can range between $350 and $650 per ton and is inclusive of management, planning/reporting, mobilization/demobilization, equipment, labor, laboratory analysis, power, and waste management (for example, disposal of postprocessed fines not meeting AK DEC CULs and spent water treatment media). These costs are competitive when compared to off-site disposal, especially in more remote project locations such as parts of Alaska.

For example, the cost of off-site disposal for this project was estimated to be almost $500 per ton just for labor and materials for loading, transportation, and disposal of PFAS-impacted soils via rail from the project location in Alaska to a Subtitle D landfill with leachate collection system in Oregon. This off-site disposal unit price does not include management, laboratory analysis and waste profiling, and reporting. Therefore, the cost per unit for soil washing provided above is very competitive. Additionally, soil washing minimizes generator risk by significantly reducing (in this case by 83%) the amount of PFAS-impacted soils requiring off-site transport and disposal to a long-term managed land application out of state. This risk is exacerbated by the ever-changing regulatory atmosphere surrounding PFAS, which is only expected to require more PFAS-impacted soils to be managed with disposal costs likely increasing over time.

15.3 Risk Assessment Case Study (2020)

The New Jersey Department of Environmental Protection (NJDEP) Division of Science, Research, and Environmental Health conducted an initial assessment of PFAS impacts at a select group of surface water bodies in New Jersey (**NJDEP 2018**) (**Figure 15-20**). The results of fish tissue sampling from each site were used in a risk assessment methodology to determine the need for fish consumption advisories for PFAS in each of those water bodies.



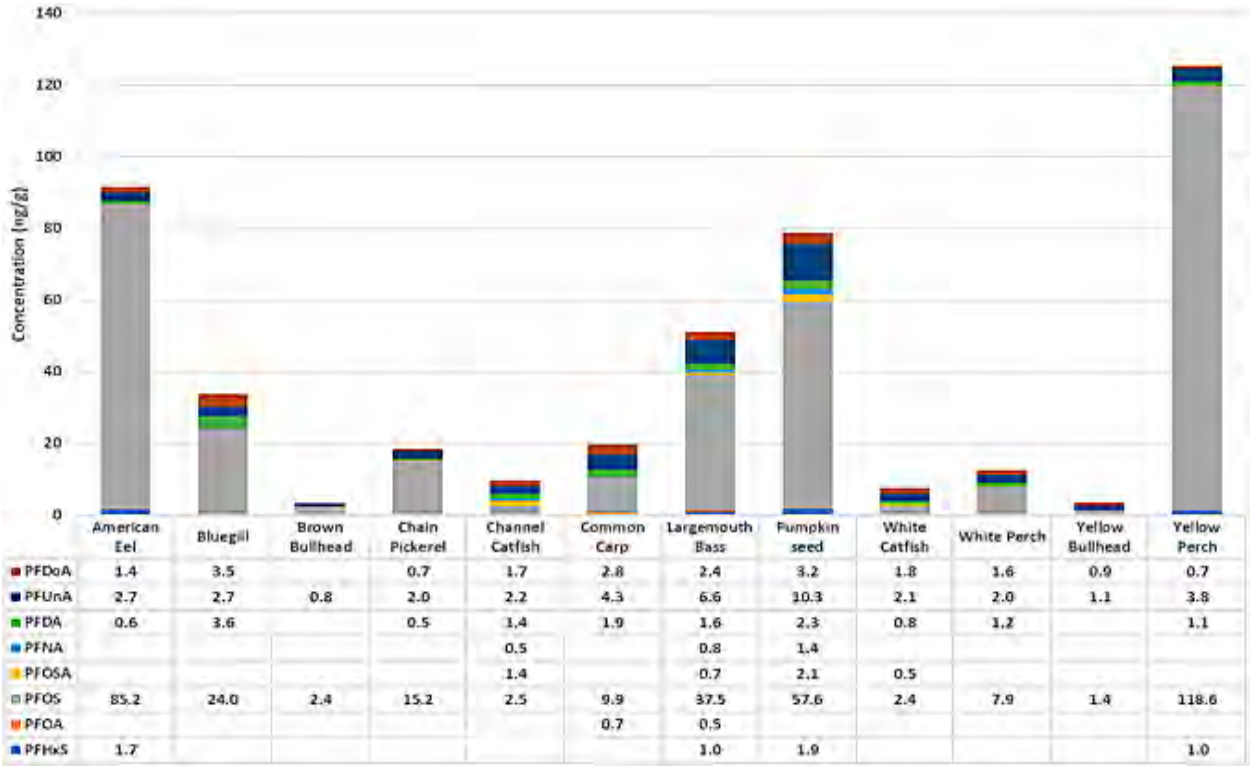


Figure 15-20. Map of water bodies included in NJDEP fish tissue study.

Overall, fish tissue samples from up to 12 different species were collected from 11 specific water bodies throughout the state. The water bodies were selected for sampling based upon their location relative to possible PFAS sources and the likelihood that they could be used for recreational fishing. Samples were analyzed for 13 PFAS (PFBA, PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnA, PFDoA, PFBS, PFHxS, PFOS, and PFOSA), and as presented in **Figure 15-21**, the results indicated that the predominant PFAS detected in the fish tissues was PFOS.

	American Eel	Bluegill	Brown Bullhead	Chain Pickerel	Channel Catfish	Common Carp	Largemouth Bass	Pumpkin seed	White Catfish	White Perch	Yellow Bullhead	Yellow Perch
PFDoA	1.4	3.5		0.7	1.7	2.8	2.4	3.2	1.8	1.6	0.9	0.7
PFUnA	2.7	2.7	0.8	2.0	2.2	4.3	6.6	10.3	2.1	2.0	1.1	3.8

*Data from **NJDEP (2018)**.*

Using the noncancer oral reference doses (RfDs) New Jersey Department of Environmental Protection derived for PFOA [2 ng/kg-day; (**NJDWQI 2017**)], PFOS [1.8 ng/kg-day; (**NJDWQI, 2018**)], and PFNA [0.74 ng/kg-day; (**NJDWQI 2015**)], and generic conservative assumptions regarding fish consumption exposure, NJDEP derived risk-based advisory triggers for each of these compounds based upon different fish consumption frequencies specifically, once/day, once/week, once/month, once/3 months, once/year.

The following equation was used to derive their risk-based triggers (which are presented in **Figure 15-22**):

$$C_{fish} = HQ \cdot RfD \left(\frac{BW \cdot AT_{nc}}{M \cdot CR} \right)$$

where

- C_{fish} is the risk-based fish concentration (ng/g)
- HQ is the target hazard quotient = 1 (unitless)
- M is the number of meals during the exposure period
- CR is the fish consumption rate (g/meal) = 8 oz/meal (227 gram/meal)
- BW is the body weight (kg) = 70 kg
- RfD is the chemical-specific oral reference dose (ng/kg-day)
- AT_{nc} is the noncancer averaging time (days)

	General Population			High Risk Population*		
	PFOA (ng/g; ppb)	PFNA (ng/g; ppb)	PFOS (ng/g; ppb)	PFOA (ng/g; ppb)	PFNA (ng/g; ppb)	PFOS (ng/g; ppb)
Unlimited	0.62	0.23	0.56	0.62	0.23	0.56
Once/Week	4.3	1.6	3.9	4.3	1.6	3.9
Once/Month	18.6	6.9	17	18.6	6.9	17
Once/3 months	57	21	51	N/A	N/A	N/A
Once/Year	226	84	204	N/A	N/A	N/A
Do Not Eat	>226	>84	>204	>18.6	>6.9	>17

**High risk individuals are considered to be at higher risk from contaminants in fish than members of the general public. This group includes infants, children, pregnant women, nursing mothers and women of childbearing age.*

Figure 15-22. Risk-based fish advisory triggers.

*Data from **NJDEP (2018)**.*

Because of concerns associated with the potential developmental health effects associated with these chemicals and given a lack of acute toxicity values for these compounds, NJDEP did not recommend advisory levels for the once/3 months and once/year exposure frequencies for high risj populations (young children, pregnant and lactating women, women of childbearing age), and the once/month value is the least frequent consumption category recommended for these high risk populations.

A comparison of the derived risk-based advisory levels with the measured concentrations in fish tissue samples from each of these waterways resulted in NJDEP recommending the following fish consumption advisories for the general population (**Figure 15-23**).

Site	Advisory (Driven By)
Echo Lake Reservoir	No more than once/month (PFOS, Largemouth Bass)
Passaic River 1&2	No more than once/3 months (PFOS, Largemouth Bass-Bluegill Sunfish)
Raritan River	No more than once/month (PFOS, Common Carp-White Perch)
Metedeconk 1&2	No more than once/3 months (PFOS, Largemouth Bass)
Pine Lake	No more than once/year (PFOS, American Eel-Largemouth Bass-Pumpkinseed Sunfish)
Horicon Lake	No more than once/month (PFOS, Chain Pickerel)
Little Pine Lake	No more than once/year (PFOS, Largemouth Bass-Yellow Perch)
Mirror Lake	No more than once/3 months (PFOS, American Eel-Bluegill Sunfish-Largemouth Bass)
Woodbury Creek	No more than once/3 months (PFOS, Largemouth Bass-Pumpkinseed Sunfish)
Fenwick Creek	No more than once/month (PFOS, Common Carp)
Cohansey River 1&2	No more than once/week (PFOS, White Perch)

15.4 Risk Communication Case Studies

15.4.1 Little Hocking Water Association (LHWA), Ohio (2020)

The communication and community participation strategy used for residents served by the Little Hocking Water Association (LHWA) in southwest Ohio produced effective results in motivating actions by

individuals, government, and industry which led to a significant, measurable reduction in residents' blood PFOA levels.

A community-first strategy was implemented at the Little Hocking, Ohio, site to effectively communicate scientific results and findings in a manner that embodies the principles of community-based participatory research (CBPR). This type of strategy combines scientific methodology with community capacity-building strategies to address the disparities and power imbalances among stakeholder groups (business owners, residents, regulatory, and responsible party). If properly implemented, CBPR can result in trust rebuilding, management of environmental justice matters, empowerment to those affected by providing information for informed action, and improved research and data collection (**Viswanathan et al. 2004**; **Hartwig, Calleson, and Williams 2006**; **O'Fallon, Tyson, and Dearry 2000**; **Executive Order 12898 1994**). The following is a case study summary of the Little Hocking, Ohio, site (**Emmett et al. 2006**; **Emmett et al. 2009**; **Emmett and Desai 2010**).

15.4.1.1 Site Description

The LHWA is a rural water authority that serves several small communities with a total population of approximately 12,000 residents in 4,000 households. The reticulation system extends around 25 miles into Ohio from Little Hocking, a small rural community along the Ohio River in Washington County, Appalachian Ohio. Based on the 2010 U.S. Census, the total population of Little Hocking was 263, predominately Caucasian, majority between the ages of 18–64 years, and 21.5% of individuals live below the poverty level. The water intake wells for the LHWA are located directly across the Ohio River from a Teflon production plant that used ammonium perfluorooctanoate (APFO, the ammonium salt of PFOA). This plant was physically located in West Virginia; therefore, the enforcement and regulation of the plant and its emissions fell to the West Virginia agencies.

Since the 1950, the plant was known to historically release APFO into the air and water and to dispose of byproducts containing APFO in local landfills (**WV DEP 2002**). APFO readily converts to its anionic form, PFOA, in the environment. When tested in 2001 and 2002, the LHWA source wells had levels ranging from 0.855 ppb to 7.69 ppb. Community concerns were raised because PFOA detections in the water supply were considerably higher than any reported PWS in the United States at the time. Prior to the study summarized here, there was no information about the sources of PFOA that was being detected in human blood in widespread locations. In the absence of this information, the West Virginia Department of Environmental Protection convened the C-8 Assessment of Toxicity Team, and developed a health protective screening level for water at 150 ppb. In addition, an interim action level of 14 ppb was established by a USEPA Consent Order with the responsible party. In August 2002, groundwater borings advanced in the LHWA well field contained PFOA concentrations up to 78 ppb. A class action suit was initiated, and distrust increased among the affected community and both the government and responsible party.

To investigate community concerns about potential PFOA contamination of residents in the LHWA district, a partnership was formed between the University of Pennsylvania School of Medicine, a local health provider, and the Decatur Community Association, made up of residents living within the LHWA district. The partnership obtained an environmental justice research grant from the National Institute of Environmental Health Sciences. The research was designed to engage the affected community on all aspects of the study to determine (1) whether blood PFOA levels were elevated in the community, compared with Philadelphia residents and with published population values; (2) if blood PFOA levels were elevated, was the source air, water, or some other combination of exposures; and (3) if levels were elevated, were there changes in certain biomarkers of potential toxic effects.

A community advisory committee (CAC) was formed with local residents served by the water supply, local physicians, state and federal government representatives, a health researcher, and a school system representative. A community project coordinator was employed as a communication enabler. The CAC

met quarterly and all meetings were open to the public with the only participation restrictions being that the attorneys and plant representatives were not permitted to take part in the discussions. Community advice was particularly sought as to which scientific questions to address, development and wording of questionnaires, communications with residents, and citizen concerns. The CAC utilized newsletters to keep local residents and other stakeholders informed. These newsletters and CAC meeting minutes were posted on a CAC study website.

The study team collected blood serum PFOA, hematologic and biochemical biomarkers, a questionnaire to obtain information on demographic and occupational information, and health conditions from a stratified random sample of residents in the LHWA reticulation area. The median blood PFOA levels for residents were approximately 80 times those of the general population and similar to levels reported for production workers at the fluoropolymer facility. PFOA levels were higher in children and the elderly. Residents using LHWA water who worked in production areas of the plant had PFOA levels that reflected additive effects from both exposure pathways. Residents who primarily used well water for domestic purposes had PFOA levels that correlated with the PFOA concentration in well water. No impact was seen from living in areas with higher estimated air levels.

15.4.1.2 Community-First Communication Strategy

After data had been collected from participants, but before any results were available, the CAC discussed and developed a communication strategy. For this purpose, the CAC developed a set of general principles for communication and a list of priority targets representing the community's preferred order for communication of results:

LHWA Residents' General Principles for Communications, from **Emmett and Desai (2010)** and **Emmett et al. (2009)**.

- Results should be released promptly, but not before the investigators are comfortable in doing so.
- Individual participants should receive their results first to avoid participants first learning study results from the press, neighbors, or friends.
- The press should be informed in a manner that is both timely and allows the investigators to control the message as much as possible.
- The study must remain a credible source of information.
- Communications should maximize constructive responses to the findings.
- Communications should minimize pointless concern.
- Questions from individuals should be answered promptly.

LHWA District Residents' List of Priority Targets for Communication of Results, from **Emmett et al. (2009)**.

- study participants and community (residents of the water district)
- community advisory committee
- relevant authorities and representatives (county and state health departments, state Department of Environmental Protection, local water authorities, state and federal elected government representatives for the area, local townships, sheriffs' departments, USEPA)
- local medical providers
- local media
- national media, as necessary.

Once the general principles of engagement were established, the CAC developed a communication strategy and plan. The CAC determined that the strategy required multiple modes of engagement that enforced consistent simple messages and consideration of careful timing to mitigate development of inaccurate perception of risk and management strategies. The communication plan was a "living

document" to facilitate continued integration of stakeholder input, regulatory development, and scientific advancement. The sequence of communications commenced with mailings to participants at the end of July 2005 and culminated in a community meeting on August 15, 2005, where full results were presented.

15.4.1.3 Results and Use of Risk Communication Tools

1. *Notifications to Participants and Authorities*—Biomonitoring results were sent via next-day-delivery mailings to individual study participants. These results included the individual's blood PFOA and biomarker levels as well as comparative information on PFOA levels (including blood levels for national and site facility workers, general US population, and community neighborhoods) and a toll-free telephone number to contact a study physician with any questions. Letters containing aggregated, not individual, results were sent simultaneously to identified authorities and CAC members, to ensure that recipients would be able to respond appropriately to inquiries from the public.
    - *Lessons and Takeaways*: Calls often needed to be returned after business hours. Most concerns focused on higher levels in children and the elderly, and possible interactions of elevated PFOA levels and particular medical conditions.

2. *Initial Press Release and Briefing*—Key local and regional media were identified and informed of the communication plan around the date the participant letters were sent. An initial press release and briefing were made the second day after the results were mailed to ensure that participants did not first learn of the issue through the press, while still providing investigators an opportunity to be the primary source of information to the press. Identified media representatives and national news outlets were invited to the news briefing. The release simply identified that levels in LHWA residents were much higher than those in the general US population, and that water had been identified as the major source of exposure. Interested stakeholders were urged to attend a community meeting where comprehensive results would be released and discussed.
    - *Lessons and Takeaways:* The reporting by local and national media did not misconstrue information and local media participated as per the communication plan. The CAC perceived the media coverage as constructive. The community expressed great satisfaction that participants had received their results first.

3. *Closed Rehearsal of Community Presentation*—A full closed-door rehearsal presentation (summarized in the subsequent bullet) was presented by the study team to the CAC prior to the community meeting. The closed rehearsal ensured that the community meeting presentation was as inclusive and useful as possible.
    - *Lessons and Take-Away:* The CAC requested a presentation that was careful and simple to understand, incorporating a clear visual map so that residents could locate their residences with respect to the study results. During rehearsal, the CAC members provided feedback on the order of the agenda, comprehensibility of slides, choice of wordings to accord with terminology and usage in the area, structure of the presentation, and dealing with likely questions.

4. *Community Meeting*—The meeting commenced with "ground rules," such as lawyers were not to solicit clients and questions were to follow the presentation. It was also communicated that continual stakeholder feedback is a success factor of the communication plan. In addition, representatives from the facility were invited to attend but were not permitted to present. The 45-minute presentation given by the study team detailed partnership objectives and study methods, results, and recommendations. A two-hour question and answer period followed the presentation. A summary of the study, recommendations (including the use of bottled water), sources of information, and how to access a study physician were distributed to all attendees on

exit. The meeting summary and information on accessing free bottled water were mailed to households in the LHWA district and local authorities and representatives.

- *Lessons and Takeaways:* The meeting proceeded in a constructive manner as CAC community members had predicted and not in the angry manner outside public relations experts had predicted. Any anger was directed at the responsible party and not at the investigators.

5. *Publication of Results and Information*—Following the community meeting, a newsletter with test result summaries was issued. A website with meeting presentation slides, test results, and FAQs was also developed. A summary of results was sent to all LHWA district residents.
    - *Lessons and Takeaways:* The website received many hits. The study and recommendations did not prove controversial. The practitioners did not encounter antagonistic relationships between the different parties.

6. *Availability to Answer Questions*—Physicians from the study team made themselves available to the public to answer questions from individuals and also from treating health care professionals.
    - *Lessons and Takeaways*: This service was appreciated. Questions mostly focused on the impact on residents with particular conditions such as liver and kidney disease. The many uncertainties surrounding the risk to humans were openly acknowledged.

15.4.1.4 Effectiveness of Communications

On the day results were presented and approximately 2 weeks after the initial press release, the responsible party announced that it would make free bottled water available to LHWA district residents (3 liters per day per person). Seventy-eight percent of eligible households accepted the offer.

Sixteen months after dissemination of the study results, a follow-up study of participants was made, which included repeat blood PFOA levels and questions about any changes in water usage. Sixty-five percent of those in the initial study participated in the follow-up, of whom 95 percent had made some change in their residential water usage in a way that would be expected to reduce PFOA intake. Eighty-eight percent had followed study recommendations to switch to using bottled water. The group median blood PFOA had declined 26%, consistent with a large effect for a pollutant with a half-life of approximately 4 years in humans.

USEPA used the results to enter into a consent agreement with DuPont to provide bottled water for the other impacted communities near the plant with >0.5 ppb of PFOA in water, and the states of Minnesota and New Jersey set provisional standards for PFOA levels in drinking water.

Lessons and Takeaways: The results and communications strategy resulted in 95% of participants had made a change to their water source. This response greatly exceeds the usual level of response seen with public health interventions. All parties, individuals, corporations, and governments acted in a prudent way with the disseminated information. Not all residents reacted by adopting the specific recommendations from the study; the alternate actions some individuals took are consistent with the information being incorporated into individuals' own risk perceptions and with the development of a free market of solutions (individual decision making based on available information).

15.4.1.5 Case Study Summary

The Little Hocking Community-First Communication Strategy resulted in a great increase in alternate water source use by impacted community members and subsequently, a reduction in community PFOA

blood levels. The success of the communication plan at the Little Hocking site was underlain by the four dimensions of risk communication:

- **Understanding:** Investigators worked with the community through the CAC to establish the communities' preferences and priorities in the form of a communication strategy and plan to maintain simplified and consistent messaging among stakeholder groups and interested parties, such as the media.

- **Perception:** Risk perception factors were incorporated into the outreach strategy, including residents' knowledge of PFOA biomonitoring results and associated illnesses, ability to access a physician, presence of vulnerable subpopulations (higher PFOA levels in children and the elderly), proximity of individual residences to elevated concentrations within the study area (sense of a safe place), and possible interactions of elevated PFOA levels and particular medical conditions.

- **Participation:** The affected community actively participated in all components of the communications.

- **Evaluation:** Success and effectiveness of the communication process were assessed based on feedback from the CAC, surveys of residents, and review of newspaper articles and other media content. In addition, a follow-up study was performed that addressed the effectiveness in terms of lowered blood levels of PFOA and a questionnaire about whether and how community members had changed their drinking water source as a result of the risk communication strategy.

15.4.2 State-Led Community Involvement Case Studies (2020)

The Environmental Council of the States (ECOS), in collaboration with the USEPA Office of Research and Development and the Association of State and Territorial Health Professionals, has developed a series of case studies presenting how state regulatory agencies are performing risk communication to PFAS-impacted stakeholders: **https://www.ecos.org/documents/state-level-risk-communication-of-pfas-and-habs/**

15.4.3 Washington County, MN: A State's Approach to Risk Communication (2020)

Washington County is home to 3M's Cottage Grove manufacturing facility as well as several disposal facilities where PFAS had been routinely disposed. Beginning in 2002, the State of Minnesota pursued drinking water investigations at the 3M facility and later near 3M's waste disposal sites in Washington County. According to the 2010 US Census, the population of Washington County, Minnesota was about 238,136, with the majority being Caucasian and between the ages of 18 and 64. Over 1,800 private wells, four major aquifers, eight municipal water supply systems, and over 150 square miles of groundwater were affected by the contamination. This impacted the drinking water supply of over 140,000 residents. After they were determined as the responsible party, 3M remained involved in the remediation efforts and paid for the majority of sampling throughout the county in coordination with MPCA.

This case study is discussed in the context of the risk communication plan.

15.4.3.1 Identify the Issue

The most widespread PFAS compound found in the region is PFBA. Additional prominent compounds include PFOS, PFOA, PFHxS. PFPeA, PFHxA, and PFBS which were always present as a mixture. When investigations began in 2002, there were many challenges to determining the impact for people as the science was in the very beginning stages of development. Therefore, MDH developed health-based

guidance for PFOA and PFOS and the MDH lab developed the method to analyze water sample for PFOA and PFOS. As the science has progressed, MDH continues to update methods and health-based guidance.

Site communications are organized and performed in collaboration primarily between the Minnesota Department of Health and the Minnesota Pollution Control agencies. However, as with other PFAS sites, the site covers multiple local, county and state entities. Communications frequently entail only one or a few cities rather than the entire site. They may also need to be coordinated through all the cities and the county. This leads to multiple plans with multiple partners that are specific to an issue or communications plans developed for a specific project. The fundamental traits of successful risk communication over time and with all stakeholders for MDH include: empathy, care, competence, expertise, honesty, dedication, and commitment.

15.4.3.2 Set Goals

General communication goals and objectives for the site:

- Goal: Inform people about potential hazards to their person, property, or community and help them to make informed decisions about risks to their health.
    - Objective: Develop approved message blocks for PFAS topics and house in accessible format to encourage consistent information is used for all materials developed.
    - Objective: Provide regular updates about remediation activities at stakeholder group meetings including agency PFAS training meetings, county workgroup meetings, city council meetings and public meetings
    - Objective: Provide regular updates about health risks as scientific information changes/evolves at stakeholder group meetings including agency PFAS training meetings, county workgroup meetings, city council meetings and public meetings
- Goal: Encourage people to take precautions to reduce exposure to PFAS
    - Objective: Homes with contaminated drinking water are issued drinking water advisories and either connected to the city water or supplied with GAC filters that are maintained by the state.
    - Objective: Keep updated information about actions people can take to lower their exposure to PFAS on MDH website and MPCA website.
    - Objective: Mobilize stakeholder groups in the county or local communities to encourage people in their area to participate in remediation activities and processes offered by MPCA and contractors.
- Goal: Provide background information and present risks in an understandable way, using plain-language messaging.
    - Objective: Provide opportunities for people impacted by contamination to connect with appropriate staff to find information and to ask questions if concerned.
    - Objective: User test materials using MDH Plain Language Workgroup

- Goal: Bring new information as soon as available to build trust
    - Objective: Provide public meetings with open house sessions before and after a main presentation to bring new information to community
    - Objective: Provide availability sessions to encourage concerned people impacted by changes to learn more about their individual situations.

Project specific communications goals example:

Since 2002, there have been multiple changes in PFAS health based values provided by MDH, analytical advances which have impacted lab results, an investigation that looked at PFAS in garden produce and dust, multiple biomonitoring studies, fish monitoring and consumption guidance, drinking water and source water investigations, and a study to test point-of-use water treatment devices. All of these projects and scientific advances have resulted in specific communications to affected communities with goals and objectives tailored to the issue or project.

15.4.3.3 Identify Communities and Constraints

MDH catered their risk communication strategy to the following:

- Residents of affected communities
- Local governments: cities, townships, and their staff of varying sizes
- Washington County public health and environmental staff
- Legislators
- Other state agencies including MPCA

Constraints include the size of the area and the multiple local governments. The character of each township and city vary widely with different capacities to manage local information dissemination to affected residents. This requires communicators to develop relationships with each stakeholder group. The risks and impacts of PFAS contamination are managed differently for those on public water and private wells. Therefore, the correct information needs to be available in many different forms for different stakeholders.

15.4.3.4 Community and Stakeholder Assessment

Minnesota's risk communication strategy in response to the Washington County PFAS drinking water contamination has been centered around community engagement and forging strong relationships with community members. Building these relationships enabled them to build trust with the community and develop new communication channels.

The Minnesota Department of Health (MDH), in conjunction with the Minnesota Pollution Control Agency (MPCA), maintains a hands-on risk communication approach. Information about community needs for information is gathered through regular update meetings with stakeholder groups and local government leaders. Public meetings, availability sessions and face to face interactions with community members during remediation activities provides a base of information for the ongoing communication efforts. MDH also maintains a 24/7 email and phone line for people to access with concerns or for information about site activities.

Minnesota had been engaging directly with affected communities since 2002. Having had a long-standing relationship with affected communities, MDH has a history of responding to the specific needs of the affected communities and has tailored its messaging to their knowledge level. Although basic information about PFAS is always available, the general level of knowledge amongst key stakeholders is

high. For this reason and with these communities, MDH representatives lead with high-level information, as the attendees to the public meetings typically are interested in specific updates as opposed to rudimentary background information.

15.4.3.5 Identify Messages

MDH maintains a message block document with approved message blocks about a variety of topics for internal staff use. This document serves as the basis for specific information sheets developed for different stakeholder activities. It is also a resource to answer questions from concerned community members. Topics include health risk of PFAS, MDH guidance value information, current site activities, exposure information, fish consumption guidance, swimming, cumulative health risk, breastfeeding and health risks, PFAS and links to health problems, testing blood for PFAS, biomonitoring information, gardening and PFAS, and results of MN Cancer Surveillance System reports.

MDH notes the importance of discussing the scientific method with stakeholders to remain transparent about their course of action. They also share new knowledge as it becomes available and do not wait until they have a perfect message or until they know all of the facts to engage with the community. In an effort to uphold their principle of transparency, MDH acknowledges points of uncertainty and are clear about what they do not know when communicating with the public.

The messages are presented in different ways to different communities depending on the level of understanding that a community has about PFAS. For example, we had several meetings in 2018 for communities. One meeting was to a community which had not had PFAS contamination issues until 2018. The information for this community was presented in more of an elementary, broad overview style and level. Another presentation in the same month was to a neighboring community that had been involved with PFAS contamination since 2002. The presentation focused more on what the new information was rather than PFAS basics as the community had a more developed understanding of PFAS.

Examples of specific messages:

- Testing is available for households on private wells that would like their drinking water tested for PFAS. If test results show elevated levels, options are available from the MPCA for treating the water and reducing exposures.
- Currently, PFAS levels found in the drinking water supply in impacted communities have been within the margin of safety for the current drinking water guidance values, and outright negative health effects from these exposures are not expected with what is currently known about PFAS exposures and health effects.
- Affected water supplies are safe to use to water produce in home gardens.
- Biomonitoring Data Shows Interventions are working

Figure 15-24 includes biomonitoring data for three PFAS compounds over the time period from 2008 to 2012. This study shows that although we can't answer questions about health effects, we can demonstrate the work we are doing to reduce exposures has paid off.

- Because of the extreme persistence and mobility of these compounds, a PFAS megaplume developed which is much larger than early modeling predicted. One of the primary factors in this was the unanticipated transport of PFAS via surface water and then re-infiltration to groundwater far away from the source areas – a transport pathway not typically seen in persistent environmental contaminants, which tend to adsorb to organic carbon in soils and sediments.

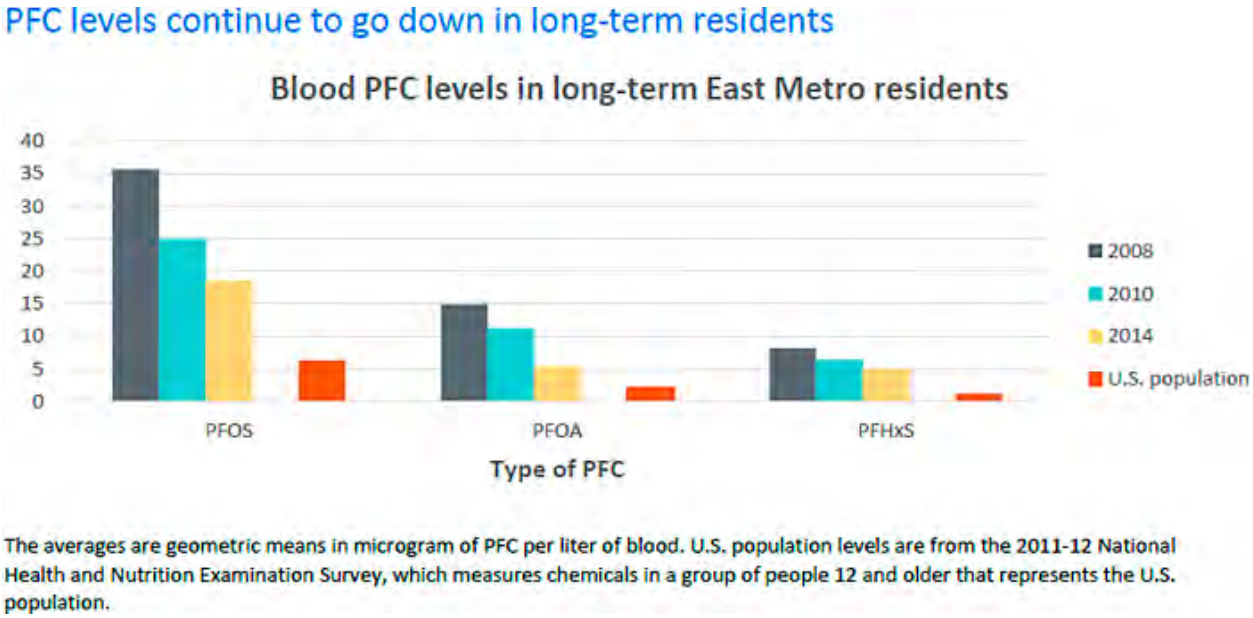

Figure 15-24. Biomonitoring Data.

15.4.3.6 Select Communication and Engagement Tools

MDH's risk communication strategy facilitates community engagement and open dialogue.

- Engaging with stakeholders and communities as soon as possible when there is any change in risk management of PFAS. Builds trust over time that MDH will be there to support and help communities.
- MDH sends the right people/experts/staff to deliver messages. Over time, staff have built relationships with stakeholders.
- When interacting with people impacted by the site, staff stays until all questions are answered – whether it is a phone call, a public meeting or availability session
- MDH has a service-oriented approach to community engagement. They recognize that educating the community members will carry a ripple effect. Attendees from the meetings who learn through the presentations and the open house format will then take the information and share it with other members of the community.

MDH used the following strategies to connect with and inform the affected communities:

- Hosting Public Meetings: Public meetings have been a significant part of community engagement in Washington County. MDH has held public meetings in an open house, presentation, and Q&A format. An open house is followed by a presentation given to the attendees, after which they provide a time for questions and answers, followed by additional open house time. Participants are able to ask questions about their particular situations in an open forum setting or in one-to-one conversations. For example, in Spring 2017, MDH in collaboration with MPCA held two presentations in different areas of Washington County. The city of Cottage Grove meeting attracted 130 people. In Lake Elmo, a region where the majority of residents have private wells, approximately 120 people attended the public meeting.

- Hosting Availability Sessions/Office Hours: MDH organized opportunities to provide people with time to interact with staff one on one and ask questions. Typically, MDH held these events after major sampling events happened or when new or updated information was released. MDH extended these opportunities upon request of the community. The events were widely used. In an event held in Fall 2017, the office hours held in Lake Elmo where the majority of residents have private wells attracted 45 people. With the affected area being so large, personal communication was helpful in establishing relationships with members of the community.

- Providing Online Resources: The MDH website outlined the history of PFAS in Minnesota as well as actions they have taken and health-based guidance information. An electronic online sampling request form was available on the MDH website. An electronic map on the website shows where MDH is sampling and community members could see and check their property's location in relation to the PFAS contaminated sites. MDH also had a widely used email address for residents to ask questions directly to the department. They could also subscribe to the government's delivery email list to get new information directly to their inbox.

- Communicating with Local Government: MDH prioritized communication with local government because it was a useful tool in keeping the communities informed. They visited city councils to provide updates on the PFAS investigations. They also provided technical support to local governments and their staff that were responsible for protecting public drinking water.

- Using the Media: MDH used press releases and interviews to disseminate information. Social media became a useful tool as well.

15.4.3.7 Implement Strategy

Strategies implemented included:

- Drinking Water Advisories: Over 2700 private wells have been sampled in the East Metro and over 1, 100 drinking water advisories have been issued. Homes that have been issued drinking water advisories are either connected to city water or provided bottled water and/or GAC filters maintained by the state. MDH and MPCA collaborated to communicate and coordinate action for this work.

- Public Water Systems: There are five community public water supplies in the East Metro that have individual wells above the MDH health-based guidance values. All of these cities put in place interim measures to manage their public water supply systems to provide drinking water at or below the MDH health-based guidance values. MDH collaborated with these communities to provide information to residents.

- Messages to Community: After developing health-based guidance values for PFAS compounds, MDH sought to explain to the community what these values mean and what concerns they address. They also explained the next steps in their action plan.

- Reiterating Commitment: MDH drives home the message that they are committed to bringing updated information to the communities to inform them of the status of their efforts. This assures the community that MDH is determined to support them and address their concerns.

- Collaboration with Other Stakeholders: MDH collaborated with MPCA on a response to the PFAS contamination. Any message that were released to the public by MDH was in conjunction with MPCA. ATSDR also developed a community engagement book which has guided MDH's risk communication strategy. Additionally, MDH worked closely with city administrators and community leaders to keep them informed prior to the public meetings.

- Concessions: When drinking water levels were found to be above guidance values in private wells, bottled water was provided by MPCA until a GAC system can be installed.

15.4.3.8 Evaluate, Debrief and Follow Up

Continuous improvement of risk communications and activities through evaluation and through providing feedback loops with stakeholders supports the ongoing implementation strategies described above. The sampling and remediation activities have been widely successful in part due to the community engagement and communications efforts that have built trust in the community for the state agencies.

Evaluation methods used to understand effectiveness of communications content and process include one on one surveys at events, hot washes with partner agencies after communications efforts, and feedback from community leaders at regular update meetings.

Continuously improving, refining, and developing materials to meet community concerns and needs that are identified by inquiries or contacts staff have with community members. Contacts are primarily through 24/7 email and phone line as well as in person while in the field or at public events.

Materials have been developed in many formats over the years and have changed due to capacity for communities to use various methods and MDH capacity to produce them – video, face to face meetings, print, social media in coordination with partners. Investigations and other information have also resulted from community concerns. These include Cancer Incidence Reports, home and garden study, site-specific meal advice for fish consumption, point-of-use filter testing, clinician information sheet, and an information sheet about testing blood for PFAS.

15.4.3.9 Successful Outcomes

The Minnesota Department of Health has been very successful in community engagement:

- They have earned the trust of the community, and residents are assured that MDH is working hard to solve the issue at hand. The number of people participating in sampling and remediation speaks to the efforts made to connect with affected people. Exit surveys from public events have shown that people feel staff are working hard and are good at the work they do.

- MDH also has invested their resources in research and has made strides in understanding the health impacts of the PFAS contamination their state is facing. Many of the investigations and projects were in response to concerns collected through contacts with community members and leaders. These include Cancer Incidence Reports, home and garden study, site specific meal advice for fish consumption, point-of-use filter testing, clinician information sheet, and an information sheet about testing blood for PFAS.

- They have used biomonitoring to demonstrate that their efforts have reduced the PFAS levels in people's bodies. This has provided the community with tangible evidence that the work they are doing is making a difference.

15.4.3.10 Lessons Learned

- It is vital to be on the ground and engage with the community face-to-face. This helps build trusting relationships with the community which has facilitated the remediation efforts and supported reducing exposures to PFAS for community members.

- The cross-agency effort to address the PFAS concerns in Minnesota is a challenge and takes effort to coordinate, but over time has been an effective strategy to address exposures to PFAS in a timely manner.

- Dealing with residential homes and homeowners can be complex. Because PFAS is a complex emerging contaminant for which research and information is constantly evolving, it can be a challenging to return to residents with new guidance values based on new health risks. The information has to fit for those who are familiar with PFAS and those who are new homeowners or residents in affected communities.

- It is important to learn what information residents are looking for and relay it in an articulate manner and in a way that is useful to them. Another concern Minnesota residents have had is a potential decline in property value, but this concern has faded with time.

- Additionally, it is important to be understanding and sympathetic toward the affected residents when they are upset. They are concerned for the well-being of their families.

15.4.3.11 Better Practices Moving Forward

Moving forward, MDH notes that sites across the state have similar circumstances and similar concerns. The lessons learned from sites they have already worked with have been beneficial in refining their approach with other affected communities and contaminants. They have had success with duplicating their strategies and methods at other sites. Although the general principles have been effective, every community is slightly different. MDH takes the time to understand the dynamics of each particular community and tailor their risk communication methods accordingly.

15.5 Surface Water Quality Case Studies

15.5.1 PFAS-Containing Foam (2023)

Case Study: Minnesota Project 1007 Feasibility Study (Contributed by Rebecca Higgins, MPCA)

15.5.1.1 Issue

The surfactant and micelle properties of per- and polyfluoroalkyl substances (PFAS) have proven to result in accumulation into foams on surface waters in many states. The observed foam has implications for exposure to people, aquatic life, wading and dabbling birds, and other wildlife. The concentrations of PFAS in these foams are documented to be thousands to millions of times higher than the concentrations in the water column.

15.5.1.2 Background

In May 2019, the Minnesota Department of Transportation (MNDOT) requested water sampling from the Minnesota Department of Health (MDH) within the area of a transit project in the East Metro of the Twin Cities Metropolitan Area (TCMA), potentially in an area of known PFAS contamination. In response, the MDH sampled surface water and foam above the surface water of Battle Creek located downstream from the area of interest for PFAS. At that time, analytical results indicated PFOS and PFOA impacts were present in the surface water at concentrations of 0.013 ppb and 0.017 ppb, respectively. Comparatively, PFOS and PFOA were present in the foam at 140,000 ppt and 11,000 ppt, respectively, indicating an enrichment compared to the paired surface water results.

In 2020, this occurrence of PFAS-containing foam led the Minnesota Pollution Control Agency (MPCA) to look for its presence as part of the Project 1007 Feasibility Study also in the East Metro under the 2018 3M settlement. Project 1007 conduit drains surface water across the northern portion of the east metropolitan area of the Twin Cities. Foam was noted on the surface of Raleigh Creek and in the corridor from the closed 3M Oakdale Disposal Site, and past the confluence of Raleigh Creek with the Project 1007 stormwater conduit (**Figure 15-25**). The foam was located on the flowing creek, stormwater ponds, and Lake Elmo. The foam was noted particularly after rain and wind events that occurred during the weeks of surface water and sediment sampling.

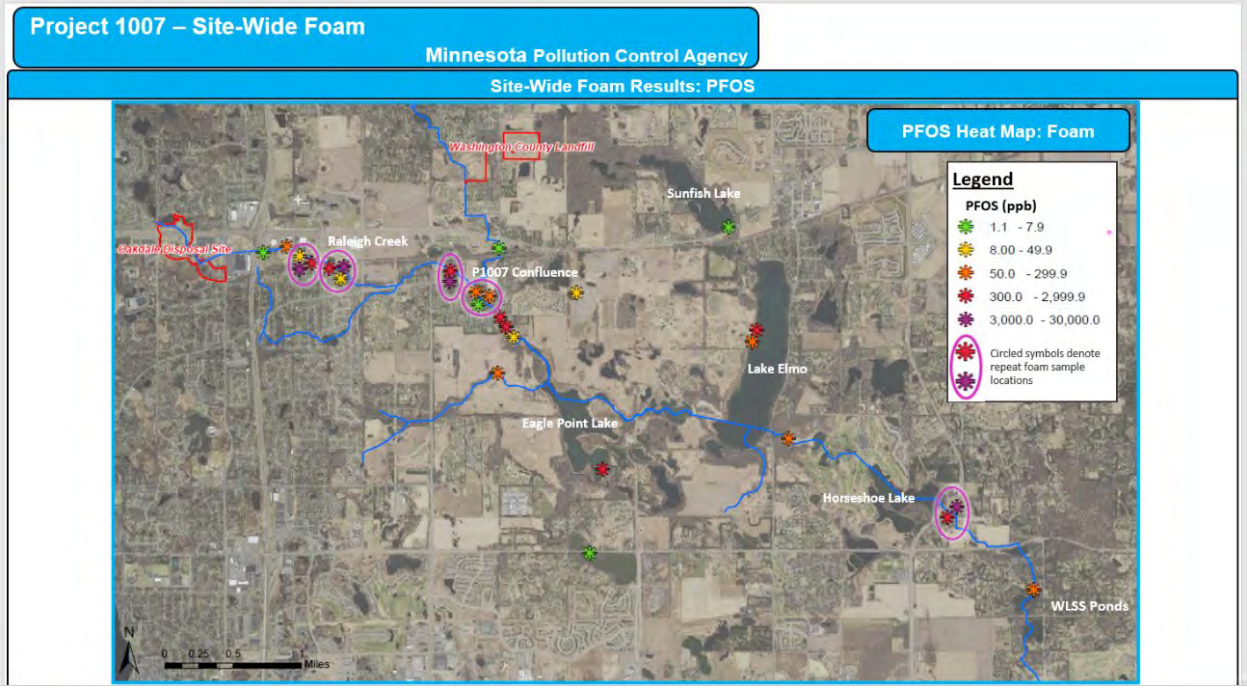

Figure 15-25. Heat map of PFAS-containing foam detections throughout Project 1007 study area.

*Source: Project 1007 Minnesota Pollution Control Agency (***MPCA 2023***).*

The foam has been collected throughout the feasibility study from surface water across the Project 1007 corridor in accordance with the Michigan PFAS Action Response Team (MPART) protocols (**MI EGLE 2019**). Following collection, the foam is allowed to condense in the PFAS-free baggie before being sent to AXYS SGS laboratory in Canada for analysis of up to 40 PFAS compounds. The foam samples are screened for potential high concentrations prior to analysis by AXYS SGS method MLA 110, which aids the laboratory in understanding the potential variation in foam concentrations prior to analysis.

15.5.1.3 PFAS-Containing Foam Varied Textures or Type

PFAS-containing foam can have several different appearances across the Project 1007 region. Specific types of foam were not tied to an exact location, precipitation events, or seasons apart from frozen foam. Examples of different foam types are shown in **Figure 15-26**.

At three locations in Project 1007 (RC5, RC7, and RC12) in 2020, foam was collected and analyzed for PFAS twice to assess potential variation in PFAS concentrations depending on foam type. At each location, a “fluffy” foam sample was collected for comparison against a “thin” foam. PFOS concentrations from the larger and fluffier piles of foam were between two and three orders of magnitude greater than

their thinner counterparts. The corresponding surface water samples had negligible variation in PFOS, suggesting that the PFAS enrichment in foam can be highly variable due to the environmental conditions.

Generic Foam Type	Description	Sampling Location Photo
Actively Generating and Reaccumulating	Foam is observed floating upstream of the accumulation point and continuing to actively accumulate at a location. Frequently source of generation is apparent, and foam will reaccumulate rapidly after sample collection. This foam can either accumulate in large quantities in singular locations or across a wide stretch of creek bank.	RC18A (5/5/20) 
Deflated (old)	Foam is typically thin, in smaller quantities, and discolored with organic matter present. Further, no foam is observed upstream or downstream of point of accumulation, and source of generation is not obvious. This foam is thought to be old because it has never been observed to be actively generating.	RC7 (8/12/2019) 
Frozen	Foam appears frozen, often has a different color and texture from surrounding snow and ice and is usually thin.	RC7A, 2/24/2020  EP19 2/25/20 

Figure 15-26. Examples of various PFAS-containing foam observations and characteristics.

*Source: Project 1007 Six-Month Investigation Progress Report, Minnesota Pollution Control Agency, October 13, 2020 (***MPCA 2020***).*

15.5.1.4 Formation and Accumulation

The requirements for PFAS-containing foam to form and accumulate are typically:

1. Turbulence—Air must be mixed into the water column for foam to form. This can be caused by water flowing over rocks, trees, or other debris in the stream. The water level greatly affects the locations of turbulence.

2. Solid substrate—After formation, the foam bubbles must have a solid substrate in relatively calmer water to accumulate along or against. Without accumulation, the foam bubbles will collapse back into the stream water column. Foam can be found to accumulate along the stream banks, debris, blocks of ice, and vegetation growing in the stream channel.

3. PFAS concentrations in surface water—Foam may naturally form regardless of the presence of PFAS. It is also not well understood how much PFAS will preferentially separate (enrich) into the foam relative to the PFAS in the corresponding surface water.

These and other factors affect the ability to predict occurrence and remediation of PFAS-containing foam. PFAS-containing foam has been encountered in surface water at the same order of magnitude (approximately 20 ppm) at a source area (Oakdale Disposal Site) and approximately 8 miles downgradient in the connected drainage system. Large masses of PFAS-containing foam have been visually noted to dissociate small portions of bubbles off from the larger mass, travelling downstream and potentially providing an additional PFAS source to the water bodies and/or sediments downstream. PFAS-containing foam has been observed to be intermittently present, as it may form and then dissolve back into the water column in a matter of minutes. This may impede response actions to removing the foam; reports of foam in known PFAS-impacted waters may not be present by the time a response action is attempted or it may form elsewhere in the surface water system.

15.5.1.5 PFAS-Containing Foam Enrichment Factors and Carbon Chain Length

An enrichment factor is the ratio of the PFAS concentration in the foam to that in the water (usually the top 6 inches of the water column). As shown in **Figure 15-27**, the enrichment factors for PFOS in the Project 1007 region varied by over an order of magnitude, supporting the environmental factors previously described as important to PFAS enrichment in foam in addition to PFOS concentrations in the corresponding surface water. The relative importance of environmental conditions that may influence PFAS enrichment are not well understood at this time.

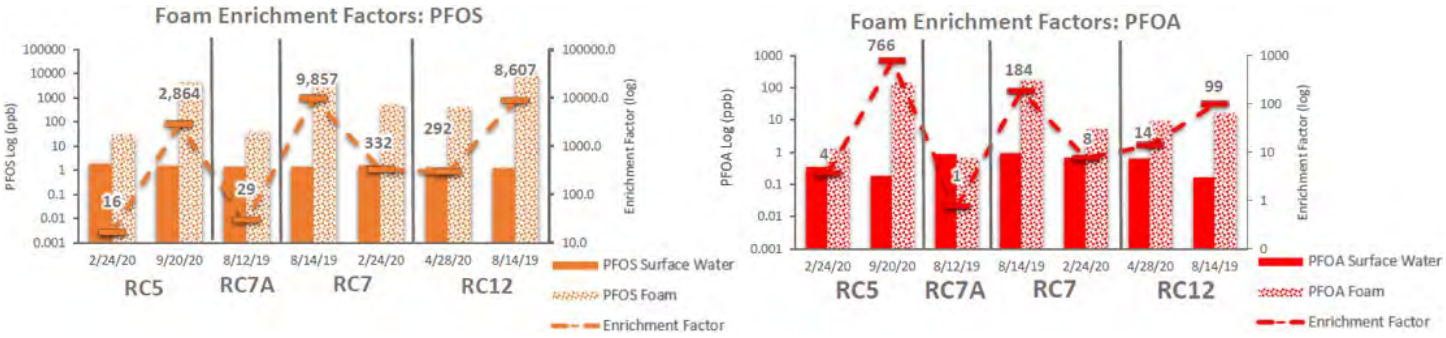

Figure 15-27. Foam enrichment factors for paired surface water and foam samples, showing PFOS and PFOA concentrations.

*Source: Project 1007 Minnesota Pollution Control Agency (***MPCA 2023***).*

Foam samples overwhelmingly consisted of long-chain PFSAs and PFCAs constituting up to 97% of the PFAS compounds in some samples (**Figure 15-28**). Longer chain PFAS like PFOA, PFOSA, PFOS, and N-EtFOSA tend to enrich or preferentially separate into the foam to a greater degree than shorter chain compounds like PFBA and PFBS because they are more hydrophobic.

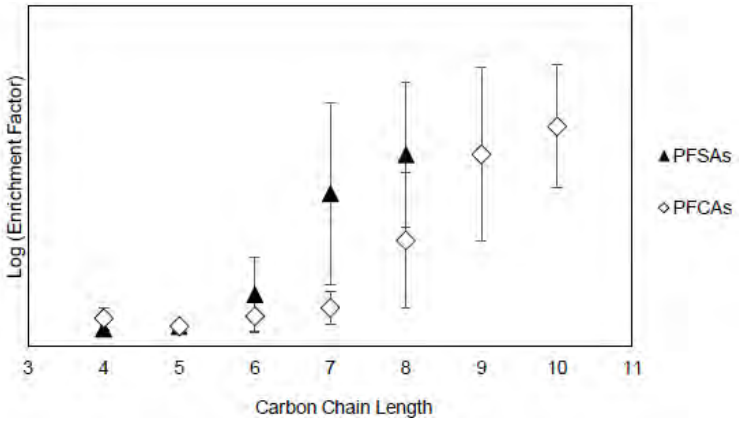

Figure 15-3. PFAS-containing foam enrichment factors and carbon chain length versus enrichment factors.

Source: Six-Month Investigation Progress Report (November 11, 2019—May 15, 2020) Project 1007 Minnesota Pollution Control Agency (MPCA 2020).

15.5.1.6 Risk Assessment

Risk assessments for PFAS are limited by lack of sufficient toxicological and exposure data for all but a few chemicals such as PFOS and PFOA. Therefore, to ensure protection to people and their pets who contact surface waters with PFAS-containing foams, the public needs to be broadly informed to avoid contact with any foam. Naturally occurring foams can also harbor bacteria and viruses. In areas with known PFAS contamination, targeted risk messages and outreach have also occurred.

According to the State of Michigan (**MI DHHS 2019**), incidental ingestion and extended, recurring, whole-body contact with PFAS-containing foam can result in a public health hazard for children and adults. Where PFAS-containing foam exists, the Michigan Department of Health and Human Services (MDHHS) recommends a health advisory to avoid the incidental ingestion of and whole-body contact with the foam as a precaution.

According to the Minnesota Department of Health (MDH), "PFAS-containing foam on surface water does not pose a risk to human health if skin contact with foam is minor and infrequent" **MPCA 2020**. MDH recommends informing people of observable foams in the PFAS-contaminated areas where concentrated PFAS could be encountered. Additionally, "MDH recommends:

- People and pets should avoid contact with foam on surface waters in this area.
- Wash skin that has come into contact with PFAS-containing foam with soap and water" **MPCA 2020**.

Other states, such as Wisconsin, provide a reporting system for suspected PFAS-containing foam across the state, and provide health advice to avoid the foam (**WI DNR 2022**).
More research is needed to determine how to estimate exposure to people, especially children; pets; aquatic organisms; water birds; and wildlife.

There are limitations on how to account for exposure estimates from foam concentrations, as well as the best way to sample for foam. Because the PFAS-containing foams form at the air-water interface, there are risks for higher exposure to swimmers, dabbling ducks, aquatic insects, etc., that are not accounted for with only collecting water column samples. Broad outreach to avoid any surface water foam is still not occurring.

In addition to outreach and messaging, using authorities from remediation or Clean Water Act regulations is critical for making progress on reducing the risks of PFAS to people and ecological species. Most

states and tribes have narrative standards in their water quality standards that prohibit nuisance conditions on surface waters. These could be applied to restrict sources causing PFAS-containing foams.

15.5.1.7 Take-Aways for PFAS-Containing Foam

Based on this case study, the following takeaways with respect to PFAS-containing foam are:

- Foam occurs on surface water bodies naturally but may contain PFAS compounds when located near a source of PFAS releases. The PFAS-containing foam may look like naturally occurring foam.
- The foam occurs more frequently during precipitation and wind events. The foam appears to be a concentrated form of PFAS compounds, at higher levels than PFAS occurring in the surface water below the foam.
- Based on data collected to date, the predominant forms of PFAS in the foam are the longer chain compounds such as PFOS, PFOA, PFOSA, and N-EtFOSA rather than the shorter chain compounds such as PFBA and PFBS.
- PFAS-containing foam has been found in multiple waters in the Twin Cities East Metro, including waters that border parks and residential areas such as Raleigh Creek and stormwater ponds in Oakdale (including Tablyn Park) and the city of Lake Elmo. PFAS-containing foam has also been found on Battle Creek in Battle Creek Regional Park in St. Paul. This has resulted in the need for institutional controls for new developments and specific outreach by letter to residents.
- The best risk assessment advice is to avoid any surface water foam, because even naturally occurring foam can carry microbial risk to people or pets contacting it.

What PFAS-Containing Foam Is Not

- Not all foam on surface water bodies contains PFAS.
- Where PFAS-impacted surface water exists, PFAS-containing foam may not always be present, as it occurs more frequently with precipitation and wind events.
- PFAS-containing foam may not be removable in all circumstances and may re-occur in locations where it has been previously removed.

More information on Project 1007 is located on the MPCA website (**MPCA 2023**).

15.5.2 Surface Water/Groundwater Interaction Case Study (2023)

As mentioned in Sections **16.4.5**, **5.3.4**, and **10.3.1.2**, surface water/groundwater interaction may play a role in a conceptual site model and locating places to sample. This case study provides three examples where this interaction can impact surface water quality.

15.5.2.1 North Carolina Example

The first example is found in the dialogue box in **Section 16.6.4.1** and looks at PFAS in groundwater impacting surface water. A surface water body in North Carolina was found to have unacceptable concentrations of PFAS. An adjacent industrial facility had caused the groundwater to be contaminated with the same PFAS. An investigation of the groundwater showed that it is discharging to the surface water and contributing approximately 60% of the PFAS load to the surface water. A portion of the remedy for the site included groundwater extraction, treatment, and discharge to reduce the mass flux of PFAS in groundwater to the receiving surface water (**NC DWR 2022**).

15.5.2.2 Minnesota Examples

The second example is from Minnesota and provides a case study of PFAS-contaminated groundwater impacting surface water and PFAS-contaminated surface water impacting groundwater. These processes have significantly contributed to a 150-square-mile PFAS plume in groundwater that has impacted eight municipal water systems and 2,700 individual private water supply wells in Washington County, east of St. Paul. Wastes containing high PFAS concentrations originating at a manufacturing facility were disposed in two off-site landfills and several burial pits at the industrial facility. PFAS contamination in groundwater was found downgradient from the two landfills. Additional locations of groundwater containing PFAS were found in areas that were not expected based on groundwater flow directions (westerly and southwesterly) at the landfills.

As it turns out, surface water emanating from wetlands around one landfill carried PFAS to the east where it infiltrated to groundwater 1 mile downstream. This groundwater resurfaced as surface water and flowed to the east in a system of creeks, ditches, and pipelines that entered several lakes and ponds. Stormwater runoff was conveyed by the same conveyance system providing additional transport of PFAS to the east. The surface water transport and the exfiltration from the conveyance features and lakes/ponds resulted in PFAS in groundwater along the surface water path and downgradient from the lakes. The PFAS contamination along this route was enhanced by the discharge of extracted groundwater containing PFAS and other pollutants adjacent the second landfill to the same stormwater conveyance system discussed above over a period of 7 years. This conveyance system terminates at the St. Croix River 6 miles downstream from the first landfill. Thus, at this site there is PFAS in groundwater, daylighting as a surface water and then re-entering groundwater as the water is transported downstream and temporarily resides in various lakes and pond. This results in exposure through use of the groundwater for municipal purposes and use of the surface waters for municipal purposes, fishing, recreation, and wildlife habitat. (**Regenesis 2019**).

The third example is from Minnesota and is a subset of the second example. In one location overlying the 150-square-mile groundwater PFAS plume is a site where several different mixtures of AFFF were used to put out a fire at a plastics manufacturer. The runoff from the fire suppression went down a ditch to a small surface water body. Migration of surface water to groundwater at that location resulted in contamination of groundwater by PFAS impacting several private water supply wells that were completed on the order of 250 feet in depth. Sampling showed that the less mobile, longer chained PFAS PFOS and PFHxS had the highest concentrations in the sediments along the ditch. The sediments at the surface water body still contained those two PFAS, but not at as high of a proportion relative to the more mobile, shorter chained PFAS PFOA and PFBA as found along the ditch. The water in the surface impoundment had substantially more PFOA and PFBA than PFOS and PFHxS. This shows not only the transport of PFAS in surface water to groundwater, but the changing composition of PFAS in the surface water due to varying portioning properties of PFAS.

15.5.2.3 Summary

These three examples demonstrate the need to assess the potential surface water/groundwater interactions when looking for sources of contamination, routes of exposure, and establishing a CSM. These examples show the potential for adverse impact, but do not provide an assessment of the potential change in PFAS constituents and concentrations that may occur during the movement of water from surface water to groundwater or groundwater to surface water. Those potential changes are associated with biotransformation that may occur due to water chemistry changes in the vicinity of the groundwater-surface water interface. A discussion of this issue is found in **Section 5.3.4.2**). An additional example of PFAS impacts from a groundwater/surface water interaction can be found in **Section 5.3.4**.

16 SURFACE WATER QUALITY

The purpose of this section is to support the PFAS Technical and Regulatory Guidance Document (PFAS Guidance Document) users (state and federal environmental staff, stakeholders, project managers, and decision makers) to gain a working knowledge of the current state of PFAS science and practice for surface water quality. The section does not include calculated criteria, rather it provides available information and references that can then be used to support development or review of criteria or guidance values to protect surface water quality.

Section Number	Topic

16.5	**Surface Water Foam**
16.6	**Effluent Limits for PFAS**
16.7	**Surface Water/Groundwater Interaction**

16.1 Introduction

This section provides information to help fill in the gaps related specifically to concerns with PFAS-impacted surface water and associated receptors. Several states have expressed a need for technical information to support the development of surface water quality criteria (WQC) or guidance values for uses other than drinking water, including but not limited to habitat for fish and other aquatic life. **USEPA (2020)** developed recommendations and provided derivation methods for surface water criteria "for determining when water has become unsafe for people and wildlife using the latest scientific knowledge." States and tribal governments may, and sometimes do, develop their own numerical criteria. To protect human health, the states and tribal governments may also establish water body–specific fish consumption advisories for certain aquatic species. These advisories are recommendations and not enforceable. This section provides technical information regarding PFAS in surface water that individual states and tribal governments can consider when developing criteria according to their own processes and policies. This information focuses on two main issues. First is the protection of human health from a variety of potential exposures to PFAS in surface water, such as drinking water, consumption of fish and other aquatic species, and from recreational activities. Second is the protection of biota, based on available ecotoxicity data, bioaccumulation and concentration factors, and aquatic-dependent wildlife considerations, among others.

USEPA has published draft national recommended aquatic life criteria for PFOA and PFOS in freshwater for public comment (**USEPA 2022**, **2022**) and a fact sheet for the criteria (**USEPA 2022**). In addition, USEPA had published their responses to external peer reviews of the draft criteria (**USEPA 2022**, **2022**). USEPA has also issued two memoranda for National Pollution Discharge Elimination System (NPDES) permits and PFAS. One addresses PFAS under USEPA-issued NPDES permits for wastewater and stormwater discharges (**USEPA 2022**) and the other discusses PFAS in state-issued NPDES permits and pretreatment programs (**USEPA 2022**). As of the writing of this document, there are few formally established surface water criteria for any PFAS that are protective of uses of surface water other than as

drinking water. Florida, Minnesota, and Michigan are examples of states that have aquatic life protection values (see the **Environmental Media Values Table** Excel file).

In addition to the well-established issues associated with PFAS in surface water, such as use of the surface water as a source of drinking water and accumulation of PFAS in biota, this section also includes a discussion of a relatively new issue related to surface water: PFAS-containing foam. Investigations in at least three states—Minnesota, Michigan, and Wisconsin—have found that concentrations of PFAS in surface water, or discharging to surface water, at sufficient levels can generate foam on surface water. That foam acts to remove PFAS from the water column, but also acts as a secondary source of PFAS as the foam leaves the surface water and is deposited in terrestrial or other aquatic locations.

16.1.1 Beneficial Uses

One of the first steps in developing the criteria is to determine the beneficial uses that are to be protected for the water body of concern. These have usually been developed by the state organization responsible for water quality and/or water resources for the state. That regulatory agency assesses potential beneficial uses and assigns appropriate designated uses for a water body. As examples, in Massachusetts this task is the responsibility of the Massachusetts Department of Environmental Protection, while in California it is under the purview of the nine Regional Water Quality Control Boards that establish potential beneficial and designated uses for the water bodies for each region. The process for establishing these beneficial uses in most instances follows protocol developed by **USEPA (2020)**.

With the potential adverse health effects associated with the ingestion of certain levels of various PFAS, negative impacts on beneficial uses of surface water may occur. Table 16.1 provides a fairly comprehensive list of potential beneficial uses for surface water. This table is a compendium taken from the *Water Quality Control Plan (Basin Plan) for the California Regional Water Quality Control Board, Central Valley Region, Fourth Edition, Sacramento and San Joaquin River Basins* (**RWQCB-CVR 2016**). Different jurisdictions use different lists of beneficial uses. The list in **Table 16-1** is used for illustration. For an evaluation of PFAS, the list may be substantially reduced in order to focus on those that are appropriate, as the presence of PFAS may not have an impact on a particular use (for example, navigation). In the table the list has been reduced by separating the beneficial uses that may be impacted by PFAS (light blue) and those that are not likely to be (light green). The list can be further reduced by combining several of the uses that evaluate similar issues, such as aquatic toxicity. As an example, the beneficial uses listed as WARM, COLD, EST, WILD, BIOL, and RARE (see **Table 16.1**) are each designed to protect aquatic species that have a range of attributes. The beneficial use for shellfish could be added to that grouping by expanding the evaluation under it to include benthic organisms and sediment quality.

Refining the list of beneficial uses reduces the number of evaluations to the following groupings:

1. Aquatic toxicity to both water column and benthic organisms. This beneficial use combines those listed as WARM, COLD, EST, WILD, BIOL, RARE, and SHELL in **Table 16-1**.
2. Protection of human health from ingestion of PFAS when surface water is used as drinking water. Listed as MUN in Table 16-1. The values for this are already covered in **Section 8** and in updated tables (the **Environmental Media Values Table** Excel file), and discussed further below.
3. Protection of human health from exposure to PFAS in the consumption of aquatic organisms, including benthic organisms. In Table 16-1 this encompasses the beneficial uses listed as COMM, AQUA, and SHELL.
4. Protection of human health from contact with and ingestion of PFAS in surface water during recreational activities such as swimming and fishing. This beneficial use is listed as REC-1 in Table 16-1.
5. Use of the surface water as an agricultural supply (AGR). Use of the surface water in this manner would allow for the uptake of PFAS into plants used for human and animal consumption, stock watering of animals used for human consumption and animal consumption, as well as recharge of excess water to groundwater or other surface water bodies (return water).

6. Groundwater recharge is also included, but the issues are the same as those for MUN, AGR, and IND as listed in Table 16-1.

Table 16-1. Beneficial Uses.

	Beneficial Use	Description	Does PFAS Have Impact on Use? Covered in this Section
1.	Municipal and Domestic Supply, Use as Drinking Water (MUN)	Uses of water for community, military, or individual water supply systems, including, but not limited to, drinking water supply.	Yes
2.	Agricultural Supply (AGR)	Uses of water for farming, horticulture, dairy operations, or ranching.	Yes
3.	Primary Water Contact Recreation (REC-1)	Uses of water for recreational activities involving body contact with water, where ingestion of water is reasonably possible.	Yes
4.	Groundwater Recharge (GWR)	Uses of water for natural or artificial recharge of groundwater.	Yes
5.	Commercial and Sport Fishing (COMM)	Uses of water for commercial or recreational collection of fish, shellfish, or other organisms.	Yes
6.	Aquaculture (AQUA)	Uses of water for aquaculture or mariculture operations.	Yes—not all components covered under other beneficial uses—harvesting of aquatic plants for human consumption
7.	Warm Freshwater Habitat (WARM)	Uses of water that support warm water ecosystems.	Yes—combine with COLD
8.	Cold Freshwater Habitat (COLD)	Uses of water that support cold water ecosystems.	Yes—combine with WARM
9.	Estuarine and Marine Habitats (EST)	Uses of water that support estuarine and marine ecosystems.	Yes—combine with WARM and COLD for ecotoxicity for all of the aquatic species
10.	Wildlife Habitat (WILD)	Uses of water that support terrestrial or wetland ecosystems.	Yes—food chain issues, in addition to WARM, COLD, and EST
11.	Spawning, Reproduction, and/or Early Development (SPWN)	Uses of water that support high quality aquatic habitats suitable for reproduction and early development of fish.	Yes
12.	Shellfish Harvesting (SHELL)	Uses of water that support habitats suitable for the collection of filter-feeding shellfish.	Yes
13.	Hydropower Generation (POW)	Uses of water for hydropower generation.	No—PFAS not expected to impact POW
14.	Industrial Process Supply (PRO)	Uses of water for industrial activities that depend primarily on water quality.	No—as below for IND
15.	Freshwater Replenishment (FRSH)	Uses of water for natural or artificial maintenance of surface water quantity or quality.	No—issues covered under other beneficial uses
16.	Non-contact Water/Secondary Contact Water Recreation (REC-2)	Uses of water for recreational activities involving proximity to water, but where there is generally no body contact with water, nor any likelihood of ingestion of water.	No
17.	Preservation of Biological Habitats of Special Significance (BIOL)	Uses of water that support designated areas or habitats, such as established refuges, parks, sanctuaries, ecological reserves, or Areas of Special Biological Significance, where the preservation or enhancement of natural resources requires special protection.	Not covered individually—covered under WARM, COLD, EST, and WILD
18.	Rare, Threatened, or Endangered Species (RARE)	Uses of water that support aquatic habitats necessary, at least in part, for the survival and successful maintenance of plant or animal species established under state or federal law as rare, threatened, or endangered.	Not covered individually—covered under WARM, COLD, EST, and WILD
19.	Migration of Aquatic Organisms (MIGR)	Uses of water that support habitats necessary for migration or other temporary activities by aquatic organisms, such as anadromous fish.	No—issues already covered under other beneficial uses
20.	Industrial Service Supply (IND)	Uses of water for industrial activities that do not depend primarily on water quality, such as mining and cooling water.	No—concern is the discharge of the water to another location
21.	Navigation (NAV)	Uses of water for shipping, travel, or other transportation by private, military, or commercial vessels.	No—PFAS not expected to impact navigation

*Source: Adapted from **RWQCB-CVR (2016)**.*

These beneficial use groupings were used to identify the topics to be included in the remainder of this section.

16.1.2 Existing Methods of Protecting Surface Water for Beneficial Uses

This section provides information about the existing methods that regulatory agencies or organizations with jurisdiction use for protecting surface water bodies from discharges of various pollutants. This information provides context for what may be implemented to address potential sources of PFAS in surface water.

After establishing the beneficial uses for a given body of water (lake, stream, creek, estuary, ocean) the regulatory agency or organization implements processes designed to protect those beneficial uses. Typically, this begins with establishing water quality protectiveness standards/criteria or guidance values to protect those specific beneficial uses. As an example, to protect aquatic species, values are established for protection of the health of the fish to allow them to continue to exist in the environment and breed without curtailment. If the fish species is fished for human consumption, then values are also established to allow for fishing to occur without unacceptable effects on those consuming the fish. As values are established for each of the beneficial uses assigned for the water body, the most stringent of the values can be used as the value that is protective of all the designated beneficial uses. In that instance, that value would be used for comparison to other beneficial use values instead of individual values for drinking water and fish protection. For PFAS those values are just beginning to be established.

Once the protective value for the water body has been established, regulatory mechanisms exist to protect the water body to maintain or reduce the concentrations to below the protective values. Discharges to surface water are regulated by state- or federally issued permits. Effluent limits are established in those permits for constituents that could pose a threat to water quality. Establishing appropriate chemical-specific effluent limits protects beneficial uses. The effluent limitations are set so that the concentrations in the surface water body stay below the protective values. In addition to chemical-specific effluent limitations, the permits typically establish acceptable toxicity limitations that must be met in the total effluent. Both effluent and toxicity limitations can take into account mixing with the surface water body within a permitted mixing zone (dilution).

If a water body already has concentrations that are greater than the protective value, then the regulatory agency can establish total maximum daily loads (TMDLs). The TMDLs identify maximum mass discharges for the chemicals that exceed protective values and are used to identify mass loading limits on discharges in the watershed for that water body. Additionally, TMDLs have a component for evaluation of nonpoint sources of discharge within the watershed that include the chemical of concern. If needed, regulations of these nonpoint discharges could be adopted to also limit those discharges. Often, best management practices are established as the control mechanism for nonpoint discharges. If nonpoint discharges are the primary contributor of the pollutant, alternate approaches, such as watershed restoration plans, may be established in lieu of TMDLs. These plans can include best management practices and pollutant minimization components.

During times when a protective value is exceeded and before corrective measures are taken to bring concentrations down below those values, temporary use restrictions can be issued to protect users of the water body. Examples of such restrictions include banning recreation or issuing fish advisories that recommend restricting consumption of various fish species. If the water is being used as a source of drinking water, additional water treatment could be required.

Effluent limitations, TMDLs, watershed restoration plans, and use restrictions have been effective in protecting beneficial uses and reducing risk to receptors for numerous chemicals. It is likely that these measures will also be useful in addressing PFAS.

16.1.3 Status of State and Federal Surface Water Protection Efforts Regarding PFAS

At the time of publication, there were no national surface water values for PFAS in the U.S., and only a handful of states have addressed PFAS in surface water; see the **Environmental Media Values Table** for updates. Many of the challenges or obstacles to developing surface water criteria are the same as for groundwater, including the large number of individual PFAS, many of which lack toxicity and published physical and chemical properties data. In addition, surface water is used in a greater number of ways than groundwater, representing potential direct exposure routes through dermal contact and water ingestion, and indirect exposure through consumption of fish and shellfish. On October 18, 2021, the USEPA announced its PFAS Strategic Roadmap (**USEPA 2021**). The Roadmap includes actions that are planned to be undertaken by USEPA. Pursuant to the roadmap, USEPA published draft recommended ambient water quality criteria for the protection of aquatic life in June 2022 for PFOA and PFOS (**USEPA 2022**). USEPA also issued health advisories for PFOA and PFOS in June 2022 (**USEPA 2022**, **2022**) and surface water quality criteria for the protection of human health are expected fall 2024. In addition, USEPA is increasing the availability of data on PFAS in fish tissue that can be used to finalize the list of PFAS for establishing fish advisories.

Enforceable vs. Nonenforceable Federal and State Values

Standard – Promulgated values that are enforceable. Example: primary drinking water standard or maximum contaminant level

Criteria – Recommended nonenforceable values that can be used to establish a standard. Example: USEPA water quality criteria

Screening/Guidance Levels – Nonenforceable values that usually represent a de minimus risk and can be used to determine if further action may be necessary. Example: USEPA regional screening levels, action-levels.

At the state level, surface water criteria development has taken a range of approaches. Alaska has adopted health advisory levels for surface water used as drinking water. These levels are used as action levels and are not enforceable under the Clean Water Act. Michigan, Minnesota, and Florida developed their own statewide criteria based on water and fish consumption using state-specific inputs and addressed PFOA and PFOS. Other states are in the process of collecting data or evaluating what approach to take to develop their own criteria in the absence of federal guidelines. Wisconsin is collecting surface water and fish tissue data to support calculation of surface water values. New Hampshire and Vermont have released detailed reports outlining potential strategies and associated costs and timing for developing state criteria. The plan from Vermont describes how its Agency of Natural Resources has developed a framework to establish water quality standards and how it may apply to developing such standards for protection of human health and aquatic life from PFAS. The report concludes that technical challenges and the constraints of deriving water quality criteria (WQC) for PFAS are "logistically difficult, would take a long time, and be very expensive." It recommends developing fish consumption advisories, tracking USEPA development of aquatic biota criteria for PFAS, incorporating USEPA criteria when they are developed, and continued collaboration with New England states on developing plans for deriving water quality standards (**Vermont DEQ 2020**). The number of states that have established values for protection of aquatic life is small and includes Michigan and Florida, see the **Environmental Media Values Table** for updates to state values.

Surface water criteria are generally established by the states, either by adopting values recommended by USEPA per section 304(a) of the Clean Water Act, or by calculating state-specific criteria that must be approved by USEPA. States have specific responsibilities when setting surface water criteria and submitting that information to USEPA:

- Water bodies must have an appropriate designated use or uses.
- The WQC must support those uses.
- Antidegradation policies to protect high-value waters must be adopted.
- The status of waters must be monitored.

- The standards must be revisited on a regular basis and if a revision is required, the state must obtain USEPA approval.

Most states are still in the process of assessing the extent of PFAS in their surface waters, some only at specific potential source areas.

16.1.4 Survey of States

In the spring of 2020, the ITRC PFAS team sent a survey to the states to gather information on their efforts to address PFAS in surface water. The survey included questions on what media states are monitoring for PFAS, whether PFAS have been detected in surface water, if the states have fish consumption advisories in place for any PFAS, and if the states are contemplating developing surface water quality criteria or guidelines. Other questions addressed the availability of data and information on sampling methods, PFAS-containing foam, and whether states have restrictions to minimize the discharge of PFAS to surface water.

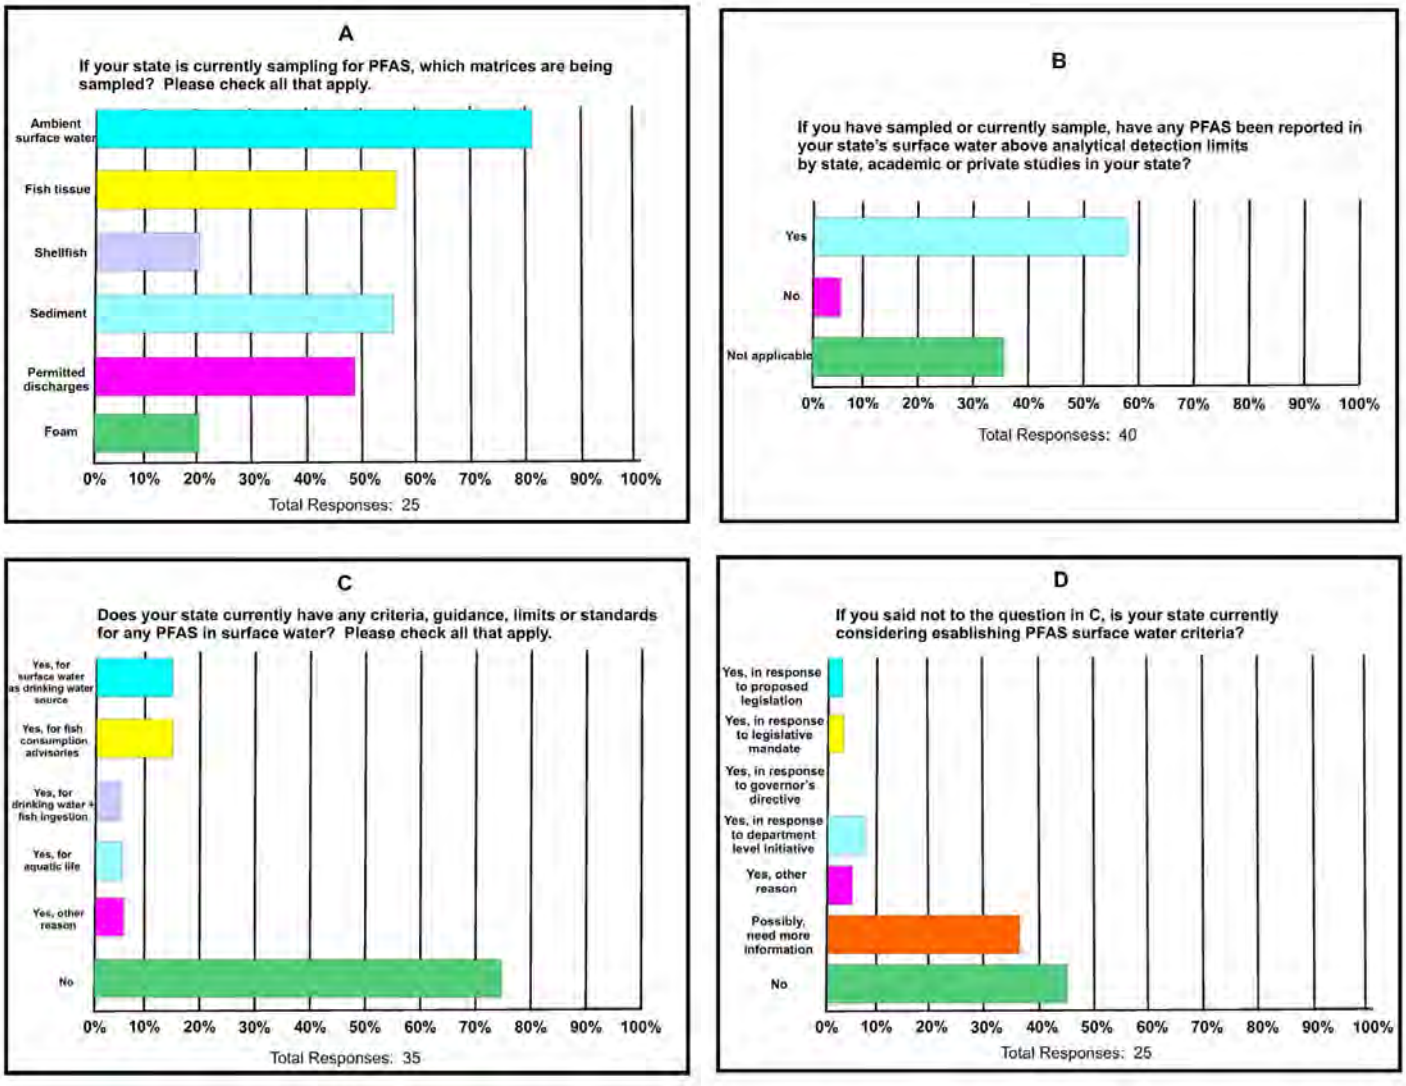

Figure 16-1A-D. Summary of Key Responses from the ITRC State Survey (2020).

A total of 42 states submitted responses. A summary of key responses is provided in Figures 16-1A-D. These show that of the different media being sampled, 80% of the states are sampling surface water (Figure 16-1A), and of those sampling for various PFAS in surface water, almost 60% detected one or more PFAS (Figure 16-1B). It was determined that 75% of states do not have any criteria, guidance, limits, or standards for PFAS in surface water (Figure 16-1C); however, it is noted that 16% do have some protective measure for surface water that is used as drinking water and 16% have guidance related to fish consumption advisories. Lastly, although 46% of the states were not considering development of criteria for PFAS in surface water, almost 40% felt they needed more information (Figure 16-1d); the remainder are currently developing criteria in response to proposed legislation, legislative mandates, or in response to department-level initiatives. For states that have developed surface water quality values, twice as many states reported using USEPA guidance for developing the values versus those using other procedures and methods.

Given the rapid pace in the state-of-the-science for PFAS and the desire for PFAS regulations in many states, it is likely there are updates since the time the survey was conducted. However, the PFAS team used the information from the survey to inform what areas to focus on in this surface water quality section and to document the fundamentals for states to consider when developing surface water quality protective values for PFAS. Where relevant, pertinent information from the survey is included in Sections 16.2–16.5.

For updates about states that have developed standards/guidance/limits, see the **Environmental Media Values Table** Excel File.

16.2 Protection of Human Health

This section discusses the human health aspects of PFAS in surface water. There are other sections in this document that discuss general human health–related PFAS issues in detail that supplement the information in this section. Those sections are **Section 7.1**, Human Health Effects and **Section 9.1**, Site Risk Assessment, Human Health.

Under the federal Clean Water Act, states must adopt water quality standards that consist of both designated uses and numerical and/or narrative criteria to protect these uses. As described in **Section 16.1**, a designated use (also called a "beneficial use" or "designated beneficial use") in some states is a use of surface waters that is considered desirable and should be protected. As noted in **Table 16-1**, surface waters have many different beneficial uses, some of which are relevant to human health and some that are not. Uses that are most relevant to human exposure and are considered for most chemicals include municipal and domestic supply (also referred to as drinking water use); agricultural supply (also commonly referred to as irrigation); primary contact recreation; secondary contact recreation/noncontact water recreation; commercial, subsistence, and sport (recreational) fishing (referred to in some states as fish ingestion); and aquaculture (also focused on fish ingestion).

In relation to beneficial uses, the exposure pathways for contaminants in surface water that most warrant consideration of human health for PFAS are included in **Table 16-2**.

Regulatory agencies use relevant and appropriate use-specific exposure factors combined with chemical-specific toxicity factors (reference doses; cancer slope factors) to develop ambient water quality criteria (AWQC) that are protective of human health for these uses and exposure pathways. The exposure pathways usually considered in development of AWQC are drinking water ingestion (for waters designated for drinking water use) and consumption of aquatic organisms.

At this time, exposure pathways involving ingestion are considered to be the most significant PFAS exposure sources. Recreational uses of surface waters for secondary contact activities, such as wading

and boating, which do not involve immersion but may result in dermal contact with water, are considered to be insignificant sources of PFAS exposures. See **Sections 17.2.2** and **17.2.3**.

Table 16-2. Exposure Pathways in Relation to Beneficial Uses.

Beneficial Use	Associated Human Exposure Pathway for PFAS
Municipal and domestic supply; use as drinking water	Drinking water ingestion and dermal contact during household use; secondary uses may include irrigation for home gardening and produce consumption
Commercial, subsistence, and sport (recreational) fishing	Consumption of aquatic organisms (fish and shellfish) that may bioaccumulate PFAS from surface water
Primary contact water recreation	Incidental ingestion and dermal contact with water and/or foam during immersion activities such as swimming, waterskiing
Non-contact/secondary contact water recreation	Dermal contact with water and/or foam during nonimmersion activities such as wading, boating, fishing; exposures considered to be insignificant for PFAS
Agricultural supply	Consumption of crops, dairy products, and meat that may bioaccumulate PFAS from irrigation water; some states may also consider direct contact with irrigation water
Aquaculture	Consumption of aquatic organisms (fish and shellfish) that may bioaccumulate PFAS from aquaculture water

Human health criteria for contaminant concentrations in surface water that are protective of fish consumption are also relevant to PFAS exposures. Additionally, some states have developed fish consumption advisories that recommend the frequency of consumption for recreationally caught fish based on levels of contaminants, including PFAS, measured in fish tissue from certain geographic regions or in specific water bodies (**Section 16.2.2.6**).

The salinity of the surface water body influences the beneficial uses considered and what type of criteria are appropriate (**USEPA 2002**, p.9). Freshwater criteria apply to waters with salinity less than one part per thousand. Saltwater criteria apply to waters with salinity greater than 10 parts per thousand. The more stringent of freshwater and saltwater criteria apply to waters with salinity between 1-10 parts per thousand. In general, saltwater criteria consider only the consumption of aquatic organisms (fish and shellfish), while freshwater criteria may consider exposure through consumption of aquatic organisms and/or drinking water. The designated uses for freshwater bodies may vary from state to state based on policy and/or actual uses as some water bodies may not support both potable use and aquatic biota consumption. Thus, criteria can be developed for the fish/shellfish consumption pathway alone or for the potable use and fish/shellfish consumption pathways combined. Surface water criteria are usually not developed for potable use alone and generally defer to guidelines such as maximum contaminant levels (MCLs) and maximum contaminant level goals (MCLGs) developed by USEPA and other agencies under drinking water programs. The combined use criterion will be more stringent than the criterion for consumption of organisms only for reasons detailed below.

16.2.1 Input Factors for Development of Surface Water Criteria and Fish Consumption Advisories

Section 16.2.2 includes information and an example equation used to develop human health criteria for relevant exposure pathways. **Section 16.2.2.6** provides information and an example equation used to develop fish consumption advisory triggers.

16.2.1.1 Toxicity Values

The development of toxicity values for PFAS is an evolving and dynamic field. Changes in methodology and values, as well as the number of PFAS with toxicity values, should be expected. As a result, the information in this document is current as of March 2023 and the reader is encouraged to consult the most current information at the time of use.

The toxicity values used for both human health criteria and fish consumption advisories are oral reference doses (RfD, ng/kg/day or mg/kg/day) for noncarcinogenic effects and oral cancer slope factors (mg/kg/day)-1 for carcinogenic effects. States may base their WQC and fish consumption advisories on toxicity values recommended by USEPA or toxicity values from sources other than USEPA or develop their own toxicity values (see **Section 8.3** for more detail). The toxicity values used for PFAS vary among agencies based on different choices of critical toxicological effect, uncertainty factors, exposure assumptions, and other considerations.

As of early 2023, the USEPA had either proposed or adopted toxicity factors for a limited number of PFAS but had not established surface water criteria for protection of human health. When information becomes available to develop surface water criteria for a PFAS, USEPA may follow a tiered process in selection of toxicity values, as it has done when developing criteria for other contaminants. When USEPA last updated its human health criteria (**USEPA 2015**), its primary source of updated toxicity values was the Integrated Risk Information System (IRIS), Other sources of toxicity values, for contaminants other than PFAS, reviewed by USEPA in its 2015 update of human health criteria include:

- USEPA Office of Pesticide Programs
- USEPA Office of Pollution Prevention and Toxics
- USEPA Office of Water
- USEPA Office of Land and Emergency Management (for example, Provisional Peer Reviewed Toxicity Values (PPRTVs))
- Agency for Toxic Substances and Disease Registry (ATSDR)
- Health Canada
- California EPA's Office of Environmental Health Hazard Assessment

The **USEPA (2015)** updates used a toxicity factor from one of the non-IRIS sources listed above if no IRIS toxicity factor was available, or if the toxicity factor from another source used a newer study or a more current risk assessment approach than IRIS.

USEPA toxicity factors for a limited number of PFAS are at different stages of development and adoption for use in human health risk assessment. The USEPA's PFAS Action Plan, which was first developed in 2019 and updated in 2020 (**USEPA 2020**), states that USEPA will evaluate several PFAS for development of toxicity values. Since then, USEPA has finalized toxicity assessments for a number of PFAS (See **Section 7.1**) which for some, serve as the basis of USEPA's final PFAS National Primary Drinking Water Regulation (**USEPA 2024**). Refer to **Section 7.1** for updates on PFAS toxicity assessments and information on PFAS health effects, and **Section 9.1** for information on the use of PFAS toxicity values in human health risk assessment.

16.2.1.2 Protected Populations and Target Risk Levels

The protected populations that are considered in the development of surface water criteria for human health typically include adults. In some cases, other populations, such as lactating women, women of childbearing age, children, and infants, may also be explicitly considered separately, depending on the nature of the chemical and the exposure route. As discussed in **Section 16.2**, the human health criteria most relevant to PFAS consider ingestion of aquatic organisms (fish and shellfish) and/or drinking water. In general, when calculating criteria for a surface water body that is used for both drinking water and fish

consumption purposes, exposure from ingestion of aquatic organisms will likely be greater than exposure from drinking water for PFAS such as PFOS that bioaccumulate in aquatic life when default ingestion rates and bioconcentration factors are assumed.

In the development of human health WQC based on standard exposure assumptions, the relative doses from fish consumption and drinking water are dependent on the bioconcentration factor (BCF) or bioaccumulation factor (BAF), the target population, and their assumed intake rates. The assumed daily dose from fish consumption (22 g/day) is greater than the assumed daily dose from drinking water ingestion (2.4 L/day) for bioaccumulative PFAS such as PFOS (see Sections **16.2.1.3** and **16.2.1.4**). However, exposures to bioaccumulative PFAS in drinking water are higher in infants, particularly in those that are breastfed, than in adults, and infants are considered to be a sensitive subpopulation for adverse effects of PFAS (**Goeden, Greene, and Jacobus 2019**). In contrast to human health criteria for surface water, drinking water guidelines for PFAS developed by USEPA (**USEPA 2016**, **USEPA 2016**) and some states are based on exposure assumptions or exposure modeling for sensitive life stages (for example, lactating women, infants (**Post 2021**)). Minnesota (**MPCA 2020**) has recently used modeling of early-life exposure in formula-fed and breastfed infants, as well as a higher fish consumption rate specific to women of childbearing age (**MPCA 2020**), to develop a human health surface water criterion for PFOS; they also developed a human health-based criterion for PFOS in fish tissue.

A target cancer risk level is used along with the cancer slope factor in calculation of criteria based on carcinogenic effects. The selection of the lifetime cancer risk level is a policy choice, not a scientific decision, and the target cancer risk level (for example, 1 in 100,000 or 10-5; 1 in 1,000,000 or 10-6) differs among states, which is one reason why criteria based on cancer risk can vary among different states. Criteria for noncarcinogenic effects are developed such that exposure to the contaminant will not exceed the RfD. When chemicals have the potential to exert both carcinogenic and noncarcinogenic effects (for example, PFOA), the final criterion may be based on the lower of the criteria based on cancer and noncancer effects.

16.2.1.3 Exposure Factors

The exposure factors typically considered in development of criteria for ingestion of drinking water and/or aquatic organisms include assumed body weight, drinking water and/or aquatic organism (fish/shellfish) consumption rates, and relative source contribution (RSC). These exposure factors and their use in developing criteria are described below.

As previously stated, the default adult body weight is usually used when developing human health criteria. USEPA currently recommends a default adult body weight of 80 kg for development of human health criteria (**USEPA 2015**). However, some states' criteria are based on the older recommended value of 70 kg. Alternative body weight assumptions for specific ages, sexes, or other subgroups can be found in the USEPA Exposure Factors Handbook (**USEPA 2011**), and certain states may use these values.

States typically use default ingestion rates recommended by the USEPA for the specified environmental media, for example, drinking water or fish tissue; however, some states use state-specific values, especially for fish ingestion. The adult drinking water consumption rate is usually used for human health criteria. In 2015, USEPA updated its recommended default adult drinking water consumption rate for human health criteria from 2 L/day to 2.4 L/day (**USEPA 2015**). It is noted that the relevant body weight-normalized exposure parameter (L/kg/day) is 0.03 L/kg/day with the updated body weight and ingestion volume, which represents a very small change from 0.029 L/kg/day based on the older values. Similarly, USEPA also updated the default rate of 22 g/day for fish consumption from the previous value of 17.5 g/day (**USEPA 2015**). Some states consider state- or region-specific rates that have been developed based on consumption data from their region, including higher consumption rates by tribes and/or for subsistence fishing in some cases (**USEPA 2014**).

Under current **USEPA (2000)** guidance, an RSC is used when a human health criterion is based on an RfD (noncancer effects), and USEPA used an RSC (**USEPA 2015**) in its updates of noncarcinogenic criteria. The RSC accounts for potential non-drinking water exposures to chemicals and is used in the development of health-based guidance and standards developed by the USEPA and related state programs. Conceptually, the RSC is the percent of total exposure assumed to come from exposure arising from surface water (ingestion of water and aquatic organisms, or ingestion of organisms only) at the criterion concentration (for example, an assumed RSC of 20% for a drinking water criterion means that the target population is assumed to be exposed to 80% of the RfD from non-drinking water sources). It is intended to ensure that total exposure from all sources (surface water and non-surface water–related) does not exceed the RfD. USEPA guidance specifies an RSC of 20–80 percent, with a default of 20 percent (the most stringent possible value) when data to derive a chemical-specific value are not available (**USEPA 2015**). Some states and USEPA use the 20 percent default value in their PFAS drinking water guidelines, while other states (for example, MN, NH, NY) use higher RSC values based on estimates of non-drinking water exposures from human biomonitoring data or in consideration of certain life stages.

16.2.1.4 Bioaccumulation, Bioconcentration, and Biomagnification Factors

Water to fish transfer factors are useful in the development of water quality criteria and to inform risk-based evaluations. Three types of factors can be used by risk assessors to relate environmental concentrations of a chemical (for example, in water, sediment, soil, or prey) to concentrations within certain organisms. These factors include bioaccumulation factors (BAF), bioconcentration factors (BCFs), biomagnification factors (BMFs) and associated trophic magnification factors, each of which are defined in the text box below, and detailed in **Section 5.5**. These factors are frequently used for risk assessment of biota such as fish and shellfish consumption by human fish consumers, as well as wildlife. The USEPA has outlined methods for developing BAFs, which are recommended for risk assessment of most chemicals, whereas BCFs and BMFs typically provide useful information about the fate, transport, and ecological risks of chemicals (**USEPA 2003**).

Certain PFAS are highly bioaccumulative in aquatic organisms such as fish, and this is especially true for long-chain PFAS such as PFOS. For the risk assessment of bioaccumulative and bioconcentrating chemicals such as PFAS, BAFs or BCFs should represent the tissues that are consumed by humans (for example, fillets or muscle tissue) and should also represent the trophic level of the fish species of interest (for example, secondary consumer or top-level predatory fish). Both BAFs and BCFs are specific to the chemical and organism in which it is detected. For BCFs, BAFs, or BMFs, larger values indicate greater accumulation in organisms, which in turn result in lower surface water criteria. At this time BCFs, BAFs, and BMFs for PFAS are primarily based on measured data. Examples of these values for PFAS in aquatic organisms are available in Table 5-1 (as a separate Excel file) and discussed in **Section 5.5**.

Transfer Factors

Bioconcentration factors (BCF, L/kg) represent the direct uptake of PFAS by an organism from the water column (through the gills) and are measured as the ratio of the concentration in an organism to the concentration in water. Typically derived from laboratory studies.

Bioaccumulation factors (BAF, L/kg) represent the amount of PFAS taken up from bioconcentration plus the contribution of PFAS in the diet of that organism. Typically estimated from field studies.

Biomagnification factors (BMF; typically unitless) describe the increase in tissue concentration as one moves up the food chain based on a predator/prey relationship (always measured in the field); often defined as the concentration of chemical in an organism divided by the concentration of chemical in its food.

Trophic magnification factors (TMF; typically unitless) express the change in contaminant level per trophic level, and therefore describe the biomagnification between different trophic levels of the food web.

When the standard USEPA equation shown in the text box in **Section 16.2.2** is used with standard exposure assumptions (drinking water ingestion – 2.4 L/day; fish consumption – 22 g/day) to develop human health criteria, the assumed contribution to total exposure from fish consumption is greater than

from drinking water when the BCF or BAF is >110. As the numerical value of the BCF or BAF increases, the proportion of assumed exposure from fish consumption continues to increase. Given the mathematical impact of BAFs, BCFs, and BMFs on resulting WQC, there are several considerations for data use and applicability. One example of these considerations is the applicability of values estimated from studies on nonnative species or from water bodies with different water chemistry from the sites intended for protection. The use of central tendency versus upper percentile values may result in less stringent criteria but may be less appropriate in cases where BAFs for a given compound vary by orders of magnitude. The USEPA encourages the use of site-specific modification to BAF, BCF, and BMF selection where such decisions are appropriate and scientifically defensible (**USEPA 2000**).

16.2.2 Human Health Criteria Development for Beneficial Uses of Surface Water

As shown below, USEPA's standard equation for development of surface water criteria incorporates terms related to receptor characteristics, exposure, and toxicity values, as described in earlier sections.

It is noted that the USEPA (**2015**) updated human health ambient water quality criteria describe a similar but more complex equation incorporating trophic level–specific fish consumption rates and BAFs (or BCFs) when available. However, this approach does not appear to be applicable to PFAS since current evidence indicates that BAFs for PFAS are not clearly associated with trophic level, and trophic level–specific BAFs have not been developed for PFAS.

Standard USEPA Equation for Combined Drinking Water + Fish/Shellfish Consumption

$$SWC = \frac{RfD \times BW \times RSC}{DI + ((BCF \text{ or } BAF) \times FIR)}$$

SWC = surface water criterion (mg/L)

RfD = reference dose (mg/kg/day)

BW = body weight (kg)

RSC = relative source contribution (unitless)

BCF = bioconcentration factor (L/kg)

BAF = bioaccumulation factor (L/kg)

FIR = fish ingestion rate (kg/day)

DI = drinking water ingestion rate (L/day)

USEPA (2000)

This section outlines issues that are relevant to development of surface water criteria for specific beneficial uses. These criteria are based on the protection of human health from exposure via intentional ingestion of contaminated media, including:

- drinking water use, **16.2.2.1**
- subsistence, commercial, and sport fishing, **16.2.2.2**
- drinking water combined with subsistence, commercial, and sport fishing, **16.2.2.3**
- contact recreation (incidental ingestion of and skin contact with surface water, sediment, and PFAS-containing foam), **16.2.2.4**
- use for agriculture, **16.2.2.5**
- fish consumption advisories, **16.2.2.6**.

Using USEPA methodology, the surface water criteria described in Sections **16.2.2.1**, **16.2.2.2**, and **16.2.2.3** can be derived using a variant of the equation in the text box to the right. As described in Sections **16.2.2.1** and **16.2.2.2**, terms accounting for exposure from drinking water or fish consumption can be removed as appropriate for the designated use of the water body.

The Environmental Council of the States (ECOS) published their updated white paper, Processes and Considerations for Setting State PFAS Standards in March 2023 (**ECOS 2023**).

16.2.2.1 Waters Designated for Domestic/Municipal Supply (Drinking Water Use)

As noted earlier, surface waters that are designated only for drinking water use may use drinking water guidelines already developed by USEPA or state agencies as WQC. Current state and federal drinking

water guidelines for PFAS are found in Environmental Media Values Table Excel File. How certain states apply this may depend on certain regulatory considerations and authorities (**ECOS 2023**). Some states derive this type of surface water criterion using the equation above but omit the denominator terms for bioaccumulation/bioconcentration factors and fish ingestion rates. This equation determines a drinking water value based on human health risk assessment but does not include consideration of analytical or treatment removal factors. Additional discussion of drinking water guidelines may be found in **Section 8.3**.

Numerically, surface water quality criteria for the protection of drinking water may be the same as or differ from drinking water standards such as MCLs, which apply to public water systems, or ambient groundwater quality standards. Drinking water standards such as MCLs are often higher than the strictly health-based goals derived by the previously described equation because they consider analytical and treatment limitations, which consider higher values. In contrast, surface water criteria do not consider these factors. However, almost all the current state and federal drinking water guidelines for PFAS are set at health-based goals because analytical and/or treatment removal considerations are not included as limiting factors in the development of the guidelines. Some states may have the authority to adopt existing drinking water values, such as MCLs, as surface water quality criteria for the protection of drinking water sources. This varies due to states' regulatory authorities and definitions of surface waters considered acceptable for potable use. Alternatively, some states may derive criteria that differ from drinking water guidelines due to consideration of drinking water use combined with other designated uses such fish/shellfish consumption.

16.2.2.2 Waters Designated for Subsistence, Commercial, and Sport (Recreational) Fishing (Consumption of Aquatic Organisms [Fish and Shellfish] Only)

Surface water criteria for fish and shellfish consumption rely on assumptions about consumption rates as well as the relationship between chemical concentrations in water and the resulting tissue concentrations in consumed aquatic organisms.

Default fish consumption rates recommended by USEPA and choices made by states to reflect regional consumption patterns were discussed in **Section 16.2.1.3**. The quantifiable relationship between chemical concentrations in water and the concentrations in tissue is represented by transfer factors such as BCFs, BAFs, or BMFs, which are defined in **Section 5.5** and included in the text box in **Section 16.2.1.4**.

The equation used to derive this type of criterion, using USEPA methods, would be the equation in the box above but omitting the drinking water ingestion rate. This equation relies on toxicity values (**Section 16.2.1.1**) and exposure factors (**Section 16.2.1.3**), as well as BAFs or BCFs for the specified chemical. More stringent toxicity values, higher exposure factors (for example, fish consumption rates), or larger BAFs or BCFs result in lower surface water criteria. For example, criteria based on the higher fish intake rates for subsistence fish consumers would be more stringent than criteria based on the average intake rates for U.S. consumers or sport fishers. Depending on state level or regional policies, such criteria may be developed separately for sport (recreational) and subsistence fishing practices. Aquaculture operations may be required to meet similar criteria for rearing, harvesting, or selling fish depending on the regulatory authority of certain states. This type of surface water criteria is typically developed in consideration of fish, especially predatory fish, as these are more commonly caught and consumed by the public than are shellfish. However, similar criteria can be developed for shellfish (for example, bivalves and crustaceans) using similar risk assessment methods.

16.2.2.3 Waters Designated for Combined Use as Drinking Water and for Subsistence, Commercial, and Sport (Recreational) Fishing

Freshwaters may support and/or be designated for both drinking water and fish consumption beneficial uses. This requires consideration of factors discussed in Sections **16.2.2.1** and **16.2.2.2**. The full

equation in the box above provides the USEPA method for deriving this type of criteria. Default input values would be similar to those listed for each use separately. Surface water criteria established for both drinking water and fish consumption will be more stringent than criteria for either use alone.

16.2.2.4 Waters Designated for Contact Recreation

WQC for recreational contact, such as swimming and wading, consider exposure primarily due to incidental ingestion and dermal contact with surface water, sediments, and potentially PFAS-containing foams. There is no standardized equation for development of criteria protective of exposure to recreational water, but certain equations in the USEPA's Risk Assessment Guidance for Superfund (RAGS) provide a framework for developing screening levels for recreational contact (**USEPA 2004**). Specifically, equations for estimating chemical intake by incidental ingestion of water and dermal absorption from water during swimming or wading are available in Chapter 3 of the RAGS Part E, Supplemental Guidance for Dermal Risk Assessment (**USEPA 2004**). There are several gaps in the current literature that limit the application of these equations, including scant information on skin permeability of several PFAS and how distribution in the water column influences dermal contact and potential for exposure to aerosols. Knowledge regarding volatilization and inhalation exposure is still evolving at this time.. Currently available information on partitioning of PFAS to air and the air/water interface is reviewed in Sections **5.2.4** and **5.2.4.1**.

Dissolved-Phase PFAS

At this time, primary or secondary contact recreation with surface water is not expected to be a significant pathway for human exposures to PFCAs and PFSAs (for example, PFOS) as compared to drinking water or to consumption of aquatic organisms. Current evidence suggests that PFAS are poorly absorbed through the skin (discussed in **Section 17.3.1.2**). Studies performed by some state agencies estimated the risks associated with observed PFAS concentrations in water via recreational exposures such as swimming, and concluded that the risks were low (**MDHHS 2019**, **MDH 2019**, **Vermont DEQ 2020**, **MPCA 2020**). Recreational screening levels are likely to be orders of magnitude higher than concentrations that are protective of consumption fish/shellfish, drinking water use, or some estimates of toxicity toward aquatic wildlife. However, there is uncertainty regarding dermal absorption capabilities (for example, skin permeability coefficients) of most PFAS, both short- and long-chain, that would have a significant impact on derived guidance values. One additional area of concern may come with inhalation in an environment where water-to-air transfer may occur from aerosol-borne PFAS in sea sprays or dam mist near known source areas (**Johansson et al. 2019**). Knowledge in these areas and knowledge regarding the volatilization and inhalation potential of PFAS is very preliminary, still evolving, and subject to change (see **Section 5.3**).

PFAS in Foams

In contrast to dissolved-phase PFAS, PFAS-containing foam may occur at and above the air-water interface on surface waters (see **Section 16.5** for details). However, as noted in Section 16.5, the presence of foam does not necessarily indicate the presence of PFAS. That said, observations concerning PFAS-containing foams present in surface waters have been reported in several states and present concerns for exposure from prolonged skin contact or incidental ingestion by small children. Unlike PFAS dissolved in water, foams may remain on the skin for a longer period, which may elicit public concerns. There are currently no WQC for the formation of foams, but some states may consider developing contact standards for exposure to foams. As noted above, a critical parameter in developing risk-based screening levels for recreational contact is the skin permeability coefficient, which is a measure of dermal absorption. There is currently high uncertainty and limited information available regarding skin permeability for PFAS (see **Section 17.3.1.2**), and this lack of data poses major challenges to risk assessment for human dermal contact with PFAS. It is anticipated that exposure to PFAS-containing foam on surface waters poses a significantly lower risk to human receptors than direct

ingestion from food and water, but if combined with drinking water or occupational exposure, could pose an added toxicological burden.

Using a similar approach to that described above, along with USEPA guidance (**USEPA 2000**, **2011**, **1989**), some states may decide to develop surface water criteria for PFAS-related foams. However, these surface water criteria would likely be far higher than any criteria needed to protect surface water for other uses by humans and wildlife and would be applicable to a limited number of sites. Some states, such as Minnesota, have published qualitative guidelines (**MPCA 2020**). In the future, some states may develop human health-based criteria for PFAS-containing foams in surface waters that would be protective of recreational exposures such as swimming and wading. It is also challenging to sample foam in surface waters, as described in **Section 16.5**.

16.2.2.5 Waters Designated for Agricultural Supply

One of the beneficial uses of fresh water is agricultural supply, for irrigation of crops for direct human consumption and silage for dairy or beef livestock that may ultimately lead to indirect human consumption (milk or beef ingestion). Since PFAS are known to bioaccumulate and have been detected in edible crops, produce, dairy, and meats (**Section 5.6**) (**ATSDR 2018**; **USFDA 2019**), there are potential concerns regarding acceptable levels of PFAS in surface water that will be protective of human health if used for irrigation of crops and silage.

The rapidly expanding literature about PFAS uptake into crops is useful in identifying a few general trends and is discussed in depth in Sections **5.2.3** and **5.6**. The potential for PFAS bioaccumulation in plants ranges from low (0.1) to approximately 10 times the soil concentration in many studies, although plants with high water content (for example, lettuce) could exhibit considerably higher bioaccumulation of certain PFAS (see **Table 5-2**, provided as a separate Excel file and discussed in **Section 5.6.2**). Chain length is a significant factor in availability for uptake into plants. While both longer chain and shorter chain PFCAs and PFSAs may be taken up by plant roots, there is generally greater translocation and distribution of shorter chain PFAS into the remainder of the plant, including the aboveground tissues (**Section 5.6.2**). In general, there is greater accumulation in vegetative tissues (for example, leaves and stems) than in storage tissues such as fruits and seeds (**Section 5.6.2**).

There is currently no USEPA guidance for development of surface water criteria for irrigation and livestock watering. However, approaches have been developed by some states, and other countries such as Canada (**ECCC 2017**), that consider human dermal and inhalation exposure to irrigation water and consumption of irrigated produce (for example, **University of Florida (2018)**). These references may be consulted for additional information on irrigation and livestock protection.

16.2.2.6 Fish Consumption Advisories Based on Consumption Frequency

Fish consumption advisories are health-protective recommendations developed by states for frequency of consumption of recreationally caught fish meals. These advisories may be applicable statewide, in certain regions of a state, or to specific water bodies or reaches/segments of water bodies. Fish consumption advisories are not surface water criteria and are not regulatory in nature. The advisories may be issued for the general public, and they may be more stringent for specific groups of people at higher risk, such as women of childbearing age, pregnant or nursing women, or children. At the time of publication of this document, several states (for example, AL, CT MI, MN, NJ, WI) have issued fish consumption advisories for PFAS, particularly PFOS.

Advisories are developed by comparing fish tissue concentrations in wet weight (“triggers”) that do not result in unacceptable risks for consumption of meals at different frequencies (for example, unlimited [daily]; once per week, once per month, once per year) with concentrations of the contaminant measured in fish tissue. The advisories may be species- and water body–specific, based on data for PFAS tissue

concentrations from the species in the water body, or they may apply regionally and/or to multiple species. Typically, limits are developed for muscle fillets of commonly caught and consumed fish, often accompanied by a recommendation to avoid consumption of skin, fat, and other nonmuscle parts of the fish. If there are populations whose consumption patterns exceed the assumptions of the advisory (for example, consumption of whole fish), there may be a potential for insufficient protection. Assumptions and parameters used in the calculation of fish tissue trigger levels include:

1. the reference dose for each PFAS
2. a consumer's body weight (BW)
3. the size of the fish meal

The generalized equation for development of fish tissue trigger concentrations based on noncancer effects used for fish consumption advisories are shown in the text box; a different equation (not shown) would be used for advisories based on cancer risk.

Standard USEPA Derivation of Fish/Shellfish Tissue Trigger Concentrations Used in Development of Consumption Advisories

$$DTC = \frac{RfD \times BW}{MS}$$

Where:

DTC = trigger concentration for daily consumption (µg/g)

BW = assumed human body weight (kg)

RfD = chronic oral reference dose (µg/kg/day)

MS = meal size (g/day)

Trigger concentrations for daily consumption are based on calculation of the concentration of a contaminant in fish tissue that results in exposure equal to the RfD from a fish meal. Trigger concentrations for less frequent meal consumption are calculated by multiplying trigger concentration for daily consumption by appropriate factor (for example, daily – 7; monthly – 30).

USEPA (2000)

16.3 Protection of Biota

16.3.1 Overview and Purpose

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about recent studies of bioaccumulation of PFAS in marine biota (see **Section 1.3.5.4**).

This section presents the technical methods and information needed to develop or review surface water criteria for PFAS that would be protective of aquatic life and their uses. There are other sections in this document where general ecological issues associated with PFAS are discussed in detail, and that information supplements the information contained in this section. That additional information can be found in **Section 7.2**, Ecological Toxicology, and **Section 9.2**, Ecological Risk Assessment. **Section 16.3.2** provides information regarding ecotoxicological data for assessing water quality criteria for PFAS that were available during development of previous versions of this document and still provides a starting point for evaluation of available values. The section is not intended to present an exhaustive compilation of the currently available data as this is an active field of research in which new information is regularly provided. It is recommended that the reader search for updated ecotoxicological data prior to development of water quality criteria for the protection of wildlife.

The types of aquatic life to be protected are usually defined by the various beneficial uses related to surface water that are described in **Section 16.1.1**. USEPA guidance (**USEPA 1985**) for derivation of such criteria are primarily intended to protect all but the most sensitive aquatic organisms from exposure to chemicals in surface water or sediment porewater. Considerations also exist to derive criteria for protection of aquatic-dependent avian and mammalian wildlife via calculation of a "final residue value" that can factor into final selection of the chronic criterion (**USEPA 1985**), or a more explicit "wildlife criterion" using methods presented for the Great Lakes Initiative (GLI; (**USEPA 1995**)).

Aquatic life criteria share the levels of protection afforded by the Clean Water Act and USEPA guidelines (**USEPA 1985**) in that criteria are derived using toxicity tests with aquatic organisms in which survival, growth, and reproduction are measured. These data are compiled to derive criteria intended to protect against unacceptable adverse effects to most animal taxa in the aquatic community, which is most commonly calculated to represent protection of approximately the 95th percentile of tested aquatic genera. As a result, acute and chronic criteria concentrations are generally said to represent protection of all but 5% of the most sensitive aquatic species. Criteria can also be lowered to protect particularly important species such as recreationally or economically important species or listed threatened or endangered species.

The following sections summarize the general USEPA methods available for derivation of aquatic life criteria for PFAS, with a focus on how to select the most appropriate toxicity test endpoints related to USEPA guidance (**USEPA 1985**). Available ecotoxicity data are then summarized for all freshwater and marine aquatic species relevant for derivation of aquatic life criteria, including invertebrates, vertebrates, and algae/vascular plants. This section closes with a summary of information necessary to develop criteria to protect aquatic-dependent wildlife such as birds or mammals, including permissible tissue PFAS concentrations, bioaccumulation and bioconcentration factors, and other food chain effects.

16.3.1.1 Derivation of Aquatic Life Protection Criteria—Methods Summary

The general approach for derivation of aquatic life criteria, according to USEPA guidance (**USEPA 1985**), is briefly summarized below, along with the definition of key terms. The first step is to compile acute and chronic toxicity data that meet the **USEPA (1985)** guidelines for the relevance and reliability of each study. This evaluation for scientific relevance and reliability largely focuses on test duration, survival in the control treatment, and methods, with distinctions made between acute (short-term) or chronic (long-term) studies. For example, acute toxicity studies must have an exposure duration of 96 hours (although 48 hours is acceptable for more short-lived species, such as cladocerans and midges), organisms must not be fed during the study, and the endpoint must be mortality, immobilization, or a combination of the two. Chronic toxicity studies must be conducted using exposure durations that encompass the full life cycle or, for fish, early life stage and partial life cycle studies. The acceptable endpoints for chronic tests include survival, growth, and reproduction (see **Section 16.3.1.4**). The duration of chronic studies may be many days, weeks, or months.

Table 16-3. Minimum database requirements for derivation of aquatic life criteria (USEPA 1985).

Freshwater	Saltwater
A bony fish in the family Salmonidae	Two families in the phylum Chordata
A second family of bony fish (preferably a commercially or recreationally important warm water fish)	A family in a phylum other than Arthropoda or Chordata
A third family in the phylum Chordata	Either the Mysidae or Penaeidae family
A planktonic crustacean	Three other families not in the phylum Chordata (may include Mysidae or Penaeidae, whichever was not used above)
A benthic crustacean	Any other family
An insect	
A family in a phylum other than Arthropoda or Chordata	
A family in any order of insect or any phylum not already represented	

To develop criteria that are protective of the diverse array of aquatic biota, an extensive database representing multiple test species, genera, and taxa is required. A minimum database of acceptable studies representing at least eight specific taxonomic families of aquatic organisms is also required. This is done to ensure that criteria are derived based on data that represent the widest possible range of likely sensitivities encountered in the environment. These minimum database requirements differ for freshwater versus saltwater species as presented in **Table 16-3**.

For each species with acceptable acute toxicity data, the species mean acute value (SMAV) is calculated as the geometric mean of available 48- to 96-hr median lethal concentrations (LC50s) or median effect concentrations (EC50s) for each species. The genus mean acute value (GMAV) is then calculated as the geometric mean of available SMAVs for each genus. The lowest 5th percentile of the distribution of available GMAVs is identified as the final acute value (FAV), which is divided by two to determine the criterion maximum concentration, which is more commonly termed the "acute criterion." The criterion continuous concentration, or "chronic criterion" can either be calculated using the same 5th percentile calculation as the FAV if all eight minimum database requirements are met, or if they are not met by dividing the FAV by the ratio of acute to chronic effects, termed the acute to chronic ratio (ACR). The ACR is determined from those species with both acute and chronic data available usually as a geometric mean of the available species ACRs. ACR values are one of the factors used to derive chronic surface water criteria for chemicals (**USEPA 2008**). They may also be used in the development of aquatic life screening values when acute toxicity data may be available but not enough chronic toxicity data are available for a chemical. Generally accepted ACR values have not yet been developed for PFAS and would need to take into account the diversity of chemical structures and behavior of PFAS. See the discussion in **Section 16.3.2** regarding the availability of acute and chronic data for select PFAS.

16.3.1.2 Problem Formulation

Recently, USEPA has been developing ambient water quality criteria documents following an ecological risk assessment framework (**USEPA 1992**) to provide a logical approach to criteria derivation based on the chemical's characteristics, fate and transport, and mode of toxic action. This information for PFAS is summarized below to assist with the development of a conceptual model and identification of endpoints needed for states to derive aquatic life criteria.

16.3.1.3 Conceptual Model

A conceptual model consists of a written and/or graphical representation of the linkages between the exposure characteristics of the chemical and the ecological endpoints of relevance to criteria derivation. PFAS will be transported to surface waters from direct soil runoff, groundwater discharge, atmospheric deposition, or point source discharges (see **Figure 17-1**). Once transported into surface waters, PFAS exposures to aquatic organisms will occur via two main pathways: direct from water (bioconcentration) and via the organism's diet as well as water (bioaccumulation). These pathways are also described and quantified in **Section 5.5**.

Biomagnification is also an important factor for some PFAS (for example, those with carbon chain lengths of eight or more) (**Section 5.5**). **Section 16.3.3** describes procedures to evaluate uptake of PFAS in aquatic-dependent wildlife.

This simple conceptual model suggests that aquatic life criteria for PFAS will need to consist of two different kinds of toxicological information:

- Toxicity data generated from water-only exposures
- Toxicity data with effects measured on the basis of receptor tissue concentration and diet, from which bioaccumulation and bioconcentration factors are estimated to back-calculate to a protective PFAS concentration in water (see **Section 16.3.3.3**).

Toxicity data measured on the basis of receptor tissue concentration can also be used to derive purely tissue-based aquatic life protection criteria for PFAS. Tissue-based aquatic life criteria would be subject to less uncertainty because the effects levels directly relate toxic dose and exposure pathways, and because BAFs or BCFs would not be needed to back-calculate to a water concentration. This approach has recently been used for methylmercury (**USEPA 2010**) and selenium (**USEPA 2016**) in fish in which tissue-based criteria concentrations take precedence over water column-based concentrations.

16.3.1.4 Assessment Endpoints

Assessment endpoints represent the expression of environmental values to be protected by the management framework (**USEPA 1992**). In the case of ambient water quality criteria, the values to be protected are aquatic life and their uses. As discussed in Section 16.3.1, the levels and types of protection are those afforded by the Clean Water Act and USEPA guidelines (**USEPA 1985**). These guidelines specify protection of all but 5% of the most sensitive aquatic organisms with respect to survival, growth, and reproduction.

16.3.1.5 Measurement Endpoints

Measurement endpoints represent the direct empirical measurements of chemical exposure and biological effects that are used to ultimately represent the assessment endpoint (**USEPA 1992**). For PFAS, the relevant measurement endpoints are as follows:

- Measures of exposure: Given the conceptual model noted above, PFAS measurements would need to include both direct aqueous concentrations and aqueous concentrations estimated using appropriate bioaccumulation or bioconcentration factors (see **Section 16.3.3** and **Section 9.2.2**). Sufficient single chemical toxicity data for aquatic life criteria mainly exist for only PFOA and PFOS, although Tier II methods have been used by **Giesy et al. (2010)** for PFBS and by **Divine et al. (2020)** for acute and chronic values for 21 PFAS. Mixture studies for commonly detected PFAS are limited with no consensus on additivity, synergism, or antagonism. Thus, it is difficult to determine at this time whether measures of exposure could be considered additive for either PFOA + PFOS, or even for other PFAS.

- Measures of effect: According to USEPA guidance (**USEPA 1985**), measures of effect (either acute or chronic) are limited to those representing survival, growth, and reproduction. Therefore, only PFAS toxicity endpoints that either directly measure, or can directly represent, these endpoints should be used for derivation of aquatic life criteria. According to toxicity data summarized in Section 16.3.2 below (and in **Section 7.2**), available PFAS toxicity endpoints include several sublethal endpoints that could potentially be used to represent growth or reproduction. These include endpoints such as development, percent emergence, time to metamorphosis, and development of malformations. Therefore, states will need to determine whether or not these sublethal effects can be considered reliable quantitative measures of chronic effects of relevance to development of criteria. USEPA developed some logical considerations for this determination relative to endocrine-disrupting chemicals. These considerations may be applicable to PFAS (**USEPA 2008**).

16.3.2 Availability of Ecotoxicological Data

Toxicity data for establishing surface water quality criteria are available in peer-reviewed sources, mainly the primary literature. As noted in **Section 7.2**, most aquatic toxicity data are for PFOS, PFOA, and several other PFAS, including PFNA, PFBA, and PFBS. USEPA has curated peer-reviewed sources of ecotoxicity data for PFAS into the USEPA Ecotoxicology (ECOTOX) Knowledgebase (**USEPA 2024**). In addition, as stated in Section 16.1, USEPA has published draft national recommended aquatic life criteria for PFOA and PFOS in freshwater for public comment (**USEPA 2022**, **2022**) and a fact sheet for the criteria (**USEPA**

2022). Furthermore, USEPA has published their responses to external peer reviews of the draft criteria (**USEPA 2022**, **2022**).

This section provides a high-level overview of the available ecotoxicity data retrieved at the time and does not represent an exhaustive literature review for the classes of organisms specifically required for developing aquatic life surface water quality criteria. As noted in **Section 7.2**, the ecological toxicology of PFAS is an active area of research and users are encouraged to query the literature for updated values. Furthermore, states that undertake criteria development should review the studies discussed here and others that are subsequently published to determine if they meet regulatory requirements prior to using them for WQC development.

When developing surface water quality criteria protective of aquatic receptors, several criteria should be met when selecting appropriate studies, such as inclusion and adequate control animal responses and availability of details on experimental design. Test animals should be native and have reproducing wild populations. Also, note that many published endpoints are based on nominal rather than measured PFAS exposures; where measured concentrations are used, they can range from very low to very high percentages of the nominal values (<10–240%). Thus, it is recommended to use measured concentrations for establishing criteria.

The following sections highlight available data, or lack thereof, for the various taxonomic families required for WQC development (refer to **Table 16-3** and **Section 16.3.1.1**).

16.3.2.1 Bony Fish

Aquatic criteria development requires toxicity data for a salmonid species and one other species of bony fish. Fish toxicity studies are mainly focused on PFOS, for which data for multiple bony fish species (for example, rainbow trout (*Oncorhynchus mykiss*), sheepshead minnow (*Cyprinodon variegatus*), fathead minnow (*Pimephales promelas*), and zebrafish (*Danio rerio*) are available. As discussed in **Section 5.5**, PFOS preferentially accumulates in fish tissue relative to other PFAS. Overall, the data for other PFAS are generally limited to a single species or are lacking entirely (see **Section 7.2**).

16.3.2.2 Salmonids

Acute salmonid studies on the rainbow trout (*O. mykiss*) have been conducted under both fresh- and saltwater conditions for PFOS. EC50 range from 17 mg/L to 22 mg/L (**Robertson 1986**; **Palmer, Van Hoven, and Krueger 2002**); a no observed effect concentration (NOEC) was reported at 6 mg/L (**Palmer, Van Hoven, and Krueger 2002**). No chronic studies were identified for this or other salmonid species.

16.3.2.3 Other Fish Species

Several acute and chronic studies are available for non-salmonid species (see **Section 7.2**) and for PFAS other than PFOS. Data from these studies indicate acute toxicity of PFOS on the same order of magnitude as that observed for the rainbow trout, with some species perhaps even more sensitive; LC50s for zebrafish (*D. rerio*; a freshwater native to Asia) and fathead minnow (*P. promelas*, a freshwater native to North America) were approximately 10 mg/L, with EC50 and NOECs ranging between 1.5 and 3 mg/L (**Drottar and Krueger 2000**; **Ulhaq et al. 2013**). Data from an acute test on the North American saltwater species sheepshead minnow (*C. variegatus*) for PFOS suggest this species is less sensitive than its freshwater counterparts, with EC50 greater than 15 mg/L (**Palmer, Van Hoven, and Krueger 2002**).

Chronic studies of PFOS toxicity are more limited; only two studies of *P. promelas* were identified and indicated a NOEC of approximately 0.3 mg/L and EC50 of 7 mg/L (**Drottar and Krueger 2000**; **Oakes et al. 2005**) for early life stage development.

Acute and/or chronic zebrafish toxicity studies are also available for PFOA, PFBS, PFNA, PFBA, and PFDA. Acute toxicity is highly variable, but in general, these compounds appear to be less toxic than PFOS, with LC/EC50 reported up to 3,000 mg/L; the exception to this generality is PFDA, where an EC50 of 5 mg/L was reported (**Ulhaq et al. 2013**). Chronic toxicity data in this species for these compounds are more limited, but the few available studies suggest chronic toxicity may occur at substantially lower concentrations; for example, **Zhang et al. (2012)** reported a LOEC of 0.01 mg/L for growth/weight was for PFNA.

16.3.2.4 Other Aquatic Chordates—Amphibians

Amphibians represent an alternative class of aquatic/semi-aquatic chordates for which PFAS toxicity studies have been conducted. There are currently limited PFAS toxicity data available for amphibians, but this class of organisms is becoming more widely studied. Nearly all the available amphibian studies entail acute studies in aquatic life stages (with mortality as the endpoint) on PFOS exposures to several species, including the African clawed frog (*Xenopus laevis*), northern leopard frog (*Rana pipiens*), black spotted frog (*Rana nigromaculata*), spring creeper (*Pseudocris crucifer*), American bullfrog toad (*Lithobates catesbeianus*), and Asiatic toad (*Bufo gargarizans*). Of these, the northern leopard frog, spring creeper, and American bullfrog toad are native to North America. Amphibian data are discussed in **Section 7.2** for PFOS and PFOA. While mortality is observed in amphibians at water concentrations over 10 mg/L, recent studies such as those reported in **Pandelides et al. (2023)** indicate chronic toxicity occurs at lower levels (for example, a chronic LOEC for PFOA of 1.4 mg/L based on growth (body mass) for the northern leopard frog, and a chronic LOEC for PFOS based on the median time to complete metamorphosis in the western clawed frog of 1.1 mg/L).

16.3.2.5 Crustaceans

Freshwater

Acute

Acute toxicity data for freshwater crustaceans are focused on various daphnids (see **USEPA 2023**), with some data on freshwater shrimps such as the cherry shrimp (*Neocaridina denticulate*) (**Li 2009**). The largest number of publications are on the water flea, *Daphnia magna*, where 24–48-hour survival data are available for PFBA, PFOA, PFNA, PFDA, PFUnDA, PFDoDA, and PFOS. For most other freshwater species, acute toxicity data are limited to PFOA and PFOS.

Chronic

A smaller number of specific PFAS have been assessed for chronic toxicity in freshwater crustaceans. This includes PFOA, PFBS, PFOS, and GenX salt (ammonium 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)-propanoate) (**Drottar and Krueger 2001**). The 21-day survival and reproduction assay with daphnids is reported for both PFOS and PFOA **Section 7.2**). A series of studies evaluated bioavailability of certain PFAS with respect to exposure cofactors such as dissolved proteins, organic carbon composition, and other solutes (**Xia et al. 2015**; **Xia et al. 2015**; **Xia et al. 2013**). Although these studies do not estimate ECs or LCs for specified PFAS, they demonstrate that abiotic factors require consideration for exposure assessment and comparison across aquatic toxicity studies.

Saltwater

Acute

Two short-term studies (96 hours) provide some data on the acute toxicity of PFOS in marine crustaceans. The two tested species, both mysid shrimp, are *Siriella armata* and *Mysidopsis bahia,* for

which NOECs of 0.550—1.25 mg/L (**Drottar and Krueger 2000**; **Mhadhbi et al. 2012**) were derived; however, the values for *S. armata* were based on nominal concentrations (**Mhadhbi et al. 2012**). Additional studies are needed to evaluate other PFAS, as well as to discern differences in acute toxicity among benthic, epibenthic, and pelagic crustacean species.

Chronic

There are very few laboratory-based chronic toxicity studies available for marine crustaceans. One study was a 35-day growth, reproduction, and survival assay for PFOS using mysid shrimps (*Mysidopsis bahia*) (**Drottar and Krueger 2000**); (see **Section 7.2**). **Simpson et al. (2021)** more recently conducted a comprehensive study of PFOS sediment, overlying water, and/or porewater exposure to various benthic marine/estuarine species, reporting chronic effects data for an amphipod (*Melita plumulosa*), a copepod (*Nitocra spinipes*), and a crab (*Macrophthalamus* sp.).

While there are multiple studies regarding the occurrence of PFAS in wild-caught crustaceans, there is little information on biological effects. There is one recent report on wild-caught eastern school prawn (*Metapenaeus macleayi*) that found associations between metabolomic profiles and certain PFAS, but the exposure history for the animals was unknown (**Taylor et al. 2019**).

16.3.2.6 Mollusks

Freshwater

Acute

For freshwater mollusks, toxicity studies of PFOA and PFOS are limited to five species: bladder snail (*Physa acuta*), fatmucket clams (*Lampsilis siliquoidea*), black sandshell mussels (*Ligumia recta*), *Unio ravoisieri,* and zebra mussels (*Dreissena polymorpha*) (**Li 2009**; **Hazelton et al. 2012**; **Fernández-Sanjuan et al. 2013**; **Amraoui, Khalloufi, and Touaylia 2018**). The fatmucket and black sandshells are native to North America, whereas the remaining three are nonnative to the U.S. or are invasive species, as in the case of zebra mussels. Following 24- to 96-hour exposures, **Hazelton et al. (2012)** estimated lower EC50s for PFOS than for PFOA in both fatmucket clams and black sandshell mussels, where larvae were more sensitive than juveniles toward PFOS.

Chronic

Assessments of chronic effects in freshwater mollusks are limited to a single study with water concentrations that were much higher than those detected at most remediation sites. Following a 28-day exposure to PFOS, **Hazelton et al. (2012)** observed impaired growth effects in larval and juvenile fatmucket clams as determined by reductions in larval viability (LOEC of 0.0045 mg/L) and impaired metamorphosis (LOEC of 0.0695 mg/L), respectively. **Fernández-Sanjuan et al. (2013)** evaluated the physiological responses of nonnative and invasive zebra mussels toward a mixture of PFOA and PFOS (0.001—1 mg/L, 10 days), but did not report any mortality.

Saltwater

Acute

Acute toxicity studies for marine mollusks are currently limited to PFOA, PFNA, PFOS, and PFDA. A larger body of literature exists on occurrence and tissue concentrations in mussels and oysters, but almost none of these assessed whole or suborganism level effects. Two 96-hour acute toxicity tests reported NOECs for mortality in *Unio complamatus* (20 mg/L) and eastern oyster (*Crassostrea virginica*) (18 mg/L) (**Drottar and Krueger 2000**).

Chronic

Chronic studies for sublethal effects of PFAS on bivalve mollusks are limited to a few marine species, including green mussels (*Perna viridis*), Mediterranean mussels (*Mytilus galloprovincialis*) and California mussels (*Mytilus californianus*). In vitro and in vivo studies of California and Mediterranean mussels offer some information relative to effects on xenobiotic transport proteins and enzymatic activities, respectively (**Stevenson et al. 2006**; **Balbi et al. 2017**; **Gülsever and Parlak 2018**), but do not quantify ECs, NOECs, or LOECs for whole-organism exposures. A series of studies using green mussels reported on multiple endpoints following 7-day exposures to PFOS, PFOA, PFNA, and PFDA. These studies evaluated biochemical markers of altered xenobiotic metabolism (**Liu, Gin, and Chang 2014**), genotoxicity (**Liu et al. 2014**), oxidative stress (**Liu, Chang, and Gin 2014**), and immunotoxicity (**Liu and Gin 2018**) and reported NOECs ranging from 0.010-0.100 mg/L (PFOA and PFNA) down to 0.001-0.01 mg/L (PFOS and PFDA). **Simpson et al. (2021)** reported chronic no-effects levels for two species of bivalve mollusks (*Tellina deltoidalis* and *Soletellina alba*) of 0.22 mg/L and ≥ 0.85 mg/L, respectively.

16.3.2.7 Aquatic Insects

Freshwater

Toxicity data for aquatic insects (for example, midges, mayflies, dragonflies) are available in the literature, although they mainly stem from acute studies of PFOS, PFOA, and PFNA in the freshwater midge species *Chironomous riparius* and *C. tentans* (see **Section 7.2.2.1**). Of the aquatic invertebrate species, the chironomids are currently reported as having the highest sensitivity to PFOS (**MacDonald et al. 2004**). Acute effects are observed to generally occur at water concentrations of approximately 60 mg/L or greater, with chronic effects induced at concentrations less than 0.002 mg/L (see **Section 7.2.2.1**).

Toxicity data for other orders of aquatic insects are very limited, although some studies indicate that the odonates may also be highly sensitive to PFAS exposures. **Van Gossum et al. (2009)** found behavior changes following long-term (4-month) exposure of PFOS to damselflies (*Enallagma cyathigerum*) with NOECs reported from 0.010 mg/L to 0.100 mg/L. **Bots et al. (2010)** conducted a lifetime exposure study of PFOS on *E. cyathigerum*, finding adverse effects on egg development, larval hatching, development and survival, metamorphosis, and body mass, with NOECs ranging from less than 0.010 mg/L (for metamorphosis) to over 10 mg/L (for egg hatching success).

Saltwater

No toxicity information was found on marine insects.

16.3.2.8 Algae/Vascular Plant Data

Section 7.2.4.1 provides a summary of aquatic plant toxicity data. Data on the toxic effects of PFAS on aquatic plants are limited to studies that evaluated PFOS exposures on several algal/microalgal species, on duckweed (*Lemna gibba*), and on watermilfoil (*Myriophyllum spicatum)*. Acute toxicity of PFOS in freshwater aquatic plants has been found to range from approximately 30–100 mg/L, with chronic values generally about tenfold lower.

In a chronic study on a saltwater species of diatom (*Skeletonema costatum*) **Desjardins et al. (2001)** reported observed effects at approximately 3 mg/L. **Simpson et al. (2021)** reported a chronic NOEC of > 4.2 mg/L for growth rate as an endpoint.

16.3.3 Aquatic-Dependent Wildlife

This section considers aquatic-dependent wildlife (primarily birds and mammals) in developing surface water criteria for PFAS. It is important to note that the development of such criteria is still in its infancy because (i) there are few laboratory or field studies with data on the toxicity of PFAS to wildlife, (ii) data of sufficient/appropriate quality on the concentration of PFAS in the diet of aquatic-dependent wildlife are limited, and (iii) the unique properties of PFAS make the modeling of food chain uptake complicated. The following sections briefly discuss why aquatic-dependent wildlife should be considered and present methods that can be used to derive surface water quality criteria for their protection.

16.3.3.1 Why Consider Aquatic-Dependent Wildlife?

As described in **Section 16.3.1**, the focus for deriving surface water quality criteria is primarily on protecting aquatic life (for example, plankton, benthic invertebrates, fish, shellfish). However, it has long been recognized that wildlife species may be more sensitive than aquatic species toward certain contaminants as a result of dietary exposure, particularly if the contaminant is bioaccumulative (**USEPA 1985**, **1989**, **2005**).

Because some PFAS are known to be bioaccumulative (see **Section 5.5**), it cannot be assumed that surface water quality criteria derived for the protection of aquatic life will also be protective of aquatic-dependent wildlife. Protection of aquatic-dependent wildlife is of importance at contaminated sites, particularly for wildlife with smaller home ranges that coincide with the extent of PFAS impacts (**Conder et al. 2020**; **Divine et al. 2020**). In developing risk-based screening levels (RBSLs) for different classes of receptors, Divine and coworkers found that for some PFAS, RBSLs for aquatic-dependent wildlife are lower than RBSLs for aquatic life. Lastly, due to the long-range transport for some PFAS (see **Section 5.3**), there could be a need for surface water quality criteria protective of aquatic-dependent wildlife in remote areas where management actions to address human exposure may not address ecological exposures.

16.3.3.2 Surface Water Quality for the Protection of Wildlife

The principal approach to developing protective surface water quality for wildlife is to use standard desktop wildlife exposure models to solve for a media concentration that results in exposure being equal to a selected toxicity threshold. In modeling exposure, such an approach either uses measured contaminant concentrations in the tissue of the prey/forage or relies on BAFs (to estimate prey/forage tissue concentrations). The same toxicity threshold can be used in either case. Another approach is to determine a critical concentration in the tissue of a prey item that is protective of the wildlife receptor. The advantage of this "body burden" approach is that it avoids the uncertainties associated with relying on BAFs; however, it entails the collection of site-specific tissue data for implementation.

These two approaches are discussed in the following sections.

16.3.3.3 Calculation of a Protective Surface Water Quality Value for Aquatic-Dependent Wildlife

In 1995, USEPA published the Great Lakes Water Quality Initiative (GLI) Technical Support Document for Wildlife Criteria (**USEPA 1995**). The GLI Technical Support Document provided technical information on the derivation of surface water quality criteria to protect birds and mammalian wildlife. The method is similar to that used to derive noncancer human health criteria and relies on the use of BAFs in a food chain model to back-calculate a surface water value (**USEPA 2017**). USEPA has used this method for chemicals such as DDT, PCBs, 2,3,7,8-TCDD, and mercury, for which aquatic life-based criteria were modified to become more stringent in order to incorporate adverse effects to wildlife (**USEPA 1995**).

States and tribes bordering the Great Lakes, as well as other states, such as California, have since adopted this approach to derive aquatic-dependent wildlife surface water quality criteria.

The GLI Technical Support Document (**USEPA 1995**), Section III, provides the equations needed to calculate a protective surface water quality value for birds and mammals from exposure via food and water ingestion (see text box).

Standard Equation for Derivation of a Protective Surface Water Quality Value for Aquatic-Dependent Wildlife

$$\text{WV (mg/L)} = \frac{\text{TD(mg/kg bw/d)} * \left(1/(\text{UF}_\text{A} * \text{UF}_\text{S} * \text{UF}_\text{L})\right) * \text{BW(kg)}}{\text{W(L/d)} + \text{sum}\,[\text{FC}_\text{i}\text{(kg food/d)} * \text{BAF}_\text{i}\text{(L/kg)}]}$$

Where:

WV = wildlife value in milligrams of substance per liter (mg/L)

The bird WV is the geometric mean of the WVs calculated for the three birds and the mammalian WV is the geometric mean of the WVs calculated for the two mammalian wildlife species.

TD = test dose in milligrams of substance per kilogram per day (mg/kg-d) for the test species. This shall be either a NOAEL or a LOAEL (expressed either on a wet weight or dry weight basis for consistency with FC).

UF_A = uncertainty factor (UF) for extrapolating toxicity data across species (unitless). A species-specific UF shall be selected and applied to each representative species, consistent with the equation.

UF_S = UF for extrapolating from subchronic to chronic exposures (unitless)

UF_L = UF for LOAEL to NOAEL extrapolations (unitless)

BW = body weight in kilograms (kg) for the representative species

W = daily volume of water consumed in liters per day (L/d) by the representative species

FC_i = daily amount of food consumed from the i^{th} trophic level in kilograms per day (kg/d) by the representative species (expressed either on a wet weight or dry weight basis for consistency with TD)

BAF_i = bioaccumulation factor for the i^{th} trophic level in liters per kilogram (L/kg)c

By extension, this method can be used in the development of surface water values for PFAS. The GLI approach uses five representative species (bald eagle, herring gull, belted kingfisher, mink, and river otter), because these species are likely to be subjected to the highest exposure from bioaccumulative contaminants through the aquatic food web. However, depending on the conceptual model under evaluation, it might be more appropriate to select different representative species (for example, sandpiper species given their relatively high incidental ingestion of sediment). **Giesy et al. (2010)** provided good examples of using the GLI approach to calculate surface water criteria for trophic level IV predatory birds for two compounds, PFOS and PFBS.

The GLI Technical Support Document includes tables with values for the exposure parameters (body weight, water and food ingestion rates, as well as prey/forage trophic level). Other sources of receptor-specific exposure parameters can be found in USEPA's Wildlife Exposures Factor Handbook **USEPA (1993)**, **Conder et al. (2020)**, and **Divine et al. (2020)**. However, it is a best practice to select exposure parameters that are most representative of the populations living within the area to which the criteria will be applied. Climate, temperature, habitat, and many other factors specific to the region underlying the studies that are the basis of the exposure factors can vary significantly.

Key PFAS-specific components to this approach are the selection of, and sources for, BAFs to estimate prey or forage tissue concentrations, and the wildlife toxicity data for PFAS (no observed adverse effect levels [NOAELs] and lowest observed adverse effect levels [LOAELs]).

As noted in **Section 16.2.1.4**, given the influence of BAFs on calculation of a water quality value, their use and applicability need to be carefully considered. Information on a literature review and selection of BAFs is provided in Section 5, with a compilation of BAFs and their sources presented in Table 5-1 (see link in **Section 5.5**).

As noted, there are currently few PFAS toxicity data for wildlife in the scientific literature or standard toxicity databases. Furthermore, given the minimum toxicity database requirements for developing Tier I criteria (see **USEPA (1995)**), it is unlikely these requirements will be met for individual PFAS at the current time. Note that the GLI technical support document does provide guidance on developing Tier II wildlife values for contaminants with limited toxicity data (**USEPA 1995**). **Conder et al. (2020)** and **Divine et al. (2020)** are good sources of PFAS toxicity reference values (TRVs) for avian and mammalian wildlife that not only include tables of recommended values, but also provide guidance on reviewing toxicity studies reported in the literature and selecting the values.

16.3.3.4 Calculation of a Protective Prey/Forage Tissue-Based Value

USEPA published a science advisory board consultation document on tissue-based criteria for "bioaccumulative" chemicals as proposed revisions to aquatic life guidelines (**USEPA 2005**). The approach is based on the recognition that for bioaccumulative chemicals, there is a need to develop criteria that account for multiple routes of exposure such as the diet, sediment, and water.

The approach is similar to that for developing a water-based value in that it is based on a daily dietary dose of a chemical that is protective of most sensitive species and integrates it with exposure potential to estimate a chemical concentration in the dietary tissue of representative species, also referred to as a wildlife value (WV). The advantage of this approach over the water-based approach is that it eliminates the uncertainty associated with using BAFs but requires the sampling of appropriate prey biota for implementation.

The equation in the text box below used to develop a tissue-based WV is based on the GLI model for aquatic-dependent birds and mammals but expressed as the chemical concentration in the diet rather than in water (see **USEPA (2005)**, Section 4.4). As discussed above, sources of exposure information can be found in **USEPA (1993**, **1995)**, **Conder et al. (2020)**, and **Divine et al. (2020)**.

Note that if the target aquatic-dependent wildlife is exposed via several trophic levels, a WV will need to be calculated for each trophic level using BAFs, or if available, applicable BMFs for the targeted aquatic-dependent wildlife receptor (see **Section 5.6**). This will then guide which species of prey/forage to target when monitoring for compliance.

Standard Equation for Derivation of a Protective Prey Tissue Value for Aquatic-Dependent Wildlife

$$\text{WVww (mg/kg food)} = \frac{\text{TD(mg/kg bw/d)} * \left(1/(\text{UF}_\text{A} * \text{UF}_\text{S} * \text{UF}_\text{L})\right) * \text{BW(kg)}}{\text{sum } [\text{FC}_\text{i}\text{(kg food/d)}]}$$

Where:

WVww = wildlife value expressed as the chemical concentration in the diet of each representative species measured as wet weight

TD = test dose expressed as daily dietary dose (wet weight) from selected study, either a NOAEL or a LOAEL

UF = uncertainty factors for interspecies variation (UF_A), subchronic to chronic (UF_S), and LOAEL to NOAEL (UF_L)

BW = body weight of a representative species

FC_i = amount of daily food consumed for each species from the i^{th} trophic level

Because this approach was developed to address the bioaccumulation of lipophilic chemicals, it assumes the chemical contribution from water is negligible, which, as discussed in **Section 5.5.2**, may not be the case for some PFAS. Furthermore, it does not consider dietary intake via the incidental ingestion of sediment, which as noted above, can be included depending on the species of wildlife being evaluated. As indicated by **Larson, Conder, and Arblaster (2018)**, incidental sediment ingestion could be a significant contributor to exposure to aquatic-dependent wildlife.

16.4 Sampling and Analysis

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about the effects of suspended sediment on surface water sampling and measurement of PFAS (see **Section 1.3.6**).

This section reviews the collection and analysis of surface water, biota, and surface sediment from aquatic systems. In most instances, the precautions taken to minimize biasing the concentrations of PFAS in the samples from sampling equipment and/or sampler protective clothing, among others, are the same as those described in **Section 11.1** when sampling groundwater, surface soils, or fish. There are some unique aspects about where to collect a surface water sample that are discussed in this section. For analysis, the methods used for PFAS in drinking water, soil samples, plant material, and groundwater described in **Section 11.2** are also used for surface water, biota, and surface sediment. Issues and recommendations unique to sampling PFAS-containing foam are covered in **Section 16.5**.

16.4.1 Surface Water Sampling

Surface water bodies include, but are not limited to, oceans, bays, estuaries, lakes, streams, ponds, creeks, springs, wetlands, reservoirs, and artificial impoundments. The sample collection for PFAS from a surface water body is essentially the same as for other chemicals or pollutants. Standard operating procedures for sampling equipment have the same limitations, such as PFAS-free samplers, that are used for collection of samples from potable water systems or groundwater monitoring wells. See **Section 11.1** for general sampling techniques and equipment requirements for PFAS sampling, including examples of PFAS-specific sampling protocols, and **Section 11.2** for analytical methods and techniques.

In addition to USEPA's Compendium of Superfund Field Operations Methods (**USEPA 1987**) for general guidance on sampling surface water, Michigan (**MI EGLE 2021**; **MI EGLE 2024**) and New York (**NY DEC 2023**) have recently developed guidance specifically for PFAS. Some examples of sampling consideration in a moving water body such as a creek include:

- sampling far enough downstream from the suspected source to allow for adequate mixing
- collecting samples from the upstream side of the sampler to minimize compromising the sample
- collecting the sample from mid-depth in the thalweg (that is, along the natural direction of water flow, below the air/surface water interface but above the surface water/surface sediment interface)
- depending on your sampling objectives, collecting samples from multiple depths to provide the necessary information. This is due to the potential for stratification of PFAS concentrations through the water column and the location of the receptors of concern (benthic organisms or fish).

Due to chemical properties of PFAS, concentrations in the surface water near the discharge location may be higher at or near the surface. Collecting samples only from the surface may inform you of the worst-case scenario but may not provide information on locations away from the discharge point, such as at a water intake for domestic and industrial use. The same concern applies to PFAS-containing foam. Including this foam in the sample will bias the PFAS concentration high due to the elevated concentrations in the foam (see **Section 16.5.5**).

Additional considerations for surface water sampling during site characterization are noted below in **Section 16.4.5**.

16.4.2 Biota Sampling

Because some PFAS are known to accumulate in aquatic biota and in some instances may drive the development of surface water quality criteria (see Sections **16.2.2.2** and **16.3.3**), sampling for biota may be an important component of a monitoring program or health assessment. The species of biota to collect and the tissue types to sample will depend on the study objectives. For example, a human health–based study should focus on collecting species within a size range targeted by recreational anglers or crabbers (**NJDEP 2018**), while an ecological-based study should focus on species representing different trophic levels, as well as benthic and pelagic habitats, and be of a size range targeted by piscivorous birds and mammals. In addition, because it has been shown that some PFAS bioaccumulate to a higher degree in the blood and liver compared to the flesh (see **Section 11.1.7.8**), collecting and analyzing different tissue types might be an important consideration in a study design.

General guidance on the use of different sampling techniques for fish and shellfish such as gill nets, seines, trawls, and electrofishing, can be found in **USEPA (2000)**, and many states have their own guidance, which should be considered. When sampling biota for PFAS analysis, the additional precautions described in **Section 11.1** should also be followed, and some states, such as Michigan, have developed their own PFAS-specific guidance (**MI DEQ 2019**). For example, collected biota should be wrapped in HDPE or polypropylene bags and/or aluminum foil, and stainless-steel tables, knives, and weighing scale hooks should be used for sample processing (in the field or in the lab), as well as untreated wooden cutting boards. Given that PFAS are widely present in the environment and human-made materials, it will be important to collect equipment blanks during sample collection and processing. Close coordination with the analytical laboratories will be needed to ensure similar PFAS-specific precautions are followed at all times (see **Section 11.2**).

Additional considerations include sampling surface water and surface sediment within the same area from which the biota are collected. While it is recognized that many aquatic biota are migratory or exhibit extended home ranges, this information will help support identification of PFAS sources as well as potentially the development of site-specific BCFs, BAFs, and biota-sediment concentration factors (BSAFs). BSAFs represent the amount of PFAS taken up by an organism from the sediment and are measured as the ratio of the concentration in an organism to the concentration in sediment. BSAFs are typically developed for those organisms in close contact with surface sediment, such as benthic and epibenthic invertebrates, as well as benthic fish (**Figure 17-1**).

16.4.3 Sediment Sampling

Because sediment can be a contaminant sink, a transport mechanism, and a source of contaminants to a surface water body and to benthic organisms, it may be necessary to sample sediment for PFAS to support an understanding of its contribution to the surface water quality and/or biota tissue concentrations. Conventional sediment sampling and coring techniques and protocols can generally be used to obtain samples for analysis of PFAS. **Section 11.1** describes sampling protocols for all types of samples, with additional detail for porewater in **Section 11.1.7.4** and sediment samples in **Section 11.1.7.7**

Examples of seven different sampling protocols typically used are detailed below:

- Where the sediment is accessible and can hold its form without collapsing, a corer or “Dormer Piston” sediment sampler could be used.
- When collecting samples from shore or wading, the sample should be collected from the upstream side of the sampler to minimize potentially compromising the sample from stirred-up sediment or from a waterproof coating on waders.
- Sediment core samples are collected directly from single-use liners and are not reused.

- There can be sites where the sediment is accessible but either the sediment is sloppy and would not hold its form, or there is a high density of tree roots or boulders and a corer or piston sampler would not be feasible. In these situations, a stainless-steel trowel could be used to collect surface sediment samples.
- For subtidal sediments, the depth below the sediment surface from which the sample is required determines what equipment is needed. For surface sediment samples, devices such as a modified van Veen grab, Ekman grab, or Ponar grab sampler can be used, while for deeper subsurface samples, devices such as a vibracorer should be used. This nondedicated equipment (equipment used for more than one water body or location) should be verified as PFAS free, and the sampling program should include collection of equipment blanks.
- For sampling subtidal sediments, the depth from which the sample is required dictates what specialized sampling equipment is needed.
- Samples should be collected in HDPE wide-mouth bottles provided by the laboratory, and fitted with an unlined (no Teflon) polypropylene screw cap. A minimum of 50 g of sample is needed. Field observations, including sediment type, texture, and color, should be recorded.

16.4.4 Analytical Methods

Analytical methods for the analysis of PFAS in a surface water share many of the same components as those used for PFAS in other non-drinking water media. A discussion of these analytical methods is found in **Section 11.2**. Most surface water samples for PFAS are analyzed by Modified USEPA 537.1 and use the DOD's Quality Systems Manual (QSM) for Environmental Laboratories, Version 5.3, Appendix B, table B-15 (**USDOD 2019**), providing the most current and comprehensive set of quality standards for PFAS analysis. In June 2019, USEPA validated USEPA SW-846 Method 8327 for the analysis of PFAS in surface water, groundwater, and wastewater (**USEPA 2021**). Method 8327 is available for use but has not yet been fully incorporated into SW-846. Method 8327 has not been widely used because it creates laboratory cleanup and accuracy issues and is not accepted by DOD.

16.4.5 Site Characterization

Conducting site characterization of PFAS at a site with a surface water body should begin with determining the beneficial uses as described in **Section 16.1.1**. Those beneficial uses should be used to select the types of samples to be collected. For example, if evaluating PFAS-containing foam, sample collection will be required near the surface; if evaluating potential impacts to benthic organisms, samples closer to the sediment/water interface should be collected, and if evaluating pelagic fish, it may be necessary to collect a surface water sample integrated throughout the water column. Point sources such as stormwater discharge pipes or a publicly owned treatment works (POTW)discharge should be located and potentially targeted for sampling to evaluate sources of PFAS to the water body. Establishing the locations of natural and human-made water inflow and outflow points to the water body will also help guide sample points and potential exposure sites. Groundwater/surface water interaction may also play a role in establishing the conceptual site model and locating places to sample. **Section 10** contains more specifics regarding site characterization and development of a conceptual site model.

16.5 Surface Water Foam

PFAS-containing foam (discussed in this section) is differentiated from AFFF (discussed in **Section 3**) in that it is the result of dissolved-phase PFAS in surface waters that have been agitated by wind or wave action and aggregated into a mass at or above the surface of the water, irrespective of the PFAS source type. As noted in **Section 16.2.2.4**, the presence of foam does not necessarily indicate the presence of PFAS. Foam can form naturally when the surface tension of water decreases and the concentration of

organic matter, such as dissolved organic carbon (DOC), increases and is mixed into the water. The decomposition of organic material into water, or a storm event mobilizing existing organic material, can lead to the natural formation of foam on surface water. For example, a study of PFAS and DOC in foam forming on a freshwater lake in Michigan showed that PFAS made up less than 0.1% of the DOC present in the foam samples, which indicated that DOC was the primary cause of the foam and not the presence of PFAS (**Schwichtenberg et al. 2020**).

This section discusses the formation of PFAS-containing foam, the characteristics of, and stratification within the foam, a brief discussion of analytical methods for foam, and the enrichment of PFAS concentrations in foam compared to the underlying water column. A case study on PFAS containing foam (the Minnesota Project 1007 Feasibility Study) is presented in **Section 15.5.1**.

16.5.1 Foam Above Water Interface

PFAS-containing foam may occur at and above the air-water interface on surface waters. In this context, surface water is subdivided and defined below. This subdivision describes vertically downward the air-water interface, surface micro layer (SML), neuston, and underlying water column. See **Figure 16-2**.

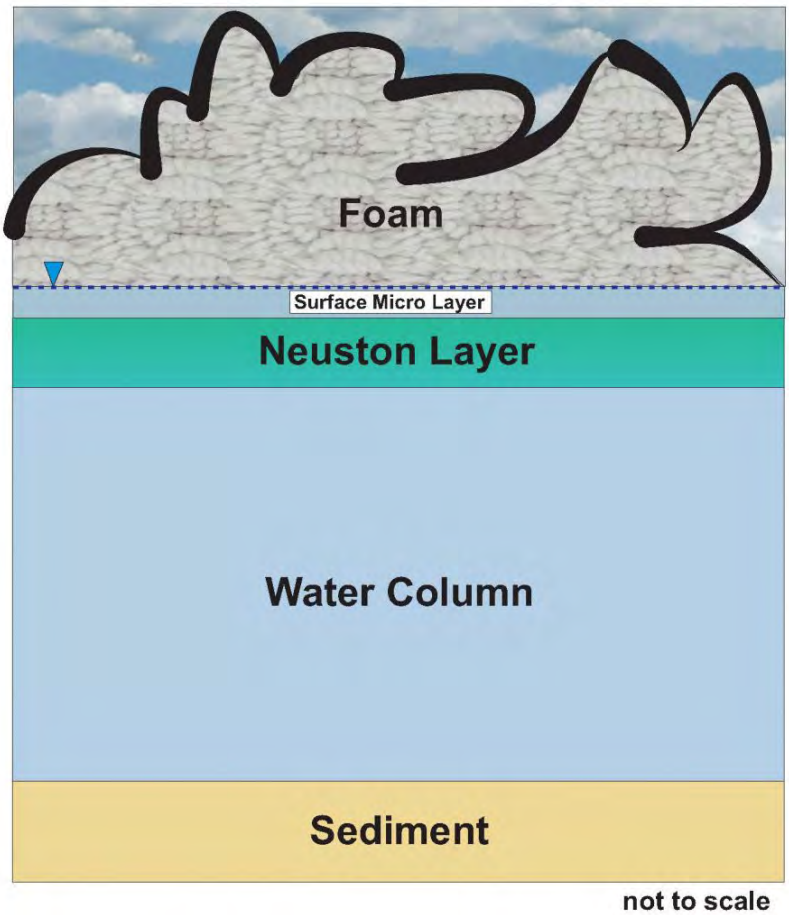

Figure 16-1. PFAS foam on surface water.

Although it is typical to find PFAS-containing foam near release source areas, it may also occur some distance away when surface water bodies are interconnected. Source proximity may impact the concentration of PFAS analytes in the foam column itself. However, concentrated PFAS-containing foam may occur on surface water bodies containing low to nondetect PFAS concentrations immediately below the foam itself some distance from the source areas (**MPCA 2020**; **Schwichtenberg et al. 2020**). Underlying partitioning considerations are discussed in **Section 5.2.2**, Considerations for PFAS Partitioning.

Variable surface water depth, flow conditions, and co-contaminant mixtures may affect the presence, aggregation, and physical movement of PFAS-containing foam in the SML and above the air-water interface. These factors may be considered when evaluating fate and transport of PFAS-containing foam, as it may partition back into solution in the water column as it moves with the flowing water. A foam column at and above the surface may be affected by physical forces, including precipitation, wind, and wave action, causing it to separate and travel as smaller foam source material “islands” or collapse and dissolve back into the water column as it travels with the wind and waves.

16.5.2 Foam Characteristics

PFAS-containing foam has wide-ranging visual and textural appearances. These characteristics range from deflated, dry, or aged in appearance, as small aggregations of bubbles accumulating into larger islands of billowed piles, frozen in standard bubble foam appearance or frozen in thin sheetlike membrane appearance, frozen on top of snow and ice, dark coloration due to detritus or organic content, and bright white, with an aerated shaving cream or whipped cream texture.

"High turbulence generated foam tends to be fluffy, actively regenerates, and does not appear to contain high levels of organic material; while older, deflated foam does not actively regenerate and appears to be rich in organic or non-organic particulates. Foam observed along creeks and streams tend to vary in appearance and can occur with any combination of the above-listed characteristics. Wind-generated foam has only been observed on lakes, has generally been white and fluffy, and has actively accumulated along a downwind shoreline. Both organic-rich foam and unfrozen foam with a wrinkled appearance have been observed to accumulate along ice dams or ice shelves" (**MPCA 2020**).

16.5.3 Stratification Within Foam

Surface water foam is known to be laden with bacteria, detritus, and other naturally occurring material. However, stratification of concentrations of PFAS within the foam column or pile may be due to a number of physical and chemical conditions. For example, co-contaminants may impact the degree of stratification in the surface water column and the foam itself. Additionally, the foam may be aged and in a dry condition toward the top of the foam column/pile, creating a concentration gradient toward the base of the column/pile.

Sampling should be conducted so as to maximize consistency and reproducibility during PFAS surface water sampling to understand PFAS stratification in the surface water column and the foam. The Michigan Department of Environment, Great Lakes, and Energy (EGLE) has published a surface water foam sampling guidance, a surface water foam study report, and has published other PFAS sampling guidance (**MI EGLE 2019**, **2024**, **2021**).

As of the date of this publication, the state of Minnesota is working with technical support from the USEPA Office of Research and Development to evaluate foam sampling techniques aimed at understanding the concentration variability within the foam, at the surface micro layer, and the underlying near-surface water column.

16.5.4 Frozen Foam

PFAS-containing foam has been confirmed in frozen form on surface water in Minnesota, Michigan, and Wisconsin (**MPCA 2019**). Appearance of the foam is difficult to distinguish from snow and ice along stream or lake embankments. PFAS-containing ice has been confirmed in Michigan and can visually take the form of thin film-type islands or within massive ice (**MPCA 2020**). The ice appears to stratify vertically in concentration where located in massive ice. Confirmation of the degree of stratification in massive ice is an on-going study at this time. Early results from Michigan indicate it appears to increase in concentration with elevation in the ice cores, indicating the ice/air interface may be where the highest concentrations exist, similar to the propensity for PFAS to travel at the air/water interface.

16.5.5 Surface Micro Layer

As previously discussed, PFAS in solution tends to accumulate at the air/water interface, also known as the surface water micro layer or SML. The SML in this context, is generally understood to mean the layer in contact with ambient air and is approximately 50µm thick (**MPCA 2020**). Variability in sample

collection techniques and the extent to which this interface is included or omitted in the collection of a bulk water sample may result in biased analytical results. This can further lead to incorrect conclusions about PFAS concentrations in surface waters at source areas and in the downgradient direction. Where the SML is not characterized and only the deeper water column is sampled, PFAS concentrations may be biased low . The SML may be the location of the highest PFAS concentration in the water column. Omitting collection of the SML could potentially lead to an inaccurate assessment of the risk to human and ecological receptors. Therefore, when preparing a sampling plan, it is important to consider the depth of the water column that is most relevant to the human and ecological receptors that may be exposed to PFAS; different receptors may require unique sampling strategies. At this time, methods to characterize PFAS concentrations and the nature of exposed biota in the SML are still under study (see SERDP project ER19-1205, **Field et al. 2021**).

Due to the physical and chemical properties of PFAAs, including their hydrophilic heads and hydrophobic tails, a given molecule may preferentially exist within the SML. **Section 4** includes information about PFAS physical and chemical properties. Sampling the SML in relative isolation from the neuston layer below it or the foam column above it may become an important factor in accurate representation of the concentrations emanating from the SML into foam above when physical agitation occurs. The Michigan EGLE guidance for sampling PFAS-containing foam provides a starting point to understanding the considerations of this sampling protocol in varied circumstances (**MI EGLE 2019**). Michigan EGLE has also published other PFAS sampling guidance that may be relevant for a project (**MI EGLE 2024**).

16.5.6 Neuston Layer

The neuston layer may be defined, for the purposes of studying PFAS-containing foam, as the zone directly underlying the SML that is typically enriched with biological life and aligns with the larger definition by **Wurl et al. (2017)**, which was related to strata thicknesses. **Wurl et al. (2017)** indicated:

> "The sea surface microlayer is the boundary interface between the atmosphere and ocean, covering about 70% of the Earth's surface. The SML has physicochemical and biological properties that are measurably distinct from underlying waters. Because of its unique position at the air-sea interface, the SML is central to a range of global biogeochemical and climate-related processes. Historically, the SML has been summarized as being a microhabitat comprised of several layers distinguished by their ecological, chemical and physical properties with an operational total thickness of between 1 and 1000 µm."
>
> "While this 1,000 µm SML definition is large enough to encompass the neuston, the refined definition of 50 µm thick SML provided above is considered the state-of-the practice for the purposes of understanding and evaluating PFAS-containing foam and layers of significance immediately underlying it. **Liss and Duce (1997)** clarify the neuston below the 50 µm SML as two distinct biological layers, "[The] neuston can be divided into epineuston and hyponeuston. The epineuston includes more than 40 species of water striders, *Halobates*, inhabiting the open ocean and coastal areas. The hyponeuston are organisms in the surface centilayer including hydrozoa, mollusks, copepods, isopods, decapod crustaceans, fishes, and the seaweed *Sargassum*."

Section 11.1.7.3 includes generalized surface water sampling guidance references. For PFAS-containing foam on surface water, it appears that the neuston layer is of particular importance in understanding dissolved-phase PFAS within the water column that may be available to the SML for aggregation and concentration into foam at the air-water interface. The neuston may also provide insight into the stratification of PFAS in the water column below the interface.

16.5.7 Analytical Methods

Analytical methods for the analysis of PFAS-containing foam are essentially the same as those used for PFAS in other non-drinking water media. A discussion of these analytical methods is found in **Section 11.2**. As with all non-drinking water samples, there is no USEPA-certified method for the analysis of PFAS at the time of this publication. Efforts are being undertaken to develop the various analytical methods for the various non-drinking water media. Since there may be very high levels of PFAS in PFAS-containing foam, the laboratory should be warned of this potential so that it can take the necessary precautions during analysis. In the Minnesota case study (**MPCA 2020**), a commercial laboratory analyzed PFAS-containing foams using their proprietary method of LC/MS/MS. These foam samples were collected following the Michigan foam sampling guidance noted above, with caution taken to prevent dilution of the sample by minimizing contact with the water during foam sample collection.

16.5.8 Enrichment Factors

Enrichment factors are defined for the context of this document as "the calculated fold increase (or decrease) of PFAS concentrations in foam compared to the co-located surface water sample. These values are unitless and are determined by dividing the foam concentration of a specific PFAS compound by the concentration of the same compound detected in the surface water sample. The foam enrichment factor for a given PFAS compound indicates whether that compound is preferentially concentrating into the foam from the bulk water column" (**MPCA 2020**).

As reported by **McMurdo et al. (2008)**, "**Kaiser et al. (2006)** observed that surface foam created by bubbling air through an aqueous solution was enriched in perfluorooctanoate PFO by up to 3.2 times." However, simple enrichment factors have been documented in PFAS analytical samples from sites in Minnesota with factors ranging up to >32,000 times (**MPCA 2020**).

Currently, the extent to which the presence of foam may deplete PFAS concentrations in surface water is unclear. Enrichment factors of short-chain versus long-chain PFAS differed in one Minnesota case study (**MPCA 2020**) where 33 PFAS analytes were provided. With few exceptions, "short chain PFAS did not tend to enrich into the foam. Often the four, five, and six-carbon length chains were not detected in the foam samples. If they were detected, their concentrations were lower compared to concentrations measured in the surface water sample. Long-chain PFAS were found to have relatively higher foam-to-water enrichment factors than short chain PFAS. In a majority of the samples, 2-(N-ethyl-perfluorooctane sulfonamide) acetic acid (ETFOSAA) and perfluorooctanesulfonamide (PFOSA) had the largest foam enrichment" (**MPCA 2020**).

The ability of surfactants to concentrate in surface water foam is well known, but may be particularly of interest near source areas due to the ability of PFOA to partition into air circumstantially. Both terminal PFOA and PFOS may become entrained in these foams at high concentration, posing particular risk to ecological receptors in the neuston, SML, and those species reliant on the biological life above and below these zones. In support of this notion, **Battelle (2018)** indicated, "Foams in the natural environment are metastable and generally dissipate within seconds to days. Compositionally, foams are very similar to the SML, they are formed from the air entrapment on SML and they destabilize back to form SML. Compared to bulk water, foams are significantly enriched in many dissolved and particulate components, including particulate and organic matter, clay minerals, lipids, hydrocarbons, proteins, bacteria, hydrophobic contaminants, and heavy metals. As such, foams can provide a mechanism for fast transport of the contaminants through aquatic systems and a potential exposure pathway for aquatic animals and humans." Due to concerns over potential adverse health effects from exposure to PFAS containing foam, the Michigan Department of Health and Human Services (MDHHS) recently issued a recommendation advising residents and visitors to avoid foam on Michigan waterbodies (**MPART 2023**).

16.6 Effluent Limits for PFAS

This section provides information about the current status of effluent limits for PFAS from discharges of wastewater to surface water. The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about PFAS in marine environments (see **Section 1.3.5**).

16.6.1 Introduction

The protection of surface water quality from the impacts of discharges from publicly owned treatment works (POTWs) and industrial wastewater treatment works is based on the establishment of effluent limits for pollutants in the discharges from those facilities. The effluent limits are enforced through National Pollution Discharge Elimination System (NPDES) permits. Those effluent limits are developed by establishing technology-based (TBELs) and water quality-based (WQBELs) effluent limits for a specific pollutant and using the most restrictive value of the two for the final effluent limit in the permit.

Effluent limits are also informed by effluent limit guidelines (ELGs) that are national wastewater discharge standards developed by USEPA on an industry-by-industry basis. These are technology-based regulations that are intended to represent the greatest pollution reductions that are economically achievable for an industry. The standards for direct dischargers are incorporated into NPDES permits issued by states and USEPA regional offices and permits or other control mechanisms for indirect dischargers (**https://www.epa.gov/eg/learn-about-effluent-guidelines**).

As of the date of this document, there are no USEPA-established ELGs for PFAS. USEPA outlined an approach for establishing ELGs for select PFAS in its PFAS Strategic Roadmap (**USEPA 2021**) and the agency released its Effluent Guidelines Program Plan 15 in 2023 (**USEPA 2023** (see **Section 16.6.5**). Currently, only North Carolina has an NPDES permit with TBELs for PFAS. These TBELs were established using Best Professional Judgment, (**USEPA 2010**), the process used when ELGs are not available. Minnesota has adopted an NPDES permit with WQBELs for PFOS (see **Section 16.6.4.1**).

16.6.2 ELG Development and Implementation

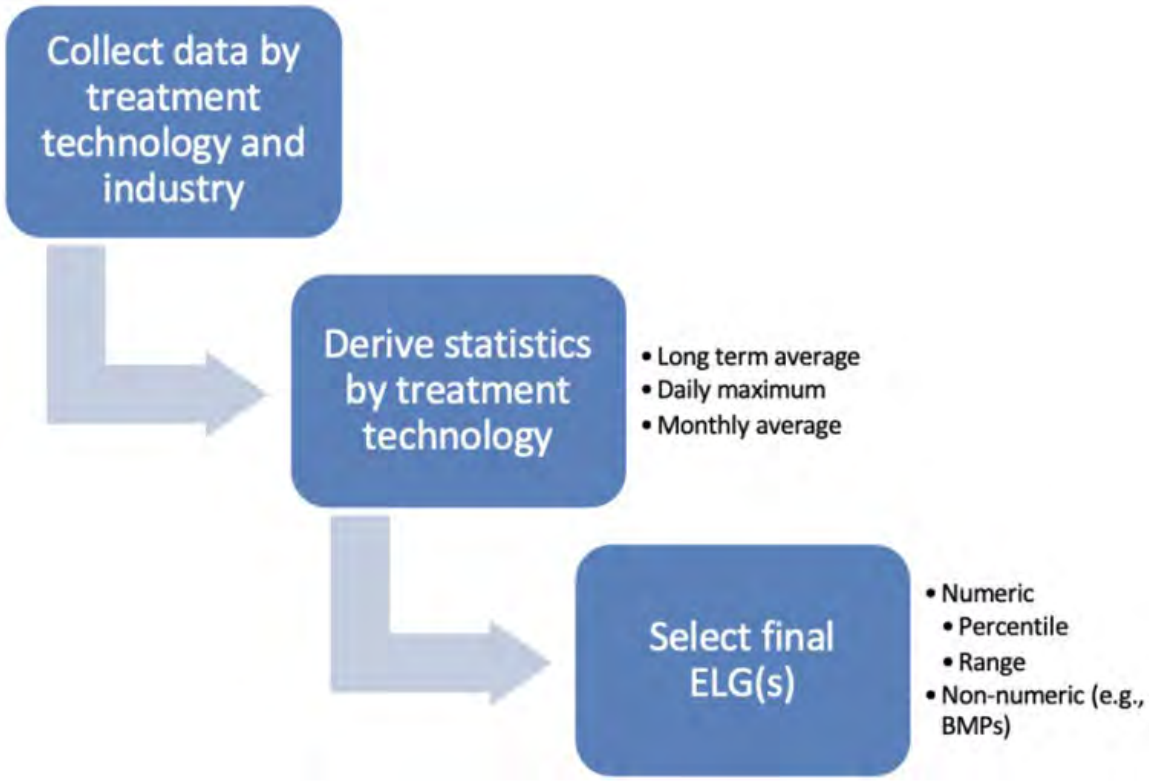
This section summarizes the state of practice for how technology-based ELGs are developed and used in the process for selecting NPDES permit effluent limits. This is followed by a discussion of the current state of knowledge regarding data collection and ELG development plans by USEPA for PFAS.

16.6.2.1 ELG Development

ELGs "represent the greatest pollutant reductions that are economically achievable for an industry" (USEPA 2021[2432]). ELGs for direct discharges to surface water are enforced through effluent limits established in NPDES permits issued by state and USEPA regional offices. For discharges to a POTW, the ELGs are enforced through a pretreatment program established by the POTW and enforced through its NPDES permit and the permits issued by the POTW for discharges into its collection system. For the process of using ELGs to develop TBELs for an NPDES permit, see section 5.2.1 of the Permit Writer's Manual developed by USEPA (**2010**).

ELGs are developed from empirical data that represent the performance of various technologies and best management practices available to any given industry type (See **Figure 16-3** for key steps in the process). For toxic and nonconventional pollutants such as PFAS, ELGs are developed based on Best Available Technology Economically Achievable (BAT) (**USEPA 2010**). The ELG based on BAT is established using the performance associated with the best control and treatment measures that facilities in an industrial category can achieve while also taking into consideration economic achievability as it relates to pollutant reduction benefits. Many other factors are also considered in establishing the ELG and not just for those

based on BAT. These factors can either be numeric or non-numeric/narrative limitations based on use of a specific best management practice (BMP). For more information, see section 5.2.1.1 of the Permit Writer's Manual (**USEPA 2010**).



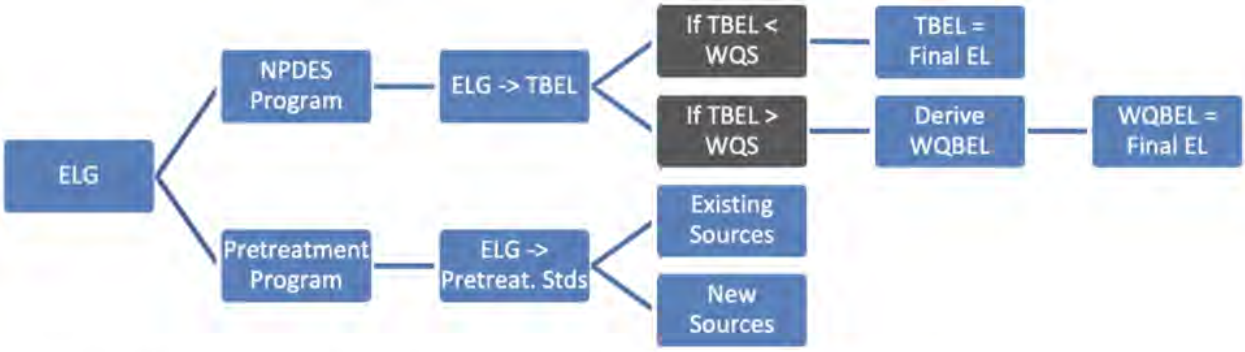


Figure 16-3. Key steps in the process of ELG development.

16.6.3 ELG Implementation

During the development of an NPDES permit, if it is found that the ELGs and/or state-established TBELs will not be sufficiently protective of water quality in the receiving water, then the CWA requires the development of WQBELs. WQBELs are developed so that the discharge authorized by the permit will not cause an exceedance of water quality standards that protect designated beneficial uses of the receiving water. See Section 16.1 for a discussion of beneficial uses for receiving waters. Some of the common beneficial uses include as drinking water, aquatic habitat, contact and non-contact recreation, and for commercial and sport fishing. Besides beneficial uses, the WQBELs take into account information about the receiving water that includes attributes such as ambient water quality, flow, dilution and additional discharges. For a comprehensive look at the WQBEL process, see Chapter 6 of the Permit Writer's Manual (**USEPA 2010**).

In summary, the implementation of ELGs depends on whether the permit is for "direct discharge" (a direct discharge from the facility to ambient surface water) or "indirect discharge" to a POTW and permitted via a pretreatment program (**Figure 16-4**). For direct discharges, the ELG is typically used to set the TBEL, which is then compared against the ambient water quality standard (WQS) to see if it can be achieved by the TBEL alone. If implementing a TBEL would not lead to an exceedance of the WQS, then the TBEL could be used to set the final effluent limitation, after consideration of site-specific factors. If the TBEL might lead to a WQS exceedance, then development of a WQBEL is typically required for setting the final effluent limitation. WQBELs must consider not only federal requirements but any state-specific requirements. Note that for PFAS, only a few states have WQS (see the Environmental Media Values

Table Excel File), so the availability of standards for use in setting WQBELs is as yet limited. As noted in **Section 16.1**, USEPA has published draft national recommended aquatic life criteria for PFOA and PFOS in freshwater (**USEPA 2022**; **USEPA 2022**). USEPA also plans to develop ambient water quality criteria for the protection of human health (based on drinking water and fish consumption) by Fall 2024. For more information on the potential risks to human health and ecological receptors from exposure to PFAS, see **Section 9.1** and **9.2**, respectively. For indirect discharges, pretreatment standards are selected from ELGs for existing sources, and for new sources.

- ELG = Effluent limit guideline (national technology-based discharge standards)
- TBEL = Technology-based effluent limit (minimum technologically achievable limit)
- WQBEL = Water quality–based effluent limit (limit needed to meet risk-based WQS instream)
- Final EL = Final effluent limit (allowable effluent discharge that meets WQS instream)
- WQS = Water quality standard (ambient, risk-based, for protection of aquatic life, human health, etc.)

Figure 16-4. Schematic for implementation of ELGs.

16.6.4 Status of ELGs and Effluent Limitations for PFAS

16.6.4.1 Existing ELGs and Effluent Limitations for PFAS

At the date of publication of this document, USEPA has not been established ELGs for PFAS. Therefore, while USEPA is in the process of developing ELGs and water quality criteria for PFAS, the agency released a memorandum in 2022 recommending that states develop permit-specific effluent limitations for PFAS based on TBELs (USEPA 2022). This was the approach taken by North Carolina in issuing an NPDES permit for the discharge of treated water from a groundwater remediation project (NC DWR 2022) (see text box below). The PFAS limits developed for this NPDES permit are considered TBELs, unique for this discharge, and should not be assumed protective for a different NPDES permit.

North Carolina NPDES Permit for a Groundwater Remediation Discharge

Problem: PFAS in groundwater discharging to river—60% of PFAS load to river.

Solution: Capture groundwater seeps to river and treat to remove PFAS.

Primary indicator PFAS – HFPO-DA (GenX); PFMOAA (perfluoro-2-methoxyacetic acid); PMPA (perfluoromethoxypropyl carboxylic acid). Sufficient reduction of these shown to be indicative of sufficient reduction of total PFAS in discharge.

Discharger provided evaluation showing that granular activated carbon (GAC) could remove the 68 PFAS listed in the permit by at least 99%. **Established as the TBEL**.

Effluent limitation set at 99% reduction on a monthly mass basis using the three indicator PFAS to show compliance. Based on current concentrations—the expected effluent would be less than 122 ng/L HFPO-DA, 643 ng/L PFMOAA, and 132 ng/L PMPA.

When USEPA adopts PFAS surface water quality criteria, a reasonable potential analysis will be conducted and the permit will be reopened to include new effluent limits based on water quality if they are more stringent than the TBEL.

Minnesota has issued an NPDES permit for a municipal wastewater treatment facility with effluent limitations for PFOS based on Minnesota's water quality standard for PFOS (**MPCA 2022**). The treatment facility discharges to a river. The effluent limitations for the permit, which are a daily maximum of 497 ng/L and a quarterly average of 287 ng/L, were developed based on a reasonable potential analysis. That analysis indicated a reasonable potential for exceedance of Minnesota's water quality standard of 12 ng/L PFOS for a river. As the facility is undergoing an expansion, the limits are enforceable upon completion and startup of the expansion, but no later than 6 months prior to permit expiration. The 2013 permit also contains a limit on the mass loading of PFOS in biosolids applied by land application of 0.384 lbs/acre. This limit is not found in subsequent permit updates in 2018 and 2022. These values were developed on a site-specific basis and are not necessarily protective for a different discharge.

16.6.4.2 USEPA PFAS Data Collection for ELG Development

USEPA's collection of data to support development of ELGs for PFAS has been primarily through its effluent guideline program plans (specifically Plans 14 and 15), a 2021 Advance Notice of Proposed Rulemaking (ANPRM), and a 2021 Multi-Industry PFAS Study. In addition, USEPA is collecting data from landfills to support possible development of PFAS effluent limits for landfill leachate, and from industrial discharges to POTWs for possible development of PFAS pre-treatment effluent limits. These activities are discussed below.

USEPA Effluent Guidelines Program Plan 14

In 2019, USEPA issued its Preliminary Effluent Guidelines Program Plan 14 (Preliminary Plan 14) (**USEPA 2019**) and a supporting report, The USEPA's Review of Per- and Polyfluoralkyl Substances (PFAS) in Industrial Wastewater Discharge (**USEPA 2019**). The preliminary plan and the report discussed an initial review of PFAS discharges to surface waters and POTWs and concluded that "…little is known about the identity, frequency, or amount of PFAS compounds discharged in industrial wastewater." The report recommended a follow-up study to collect data on PFAS manufacture, use, control, and discharge to surface water by industries USEPA determined to be likely dischargers of PFAS. These consisted of airports, organic chemical manufacturers, paper and paperboard manufacturers, and textile and carpet manufacturers. This became the Multi-Industry PFAS Study (see below). With publication of the final Plan 14 in 2021 (**USEPA 2021**), metal finishers were added to the Multi-Industry PFAS Study.

Advance Notice of Proposed Rulemaking

In March 2021, USEPA issued an Advance Notice of Proposed Rulemaking (ANPRM) titled "Clean Water Act Effluent Limitations Guidelines and Standards for the Organic Chemicals, Plastics and Synthetic Fibers Point Source Category" (**USEPA 2021**). The ANPRM noted that USEPA was "initiating further data collection and analysis to support potential future rulemaking under the CWA relating to ELGs, pretreatment standards, and new source performance standards applicable to the OCPSF point source category."

Multi-Industry PFAS Study

As an outcome of USEPA's effluent guideline program, The Multi-Industry PFAS Study (**USEPA 2021**) focused on collecting, compiling, and reviewing information and data on PFAS in discharges from industries in the following point source categories:

- Organic chemicals, plastics and synthetic fibers (OCPSF) manufacturers and formulators
- Metal finishing
- Pulp, paper, and paperboard manufacturers
- Textile mills
- Commercial airports (excludes USDOD facilities)

In addition, the study also attempted to acquire information on the types and concentrations of PFAS discharged in wastewater, as well as assess availability and feasibility of control practices and treatment technologies capable of reducing or eliminating PFAS in wastewater discharges. The information was collected through outreach to stakeholders, including company representatives and trade associations; state, regional, and local wastewater regulatory authorities; and treatment technology vendors. Data sources included 2019 and 2020 NPDES DMRs, USEPA's Industrial Wastewater Treatment Technology Database, USEPA's drinking water treatability database, and data made available through other federal agencies such as Department of Transportation, Federal Aviation Administration, Department of Health and Human Services, and Food and Drug Administration, and organizations such as the American Chemistry Council. The report includes detailed information on data sources, and whether any PFAS ELGs have been developed for industries within each of the point source categories.

USEPA Effluent Guidelines Program Plan 15

USEPA discussed its findings from the Multi-Industry PFAS Study and its plans to develop ELGs for PFAS in the 2021 Preliminary Effluent Guidelines Program Plan 15 (**USEPA 2021**) and the subsequent 2023 Effluent Guidelines Program Plan 15 (Plan 15) (**USEPA 2023**). A summary is provided below.

OCPSF Manufacturers and Formulators

In December 2021, USEPA used its authority under Section 308 of the CWA to collect data on characterization of wastewater generation, treatment, and discharge from PFAS manufacturing facilities. USEPA "verified that PFAS, including legacy long-chain PFAS and short-chain replacement PFAS, are present in wastewater discharges from OCPSF facilities" (**USEPA 2021**) to surface waters and POTWs. For both PFAS manufacturers and formulators, average concentrations of short-chain perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkane sulfonic acids (PFSAs) were generally higher relative to long-chain PFCAs and PFSAs. USEPA determined that the development of ELGs for PFAS manufacturers is warranted and plans to revise the existing OCPSF ELGs (40 CFR Part 414). As noted in Program Plan 15, depending on available resources, USEPA intends to publish a proposed rule in spring 2024. In addition, USEPA will continue to evaluate the need to develop regulations to address PFAS discharges from PFAS formulators/processors.

Metal Finishing

USEPA determined that PFAS have, and continue to be, used by metal finishing facilities in the United States. USEPA identified chromium electroplating facilities as the most significant source of PFAS due to their use of PFAS-based mist/fume suppressants to control toxic hexavalent chromium emissions. USEPA determined that the development of effluent guidelines and standards for chromium electroplating facilities is warranted and plans to revise the existing metal finishing ELGs (40 CFR Part 433). Depending on the availability of resources, USEPA intends to collect the data necessary to revise these ELGs, which will include conducting a survey of the industry and analysis of wastewater samples. According to the finalized Program Plan 15, USEPA intends to publish a proposed rule by the end of 2024.

Pulp, Paper, and Paperboard

While USEPA determined that PFAS have been and continue to be used by U.S. pulp, paper, and paperboard facilities, only a small subset of facilities are actively applying PFAS to paper products. The information collected by USEPA indicates that the industry phased out the use of PFOA and PFOS approximately a decade ago but continues to use FDA-approved short-chain PFAS in limited quantities for the manufacture of food contact packaging and specialty paper products. The industry is expected to transition to PFAS-free technologies and eliminate all application of PFAS in U.S. pulp and papermaking operations by 2024. This schedule coincides with an FDA agreement with chemical manufacturers to voluntarily phase out use of PFAS that contain or may degrade to 6:2 fluorotelomer alcohol (6:2 FTOH) in

food contact applications by 2024. As a result, a rulemaking on the pulp, paper, and paperboard category is not a priority for USEPA at this time. USEPA plans to continue to study this point-source category, paying particular attention to the potential for legacy discharges after the transition to PFAS-free additives.

Textile and Carpet Manufacturers

As reported in Preliminary Plan 15 (**USEPA 2023**), much of the information on textile and carpet manufacturers obtained was through a review of publicly available information and literature. Based on a small number of sample results, USEPA determined that PFAS, including legacy long-chain PFAS, are present in wastewater discharges from textile mills to POTWs and that most textile mills were not monitoring for PFAS. Subsequently in November 2021, USEPA used its authority under Section 308 of the CWA to require nine textile manufacturers to provide information on PFAS use and import, PFAS in industrial wastewater discharges, and treatment of PFAS-containing wastewater. Nineteen of 92 (21 percent) reported they used PFAS in 2020, and of those, 18 of the 19 (95 percent) indicated their intention to reduce or eliminate use of PFAS by the end of 2026 by using alternative surface treatment products or technologies. More than half of the textile mills that responded to the survey discharge their process water to a POTW. Two indicated they operate a wastewater treatment system that can effectively remove or eliminate PFAS in wastewater. USEPA plans to expand its study of this category through use of a mandatory, nationally representative questionnaire.

Commercial Airports

USEPA determined that commercial airports may generate PFAS-containing wastewater from live-fire firefighting training, emergency response activities, and accidental leaks from stockpiles of AFFF. However, one outcome of the Federal Aviation Administration (FAA) Reauthorization Act of 2018 was that the FAA has approved and encourages use of different types of AFFF testing equipment that do not require dispensing AFFF when airports conduct periodic equipment testing and training. As of March 2022, the FAA has approved and is funding the use of four different types of firefighting testing devices that do not dispense AFFF and more than half of certified airports have applied these procedures. In addition, as of June 2022, all firefighting foam formulations that meet current military specifications contain less than 800 ppb of PFOS or 800 ppb PFOA. Based on this information, USEPA is not prioritizing rulemaking for this category at this time. However, USEPA will continue to study commercial airport use of AFFF that contains PFAS and will continue to monitor the industry's transition to fluorine-free foam (see **Section 3.11** for more information).

Landfills

Based on public comments to Preliminary Plan 14, USEPA initiated a Landfill Leachate Detailed Study of wastewater discharges from landfills with a focus on PFAS discharges to surface waters and POTWs. Program Plan 15 notes that since September 2021, USEPA has collected data and information on the industry's facilities, discharge practices, and effectiveness of control practices/technologies to remove PFAS. Depending on available resources, USEPA intends to revise the existing Landfills Point Source Category ELG to address PFAS (schedule yet to be determined).

POTW Influent Study

As noted in Program Plan 15, USEPA intends to collaborate with wastewater treatment facilities to initiate a nationwide study on industrial discharges of PFAS to POTWs. This includes indirect discharges from industrial categories that have been reviewed, as well new categories for which there are very little PFAS data. The goal is to collect samples of PFAS from industrial sources upstream of POTWs (that is, before mixing and dilution from other waste streams). USEPA also intends to develop an Information Collection Request (ICR) and a sampling strategy providing more details about the POTW Influent PFAS Study.

16.7 Surface Water/Groundwater Interaction

The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about recent studies of PFAS at the groundwater-surface water interface (see **Section 1.3.4.3**) and conducting mass flux analysis to understand PFAS migration in groundwater and potential discharge to surface water (see **Section 1.3.8.2**).

As mentioned in **Section 16.4.5**, surface water/groundwater interaction may play a role in a conceptual site model and locating places to sample. It has been found that PFAS in groundwater that migrates to surface water can be a significant source of PFAS in the surface water, potentially impacting beneficial uses. The same can be said for PFAS in surface water migrating and impacting groundwater quality. These concepts are demonstrated by a case study presented in **Section 15.5.2** which describes two examples, one from North Carolina and one from Minnesota. Also see **Section 5.3.4.1** for information on the fate and transport of PFAS due to groundwater/surface water interactions and **Section 5.3.4.2** for information on surface water/sediment interactions.

17 ADDITIONAL INFORMATION

This section provides supplemental information for **Section 6** on media-specific occurrence, **Section 7.1** for human health effects, and for **Section 9** on site risk assessment.

Section Number	Topic
1.4	**Priority Topics for Human and Ecological Health Effects (2025)**
1.7	**Priority Topics for Biosolids Land Application (2025)**
17.1	**Additional Information for Media-Specific Occurrence**
17.2	**Additional Information for Human Health Effects**
17.3	**Additional Information for Risk Assessment**

17.1 Additional Information for Media-Specific Occurrence

This section includes links for the tables of media-specific occurrence information that are summarized in **Section 6** and included in the figures in that section.

- **Tables 17-1 A-C** – outdoor air, indoor air, settled dust, precipitation
- **Tables 17-2 A-C** – soil, sediment, and biosolids

The **Section 6 interactive plots webpage** provides additional information for the data included in the figures. The interactive figures were developed using **R software** and **plotly**.

The previous version of Section 6 (June 2022) is archived as a PDF under **Archived External Tables and Sections** on the home page of this site. The previous version of Section 17.1 (June 2022) is archived as a PDF under **Archived External Tables and Sections** on the home page of this site.

Table numbers 17-3, 17-4, and 17-5 are reserved for future updates in media-specific occurrence.

17.2 Additional Information for Human Health Effects

This section supplements information provided in **Section 7.1** on biomonitoring, exposure, toxicokinetic, toxicology, and epidemiology data for long-chain and short-chain PFAAs. The PFAS discussed in Sections 17.2.3 and 17.2.4 include perfluorocarboxylic acids (PFCAs) with four to fourteen carbons and perfluorosulfonic acids (PFSAs) with four or more carbons. Also covered are two per- or polyfluorinated ether carboxylates (FECAs)—ammonium 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoate (also known as perfluoro-2-propoxypropanoic acid (PFPrOPrA); hexafluoropropylene oxide [HFPO] dimer acid, commonly known as GenX) (**Section 2.2.3.5**); and 4,8-dioxa-3H-perfluorononanoate (commonly known as ADONA); and per- and polyfluoroether carboxylates (PFECAs); per- and polyfluoropolyether carboxylates (PFPECAs) including chlorinated PFPECAs (ClPFPECAs); per- and polyfluoroether sulfonates (PFESAs) including chlorinated PFESAs; per- and polyfluoropolyether sulfonates (PFPESAs), fluorotelomer alcohols, and fluorotelomer sulfonic acids. These PFAS that contain ether group(s) are replacements for PFOA, PFNA, and/or PFOS as processing aids in certain fluoropolymer production, and some are also formed as industrial byproducts. They are included because they are of current interest and health effects data are available. There is little or no publicly available health effects information for most of the many other PFAS used in commerce (**Section 2.5**), including precursors that can be converted to PFAAs in the environment and in the human body.

For further detail of scientific names and carbon chain length of PFAAs see **Section 2.2**.

17.2.1 Overview

Based on the number of studies located through searches of the National Library of Medicine's PubMed, a database containing relevant peer-reviewed publications, much of the information summarized here became available after 2005. Additional studies may be available, particularly for those compounds with large health effects data sets, and additional information on the topics in this section can be found in databases such as PubMed and references listed in **Section 7.1**.

The publicly available toxicological data set is currently largest for PFOA and PFOS, with considerable data also available for PFBA, PFBS, PFHxA, PFNA, PFDA, and GenX. Fewer studies are available for PFHxS, PFUnA, PFDoA, ADONA, and the other ether and polyether PFAS mentioned above, and little or no data for PFPeA, PFHpA, PFTrA, PFTA, PFPeS, PFHpS, PFNS, or PFDS. Most of the mammalian studies were conducted in rodents, with a few in nonhuman primates (monkeys). The most notable toxicological effects from the mammalian studies of these PFAS, with relevant citations, are discussed in **Section 17.2.5** and are summarized in **Table 17-8 Toxicological Effects** Excel file (last updated November 2021). However, due to the large size of the toxicological data set, it is beyond the scope of this section to identify no observed adverse effect levels (NOAELs) and lowest observed adverse effect levels (LOAELs) for these effects. The numerous reviews of potential epidemiological associations of health endpoints with PFAAs are discussed in Section 17.2.4. Many of the epidemiology studies evaluate associations of health endpoints with multiple PFAAs detected in the blood serum of the subjects. Epidemiologic data from the general population have been used to develop draft reference doses for PFOA and PFOS (**CA OEHHA 2023**; **USEPA 2023**), as well as for PFHxS and PFDA (**USEPA 2023**), and draft cancer slope factors for PFOA (**USEPA 2023**; **CA OEHHA 2023**) based on human data.

Finally, data gaps and research needs are discussed.

17.2.2 Human Biomonitoring and Sources of Exposure

Several long-chain PFAAs (from highest to lowest geometric mean [GM] serum levels, as follows: PFOS, PFOA, PFHxS, PFNA) are present in the low parts per billion (ng/ml) range in the blood serum of almost all adult residents of the United States, while other PFAS are detected in a smaller percentage of the population (**CDC 2022**; **Olsen et al. 2017**)). In contrast, short-chain PFAAs such as PFBS and PFHxA are more rapidly excreted and were infrequently detected in the blood serum of the U.S. general population (**CDC 2022**; **Olsen et al. 2017**). For example, PFBS was detected in less than 5% of serum samples in all National Health and Nutrition Examination Survey (NHANES) years except 2005–'06 (**CDC 2022**). Both NHANES and the blood donor studies show generally higher levels of long-chain PFAAs in males than females, with generally decreasing serum levels of long-chain PFAAs over time. NHANES 2013–'14 evaluated PFAS in children 3–11 years old (**CDC 2022**) and found serum levels of PFOS, PFOA, PFHxS, and PFNA generally similar to those in older adolescents and adults in the same time period. It was noted that most of the children studied were born after PFOS manufacturing was phased out in the United States in 2002 (**Ye et al. 2018**). Long-chain PFAA human serum levels in other industrialized countries are generally similar to the United States (**Kato 2015**) and may be lower in less developed nations (for example, Afghanistan) where they are less likely to be used industrially and consumer products containing them are less frequently used (**Hemat et al. 2010**). Testing in 2017 by the North Carolina Department of Health and Human Services (NC DHHS) did not detect HFPO-DA ("GenX") in the blood serum or urine of North Carolina residents with previous or current exposure from private wells, but did detect other PFAS (**NC DHHS 2018**). A North Carolina State University study of a public water system and its users included a larger list of PFAS analytes and, although no GenX was detected, they identified four newly identified PFAS in the drinking water and blood serum of most participants (**Hogue 2019**; **Hopkins et al. 2018**). A study of a potentially exposed population detected ADONA in only a few subjects (**Fromme et al. 2017**).

Human exposures can result from consumption of fish from waters contaminated with bioaccumulative PFAAs (for example, **MDCH 2014**). PFSAs with more than eight fluorinated carbons (that is, PFOS and longer chain for PFSAs; PFNA and longer chain for PFCAs) are substantially more bioaccumulative than shorter chain PFAAs, with PFSAs generally more bioaccumulative than PFCAs with the same number of fluorinated carbons (**Conder et al. 2008**; **Martin et al. 2003**). When drinking water is contaminated with even relatively low levels of long-chain PFAAs, exposure from drinking water may dominate contributions from exposure sources such as food and consumer products that are prevalent in the general population. For example, **USEPA (2011)** predicted that ongoing exposure to 20 ng/L PFOA in drinking water will increase serum PFOA levels more than two-fold from the U.S. median of 2 ng/L. Elevated serum levels of long-chain PFAAs have been observed in communities with contaminated drinking water in several U.S. states, including Ohio and West Virginia (**WV University 2008**; **Emmett et al. 2006**; **Steenland et al. 2009**) (**Hoffman et al. 2011**), New Hampshire (**NH DHHS 2015**), Alabama (**ATSDR 2013**), Minnesota (**MDH 2009**; **Landsteiner et al. 2014**), New York (**NYS DOH 2016**), and in other nations, including Germany (**Hölzer et al. 2008**) and Sweden (**Li et al. 2018**) (**Table 17-6**). **ATSDR (2022)** has conducted exposure assessments that included biomonitoring in eight U.S. locations impacted by PFAS in drinking water.

Understanding exposures to PFAS at different developmental phases (for example, fetus, infant) is important to ensure protection of the most sensitive subpopulations. Evidence for developmental effects from early life exposures to long-chain PFAAs in humans is discussed in **Section 17.2.4** and in animals in **Section 17.2.5**. PFAAs (primarily PFHpA and longer chain PFCAs; PFHxS and longer chain PFSAs) have been detected in human amniotic fluid (**Stein et al. 2012**; **Zhang et al. 2013**), umbilical cord blood (**Kato 2015**; **Kudo 2015**), and breast milk (**Liu et al. 2010**; **White et al. 2011**; **Post, Cohn, and Cooper 2012**; **Kato 2015**; **Kudo 2015**). Although the specific compounds analyzed for and/or detected vary among studies, other PFAAs that have been analyzed for in breast milk rarely exceeded the limit of quantitation (**Tao et al. 2008**; **Tao et al. 2008**). Serum levels of several long-chain PFAAs were higher in breast-fed infants than in their mothers and declined slowly following weaning (**Fromme et al. 2010**), and serum levels of infants who drank formula prepared with PFAS-contaminated water are predicted to be higher than in older individuals using the same water source (**Goeden, Greene, and Jacobus 2019**). Infants and toddlers may also receive higher exposures because of age-specific behaviors such as hand-to-mouth activity that results in greater ingestion of house dust, and more time spent on floors with treated carpets relative to older children or adults (**Trudel et al. 2008**; **Shoeib et al. 2011**).

Elevated serum levels of PFAAs, in some cases >100,000 ng/ml, have been found in industrially exposed workers (**Olsen 2015**). Serum concentrations of PFCAs (PFHpA and longer) were also increased in professional ski waxing technicians due to exposures to fluorinated ski waxes (**Freberg et al. 2010**; **Nilsson et al. 2010**). Higher serum levels of PFDA (**Dobraca et al. 2015**), PFOS, and PFHxS (**Rotander et al. 2015**) have been reported in firefighters relative to those in the general population.

17.2.3 Toxicokinetics

PFAAs for which data are available (PFOA, PFHpA, PFHxA, PFOS) were well absorbed orally (≥90%) in rodents (**Kudo 2015**). PFOA and PFNA were absorbed via inhalation as dusts or aerosols (**Kinney, Chromey, and Kennedy 1989**; **Hinderliter, DeLorme, and Kennedy 2006**). PFOA was absorbed to a limited extent from dermal exposure in studies of isolated human and rodent skin (**Fasano et al. 2005**; **Franko et al. 2012**). Several recent in vivo studies demonstrate dermal absorption in laboratory animals and humans. Chen et al. (**2022**) reported that the tested PFAS (PFCAs with 4 to 12 carbons; PFBS, PFHxS, PFOS; 6:2- and 8:2 diPAP) were absorbed after a single application to skin; the extent of dermal absorption varied with compound and dose. Weatherly et al. (**2023**) reported toxicity and gene expression changes in liver and skin, as well as detection in urine and serum, after daily application of PFPeA, PFHxA, and PFHpA to the skin of mice for 28 days. **Abraham and Monien (2022)** demonstrated dermal absorption of isotopically labelled PFOA mixed with sunscreen in a human volunteer. **Section 1.4.3** includes information about dermal uptake of PFAS in the environment. **Section 1.4.2.3** includes information about potential PFAS exposures from cosmetics and personal care products including sunscreen.

PFAAs, particularly long-chain PFCAs and PFSAs, have unique toxicokinetic properties as compared to other types of POPs. Unlike most other bioaccumulative organic compounds (for example, dioxins, PCBs), PFAAs do not have a high affinity for adipose tissue. In contrast, PFAAs are water soluble, have an affinity for proteins (which varies among compounds), and generally distribute primarily to the liver, blood serum (where they are bound to albumin and other proteins), and kidney (**Bischel et al. 2011**; **Lau 2012**, **2015**; **Kato 2015**).

PFAAs are highly resistant to chemical reactions. As such, they are not metabolized, and this is also true for HFPO-DA (**Gannon et al. 2016**) and ADONA (**Gordon 2011**). However, PFAA precursors can be metabolized to PFAAs within the body, and reactive intermediates may be formed in these metabolic pathways (**Rand and Mabury 2016**). Some examples are the metabolism of 6:2 fluorotelomer alcohol (6:2 FTOH) to PFBA, PFPeA, PFHxA, and PFHpA (**Buck 2015**); 8:2 FTOH to PFOA and PFNA (**Kudo 2015**; **Kabadi et al. 2018**); and perfluorooctane sulfonamidoethanols (FOSEs), perfluorooctane sulfonamides (FOSAs), and perfluorooctane sulfonamidoacetic acids (FOSAAs) to PFOS (**Gebbink, Berger, and Cousins 2015**). Additionally, larger PFAS molecules such as polyfluoroalkyl phosphoric acid diesters (diPAPs) have been found in human blood serum and can be metabolized to FTOHs, which are further metabolized to PFCAs (**D'Eon and Mabury 2011**; **Lee and Mabury 2011**).

Excretion of PFAAs and HFPO-DA is primarily through the urine, with a much smaller percentage, if any, eliminated in the feces. In women of childbearing age, excretion also occurs through menstruation and lactation (**Harada and Koizumi 2009**; **Thomsen et al. 2010**). Serum PFAS levels were lower in adult males undergoing venesection (ongoing blood withdrawal) for medical reasons (**Lorber et al. 2015**) and in firefighters who had donated blood, as compared to other firefighters (**Rotander et al. 2015**). The excretion rate for long-chain PFAAs varies substantially between animal species, and it is much slower in humans than in laboratory animals. Additionally, for some PFAS, including PFOA, PFNA, and others, the excretion rate is very different in males and females of the same rodent species, likely due to differences in the extent of secretion and reabsorption by organic anion transporter proteins (OATs) and possibly other transporter proteins in the kidney, reviewed in **Lau (2012)**; **Lau (2015)**; **Kudo (2015)**; and **USEPA (2023)**. Half-lives in rodents, nonhuman primates, and humans for the PFAS included in this section are shown in **Table 17-7**.

As shown in **Table 17-7**, excretion rates in mammalian species vary among PFAS for which half-life data are available, with short-chain PFAAs and GenX generally excreted more rapidly than longer chain PFAAs. Half-lives in rodents and nonhuman primates are generally in the range of several weeks to several months for long-chain PFAAs, and about 1 hour to several days for short-chain PFAAs and GenX. However, PFOA, PFNA, and PFHxS (reviewed in **Kudo 2015**) are excreted much more rapidly (hours to days) in female than male rats; this sex difference in rats also exists but is not as pronounced for PFBA, PFHxA, PFHpA, and PFBS (**Kudo 2015**). This difference in excretion rate is important in interpretation of rat toxicology studies of these compounds, particularly for developmental effects.

Human half-lives for PFAS are longer than in other mammalian species that have been studied, with estimates of several years for long-chain PFAAs (PFOA, PFNA, PFOS, PFHxS); 1 year for PFHpA, and several days to 1 month for shorter chain PFAAs (PFBA, PFHxA, PFBS; **Table 17-7**). The estimates of human half-life shown in **Table 17-7** are based on measured declines in serum PFAS levels in the same individuals over time after a source of elevated exposure, such as occupational exposure or ingestion of contaminated drinking water, ceases. Such estimates are less uncertain than population-based estimates from modeling of PFAS intake and biomonitoring data for serum PFAS levels from different sets of individuals from the general population at different time points. Half-life estimates based on urinary excretion are available for several PFAAs, including some with no serum-based half-life estimates ((**Zhang et al. 2013**) shown as G-U in **Table 17-7**); these urinary estimates are less certain because they include modeled estimates of menstrual excretion in women of childbearing age and do not consider fecal excretion or blood loss other than menstruation (for example, blood donation). It should be noted

that there are large inter-individual variations in human half-lives, which may arise from physiological factors (for example, differences in renal transport by OATs; **Yang, Glover, and Han 2010**).

Because of the large species and sex differences in excretion rates, the internal dose resulting from a given administered dose varies widely among species and, in some cases, males and females of the same species. Therefore, interspecies (for example, animal-to-human) comparisons must account for the large interspecies half-life differences with approaches such as use of internal dose (as indicated by serum level) as the dose metric, interspecies toxicokinetic extrapolation based on the ratio of half-lives in humans and animals, or use of physiologically based pharmacokinetic models.

17.2.3.1 Toxicokinetics Relevant to Developmental Exposures

Toxicokinetics relevant to developmental exposures to PFAAs are important because developmental effects are sensitive endpoints for toxicity of long-chain PFAAs in rodents, and prenatal exposure to some long-chain PFAA was associated with decreased fetal growth in some human epidemiology studies (see **Section 17.2.3.4**). Developmental exposures have been studied in rodents for several PFAAs, but not in nonhuman primates. PFAAs cross the placenta to reach the developing fetus in both humans and rodents (reviewed in **Lau 2012** and **Kudo 2015**), and are transferred to milk, resulting in exposure via lactation (**Luebker et al. 2005**; **White et al. 2009**; **Kato 2015**). In humans, long-chain PFAAs have been detected in cord blood (for example, **Wang et al. 2019**) and amniotic fluid (**Stein et al. 2012**; **Zhang et al. 2013**).

In humans, the greatest exposures to PFAAs in breast milk occur during the first few months of infancy because both PFAA concentrations in milk and the breast milk ingestion rate on a BW basis (ml/kg/day) are highest then; PFAA levels in milk may be lower in mothers who previously nursed other infants (**Tao et al. 2008**; **Haug et al. 2011**; **Thomsen et al. 2010**). Serum concentrations of long-chain PFAAs in breast-fed infants increase several-fold from the levels at birth during the first few months of life, followed by a decline in older infancy and early childhood (**Fromme et al. 2010**; **Mogensen et al. 2015**; **Verner et al. 2016**, **2016**; **MDH 2018**, **2019**; reviewed in **NJDWQI 2015**, **2017**, **2018**). Because of their higher rate of fluid consumption on a BW basis (**USEPA 2019**), exposures to infants who consume formula prepared with PFAS-contaminated water are also highest during the first few months of life. **Goeden, Greene, and Jacobus (2019)** presented a model that predicts transplacental transfer and exposure to breast-fed and formula-fed infants for long-chain PFAAs in drinking water.

17.2.3.2 Relationship of Human Exposures to Serum Levels

Clearance factors (CL) that describe the relationship between oral exposures or dose (ng/kg/day) and steady-state serum levels (ng/L) in humans have been developed for PFOA (**Lorber and Egeghy 2011**; **USEPA 2016**) and PFOS (**USEPA 2016**):

Dose [ng/kg/day] x CL [L/kg/day] = serum concentration [ng/L].

These clearance factors, which indicate bioaccumulative potential, are based on average values for human PFAS half-lives and volumes of distribution (Vd);

CL [L/kg/day] = Vd [L/kg Body Wt] x [Ln2/half-life in days].
Where Ln2 is the natural log of 2.

When combined with mean daily U.S. water ingestion rates (**USEPA 2011**), the CLs have been used to predict the expected average increase in serum levels (above the “baseline” serum level from non-drinking water sources) that results from ongoing exposure to a given drinking water concentration of PFOA or PFOS (**Bartell 2017**; **NJDWQI 2017**; **Post, Gleason, and Cooper 2017**). For PFOA, this average serum:drinking water ratio was predicted to be greater than 100:1 (**NJDWQI 2017**); this ratio is consistent with data from exposed populations and toxicokinetic modeling (**Emmett et al. 2006**; **Hoffman et al.**

2011; **Bartell 2017**). The CL for PFOS predicts an average serum:drinking water ratio of about 200:1 (**NJDWQI 2018**; **Post, Gleason, and Cooper 2017**; **Lu and Bartell 2020**), and available toxicokinetic data also support an estimated ratio of 200:1 for PFNA (**NJDWQI 2015**; **Lu and Bartell 2020**) and PFHxS (**Lu and Bartell 2020**). It should be noted that PFAA serum:drinking water ratios vary among individuals using the same source of contaminated drinking water, due to inter-individual differences in daily water consumption rates (L/kg/day) and/or physiological differences relevant to toxicokinetics.

Bartell (2017), **Lu and Bartell (2020)**, and **ATSDR (2022)** have developed online calculators that provide estimates of an individual's serum concentrations of PFOA, PFOS, PFNA, and PFHxS from the information that is entered, including drinking water levels of these PFAS and other relevant factors. These estimates are based on long-term exposure to a constant drinking water concentration and that serum PFAS concentrations are impacted by interindividual variability in both toxicokinetic factors (for example, PFAS half-lives) and daily drinking water ingestion rate.

17.2.3.3 Isomer-Specific Toxicokinetics

Some PFAAs exist as a mixture of linear and branched isomers; the isomer profile varies depending on the manufacturing process used (telomerization yields primarily linear PFAS; electrochemical fluorination yields a mixture of linear and branched PFAS; **Section 2.2.5.2**. Toxicokinetics may differ among isomers of the same PFAA in rodents (**Loveless et al. 2006**; **De Silva et al. 2009**) and humans (**Zhang et al. 2013**; **Gao et al. 2015**; **Beesoon et al. 2011**; **Xu et al. 2020**; **Li et al. 2022**).

17.2.4 Human Epidemiology Studies

As discussed in **Section 7.1.3**, the epidemiological database for long-chain PFAAs, particularly PFOA and PFOS, is more extensive than for many other environmental contaminants. Many of the studies are recent, and the number of available studies is constantly increasing. In contrast, there are few or no epidemiology studies for many other PFAS (**Carlson et al. 2022**; **Radke et al. 2022**).

Many U.S. general population studies are based on data from NHANES (**CDC 2022**), and other general population studies come from various worldwide locations. These include studies of specific subpopulations such as pregnant women, infants, children, or the elderly, as well as evaluations of associations of prenatal exposures with effects later in life. Data on communities exposed to PFOA through contaminated drinking water come primarily from the C8 Health Study evaluations of approximately 70,000 Ohio and West Virginia residents exposed in drinking water for at least 1 year at concentrations of 50 ng/L to >3,000 ng/L, including evaluations by the C8 Science Panel (**Frisbee et al. 2009**; **C8 Science Panel 2020**). This panel consisted of three prominent environmental epidemiologists charged with determining whether there are "probable links" (defined as "given the scientific evidence available, it is more likely than not that a connection exists between C8 exposure and a particular human disease among class members") between PFOA exposures in this study group and disease. Researchers who participated in the C8 Science Panel recently evaluated current epidemiologic evidence for PFOA and the diseases for which the C8 Science Panel had concluded in 2011–12 that there was a "probable link" with PFOA exposure (kidney and testicular cancer, high cholesterol, thyroid disease, pregnancy-induced hypertension, ulcerative colitis; C8 Science Panel Probable Link reports (**C8 Science Panel 2017**). They also reviewed evidence for associations of PFOA and additional health effects (**Steenland et al. 2020**). The conclusions of **Steenland et al. (2020)** for specific health effects are discussed below.

Until recently, health effects studies were not available from communities with drinking water contaminated with either the other PFAS discussed in this section or the complex mixtures of PFAS present in AFFF. Studies of associations of PFAS with a variety of health effects in a community exposed to AFFF-contaminated drinking water in Sweden have now been reported (**Andersson et al. 2019**; **Li et al. 2020**, **2021**, **2022**; **Xu et al. 2020**, **2022**; **Hammarstrand et al. 2021**; **Nielsen and Joud 2021**; **Engstrom et al. 2022**; **Nielsen et al. 2022**). Additional epidemiological studies of seven communities exposed to PFAS

found in AFFF or specific PFAS other than PFOA (for example, PFNA) are now being conducted through the ATSDR-funded multisite study (**ATSDR 2022**). **Section 1.4.1** includes information about potential human health effects from PFAS exposure arising from AFFF in drinking water.

Finally, health effects of several long-chain PFAAs, including PFOA, PFOS, and PFNA, have been studied in occupationally exposed workers (**Khalil 2015**). Because these workers were primarily male, relatively few women were included in these studies.

Exposure assessment in most but not all of the epidemiology studies of PFAS is based on blood serum levels of PFAS as an indicator of internal dose. The studies often evaluate associations between health endpoints and multiple PFAS detected in blood. Serum levels of long-chain PFAAs are indicators of long-term exposures (**Section 7.1.2**) that reflect individual differences in both exposure (for example, daily water consumption) and rate of excretion. Therefore, serum levels are less uncertain as indicators of exposure than external parameters such as drinking water concentration. In contrast to long-chain PFAS, there is little epidemiological information on short-chain PFAS because they are infrequently detected in blood serum due to their more rapid excretion. Exposure assessment in some of the C8 studies of communities with PFOA exposure from an industrial source is based on serum PFOA levels estimated from modeling of drinking water and air PFOA concentrations over time, rather than measured serum levels **Savitz et al. 2012**; **Winquist and Steenland 2014**, **2014**; **Dhingra et al. 2016**, **2016**; **Herrick et al. 2017**). Finally, exposure is based on job classification, rather than serum PFAA measurements in some occupational studies of PFOA (**Gilliland and Mandel 1993**; **Leonard 2003**; **Lundin et al. 2009**; **Raleigh et al. 2014**), PFNA (**Mundt et al. 2007**), and PFOS (**Alexander et al. 2003**; **Olsen et al. 2004**; **Alexander and Olsen 2007**; **Grice et al. 2007**).

As is the case for epidemiologic studies of environmental contaminants in general, the human studies of PFAAs are observational, in contrast to toxicology studies, which are experimental. Additionally, most epidemiology studies of PFAAs are cross-sectional, although some use other designs (prospective, retrospective, case-control). In cross-sectional studies, exposure and outcome are evaluated at the same point in time. Such cross-sectional studies cannot reveal whether increased exposure led to the health endpoint or vice versa, and reverse causality (for example, when a physiological change affects serum PFAS levels, rather than the serum PFAS levels causing the physiological change) has been hypothesized by some researchers as partially or totally explaining some of the associations in the epidemiological literature, including reduced birth weight and decreased kidney function (reviewed in **NJDWQI 2017**). In general, publications of epidemiology studies report results in terms of associations with the endpoints of interest based on statistical analysis. When there are multiple studies of associations of an environmental contaminant such as PFAA(s) with a health endpoint, results often differ among studies. The differing results can arise from difference in the study design (for example, sex, age, ethnicity of population studied; magnitude and/or duration of exposure; method for assessment of endpoint of interest), size of population studied (may be too small to detect statistically significant associations), method used for statistical analysis, consideration of potential confounding factors, or chance.

Therefore, conclusions about whether the overall body of evidence supports an association are based on scientific judgment and may differ among scientists who review the same body of data. Additionally, for PFAS, because many new epidemiology studies continually become available, more recent evaluations may include considerable data not available for earlier evaluations. Because observational studies are not designed to prove causality for health effects, conclusions about evidence for causality are based on criteria, such as the Hill criteria (**Lucas and McMichael 2005**) related to the overall body of relevant scientific information (for example, consistency, dose-response, biological plausibility, potential for reverse causality). For example, observations of associations with the same health endpoint in studies from multiple locations and in different types of populations (for example, general population, exposed communities, workers), as is the case for some effects associated with PFOA and PFOS (**Post, Cohn, and Cooper 2012**; **USEPA 2023; USEPA 2023**) strengthen the weight of evidence for that effect. Use of systematic review methods are increasingly used to evaluate the quality of epidemiological studies as

well as the potential confounders (for example, **USEPA 2023**). As is the case for associations, conclusions about causality may differ among scientists reviewing the same body of data.

17.2.4.1 Noncancer Health Endpoints

This section summarizes information for various categories of noncancer health endpoints: Changes in systemic markers, Fetal growth, Immune system effects, Thyroid effects, and Other effects.

Systemic Markers

For PFOA and PFOS (**Khalil 2015**; **USEPA 2023**, **2016**; **NJDWQI 2017**, **2018**; **ATSDR 2021**), PFNA (**NJDWQI 2015**; **ATSDR 2021**), and PFDeA (**ATSDR 2021**), the cited reviews concluded that associations are generally consistent for increases in total cholesterol and/or low-density lipoproteins. **Australia Government DOH (2018)** concluded, based on a review of key reports and published systematic reviews, that an association of both PFOA and PFOS with small changes in cholesterol is generally observed. Additionally, the C8 Science Panel concluded that there is a "probable link" between PFOA and clinically defined high cholesterol (**C8 Science Panel 2012**). **Rappazzo, Coffman, and Hines (2017)** concluded that the evidence for an association of prenatal or childhood exposure to PFAS with increased cholesterol is generally consistent; studies reviewed found associations with PFOA, PFOS, PFNA, and/or total PFAS. Regarding causality, **NJDWQI (2017)** concluded that the evidence supports multiple criteria for a causal relationship between increased serum cholesterol and PFOA, while **Australia Government DOH (2018)** concluded that it cannot be established whether PFOA or PFOS causes increased cholesterol based on currently available data. **NASEM (2022)** concluded that there is sufficient evidence for an association of PFAS with dyslipidemia in adults and children.

Steenland et al. (2020) noted continued consistent findings of an association between PFOA and high cholesterol. However, although high cholesterol is a risk factor for cardiovascular disease, the C8 Science Panel did not find a "probable link" for PFOA and heart disease, and subsequent studies have also not found an association. Relevant to this issue, **Steenland et al. (2020)** stated that this apparent inconsistency might be explained by associations of PFOA not only with increased cholesterol, but with increased high density lipoprotein (HDL) and decreased C-reactive protein, both of which decrease heart disease risk

Most reviews have concluded that PFOA (**Gleason et al. 2015**; **Khalil 2015**; **2023**; **NJDWQI**; **ATSDR 2021**) and PFNA (**NJDWQI 2015**) are generally associated with increases in certain liver enzymes, particularly alanine aminotransferase (ALT). **NJDWQI (2017)** concluded that there is some evidence to support a causal relationship between PFOA and ALT. In contrast, most earlier evaluations of PFOS have found weaker or no evidence for associations with increased liver enzymes (**Gleason et al. 2015**; **Khalil 2015**; **NJDWQI 2018**, **2018**. However, **ATSDR (2021)**, p. 26, concluded that "increases in serum enzymes and decreases in serum bilirubin, observed in studies of PFOA, PFOS, and PFHxS, are suggestive of liver alterations." **NASEM (2022)** concluded that there is limited or suggestive evidence for an association of PFAS with liver enzyme alterations in adults and children. For PFOA, **USEPA (2023)** concluded that there is consistent evidence of a positive association with ALT in adults, at median PFOA levels as low as 1.3 ng/mL. **USEPA (2023)**, p. 3-28 to 3-29, concluded that "there is generally consistent evidence of a positive association between exposure to PFOS and ALT. However, one source of uncertainty in epidemiology studies of PFAS is confounding across the PFAS, as individuals are exposed to a mixture of PFAS and it is difficult to disentangle the effects. This cannot be ruled out in this body of evidence given the attenuation of the association in **Lin et al. (2010)**, the only general population study that performed multi-pollutant modeling. ... Thus, while there is evidence of an association between PFOS and ALT, there is residual uncertainty. "**Australia Government DOH (2018)** concluded that an association of PFOA and PFOS with elevated levels of the liver enzyme ALT was observed in many studies. **Steenland et al. (2020)** also concluded that the limited currently available data do not support an association of PFOA and liver disease. However, **Steenland et al. (2020)** noted that the lack of human studies with sufficient power

to detect this effect, well established liver toxicity of PFOA in experimental animals, bioaccumulation of PFOA in human liver, and extensive evidence for associations with markers of liver damage indicate the need for additional research, particularly in regard to potential associations with nonalcoholic fatty liver disease.

Various reviews have concluded that there is some evidence or limited evidence for an association of increased serum uric acid and/or hyperuricemia with exposure to PFOA, PFOS, and/or PFNA (**Gleason et al. 2015**; **Khalil 2015**; **NJDWQI 2015**, **2017**, **2018**; **Australia Government DOH 2018**).

Fetal Growth

Exposure to PFOA and PFOS were associated with relatively small changes in measures of decreased fetal growth (for example, birth weight, [glossary_exclude]head [/glossary_exclude]circumference) in most studies, while some studies did not find such an association. A systematic review and meta-analysis by **Johnson et al. (2014)** found that there is "sufficient" human evidence that developmental exposure to PFOA reduces fetal growth in humans and provided a quantitative estimate of the decrease in birth weight per ng/ml serum PFOA. The main analysis included nine studies in which maternal or umbilical cord serum PFOA levels were measured in pregnant women. These studies met other inclusion criteria defined by the researchers; study subjects were from the general population in various locations. An additional analysis included a large study from the C8 Health Study population with exposure from contaminated drinking water in which maternal serum levels were retrospectively modeled. PFOA was associated with decreased birth weight in most of the studies from the general population but not in the study of the more highly exposed community. Inclusion of this study from the C8 Health Study population, in which serum PFOA levels during pregnancy were modeled from pre-pregnancy serum PFOA data and thus would not be impacted by potential changes in GFR, reduced the magnitude of decreased birth weight per ng/ml serum PFOA.

Several other reviews also evaluated the associations of PFOA and PFOS with decreased fetal growth. **Bach et al. (2015)** concluded that PFOA and PFOS are associated with decreased birth weight in most studies, but that associations in some studies were not statistically significant, and that the existing information is insufficient to determine whether or not there is an association. **Khalil (2015)** concluded that there is inconsistent evidence for association of decreased birth weight and PFAS. A later meta-analysis by **Negri et al. (2017)**, which included more recent studies not considered by **Johnson et al. (2014)**, also reported a quantitative relationship between decreased birth weight and serum PFOA and PFOS levels. A recent meta-analysis by **Steenland, Barry, and Savitz (2018)** considered additional studies not included in the two earlier meta-analyses, including the large studies from the C8 Health Study in which serum PFOA levels during pregnancy were modeled from pre-pregnancy serum PFOA data. Although **Johnson et al. (2014)** concluded that results from studies without measured serum data during pregnancy are too uncertain to include in a metanalysis, **Steenland, Barry, and Savitz (2018)** concluded that use of modeled or pre-pregnancy serum data may actually be preferable to serum levels measured during pregnancy because these exposure estimates would not be affected by potential reverse causality or confounding related to expansion of maternal plasma volume during pregnancy or renal glomerular filtration rate. Additionally, **Steenland, Barry, and Savitz (2018)** concluded that the decrease in birth weight in studies based on late pregnancy serum PFOA levels was larger than in those based on preconception or early pregnancy serum PFOA levels. They concluded that these findings are consistent with confounding or reverse causality as an explanation for the observed association of PFOA and decreased birth weight. A systematic review and modeling effort by **Verner et al. (2015)** found that PFOA is associated with decreased birth weight, and that a portion (less than half) of the reduction in birth weight results from confounding by associations of PFAS with decreases in both birth weight and maternal renal glomerular filtration rate (that is, reverse causality). USEPA (**2023**, **2023**) concluded that there is general consistency in associations of PFOA and PFOS with decreased fetal growth, including low birthweight/small for gestational age. However, they noted uncertainties about the potential bias due to impact of changes in maternal hemodynamics, which may impact both serum PFAS levels and fetal

growth, in the studies in which serum PFAS levels were evaluated later in pregnancy. The **USEPA (2023)** also concluded that PFDA is a likely developmental hazard based on evidence of decreased birth weight from studies of exposed humans where PFDA was measured during pregnancy.

ATSDR (2021), p.27, concluded that "evidence is suggestive of an association between serum PFOA and PFOS and small decreases in birth weight; the decrease in birth weight is <20 g (0.7 ounces) per 1 ng/mL increase in blood PFOA or PFOS level." **NASEM (2022)** concluded that there is sufficient evidence for an association of PFAS with decreased infant and fetal growth. Australia Government **DOH (2018)** concluded that PFAS exposure was often associated with generally small decreases in weight and length at birth in general population studies. **Steenland et al. (2020)** reviewed the factors considered in evaluation of epidemiologic studies of PFAS and birthweight that are discussed above and concluded that collectively, the studies of PFOA and birthweight that are currently available provide inconsistent results.

Immune System Effects

Of the several potential effects of PFAS on immune function, the discussion below focuses on associations with antibody response to vaccines, including in children, because this endpoint has been evaluated and reviewed most extensively. A systematic review by the National Toxicology Program (**NTP 2016**), p.1, concluded that PFOA and PFOS are "presumed to be an immune hazard to humans" based on a high level of evidence from animal studies and a moderate level of evidence from human studies for suppression of antibody response. **ATSDR (2021)**, p.27, concluded that "evidence is suggestive of an association between serum PFOA, PFOS, PFHxS, and PFDeA (meaning PFDA) levels and decreased antibody responses to vaccines." For PFOA, PFOS, PFHxS and PFDA, the **USEPA (2023)** identified decreased antibody response to vaccination in children as an effect of exposure to these PFAS. **Rappazzo, Coffman, and Hines (2017)** found that there is generally consistent evidence for association of PFAS with this effect in children. NJDWQI (**2017**, **2018**) concluded for PFOA that associations and decreased vaccine response are consistent among studies, and for PFOA, while decreased vaccine response was consistently observed, evidence is limited because most of the vaccine types were evaluated in only one or two studies. **Pachkowski, Post, and Stern (2019)** concluded that there is evidence that PFOS is associated with a decrease in some vaccine antibody responses following vaccination. **Chang et al. (2016)** concluded that a consistent association with vaccine response in general has not been demonstrated for PFOA and PFOS, and that some associations for specific vaccines are "striking in magnitude" but require replication in other studies. **Australia Government DOH (2018)**, p. 11, concluded, based on review of key reports and systematic reviews, that "the strongest evidence for a link between PFAS and clinically important immunological effects is for impaired vaccine response." They note both that the overall human evidence is weak, but that animal data suggests that "PFAS may alter immune function at concentrations found in humans with environmental and occupational exposures." **Khalil (2015)** stated that PFAS exposure has been associated with immunotoxicity, including decreased vaccine response, but that the data are inconsistent. **NASEM (2022)** concluded that there is sufficient evidence for an association of PFAS with decreased antibody response in adults and children. USEPA (**2023**, **2023**) concluded that PFOA and PFOS are associated with decreased antibody response to vaccines in children and concluded that the dose-response for each of these two PFAS can be modeled from the available human studies.

The C8 Science Panel concluded in 2012 that there was not a probable link between PFOA and common infections. **Steenland et al. (2020)** noted that there was insufficient evidence to infer such a probable link at that time, and that subsequent human and animal studies have evaluated the potential for PFOA to cause immunosuppression (for example, decreased vaccine response, increased infection) and hypersensitivity (for example, asthma, allergy). They reviewed the conclusions of several agencies (**NTP 2016**; **ATSDR 2018** draft; **EFSA 2018**) and other available reviews regarding the evidence for immune system effects of PFOA, as well as recent studies that are relevant to this topic. The overall conclusion made by **Steenland et al. (2020)** was that "a relatively large number of studies consistently report that

PFOA impairs immune function," but that "evidence that PFOA increases the risk of infectious disease or asthma is inconsistent."

Thyroid Effects

Evaluations of PFAAs and thyroid disease have reached varying conclusions. Although stating that the overall database was mixed, the C8 Science Panel determined a "probable link" for PFOA and thyroid disease (**C8 Science Panel 2012**). (**NJDWQI 2017**, **2018)** found limited evidence for association of PFOA and thyroid disease, while associations of PFOS with thyroid disease were not noted, and **Khalil (2015)** found that the data for PFAS in general are inconsistent. **Australia Government DOH (2018)** concluded that "there are no consistent associations between any particular PFAS and thyroid hormones," and that there is limited evidence of an association between PFOA and thyroid disease in women but not in men. **Rappazzo, Coffman, and Hines (2017)** stated that conclusions about PFAS and thyroid disease in children cannot be reached with certainty due to the small number of studies and variable results. **Coperchini et al. (2017)** found that hypothyroidism was the most consistent thyroid effect for PFOA, and for PFOS to a lesser extent, with women and children most susceptible. **Ballesteros et al. (2017)** stated that although there is a small number of studies with comparable data, there is some consistency in evidence for increased thyroid-stimulating hormone (TSH) with PFHxS and PFOS in pregnant women, and with PFNA TSH in teenage boys; associations with thyroid disease were not noted. More recently, a very large study (n = ~ 63,000) evaluated thyroid diseases in a Swedish community in which one-third of the population had previous residential exposure to very high levels of PFOS (8,000 ng/L) and PFHxS (17,000 ng/L) in drinking water. (**Andersson et al. 2019**). A consistent pattern of increased risk of hypothyroidism or hyperthyroidism was not found in men or women with residential exposure to the contaminated water. **Steenland et al. (2020)** concluded that there is less evidence for an association of PFOA and thyroid disease than when the "probable link" conclusion for this effect was made, and that studies of PFOA and thyroid hormone levels report inconsistent results. Similarly, **ATSDR (2021)**, p.264, concluded that associations between PFOA, PFOS, PFHxS, PFNA, PFDA, and PFUnA and thyroid-related hormones and thyroid disease are inconsistent across studies, with the majority of studies not finding associations, and that most of the small number of studies of PFDoDA and thyroid hormones did not find "consistent associations." **NASEM (2022)** concluded that there is limited or suggestive evidence for an association of PFAS with thyroid disease and dysfunction in adults and children. **USEPA (2023)** did not prioritize PFOA and thyroid disease as one of the key endpoints for evaluation of epidemiological associations. For PFOS, **USEPA (2023)** concluded that there is "slight evidence to suggest human endocrine toxicity, including associations between PFOS exposure and thyroid disease," and that this conclusion is based on only one study rated as being of high confidence.

Other Effects

The C8 Science Panel also found probable links for PFOA with ulcerative colitis (**C8 Science Panel 2012**) and pregnancy-induced hypertension [PIH] (**C8 Science Panel 2012**); PIH was also associated with PFOS in the same two studies that linked it with PFOA (**Stein, Savitz, and Dougan 2009**; **Darrow, Stein, and Steenland 2013**). **ATSDR (2021)**, p.26, concluded that "there is suggestive epidemiological evidence for an association between serum PFOA and PFOS and [PIH] and/or pre-eclampsia." In the opinion of **Steenland et al. (2020)**, current evidence continues to support a link of PFOA and ulcerative colitis, although more research is needed for a definitive conclusion, and NASEM (**2022**) concluded that there is limited or suggestive evidence for association of PFAS and this effect in adults. For pregnancy-induced hypertension, **Steenland et al. (2020)** reported mixed results; one recent study found an association with preeclampsia, a related effect, while another did not, and **NASEM (2022)** concluded that there is limited or suggestive evidence for association of PFAS and these effects.

For many other epidemiological endpoints that have been studied, generally consistent associations were not found and/or the available data are too limited to make firm conclusions.

It is notable that associations for several of the effects mentioned above (serum lipids, liver enzymes, vaccine response, birth weight) were observed even within the exposure range prevalent in the general population (without specific exposures from environmental sources), as well as at higher exposures. For several of these effects (for example, **cholesterol—Steenland et al. 2009**; **Frisbee et al. 2010**; **ALT—Gallo et al. 2012**), the dose-response curves (for example, serum lipids, liver enzymes) are steepest at very low exposures with a much flatter slope approaching a plateau at relatively low serum concentrations (for example, ~40 ng/L for PFOA and cholesterol).

17.2.4.2 Carcinogenicity

Several evaluations of the epidemiological evidence for carcinogenicity are available for PFOA and PFOS, while such evaluations have not been conducted for other PFAAs. The **C8 Science Panel (2012)** found a "probable link" of PFOA with testicular and kidney cancer based on an increased incidence of these cancers in the Ohio and West Virginia communities with drinking water exposure as well as data from other human and animal studies. Although some other occupational studies of PFOA, such as **Raleigh et al. (2014)**, did not find increased incidence of these tumors, increased kidney cancer was reported in workers exposed to PFOA in the West Virginia industrial facility (**Steenland and Woskie 2012**). In consideration of these findings, **IARC (2016)** classified PFOA as "possibly carcinogenic to humans" (Group 2B) based on limited evidence that PFOA causes testicular and renal cancer, and limited evidence in experimental animals. Based on reviews of key reports and systematic reviews, the **Australia Government DOH (2018)**, p.70, concluded that "the evidence on cancer risk is limited;" that it is possible that PFOA is associated with an increased risk of kidney and testicular cancer; and that the evidence does not support PFAS being a major contributor to cancer burden in workers or exposed community populations.

A recent study by the National Cancer Institute (**Shearer et al. 2021**) evaluated associations of serum concentrations of PFOA and other PFAS with renal cell cancer in a subset of participants in a much larger ongoing cancer screening trial. The analysis included 324 subjects diagnosed with renal cell cancer and 324 individually matched controls. PFAS were measured in blood samples taken prior to cancer diagnosis, and serum PFOA concentrations were within the range that was prevalent in the general population at the time of sample collection (1993–2001). Increased serum PFOA was associated with increased risk of renal cell cancer. This association remained even when subjects with decreased kidney function were excluded, and when only subjects with serum PFAS levels measured $\geq$ 8 years before cancer diagnosis were included. Associations of serum PFOS and PFHxS with increased renal cell cancer risk were not statistically significant after adjustment for the other PFAS, while the association of increased risk with PFOA remained after this adjustment. The authors concluded that these results "add substantially to the weight of evidence that PFOA is a renal carcinogen and may have important public health implications."

Steenland et al. (2020) concluded that the evidence for an association of PFOA and kidney and testicular cancer remains "supportive but not definitive." They stated that although the results of three newer studies (published since the C8 Panel's reports) are not consistent, the evidence for an association of PFOA with kidney cancer is strengthened by positive findings in the recent large case-control study in the general population (**Shearer et al 2021**).

NJDWQI (2017)–PFOA, **NJDWQI (2018)**–PFOS, concluded that PFOA and PFOS have suggestive evidence for human carcinogenicity, based primarily on animal data, while a more recent evaluation (**NJDWQI 2023**) concluded that current evidence for PFOA indicates that it is a likely human carcinogen. **USEPA (2023)** concluded that PFOA is a likely human carcinogen, citing recent animal (**NTP 2020**) and human (**Shearer et al. 2021**) studies that add support to earlier evidence of carcinogenicity. **USEPA (2023)** also concluded that PFOS is a likely human carcinogen, with a determination of a statistically significant trend for increased pancreatic acinar carcinomas in the chronic rat study (**Thomford 2002**; **Butenhoff et al. 2012**) adding support to earlier evidence. **USEPA (2018)** also concluded that GenX has

suggestive evidence for human carcinogenicity. **NASEM (2022)** concluded that there is sufficient evidence for an association of PFAS and kidney cancer in adults and that there is limited or suggestive evidence for PFAS and breast and testicular cancer in adults.

In contrast to PFOA, studies of cancer incidence in large populations with exposure to contaminated drinking water with elevated levels of only PFOS are not available although a recent study evaluated communities with exposure to drinking water contaminated with PFOA, PFOS, and PFHxS (present at the highest concentration) from AFFF (**Li et al. 2022**). **Arrieta-Cortes et al. (2017)** concluded that while associations with cancer were not observed in the available occupational and general population studies of PFOS, such associations cannot be ruled out because problems with the studies may have precluded detection of associations if they were present. They therefore concluded that there is "inadequate evidence of carcinogenicity" based on the human data. **Chang et al. (2014)** stated that "many positive associations with PFOA exposure were detected in community settings" but were not confirmed in studies of workers with much higher exposures, although increases in certain cancers in some occupational studies are noted within the paper. They concluded that a causal association between PFOA or PFOS and human cancer is not supported by the currently available epidemiological evidence.

17.2.5 Animal Toxicology Studies

Many scientific considerations and decision points are involved in developing human health toxicity factors from animal toxicology data. In the hazard identification component of the toxicity factor development, the toxicological endpoint selected as the basis for the reference dose should be determined to be well established (that is, supported by multiple studies), related to an adverse health outcome, and relevant to humans based on mode of action considerations.

Peroxisome proliferator-activated receptor-α (PPAR-α) is a nuclear receptor found in many human and animal tissues that is involved with numerous physiological processes (**Corton, Anderson, and Stauber 2000**; **Michalik et al. 2006**). The role of PPAR-α in the effects caused by PFAS and the human relevance of effects in rodents that are mediated by PPAR-α have been a focus of research on the mode of action for the toxicological effects of PFAAs (**Lau 2012**; **Post, Gleason, and Cooper 2017**). As reviewed by **Post, Gleason, and Cooper (2017)**, most PFAAs that have been evaluated for this effect can activate PPAR-α to some extent. Specific toxic effects of some PFAAs in rodent models occur wholly or partially via PPAR-α, while other effects are independent of PPAR-α. One important example is hepatic toxicity of PFAAs. For PFOS, hepatic effects are clearly primarily PPAR-α independent, while hepatic effects of PFOA and PFNA involve substantial contributions from both PPAR-α dependent and independent processes.

In the dose-response evaluation portion of toxicity factor development, the selected endpoint must provide the data needed to determine a point of departure (that is, benchmark dose [BMD], NOAEL, or LOAEL). To appropriately account for the large differences in PFAA half-lives among species, and among sexes of the same species in some cases, dose-response evaluation for long-chain PFAAs is most appropriately based on internal dose, as indicated by serum level, rather than external (administered) dose. Finally, in development of RfDs, uncertainty factors appropriate to the specific study and endpoint are selected and applied to the point of departure to account for factors such as sensitive human subpopulations, interspecies differences, shorter-than-chronic exposure duration, extrapolation from a NOAEL to a LOAEL, and potentially more sensitive toxicological effects (**Section 8.3**).

Toxicological effects that have been reported as statistically significant in mammalian laboratory animal studies for each PFAS, with relevant citations, are presented in the **Table 17-8 Toxicological Effects** Excel file. The sections following the table present general discussions of systemic, reproductive and developmental, and carcinogenic effects of these PFAS.

17.2.5.1 Systemic Effects

All of the PFAS included in the Table 17-8 Toxicological Effects Excel file for which data are available caused increased liver weight in the rodent and nonhuman primate species studied. For most of these PFAS, increased liver weight was accompanied by hepatocellular hypertrophy. Developmental (in utero or lactational) exposures to some PFAAs caused increased liver weight in rodent offspring. Many PFCAs, as well as PFOS and GenX, caused additional hepatic effects that are more severe in nature such as hepatocellular necrosis and/or vacuolation in rodents and nonhuman primates, or hepatic lipid accumulation in rodents. For PFOA (**Butenhoff et al. 2012**; **NJDWQI 2017**) and PFOS (**Butenhoff et al. 2012**; **NJDWQI 2018**), these hepatic effects increased in severity with longer duration of exposure and may represent a progression to neoplastic changes, including hepatic adenomas. Additional effects reported for some PFAS include bile duct toxicity in rodents and increased serum levels of liver enzymes in rodents and/or nonhuman primates.

Some PFAAs and PFECAs caused decreased serum cholesterol in rodents and/or nonhuman primates. The increased cholesterol in humans associated with much lower exposures to some PFAS may be attributable to interspecies differences, such as differences in activity of relevant receptors involved with cholesterol metabolism. However, these contrasting observations in rodents and humans may also arise from differences in the fat content of a typical low-fat laboratory diet and the higher fat diet in the humans who were studied (**Tan et al. 2013**; **Rebholz et al. 2016**), or to dose-related differences in this response, because the doses in the toxicology studies are much higher than human exposure levels.

Some long-chain PFAAs caused immune system toxicity in the (Table 17-8 Toxicological Effects Excel file. Decreased antibody response to antigens has been identified as a sensitive endpoint for PFOA and PFOS toxicity, and this endpoint in animal studies have been used as the basis for toxicity factors and health-based regulatory criteria developed by government agencies, including **MDH (2019)**; **ATSDR (2021)**; **NJDWQI (2018)**; **Pachkowski, Post, and Stern (2019)**.

The majority of PFAS covered herein have not been tested for neurobehavioral effects. Of those PFAAs that have been evaluated in rodents, exposure-related effects were not observed for PFBA and PFHxA, while exposure of adult rodents to PFOS and PFDA caused effects including changes in learning, memory, activity, and habituation or other effects indicative of cognitive defects (see studies cited in the Table 17-8 Toxicological Effects Excel file). Additionally, developmental exposures to PFOA, PFOS, and PFHxS caused persistent neurobehavioral effects in mice (**Johansson, Eriksson, and Viberg 2009**; **Onishchenko et al. 2011**; **Lee and Viberg 2013**).

17.2.5.2 Reproductive and Developmental

Reproductive effects in males and females and developmental effects of several PFAS have been evaluated in rodents (Table 17-8 Toxicological Effects Excel file), but these effects have not been studied in nonhuman primates. In addition to the considerations common to developmental toxicity studies in general, the much faster excretion of several PFAS in female rats than in males must be considered when interpreting results of the rat reproductive and developmental studies.

Dosing of pregnant females with PFAAs results in gestational exposure to the fetus and also to the offspring during lactation. Cross-fostering studies of PFOA (**White et al. 2009**) and PFOS (**Luebker et al. 2005**) in which dosed dams fostered pups from control dams and vice versa showed that effects such as delayed development can result from exposures during either gestation or lactation.

Although malformations have been reported in a few rodent studies of PFOA and PFOS, effects such as full litter resorptions, decreased litter or number of live pups at birth, decreased survival of neonates, and decreased fetal and neonatal weight have been more frequently and consistently found (**USEPA 2023**, **2023**). These developmental effects may result from toxicity to the placenta, as has been observed for

PFOA (**Suh et al. 2011**) and PFOS (**Lee et al. 2015**). With PFOS at relatively high doses, neonatal mice and rats appeared normal at birth but died within a few hours; the genesis of this phenomenon is not understood (multiple studies reviewed in **NJDWQI 2018**).

Decreased growth of offspring and/or delays in reaching developmental milestones was observed for several PFAS in rodent studies (Table 17-8 Toxicological Effects Excel file). For PFBS (**Feng et al. 2017**) and PFNA (**Das et al. 2015**), body weight decrements persisted until adulthood. PFOA caused delays in ossification of bones and eruption of teeth (**Lau et al. 2006**; **Yahia et al. 2010**). Developmental markers such as eye opening and/or reaching sexual maturity were also delayed by some PFAAs, while noting that sexual maturity was conversely accelerated in male mice by PFOA (**Lau et al. 2006**). Persistent neurobehavioral effects in mice resulted from developmental exposures to several long-chain PFAS (**Johansson, Eriksson, and Viberg 2009**; **Onishchenko et al. 2011**; **Lee and Viberg 2013**).

Certain developmental effects of some PFAAs persisted into adulthood. These include decreased size of uterus and ovaries, accompanied by decreased number of follicles and corpora lutea, and changes in reproductive and thyroid hormone levels in female mouse offspring exposed to PFBS (**Feng et al. 2017**). Developmental exposures of mice to PFOA caused persistent delays in mammary gland development (**White et al. 2009**) and persistent liver toxicity (**Quist et al. 2015**) at doses lower than those that caused other systemic and developmental effects; these endpoints have not been evaluated for other PFAS.

17.2.5.3 Chronic Toxicity and Tumorigenicity

PFAAs have generally not been found to be mutagenic or genotoxic (**Lau 2015**). Of the PFAS included in Table 17-8 Toxicological Effects Excel file, chronic studies that evaluated carcinogenicity and other effects of long-term exposure have been conducted in rats only for PFHxA, PFOA (three studies; one in males only), PFOS, and GenX. PFHxA did not increase the incidence of tumors in either sex of rats. PFOA increased the incidence of several types of tumors, including testicular Leydig cell adenomas in two of the three studies, and hepatic adenomas and/or carcinomas and pancreatic acinar cell adenomas and/or carcinomas in two of the three studies, and uterine adenocarcinomas in one of the three studies. In the chronic PFOS study, pancreatic acinar carcinomas and benign tumors in other organs were increased, including hepatic adenomas in females, and thyroid follicular cell adenomas in males only in the high dose "recovery group" (dosed for the first year only and evaluated at the end of the 2-year study). GenX increased the incidence of both hepatocellular adenomas and carcinomas in females, and the incidence of combined pancreatic acinar cell adenomas and carcinomas and testicular Leydig cell adenomas in males.

IARC (2016) classified PFOA as "possibly carcinogenic to humans" (Group 2B) based on limited evidence that PFOA causes testicular and renal cancer, and limited evidence in experimental animals. **IARC (2023)** is currently reevaluating the classification of PFOA and evaluating PFOS for the first time. Based on the **USEPA (2005)** Guidelines for Carcinogen Risk Assessment, **USEPA (2023**, **2023**, **2018**) described PFOA and PFOS as likely human carcinogens, and GenX as having suggestive evidence for human carcinogenicity. A recent review by **NJDWQI (2023)** concurred with **USEPA (2023)** that PFOA is a likely human carcinogen; this review also concluded that PFOS has suggestive evidence but did not consider the **USEPA (2023)** evaluation that found a statistically significant trend for pancreatic acinar tumors in the chronic rat study (see **Section 17.2.3.5**). For PFOA, **ATSDR (2018), draft** concluded that the hepatic tumors are unlikely to be relevant to humans. In contrast, **USEPA (2023)** concluded that, in the "absence of definitive information supporting a single, scientifically justified mode of action (MOA) and "evidence supporting the potential for multiple plausible MOAs, … USEPA takes the health-protective approach and concludes that the hepatic tumors observed [in two chronic rat studies]… can be relevant to human health." Human relevance was not discounted for the testicular and pancreatic tumors by either **ATSDR (2018)** or **USEPA (2023)**. For PFOS, **USEPA (2023)** and **NJDWQI (2018)** did not discount human relevance of the hepatic tumors. **NJDWQI (2017)** developed cancer slope (potency) factors for PFOA based on the incidence of testicular Leydig cell tumors in rats, while the California EPA (**CA OEHHA 2023**) and **USEPA**

(2023) slope factors are based on the incidence of kidney cancer in humans and are much more stringent than PFOA slope factors based on animal data. **NJDWQI (2018)** and **USEPA (2023)**) both developed cancer slope factors for PFOS based on the incidence of liver tumors in rats.

17.2.6 Health Effects Information for Some Additional PFAS of Current Interest

17.2.6.1 Information Relevant to Human Health Effects of Ether and Polyether PFAS

There is increasing awareness and interest in potential human exposure to PFAS other than PFAAs. These include ether and polyether PFAS and dicarboxylic acid polyether PFAS used as replacements for long-chain PFAAs. Additionally, ether and polyether PFAS and PFAS with other structures can be formed as unintentional byproducts of industrial processes (**Wang et al. 2019**). Health effects information for hexafluoropropylene oxide dimer acid (HFPO-DA, GenX), a 6-carbon perfluoroether, and ADONA, a 7-carbon polyfluoropolyether, which are both used as replacements for PFOA, is discussed in **Sections 7.1.4** and **17.2.5**. Information on the environmental occurrence, ecological effects, toxicology and toxicokinetics in laboratory animals, and bioaccumulation and potential health effects in humans is currently becoming available for additional non-PFAA PFAS at a rapid pace, particularly for additional ether and polyether PFAS (**Wang et al. 2019**). Collectively, this information indicates that the toxicological and bioaccumulative properties of some of these ether and polyether PFAS, particularly those with longer total chain lengths (carbons plus ether oxygens in the chain), are similar to those of the phased out long-chain PFAAs (for example, PFOA, PFOS, PFNA) (see **Figure 2-4**).

This section summarizes the currently available laboratory animal and human studies that are relevant to human health effects of some additional ether and polyether PFAS. This material expands the discussion of these groups of compounds beyond HFPO-DA (GenX) and ADONA that were discussed in **Section 17.2.5**. These additional ether and polyether PFAS include:

- per- and polyfluoroether carboxylates (PFECAs)
- per- and polyfluoropolyether carboxylates (PFPECAs)
- per- and polyfluoroether sulfonates (PFESAs)
- per- and polyfluoropolyether sulfonates (PFPESAs)

As discussed below, some of the most thoroughly studied PFESAs and PFPECAs have chlorine atoms on the terminal carbon (ClPFESAs and ClPFPECAs, respectively). Toxicity data for dicarboxylic acid PFPECAs are also discussed. Specifically, longer chain PFPECA analogues of GenX (HFPO-DA), including hexafluoropropylene oxide-trimer acid (HFPO-TA) and hexafluoropropylene oxide-tetramer acid (HFPO-TeA), and numerous other PFPECAs of various structures and chain lengths are of interest because they are used as replacements for phased-out long-chain PFAAs and/or formed as industrial byproducts. Many of these PFPECAs have been detected in the environment, including in drinking water in some cases (**Pan et al. 2019**; **Munoz et al. 2019**; **Wang et al. 2019**; **Kotlarz et al. 2020**). Industrial mixtures of ClPFPECAs of various chain lengths, as well as dicarboxylic acid polyether PFPECAs, are also of interest because they are used as alternatives for phased-out long-chain PFCAs, including PFNA (**NJDEP 2021**; **Wang et al. 2013**), and ClPFPECAs have been detected in environmental media near industrial sources (**McCord et al. 2020**; **Washington et al. 2020**; **Mazzoni et al. 2015**).

F53B is a PFOS alternative that consists primarily of 6:2 chlorinated polyfluoroether sulfonate (6:2 ClPFESA), with smaller proportions of 8:2- and longer chain ClPFESAs (**Munoz et al. 2019**; see also **Section 2.6.1.3**). These ClPFESAs are used primarily in China, and are of interest because they have been found in multiple environmental media and, as discussed below, in human biomonitoring studies. Nafion byproducts are PFPESAs formed as industrial byproducts in the production of Nafion, a sulfonated tetrafluoroethylene-based fluoropolymer-copolymer, and are of interest because they have been found in

drinking water impacted by industrial discharges (**Hopkins et al. 2018**). With some exceptions, the toxicity and bioaccumulative potential of PFAAs with similar structures (for example, PFCAs, PFSAs) generally increase with increasing carbon chain length (see **Section 7.1.4**). Similarly, currently available information on the ether and polyether PFAS with analogous structures (for example, HFPO-DA, -TA, -TeA; 6:2 and 8:2 ClPFESA) discussed in this section suggests that their toxicity and bioaccumulation also generally increase with increasing chain length (including both carbons and ether oxygens).

Human Biomonitoring and Health Effects Studies

PFECAs and PFPECAs

As discussed below, recent biomonitoring studies show that, as is the case for long-chain PFAAs, many ether and polyether PFAS are bioaccumulative in humans, although this may not be the case for some shorter chain members of this group such as GenX (HFPO-DA). Associations with changes in health-related endpoints (for example, clinical chemistry parameters) were also reported in some studies.

A biomonitoring study of Wilmington, NC, residents evaluated blood serum PFAS levels 5 months after cessation of exposure to drinking water from the Cape Fear River that was contaminated by multiple PFAS. Nafion byproduct 2 and two longer chain PFPECAs were detected in the blood serum of >85% of subjects; two other fluoroethers were less frequently detected. The shorter chain PFECA, GenX (HFPO-DA), which was also present in drinking water, and several other PFAS that were detected in the Cape Fear River, were not found in human serum (**Kotlarz et al. 2020**). This study did not evaluate potential associations of health effects and exposure to fluoroethers. **Yao et al. (2020)**, whose study population lived near a fluorochemical plant in China, also detected multiple PFECAs and PFPECAs, as well as sulfonate ether PFAS (discussed below), in blood serum. They reported associations between PFO5DoA, a long-chain PFPECA that has 7 carbons and 5 ether oxygens, and increased serum lipids, liver enzymes, and uric acid. Two other PFECAs (HFPO-TA, 9 carbons and 2 ether oxygens; PFO4DA, 6 carbons and 4 ether oxygens) were associated with increases in one or more serum lipid parameters, and PFO4DA was also associated with increased uric acid.

A summary of an unpublished biomonitoring study of workers with occupational exposure to industrial mixtures of ClPFPECA congeners of various chain lengths reported an estimated human half-life of 2.5–3 years. Associations with increased serum lipids, liver enzymes, triglycerides, albumin, albumin/globulin ratio, thyroid stimulating hormone (TSH), free thyroxine, and prostate-specific antigen (PSA), and decreases in estradiol and indicators of immune system function (alpha-2-globulins and immunoglobulins) were reported (**Solvay 2019**). It was noted that the changes in serum lipids and liver enzymes may have been confounded by exposure to PFOA, and that associations with increased TSH and PSA were less reliable because they were based on fewer data points (**Solvay 2019**).

PFESAs and PFPECAs

6:2 ClPFESA was consistently detected in human blood serum in several recent biomonitoring studies in China (**Jin et al. 2020**; **Liu et al. 2020**; **Pan et al. 2017**; **Yao et al. 2020**). The median and mean human half-life of 6:2 ClPFESA were estimated as 15.3 and 18.5 years, respectively, as compared to an estimated median and mean of 6.7 and 7.7 years, respectively, for PFOS in the same study (**Shi et al. 2016**). 6:2 ClPFPESA was included in the suite of PFAS measured in blood serum of U.S residents in NHANES for the first time in 2017–18 (**CDC 2022**). It was found at the detection limit (0.100 ng/ml) in the 95th percentile of the total population, and at the same or similar levels in most racial/ethnic groups as follows: Mexican Americans – not detected at 90th percentile, 0.100 at 95th percentile; non-Hispanic blacks - 0.100 ng/ml at 90th and 95th percentiles; non-Hispanic whites - not detected at 95th percentile; all Hispanics – not detected at 90th percentile, 0.100 at 95th percentile [values are geometric means]. The maximum level detected in any of these subgroups was 0.200 ng/ml. However, it was detected more frequently and at higher levels in Asians (0.200 ng/ml at 75th percentile; 1.00 ng/ml at 90th percentile;

2.30 ng/ml at 95th percentile; maximum – 10.9 ng/ml). It is not known whether the more frequent detections and higher serum levels in Asians results from their exposure while in Asia or from other sources such as consumption of foods contaminated with 6:2 ClPFESA that are imported from Asia.

As is the case for long-chain PFAAs, biomonitoring data demonstrate exposure to ClPFESAs in utero and through breast milk. Both 6:2 and 8:2 ClPFESA were found in matched maternal:umbilical cord blood samples, indicating fetal exposure, with 8:2 ClPFESA having a higher rate of transfer to cord blood (**Cai et al. 2020**; **Chen et al. 2017**; **Pan et al. 2017**; **Xu et al. 2019**). The only study that evaluated potential health outcomes associated with fetal exposure found no evidence of an association between ClPFPESAs exposure and birth outcomes (**Xu et al. 2019**). 6:2 and 8:2 PFESA were also found in human breast milk from several locations in China, but not from Sweden (**Awad et al. 2020**; **Jin et al. 2020**). Breast milk levels of these PFESAs were associated with decreased infant growth in one of these studies (**Jin et al. 2020**).

Rodent Toxicology Studies

PFECAs and PFPECAs

As discussed above, hepatotoxicity is an effect common to many PFAS. In mouse studies, HFPO-TeA, with 12 carbons and 3 ether oxygens, was more hepatotoxic than its shorter chain analogue HFPO-DA (GenX; **Wang et al. 2017**), and HFPO-TA, with 9 carbons and 2 ether oxygens, was more hepatotoxic than PFOA, which has an 8-carbon chain (**Sheng et al. 2018**). In mice, the bioaccumulation in blood serum and liver increased with chain length for a series of PFPECAs with two to four O-CF2 groups, and only the largest PFAS, with four such groups (PFO4DA), caused increased liver weight at the doses tested (**Guo et al. 2019**). A recent study (**Chen et al. 2021**) reported half-lives in male mice of 24 hours for PFO4DA and 43 days for its larger homologue, PFO5DoA after a single intravenous dose. In a 140-day study of male mice, both compounds accumulated in the liver and caused increases in body weight, relative liver weight, and serum glucose, triglycerides and free fatty acids, as well as biochemical changes in the liver consistent with reduced glycolysis (**Chen et al. 2021**).

As reviewed in **NJDEP 2021**, industrial products consisting of mixtures of ClPFPECA congeners of various chain lengths ranging from 8 carbons and 3 ether oxygens to 14 or 17 carbons and 5 ether oxygens caused toxicity to liver, lung, thymus, seminal vesicles, and thyroid in 4-week and/or 13-week rat studies, with some changes persisting after a several-week recovery period (**Research Toxicology Centre 2006**, **2016**). The doses at which hepatic effects occurred were similar to those reported for long chain PFCAs (for example, PFOA, PFNA; **NJDWQI 2015**, **2017**). The half-lives for five of the congeners (ranging from 8 carbons and 3 ether oxygens to 14 carbons and 5 ether oxygens) were reported as 8–29 days in male rats and 1.6–91 days in female rats. These half-lives are similar to those documented for PFOA (4-6 days) and PFNA (30 days) in male rats (**Table 17-7**).

Additionally, industrial products consisting of mixtures of another type of PFPECAs, dicarboxylic acid polyether carboxylates (chain lengths not specified), caused toxicity to the liver, lung, thymus, seminal vesicles, and kidneys, with hepatic effects at very low doses, in 4- and/or 13-week studies in rats. As for the ClPFPFECAs, some effects persisted after a several week recovery period. The estimated half-life in male rats after a single dose was 43 days, and the estimated half-lives after repeated dosing were approximately 8 days in males and 11 days in females (**Research Toxicology Centre, 2005**; **Research Toxicology Centre, 2006**). In contrast, PFOA and PFNA, with half-lives of 2-4 hours and 1-2 days, respectively, as well as some other PFAS, are much less persistent in female rats (**Section 17.2.3**; **Table 17-7**).

PFESAs and PFPESAs

6:2 ClPFESA, the primary component of F53B, and Nafion byproduct 2, also a PFPESA, caused liver toxicity in mice (**Zhang et al. 2018**; **Lang et al. 2020**). In a subchronic study of reproductive toxicity of 6:2 ClPFESA in male mice, relative weights of reproductive organs decreased at the highest dose tested. However, at the doses used in the study, there were no histopathological changes in these organs, and hormone levels, sperm counts, fertility, and expression of several testicular genes were not affected (**Zhou et al. 2018**). After subchronic exposure to mice, 6:2 ClPFESA accumulated in the small and large intestine, damaged the gut barrier, and caused inflammation of the colon (**Pan et al. 2019**).

Zebrafish Studies

Zebrafish are well accepted as an in vivo model system for human health effects. Zebrafish studies for the ether and polyether PFAS are relevant to evaluation of their potential human health effects and are discussed below.

PFECAs and PFPECAs

The hexafluoropropyl acids—HFPO-DA, HFPO-TA, and HFPO-TeA—caused estrogenic effects in zebrafish (**Xin et al. 2019**). A suite of PFPECAs of various chain lengths decreased thyroid hormone levels in developing zebrafish embryos, leading to thyroid hormone-dependent malformations of the swim bladder (**Wang et al. 2020**).

6:2 ClPFECA

A number of studies have reported toxic effects of 6:2 ClPFECA in zebrafish. These include: bioaccumulation in larvae and adults (**Wu et al. 2019**); hepatoxicity, in adults (**Shi et al. 2019**; **Wu et al. 2019**); reproductive toxicity in a two-generation study (**Shi et al. 2018**); disruption of cardiac development (**Shi et al. 2017**); and thyroid toxicity from developmental exposures to environmentally relevant concentrations (**Deng et al. 2018**) and in unexposed offspring after exposure of the parental generation (**Shi et al. 2019**). **Tu et al. (2019)** reported that 6:2 ClPFECA was more bioaccumulative and was a more potent disruptor of metabolism than PFOA in zebrafish.

17.2.6.2 Fluorotelomer Alcohols

Fluorotelomer alcohols (FTOHs) are polyfluoroalkyl substances synthesized as intermediates for the manufacture of various fluorosurfactants and fluoropolymers (**Dinglasan-Panlilio and Mabury 2006**; **ECHA 2012**). The telomer alcohols are named with the number of fully fluorinated carbon atoms first, followed by the number of partially fluorinated carbon atoms (for example, 8:2 FTOH, 6:2 FTOH). In the environment, FTOHs may degrade to PFCAs with 8:2 FTOH degradation capable of forming PFOA and PFNA (**Butt, Muir and Mabury 2014**). FTOHs are present in multiple consumer products, with 6:2 FTOH the primary FTOH manufactured for end use. Humans may be exposed by ingestion of FTOH-contaminated food or dust (**Yuan et al. 2016**). Some FTOHs are volatile, and human exposure may also occur via inhalation (**Huang et al. 2019**).

The following section summarizes currently available information on the toxicokinetics and adverse health effects of 6:2 and 8:2 fluorotelomer alcohol (6:2 and 8:2 FTOH, respectively) in experimental animals and humans. No peer-reviewed data were identified for other FTOHs.

Toxicokinetics

As polyfluoroalkyl substances, FTOHs are extensively metabolized in rodents and humans. Depending on the specific FTOH, the terminal metabolites include long- and/or short-chain PFCAs, unsaturated

fluorotelomer acids (FTUCAs), fluorotelomer acids (FTAs) and glutathione, sulfate, and glucuronide conjugates (**Kudo et al. 2005**; **Fasano et al. 2006**, **2009**; **Himmelstein et al. 2012**; **ECHA 2012**; **Nilsson et al. 2013**; **Kabadi et al. 2018**; **Huang et al. 2019**; **Rice et al. 2020**).

6:2 FTOH is rapidly absorbed following oral exposure, and undergoes metabolism in rats to form PFBA, PFPeA, PFHxA, PFHpA, certain FTAs, and glutathione, sulfate, and glucuronide conjugates (**Russell et al. 2015**; **Kabadi et al. 2018**). In vitro metabolic data from hepatocyte cultures indicate that 6:2 FTOH is likely metabolized similarly in rat, mice, and humans (reviewed in **Rice et al. 2020**). One of the non-PFCA metabolites, 5:3 FTA, is persistent, having an estimated half-life of ~100 days in male and female rats after repeated dosing (**Kabadi et al. 2020**). **Russell et al. (2015)** calculated an apparent geometric mean elimination half-life of 43 days for 5:3 FTA in humans based on occupational data of **Nilsson et al. (2010**, **2010**, **2013**). PFHxA and the other terminally stable short-chain PFCAs formed by the metabolism of 6:2 FTOH do not undergo further degradation and are eliminated rapidly in rodents (see **Table 17-7**). The metabolic pathways, rate determining steps, and elimination half-lives of the parent 6:2 FTOH and other metabolites have not been established.

8:2 FTOH administered orally or by inhalation is also rapidly absorbed and metabolized in rats and mice, with PFOA, 7:3 FTA, 8:2 FTA, PFNA, PFHxA, PFHpA, and glucuronide, glutathione, and other conjugates identified as metabolites (**Kudo et al. 2005**; **Fasano et al. 2006**, **2009**; **Himmelstein et al. 2012**; **ECHA 2012**). In vitro data from rat, mouse, and human hepatocytes indicate that 8:2 FTOH is metabolized to PFOA in rodents and humans, although rodent hepatocytes appear to transform greater amounts of 8:2 FTOH to PFOA than human hepatocytes. Other in vitro metabolites in rodent hepatocytes include 8:2 FTCA, 8:2 FTUCA, and PFNA (**ECHA 2012**).

Data from the NTP (**Huang et al. 2019**) confirmed that 8:2 FTOH is rapidly absorbed and distributed in male and female rats after a single oral or intravenous (IV) dose. The plasma elimination half-life of the parent compound was 1.1–1.7 hours, and the two primary metabolites were 7:3 FTA and PFOA. The half-life of 7:3 FTA was 2–3 days in both sexes of rats; PFOA's half-life was sex-dependent (approximately 8–15 days in males, and 4.5–6.9 h in females). **Nilsson et al. (2010**, **2010**) measured a mixture of 6:2, 8:2, and 10:2 FTOH and other PFAS in the workplace air of ski wax technicians and subsequently documented the presence of PFOA, PFNA, PFDA, PFDoA, PFTDA, 5:3 FTA, and 7:3 FTA in all samples of the technicians' blood (**Nilsson et al. 2013**). The metabolites, 8:2 FTUCA and 10:2 FTUCA, were also detected in blood samples from multiple technicians. Although concentrations of 8:2 FTOH were several-fold higher than other PFAS in workplace air, the relative importance of 8:2 FTOH and 10:2 FTOH to the metabolic formation of PFOA, PFNA, other long-chain PFCAs, or the FTAs cannot be determined from these data given that exposures were to multiple PFAS.

Toxicity

6:2 FTOH

Consistent with other data that have demonstrated a lack of genetic toxicity of PFAS (see **Section 17.2.5.3**), 6:2 FTOH was negative when tested in the Ames bacterial mutagenesis assay. It was not mutagenic in the mouse lymphoma assay and was not clastogenic in a chromosome aberration assay in human lymphocytes. It was found not to be a skin or eye irritant (**Serex et al. 2014**).

Given the metabolic transformation of 6:2 FTOH and 8:2 FTOH to several PFCAs, 5:3 FTA (6:2 FTOH metabolite), and multiple additional metabolites of unknown toxicity, it is unclear whether adverse effects associated with exposure of experimental animals to FTOHs (see following) are attributable to the parent FTOH, one or more metabolites, or to combined exposure to multiple compounds. With the exception of the persistent 5:3 FTA metabolite of 6:2 FTOH, for which limited data demonstrating toxicity are available (**Rice et al. 2020**), the relationship between the adverse effects of FTOHs and their metabolites has not been established.

Rice et al. (2020) synthesized toxicity data on 6:2 FTOH from a 28-day NTP study, a number of peer-reviewed publications (**Miyata et al. 2007**; **Kirkpatrick 2005**; **O'Connor et al. 2014**; **Serex et al. 2014**; **Mukerji et al. 2015**), and OECD-compliant studies submitted on behalf of FTOH manufacturers. These studies reported that 6:2 FTOH causes multiple effects in the liver (for example, increased serum liver enzymes, hepatocellular necrosis, and oval cell hyperplasia) and kidney (renal tubular necrosis, mineralization, and degeneration) in rats and mice, as well as decreased thymus weight in rats. Reproductive effects of 6:2 FTOH in rats were observed only when high maternal mortality occurred. In contrast, 6:2 FTOH caused decreased body weight gain during lactation, mammary gland lesions, decreased uterine and ovarian weights, and an increase in anestrus in mice. 6:2 FTOH elicited developmental effects in both rats and mice, including increased pup mortality, delayed skull ossification, decreased pup body weight gain in rats, and decreased pup survival during lactation in mice.

Rice et al. (2020) also summarized the results of a 2-week oral toxicity study of the persistent 6:2 FTOH metabolite 5:3 FTA as reported by the industrial manufacturer. Those data indicate that in rats, 5:3 FTA caused adverse effects on the liver (decrease in total cholesterol, hepatocyte necrosis); kidney (increase in creatinine and urine volume, decrease in total urine protein); thyroid (follicular cell hyperplasia); and thymus (decrease in thymus weight).

There are no publicly available chronic toxicity studies for 6:2 FTOH.

8:2 FTOH

8:2 FTOH was negative when tested in the Ames bacterial mutagenicity study (**NTP 2018**), and in micronucleus assays reported by the OECD (**ECHA 2012**).

The liver and kidney were the primary target organs in rats administered 8:2 FTOH orally over a 90-day period (**Ladics et al. 2008**). 8:2 FTOH caused hepatic necrosis in males, and induced kidney nephropathy in females. Urinary and/or plasma fluorine levels were elevated in animals from all dose groups, an effect attributed to metabolism of the parent compound and an associated increase in fluoride levels. **Wang et al. (2019)** also documented effects of 8:2 FTOH on the livers of mice, including cellular vacuolation and swelling; swelling of cell nuclei; and immune cell infiltration in animals exposed orally for 28 days. 8:2 FTOH significantly altered mRNA levels of inflammatory cytokines in the thymus and spleen, although it is unclear whether these changes would translate to biologically significant effects on the immune system, as there were no accompanying histological changes in these organs.

Mylchreest et al. (2005) assessed the developmental toxicity of 8:2 FTOH in rats, finding that increased skeletal malformations in pups (delayed pelvic bone ossification and wavy ribs) occurred only at a dose that also elicited maternal toxicity. **Mylchreest et al. (2005)** also evaluated the reproductive and developmental toxicity of a commercial mixture of FTOH in rats, and observed decreases in litter size, pup weights, and the number of live pups per litter on days 0 and 4 of lactation. Developmental effects were seen only at a dose that also caused maternal toxicity.

There are no publicly available chronic toxicity studies for 8:2 FTOH.

17.2.6.3 Fluorotelomer Sulfonic Acids

Fluorotelomer sulfonic acids (FTSAs) and their salts, the fluorotelomer sulfonates (FTS), are polyfluorinated chemicals that are formed both by direct manufacture and by the degradation of precursors found in certain AFFFs or other industrial products (see **Section 2.2.4.1**; **Field and Seow 2017**). Because FTSAs and FTSs exist in anionic form in the body, they are equivalent toxicologically, and the term FTSA is used here to refer to both forms of these chemicals.

4:2 FTSA, 6:2 FTSA, and 8:2 FTSA have been detected in human blood (**Lee and Mabury, 2011**; **Loi et al. 2013**; **Yeung and Mabry 2016**; **Eriksson et al. 2017**), and 6:2 FTSA and 8:2 FTSA can cross the human placenta (**Yang et al. 2016**). Humans may potentially be exposed to FTSAs through ingestion of contaminated drinking water or food, or by inhalation of dust (**Field and Seow 2017**). It is not known if the detection of FTSAs in human blood is due to direct exposure to the parent compounds or to indirect exposure to FTSA or precursors (**Field and Seow 2017**).

Toxicokinetics

Information on the toxicokinetics of FTSAs is limited. No studies have evaluated the absorption of FTS versus FTSA. Since FTS and FTSA exist in the same anionic form within the body, their toxicokinetics would not differ after absorption. **ECHA (2018)** provided summary information on a single rodent in vivo study that examined the disposition and metabolism of 6:2 FTSA (species and dose levels not given). Following a single oral dose of 6:2 FTSA, 65–68% of the parent compound was recovered in urine 4 days post-dosing, indicating that metabolism of the majority of the administered dose did not occur. However, because no data were provided on metabolite formation or elimination, many questions remain regarding the metabolism of 6:2 FTSA in animals. In vitro data from **ECHA (2018)** and **Hoke et al. (2015)** also suggested that 6:2 FTSA is not extensively metabolized in animals. When 6:2 FTSA was incubated with rat liver microsomal fractions for 2 hours (**ECHA 2018**) or with rainbow trout hepatocytes for 4 hours (**Hoke et al. 2015**), no metabolism was detected. FTSA may have the potential to bioaccumulate, in that substantial levels of FTSA were measured in the livers of mice administered FTSA for 28 days (**Sheng et al. 2017**). The potential of FTSA to bioaccumulate is supported by observations of **Yan et al. (2014)**, who found comparable levels of the bioaccumulative PFOA in the serum and livers of mice exposed under the same experimental conditions used for FTSA by **Sheng et al. (2017)**. In the few human biomonitoring studies that included 6:2 FTSA, it was detected infrequently. For example, the Biomonitoring California Asian/Pacific Islander Community Exposures Project reported no detections of 6:2 FTSA in 2016 (N=96) and FTSA was detected in only 3% of samples analyzed in 2017 (N=99) (LOD=0.05 ng/ml) (**CA OEHHA 2020**).

Toxicity

6:2 FTSA was not genotoxic in assays of bacterial mutagenesis, or in mammalian cell assays of DNA repair or damage, micronucleus formation, or chromosome aberrations (**ECHA 2018**).

ECHA (2018) reported the results of unpublished oral range-finding and reproductive toxicity studies in rats. The 14-day range-finding study identified a NOAEL of 10 mg/kg-d based on changes in body and kidney weights and clinical chemistry (creatinine and urea) in one or more dose and gender groups. In the 90-day reproductive toxicity study, 6:2 FTSA did not affect male or female fertility or reproductive performance, and there were no effects on the number of pups, or on pup survival, growth, or sex ratio. The NOAEL for reproductive effects was $\geq$ 45 mg/kg-d.

Adult male mice administered 6:2 FTSA at 5 mg/kg-d over 28 days exhibited increases in liver weight, hepatocellular hypertrophy, hepatocellular necrosis, and biochemical markers associated with liver inflammation. Serum levels of the liver enzyme AST, an indicator of liver damage, and albumin were also elevated, and histological evidence of liver necrosis was observed (**Sheng et al. 2017**).

Adult male and female mice administered were administered 6:2 FTS over 112 days. 6:2 FTS is the anionic form of 6:2 FTSA which dissociates into 6:2 FTS, as is described in **Section 2.2.3.1**. Male and female mice exhibited signs of immunotoxicity including decreased plaque-forming cells in the spleen in response to sheep red blood cells in males and females administered 5 and 25 mg/kg-d and increased spleen weight in males administered 5 mg/kg-d (**Bohannon et al. 2023**).

17.2.7 PFAS Mixtures

This section provides a brief overview of current toxicity-based approaches for addressing mixtures of PFAS and currently available information on toxicity of PFAS mixtures. This is an active area of research.

17.2.7.1 Proposed Approaches, for Addressing Toxicity of PFAS Mixtures

Total Concentration Approach (Called Simple Additive Approach by Cousins et al. 2020)

In this approach, a single guideline concentration is applied to the total concentration of a specified set of PFAS. This approach is based on the assumption that all of the included PFAS have the same toxic effects and MOA, are equally potent, and their combined toxicity is additive. In the absence of complete information on toxicity and MOA for all of the selected PFAS, this approach has been applied as a conservative public health-protective science-policy strategy.

Examples of this approach are the drinking water guidelines of 20 ng/L (Vermont) and 70 ng/L (Connecticut) for the total concentration of five long-chain PFAAs (PFOA, PFNA, PFHpA, PFOS, PFHxS) and 20 ng/L (Massachusetts) for the total concentration of six long-chain PFAAs (PFOA, PFNA, PFHpA, PFOS, PFHxS, PFDA) (**CT DPH 2016**; **Vermont DOH 2018**; **MA DEP 2019**), as well as in several other nations (**Cousins et al. 2020**).

MA DEP (2019) provided a detailed rationale for their approach based on the sum of the six long-chain PFAS. They concluded that this approach is supported by similarities in chemical structures, toxicity values developed by other agencies, toxicological responses, and long serum half-lives for these six PFAS. PFHxA was also considered but was not included, because it has a shorter half-life and causes toxicity at higher doses than the PFAS that were included.

MA DEP (2019) used results of Bayesian benchmark dose (BBMD) modeling of data for thyroid effects (free thyroxine; fT4) and increased liver weight for five of the six PFAS from NTP 28-day rat toxicology studies (**NTP 2019**). Using PFOA as an index compound with a BBMD of 1, relative BBMDs for fT4 for the other PFAS ranged from 0.5 to 3 on a serum-level basis and 0.8 to 4 on a human equivalent dose (HED) basis. For an increase in liver weight, relative BBMDs based on both serum PFAS levels or HEDs ranged from 0.2 to 2. **MA DEP (2019)** considered these BBMDs to be sufficiently similar to assume equivalence of the five PFAS.

As discussed by **MA DEP (2019)**, there is a lack of data on toxicological effects, potency, and half-life of PFHpA (the 7-carbon PFAA included in the Connecticut, Vermont, and Massachusetts approaches), and no toxicity values (for example, reference doses) have been developed. Although Massachusetts recognized that PFHpA's half-life is likely shorter than for PFOA, they concluded that there are no data to develop a compound-specific or relative toxicity value for PFHpA, or to conclude that it is toxicologically dissimilar to PFOA. Based on "read-across," (prediction of toxicity based on data from similar compounds) these states consider PFHpA to be equipotent to PFOA.

Hazard Index Approach

Human health risk assessment often uses a hazard index approach, first developed by **USEPA (1989)**, to evaluate the potential cumulative noncancer toxicity from co-exposure to multiple contaminants (**USEPA 1989**). As discussed in **Section 9.1.3.1**, calculation of a hazard index is based on the assumption of dose additivity, but it does not necessarily require that the MOA or toxicological endpoint is the same for all components of the mixture. As discussed in **USEPA (2023)**, the Hazard Index approach can be based on a "general" Hazard Index, in which noncancer toxicity factors for multiple contaminants are used regardless of whether they are based on effects in the same or different target organs, or a "target organ specific" Hazard Index in which noncancer toxicity factors are based on effects in the same target organ.

USEPA (2023) presented the basis for a proposed MCLG and MCL of a Hazard Index of 1 for mixtures of four PFAS (PFBS, PFHxS, PFNA, GenX). The draft MCLG and MCL use the "general" Hazard Index approach in which the Hazard Index considers toxicity values based on differing toxicological endpoints for evaluation of the toxicity of the mixture.

Health Canada (2018, 2018) has concluded that, although there are no in vivo studies of PFAS mixtures, the similarity in health effects of PFOA and PFOS support an assumption of dose additivity and thus support the use of a hazard index approach to address co-occurrence of PFOA and PFOS in drinking water. ATSDR has also applied the hazard index approach to evaluate potential risk from site-specific exposure to mixtures of several long-chain PFAAs, noting that their approach assumed dose additivity based on "toxicologic similarities" (**ATSDR 2020**).

Minnesota Department of Health (undated) uses a health risk index approach—similar to the target organ specific Hazard Index approach—to evaluate concurrent exposures to multiple chemicals in groundwater. It is based on grouping chemicals (including PFAS and others) that cause the same general type of adverse health effect (i.e., the same target organ—for example, thyroid, endocrine). In the Minnesota health risk index approach, multiple health endpoints may be considered for each individual contaminant.

Mumtaz et al. (2021) provided a "proof of concept" demonstration of the potential use of an ATSDR hazard index approach based on target organ toxicity doses (TTDs) for specific toxicological effects (endocrine, hepatic, reproductive, developmental, and/or immune) to assess the risks of PFOA, PFOS, tetrachlorodibenzo-p-dioxin (TCDD), and polybrominated diphenyl ethers (PBDEs). This approach is intended for use as a screening tool, with a hazard index of >1 for a specific effect indicating the need for further evaluation.

USEPA (2023) has recently proposed to regulate four PFAS (PFBS, PFHxS, PFNA, GenX) in drinking water based on the general Hazard Index approach.

Relative Potency Factor (RPF) Approach

In the RPF approach, each PFAS is assigned an RPF based on its potency compared to an index compound (for example, PFOA), which is assigned a potency factor of 1. The RPFs are applied to the concentration of each PFAS present in the mixture, and the toxicity of the total of the RPF-adjusted concentrations is assumed to be the same as the equivalent concentration of the index compound (for example, PFOA). See **USEPA 2023** for more information about the RPF approach.

The RPF approach is based on dose additivity of the compounds that are included (see discussion in Hazard Index section above). The RPF approach (also known as the toxicity equivalency factor approach) has been adopted for several groups of chemicals known to cause toxicity through a common and well-defined MOA, including cholinesterase-inhibiting pesticides (organophosphates) and dioxins (PCDDs) and dioxin-like compounds (furans [PCDFs]; PCBs) that cause toxicity through activation of the AhR receptor.

The application of the RPF approach for risk assessment of PFAS mixtures is associated with greater uncertainty than for the groups of compounds noted in the preceding paragraph. In contrast to the groups of compounds discussed above, the range of adverse effects of PFAS is not due to a single specific MOA, such as activation of a specific receptor. Furthermore, the MOA may not be the same for all toxicological effects (for example, hepatic toxicity; developmental toxicity) and may vary among PFAS (discussed in this Mixtures section above).

Bil et al. (2021) proposed RPFs for 22 PFAS, with PFOA as the index compound. This is an extension of an earlier proposal of RPFs for 18 PFAS developed by RIVM (Netherlands National Institute for Public Health and the Environment) scientists (**Zeilmaker et al. 2018**). The RPFs were based on hepatic effects of PFOA and 15 other PFAS in male rats from studies with durations of 40–98 days. Hepatic effects in

male rats were selected because these effects are common to many PFAS, and there is a large data set on these effects in male rats. Endpoints evaluated included relative liver weight (all 16 PFAS), absolute liver weight (15 PFAS), and hepatocellular hypertrophy (14 PFAS), and the final RPFs were based on relative liver weight because the data set was most complete. Relative liver weight data for all PFAS (based on external dose) were fit to parallel dose-response curves, which were determined to provide an acceptable fit to the data. BMDs for each PFAS for each effect were developed from the dose-response curves based on a 5% change in absolute or relative liver weight and a 10% change in the incidence of hepatocellular hypertrophy. RPFs were based on the ratio of the BMDs for each PFAS to the BMD for PFOA and ranged from 0.001 (PFBS) to 10 (PFNA). RPF ranges for seven additional PFAS for which no relevant data were available were estimated by read-across/interpolation.

In contrast, **Peters and Gonzalez (2011)** concluded that it is not appropriate to develop TEFs (similar to RPFs) for PFAS for reasons including differing modes of actions among PFAS. However, **Bil et al. (2021)** discussed that although the MOA for hepatic effects may differ among PFAS, the similarly shaped dose-response curves for these effects support the assumption of additivity and the application of RPFs for hepatic effects. They also note the need to determine whether the RPFs based on hepatic effects are applicable to other types of toxicity caused by PFAS, such as developmental and immune system effects—an analysis that has not yet been conducted. **Goodrum et al. (2021)** concluded that the shapes of the dose-response curves for hepatocellular hypertrophy for PFOS and PFHxS in male rats, based on administered dose, differ from the dose-response curves for this effect for other PFAAs. When based on internal dose (serum levels), the shape of the curve for PFHxS differed from the shape of the curves for the other long-chain PFAAs. These results suggest that PFHxS, and possibly PFOS, are not additive with other PFAAs for hepatocellular hypertrophy in male rats; curves for liver weight were not evaluated.

17.2.7.2 Toxicology Studies of Defined PFAS Mixtures

Only a few studies of the toxicity of mixtures of PFAS, including studies of defined mixtures (i.e., mixtures for which the identities and concentrations of the components are known) of PFAS and studies of complex mixtures (i.e., mixtures for which the identities and concentrations of the components are not fully characterized) of PFAS such as AFFF were located; these are summarized below. These include in vitro studies of nuclear receptor activation in cultured cells transfected with the receptor of interest, and toxicity in cultured cells, zebrafish (a model species for human toxicity), and rodents.

Mammalian Studies

Defined PFAS Mixtures

Several recent studies have evaluated effects of defined mixtures of PFAS in mammalian species. **Marques et al. (2021)** dosed pregnant mice fed either a standard lab diet or a high fat diet with 1 mg/kg/day PFOA, PFOS, or PFHxS, individually, or 1 mg/kg/day of all three PFAS, throughout gestation. The authors concluded that "the PFAS mixture had very distinct effects when compared to single compound treatment, suggesting cumulative properties of the mixture, particularly when evaluating PFAS transfer from dam to pup," and that "these results suggest that there are multiple pathways in which PFAS could add, synergize, or antagonize specific effects, and warrants further investigation of dose response data with model predictions of additivity." However, as noted by **USEPA (2023)**, "these studies did not include individual PFAS dose response data or conduct any mixture model-based analyses, so it is not possible to ascertain if the mixtures behaved in a dose additive or risk additive manner, or if interactions occurred."

Roth et al. (2021) evaluated the effects of exposure to a mixture of PFOA, PFOS, PFNA, PFHxS, and GenX (2 mg/L each) in drinking water in mice fed a high fat diet. This treatment increased serum cholesterol, sterol metabolites, and bile acids, and caused liver toxicity, with some differences between males and

females. However, the toxicological interactions among PFAS in this study cannot be determined because effects of individual PFAS were not evaluated.

Conley et al. (2022) evaluated the dose-response curves for range of effects in rat dams and their offspring from dosing with PFOA and PFOS alone and in combination during gestation and early lactation. Mixtures of PFOA and PFOS caused effects at lower doses compared to PFOA alone for endpoints including decreased offspring survival; maternal and offspring body weight; offspring serum T3 and glucose; and increased maternal kidney weight; maternal and offspring liver weight; and offspring bile acids, BUN, and bilirubin. Histopathological changes were observed in maternal liver and kidney and offspring liver after exposure to the mixture. The effect of co-exposure to PFOA and PFOS for effects in dams and offspring was consistent with dose additivity, with the exception of maternal body weight at term and gestational weight gain, which were less than additive. **USEPA (2023)** stated that "this work is ongoing with multiple KE analyses still to be conducted on samples collected during the studies. However, results thus far support the hypothesis of joint toxicity on shared endpoints from PFOA and PFOS co-exposure, and dose additivity as a reasonable assumption for predicting mixture effects of co-occurring PFAS."

Complex Mixtures—AFFF

McDonough et al. (2020) evaluated several endpoints in mice associated with exposures to a commercial AFFF formulation containing known concentrations of PFOS and PFOA. The results were compared to those from an unexposed control and another set exposed to a similar concentration of PFOA alone. The study identified elevated concentrations of several other perfluorosulfonic acids in the exposed mice compared to the controls, and statistically significant increases in liver mass. T-cell dependent antibody suppression in mice exposed to an AFFF dose, expressed as PFOS + PFOA, was comparable to that of an equivalent dose of PFOA alone, both of which were statistically significant in comparison to the control group. Blood serum analysis of the mice exposed to the AFFF showed that they had also been exposed to a range of perfluorosulfonic acids from PFPeS to PFDS, though PFHxs and PFOS were predominant.

Receptor Activation

As discussed in **Section 17.2.5**, an important MOA for many PFAS is activation of cellular receptors, including PPAR-α and others, that regulate expression of genes that control many biological pathways. **Wolf et al. (2014)** studied PPAR-α activation by PFOA, PFNA, PFHxA, PFOS, and PFHxS singly, and in binary mixtures of PFOA with each of the other four PFAAs using a cultured cell line transfected with the PPAR-α receptor. They concluded that there was additivity for PPAR-α activation in PFAS mixtures at concentrations up to 32 µM. An earlier study from the same research group used this test system with higher concentrations of PFAAs and found that PPAR-α activation in binary mixtures of PFOA, PFOS, PFNA, and PFHxS was antagonistic in the mixture of all four PFAS (**Carr et al. 2013**).

Activation of the estrogen and androgen receptors by PFOA, PFNA, PFDA, PFUnA, PFDoA, PFHxS, PFOS individually, and an equimolar mixture of all seven PFAAs, was evaluated in cultured cell lines transfected with these receptors (**Kjeldsen and Bonefeld-Jorgensen 2013**). The results of this study illustrated the complexity of interactions of mixtures of PFAS in regard to receptor activation. PFOA, PFOS, and PFHxS singly, as well as the mixture of the seven PFAAs, were weak agonists of the estrogen receptor and also enhanced activation by the endogenous estrogen, 17-beta estradiol. These three PFAS also inhibited activity of the androgen receptor, and the same three PFAS, as well as PFNA and PFDA, antagonized activation by the endogenous androgen, dihydrotestosterone. In contrast to some of the individual PFAAs, the PFAA mixture did not affect androgen receptor activity in the absence of dihydrotestosterone, but it did antagonize activation of the receptor by dihydrotestosterone. Comparison of the androgen receptor dose-response data for the inhibitory PFAAs and the mixture indicated a synergistic antagonistic effect (greater than additive inhibition) of the PFAAs in the mixture.

Nielsen et al. (2022) developed an in vitro system to predict the effects of defined PFAS mixtures on activation of human PPARα. They determined that PFCAs tended to act as full PPARα agonists and PFSAs tended to act as partial PPARα agonists, with individual PFAS differing in potency. **Nielsen et al. (2022)** also found that concentration additive approaches to predicting mixtures effects on PPARα may overpredict the effects of PFAS mixtures on PPARα activation.

Effects in Cultured Hepatocytes

Defined PFAS mixtures

The effects of PFHpA, PFOA, PFNA, PFDA, PFHxS, and PFOS individually, and in 11 binary and 4 ternary mixtures on cell viability of the human liver cell line, HepG2, were evaluated by **Ojo et al. (2020)**. The concentrations that were tested for each PFAS were based on dilutions of the concentration that caused 50% loss of cell viability. Effects of many binary and ternary combinations were synergistic, while other combinations were antagonistic at some concentrations. PFOS was synergistic with the other five PFAS at almost all concentrations, while interactions in mixtures that included PFOA were either synergistic or antagonistic, with synergism predominating at lower concentration levels. In another study of the same cell line, PFOA and PFOS induced and promoted apoptosis, and a mixture of both PFAS showed additivity for this effect (**Hu and Hu 2009**).

Effects on gene expression of six individual PFAS (PFOA, PFNA, PFDA, PFDoA, PFOS, 8:2 FTOH) and four mixtures (PFOA plus PFOS; three mixtures of all six PFAS in different proportions) were evaluated in primary cultures of hepatocytes from rare minnow (**Wei et al. 2009**). No clear patterns of response were observed, in those mixtures of PFAS affected the expression of some genes that were not affected by individual PFAS, and vice versa.

Complex Mixtures—AFFF

Ojo et al. (2022) evaluated the toxicity of 24-hour exposure to varying concentrations of two historically used AFFFs containing PFAS in the HepG2 human liver cell line. PFAS in one of the AFFFs were primarily long- and short-chain PFAAs, while PFAS in the second AFFF were at lower concentrations and was primarily 6:2 FTS. Both AFFFs caused concentration-dependent decreases in cell viability and increases in two biochemical markers of toxicity; the AFFF containing PFAAs was more potent for these effects. Cellular DNA damage was induced only at the highest concentration tested (0.038%) of the AFFF containing PFAAs.

Zebrafish Studies

Defined PFAS mixtures

Fey et al. (2022) evaluated the effects of varying concentrations of PFOS and 6:2 FTS singly and as a mixture on mortality, hatching, and developmental endpoints in zebrafish. The authors concluded that the relative potencies of PFOS and 6:2 FTS in this study were not constant and varied at different concentrations of the test substances, and, therefore, dose additivity could not be assumed.

The lethality of PFOA, PFOS, and a mixture of both chemicals was studied in zebrafish embryos (**Ding at al. 2013**). The interaction between PFOA and PFOS was concentration-dependent, with additive, synergistic, antagonistic, and then synergistic effects observed as the proportion of PFOS was increased.

Behavioral effects in zebrafish embryos were evaluated for PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFBS, PFHxS, PFOS, and 6:2 FTSA individually, and with mixtures of equal concentrations of all nine PFAS (**Menger et al. 2020**). PFHpA, PFOA, PFNA, PFHxS, PFOS, and 6:2 FTSA alone, as well as the mixture, caused behavioral effects in tests of locomotor activity, while PFBA, PFHxA, and PFBS did not. Specific

behavioral effects varied among individual PFAS. The mixture of PFAS was less potent than the individual PFAS present in the mixture, suggesting antagonistic interactions among the PFAS in the mixture.

17.2.7.3 Studies of Mixtures of PFAS and Contaminants Other than PFAS

Several additional studies evaluated toxicological interactions of individual PFAS with other environmental contaminants. In male mice, co-exposure to PFOS and PCB126 (a dioxin-like PCB) caused synergistic effects on hepatic expression of genes related to oxidative stress, inflammation, and atherogenesis; levels of a protein that is a biomarker for thrombosis and fibrosis (indicators of cardiovascular disease risk); and hepatic lipid levels. Co-exposure, but not the individual compounds, caused pathological changes indicative of liver injury.
The effects on gene expression in zebrafish embryos of PCB126 alone, PCB126 plus PFOS, PCB126 plus PFHxA, and PCB126 plus both PFOS and PFHxA were evaluated by **Blanc et al. (2017)**. The PFAS were not tested in the absence of PCB126. PCB126 with both PFOS and PFHxA had a greater effect on the expression of several genes than PCB126 alone or PCB126 with PFOS or PFHxA individually. The results suggest synergistic effects of PFOS and PFHxA on the effects of PCB126 in this test system.

17.2.8 Evaluating PFAS Using New Approach Methodologies

In one of its most resource-intensive efforts on PFAS to date, the USEPA developed a screening library containing PFAS. This USEPA-curated list spanned several public-interest lists of PFAS, including those from the USEPA, United States Food and Drug Administration (FDA), Department of Defense (DOD), Agency for Toxic Substances and Disease Registry (ATSDR), Consumer Product Safety Commission (CPSC), and state regulatory agencies. The screening library was developed to support the development of analytical methods, environmental monitoring, and toxicity testing. Further information on the initial list of 430 PFAS is available on USEPA's CompTox Chemicals Dashboard (**USEPA 2020**), which was developed by the USEPA's Chemical Safety for Sustainability Research Program (**USEPA 2020**). The purpose of the dashboard, along with related databases and web applications developed by the agency, is to support the USEPA's computational toxicology research efforts to develop new and innovative methods with the goal of incorporating advances in a wide variety of scientific disciplines (biology, biotechnology, chemistry, and computer science) to help identify important biological processes that may be disrupted by chemicals. Using computational toxicology research methods, it is hoped that thousands of chemicals can be rapidly evaluated for potential risk at small cost, and chemicals can be prioritized for further studies based on potential health risk information derived from this initial evaluation (**USEPA 2020**).

From the initial list of 430 PFAS (discussed above), a subset of 150 PFAS were chosen by USEPA with the overall goals of maximizing the ability to perform read-across (for example, predicting toxicity of a target PFAS compound by extrapolating such information from a PFAS compound that has been more extensively studied) and capturing structural diversity among PFAS. The USEPA also took into consideration likelihood of exposure or occurrence, and the availability of in vivo (mammalian) or in vitro (for example, cell culture) toxicity data for validation. Because compounds that exist as gases cannot be tested and some PFAS (for example, HFPO-DA [GenX]) rapidly degrade in dimethyl sulfoxide (DMSO), which is used as the vehicle in many of these assays (**Liberatore et al. 2020**), practical considerations such as the ability to procure in nongaseous form and to solubilize samples in the solvent DMSO without degradation were also considered (**Patlewicz et al. 2019**; **USEPA 2020**, **2020**).

This group of 150 PFAS is also currently being evaluated at Oregon State University, the University of Pittsburgh, East Carolina University, and other institutions in a USEPA-funded effort to use in vivo and in vitro methods to systematically study PFAS toxicity. The goal of this research is to support the prioritization of PFAS in risk assessment and risk management (**USEPA 2019**) by using a combination of in vivo toxicity screening assays and transcriptomics (evaluation of changes in RNA expression in specific tissues in response to biologic or environmental cues; these RNA molecules often code for

proteins) in the zebrafish model to characterize the toxicity and pharmacokinetics of a range of volatile and nonvolatile PFAS. The subset of 150 PFAS is also being evaluated in in vitro assays intended to be predictive of various endpoints such as hepatotoxicity, developmental toxicity, immunotoxicity, neurotoxicity, mitochondrial toxicity, developmental neurotoxicity, endocrine disruption, and general toxicity (**USEPA 2019**). Results of these studies will be used to group PFAS by structures and biological activity. As mentioned above, the intent is to capture the structural diversity across the spectrum of PFAS of interest to USEPA and to support determination of the feasibility of read-across within structure-based groupings, an approach in which information from PFAS with extensive in vivo toxicity data could be used to predict toxicity of other PFAS that lack such data.

It is hoped that the results of these high throughput assays will (a) inform PFAS hazard characterization, (b) provide toxicokinetic information that may help predict disposition and excretion of PFAS from the body, and (c) prioritize PFAS for risk assessment and further in vivo mammalian testing that is needed for risk assessment. A further goal of this program is to determine, based on data for PFAS that have been evaluated in both in vitro and mammalian in vivo systems, whether the read-across approach can be used to support in vitro to in vivo extrapolation for estimation of oral equivalent exposures for PFAS (**Fenton et al. 2020**).

17.2.9 Data Gaps and Research Needs

Although many studies relevant to health effects of PFAAs have become available in the last few years, important data gaps remain for most of the PFAAs and PFECAs discussed here, as well as for many additional PFAS used in commerce or found in AFFF.

Human half-lives and other toxicokinetic data are not available for some PFAS found in drinking water and other environmental media. This information is critical for adequately assessing the bioaccumulative potential and relevant routes of exposure (for example, placental and breast milk transfer), and for extrapolation of animal toxicity information to humans.

Available data suggest that reactive intermediates can form in the metabolic pathways that convert PFAA precursors to PFAAs within the body. Additional information on the formation and potential toxicity of these reactive intermediates is needed.

Additional toxicology data are needed for some PFAAs found in environmental media, including drinking water. For example, there are very limited toxicology data for PFHpA, and no information was located for PFPeA. Additionally, although humans are exposed to multiple PFAS, very little toxicological data are available for mixtures of PFAS. Multigeneration studies are important for assessment of reproductive and developmental effects, and they are available for only a few PFAS. PFHxS is a PFAA with a long human half-life that has been found in human serum and in drinking water impacted by both industrial discharges and AFFF. Although developmental effects of PFHxS are of concern, there are currently no multigenerational developmental studies for PFHxS. Available information from rodent studies suggests that developmental exposures to some long-chain PFAS (PFOA, PFOS, PFHxS) cause permanent neurobehavioral effects, but these data are limited. Additional studies are needed on neurobehavioral effects of PFAS, particularly from early life exposure.

Studies that provide data on chronic effects, including carcinogenicity, are available for only four PFAS (PFHxA, PFOA, PFOS, GenX), and such studies are needed for PFHxS, PFNA, ADONA, and other PFAS to which humans may be exposed. All of the chronic studies were conducted in rats, and chronic studies in a second species such as mice would provide valuable information, particularly for those PFAS that are rapidly excreted in female rats.

The mode(s) of action for the toxicological effects of PFAAs are not fully understood and continue to be the focus of ongoing research. Although not the focus of this section, data on bioavailability of PFAS

from environmental media other than drinking water (for example, soil) are limited, and such information can be useful in assessing exposures at contaminated sites.

Challenges related to the use of toxicity information from surrogates for PFAS for which no toxicity data are available are discussed in **Section 9.1.1.2**. There is a need to further develop and validate approaches for addressing groups and mixtures of PFAS, such as those described in **Section 17.2.7**.

Finally, **OECD (2018)** identified 4,730 PFAS-related CAS numbers, including compounds with many different structures, including some that have not been used commercially. The majority of these PFAS, including those in commercial use, have very limited or no toxicity data (**Wang et al. 2015**; **Wang et al. 2017**), indicating a critical data gap in health effects information for PFAS. The approaches currently under development at USEPA and the National Toxicology Program (NTP) that are discussed in **Section 17.2.8** may prove useful for screening of a large number of PFAS with rapid assays that evaluate parameters related to toxicokinetics and toxicity (**USEPA 2018**). Additional information is found on the USEPA CompTox website (**USEPA 2020**; **Williams et al. 2018**) and from the NTP Rapid Evaluation and Assessment of Chemical Toxicity (REACT) Program (**DeVito 2018**). If this effort is successful, the results could be used, along with data on human exposure, for prioritization of PFAS for more detailed toxicological studies (**USEPA 2018**).

17.3 Additional Information for Risk Assessment

17.3.1 Human Health Exposure Assessment

Figure 9-5 illustrates predominant exposure pathways. In the following sections, summary information is presented for exposures by environmental medium. Information about site risk assessment is in **Section 9**. Information about PFAS occurrence in environmental media is discussed in **Section 6**. Links are provided to other sections for more details on related topics.

17.3.1.1 Soil

Soil exposure scenarios are possible at a site. Many PFAS are mobile and persistent in soil. As indicated in **Section 5**, PFAS distribution in soils is complex, reflecting several site-specific factors and individual PFAS-specific factors.

Sorption and retardation generally increase with increasing perfluoroalkyl tail length, and functional groups contribute to the degree to which a PFAS has the affinity to leach from soil to groundwater. A detailed discussion of the fate of PFAS in soil is provided in **Section 5**. Receptors, such as humans, terrestrial animals, and plants, in contact with soil containing PFAS may be exposed to the compounds.

PFAS may be absorbed through the skin; some relevant studies are summarized in **Section 17.2.3**, **Section 1.4.3**, and by ATSDR (**2021**). Therefore, current evidence combined with existing toxicity factors suggest that dermal absorption from soils or associated groundwater is not expected to be an important exposure route for the general public compared to other exposure pathways, but may contribute to less significant exposures such as incidental ingestion of soils in combination with skin contact. Construction workers may contact PFAS in soils (if within the depth of construction activities).

17.3.1.2 Potable Water

Ingestion of PFAS-containing drinking water typically represents the dominant exposure pathway in comparison to ingestion of food or other exposure pathways especially when PFAS concentrations in drinking water reach a certain level (**Post, Gleason, and Cooper 2017**; **Bartell 2017**). **Section 1.4.1** includes information about potential human health effects from PFAS exposure arising from AFFF in

drinking water. However, the dominance of the drinking water pathway is relative and can be context specific as highly contaminated sources of food (e.g., fish or agricultural products) might result in significant exposure greater than that of water. As discussed and cited in **Section 7.1.2**, PFAS levels in young children (up to the age of 6) are often higher than in adolescents and adults consuming the same drinking water source (see also **Section 17.2**). This is most likely due to the relatively higher levels of water ingestion per unit of body mass at these ages. If bottled water is supplied for drinking water and food preparation purposes, potential exposures from potable water used for non-drinking water purposes (for example, showering, bathing, and hand-washing dishes) are expected to be minimal, with the possible exception of inhalation exposure to volatile PFAAs (see **Section 17.3.1.6**), which is not yet well characterized.

17.3.1.3 Groundwater

The same potential exposure pathways described above for potable water apply to groundwater when used as a potable source. As discussed for soils, construction workers may contact PFAS in shallow groundwater (if within the depth of construction activities), although dermal absorption potential from water is low. If PFAS-impacted groundwater is used as irrigation water for crops, homegrown produce, or animal watering, PFAS in groundwater may be transferred to biota (plants or animals), resulting in potential dietary exposures (see **Section 17.3.3**).

As indicated in **Section 5.3**, due to the mobility and persistence of PFAS in soil and groundwater, certain PFAS are expected to form larger plumes than certain less-soluble contaminants in the same hydrogeological setting. However, sorption and partitioning might restrict leaching rates from the vadose zone and reduce the advection-driven transport velocity of PFAS in groundwater, depending on specific properties of the PFAS. These processes might limit plume development and discharge to surface water and might provide time for transformation of PFAS precursors. Groundwater geochemistry can also affect the extent of biotic and abiotic transformation of PFAS precursors (**Liu and Mejia Avendaño 2013**).

17.3.1.4 Surface Water

Surface water impacted with PFAS by surface runoff or groundwater discharge also present possible exposures. Surface water exposures can occur through drinking water or by consuming aquatic biota from contaminated water bodies. Much of the PFAS reaching surface water tend to remain in solution, although there is likely to be partitioning to sediment and uptake to biota. Once in surface water, PFAS could contaminate groundwater through groundwater recharge (**Liu et al. 2016**; **ATSDR 2008**). See **Section 16.2** for human health aspects of PFAS in surface water. The Priority Topics for Fate and Transport, Surface Water, Source ID, and Site Characterization include information about PFAS in marine environments (see **Section 1.3.5**) and the effects of suspended sediment on surface water sampling and measurement of PFAS (see **Section 1.3.6**).

Biofilms on surface water are known to accumulate PFAS (**Munoz et al. 2018**), as do other organic-/protein-rich particles in aquatic systems (**Ahrens and Bundshuh 2014**). Therefore, surface water films that contain these matrices could be repositories (and potential sources of exposure), especially of long-chain PFAS. Similarly, PFAS-containing foams may form on certain surface waters and contribute to recreational exposures. PFAS-containing foam is discussed in **Section 16.5**.

17.3.1.5 Sediment

PFAS in surface runoff or groundwater discharge can partition to sediment and be taken up into biota. The exact processes that control affect sorption and bioavailability of PFAS in sediments are poorly understood and likely determined by several factors including the mixture of PFAS, salinity, and sediment composition (see **Sections 6.5** and **5.3.4.2**). Considerations for PFAS in sediments and the potential

implications for human health risk assessment (for example, bioaccumulation into fish and recreational contact) are detailed in **Sections 9.1** and **16.2**.

17.3.1.6 Air

PFAS inhalation exposure scenarios are possible. Examples include dusts containing PFAS may be generated from a site where PFAS are present in soil, as well as aerosols derived from surface waters (**Section 5.2.4**). In addition, some PFAS (for example, FTOHs and some perfluoroalkyl sulfonamides) have higher volatilities and can partition into air from other media (**Section 5.2.4**). Certain PFAS are found in ambient air with elevated concentrations observed or expected in urban areas near emission sources, such as manufacturing facilities, wastewater treatment plants, fire training facilities, and landfills (**Barton et al. 2006**; **Ahrens et al. 2011**; **Liu et al. 2015**). See **Section 6.1** for more information about PFAS occurrence in air. See also the **PFAS and Vapor Intrusion Fact Sheet** developed in 2025.

17.3.1.7 Diet

PFAS exposures may occur from food consumption, such as ingesting aquatic and terrestrial plants and animals that have taken up PFAS. Crops may be impacted by PFAS if irrigated with contaminated groundwater or surface water; if impacted by soil, runoff, or atmospheric deposition; or where biosolids have been applied to soil. In addition, because some PFAS biomagnify in food webs, ingestion of contaminated biota, especially fish and animals that eat fish, may be an important exposure route (**ATSDR 2020**; **ATSDR 2021**; **USEPA 2016**; **USEPA 2016**). Recreationally caught fish from areas with PFAS contamination may be a specific source of elevated exposures to PFAS that bioaccumulate in fish. PFAS exposures may also occur from food packaging materials containing PFAS (see **Section 17.3.1.8**, Consumer Products). The Priority Topics for Biosolids Land Application (see **Section 1.7**) include information about potential risks from agricultural impacts, plant uptake, and uptake by animals.

Breast Milk and Infant Formula

Consumption of breast milk and infant formula are potential exposure scenarios for infants. Breast milk may be impacted from a lactating mother's exposure to PFAS-contaminated media, and infants may ingest PFAS from formula prepared with PFAS-contaminated water (**Fromme et al. 2010**; **Mogensen et al. 2015**). Higher exposures to infants are of concern because infants are sensitive subpopulations for developmental effects of PFAS, as discussed in **Section 7.1** and **Section 17.2**. Infants may have a higher level of exposure to PFAS through breast milk or formula prepared with contaminated water than adults typically have through consuming contaminated water due to differences in the volume of water consumed relative to body weight. The USEPA Exposure Factors Handbook (**USEPA 2019**) provides detailed information on breast milk consumption rates and the higher water consumption rate of infants.

17.3.1.8 Consumer Products

Typically, exposure scenarios associated with consumer products are not included in human health risk assessments (HHRAs) for contaminated sites. However, the HHRA should acknowledge that analytical results for environmental media (including indoor air and dust) may reflect impacts from consumer products (for example, carpets and upholstered furnishings) containing PFAS that have degraded, released fibers, or volatilized (see **Section 2.5**). **Section 1.4.2** includes information about potential PFAS exposures from consumer products.

17.3.2 Other Considerations When Calculating Exposure Point Concentrations

Other contaminants present at the site can affect the movement of PFAS, which are not easily accounted for in fate and transport models. For example, petroleum hydrocarbon co-contaminants, particularly light nonaqueous phase liquids (LNAPLs), may affect the fate and transport of AFFF-derived PFAS (**Guelfo and Higgins 2013**; **Lipson, Raine, and Webb 2013**; **McKenzie et al. 2016**). As discussed in detail in **Section 5** and **Section 10.4**, PFAS movement in environmental media depends on both site-specific media properties and properties of the specific PFAS. Leaching potential is a function of both media properties (for example, pH, redox conditions) and PFAS structural properties (for example, chain length) (**Gellrich, Brunn, and Stahl 2013**; **Gellrich, Stahl, and Knepper 2012**).

It is critically important to collect site-specific soil partitioning and soil-to-groundwater pathway data for PFAS sites. Existing models and standard methods are not able to accurately predict or calculate soil-to-groundwater movement of PFAS given their hydrophobic and hydrophilic properties. Therefore, site-specific empirical data are necessary.

As discussed in detail in **Section 5.4**, the composition of PFAS can change in media. Studies have reported both biotic and abiotic transformations of some polyfluorinated substances (precursors), which may form PFAAs (**Buck et al. 2011**). Precursors that are ingested can be transformed in the body to PFAAs (**USEPA 2016**; **USEPA 2016**). However, PFAAs likely do not degrade or otherwise transform under ambient environmental conditions. PFAS composition may also change in surface water because of biotic and abiotic degradation of PFAA precursors. These complex transformations are not incorporated in current fate and transport models.

17.3.3 Information about Selecting Bioaccumulation and Bioconcentration Factors

Certain PFAS can bioaccumulate in the food web including aquatic organisms (see **Section 5.5** [PFAS Uptake into Aquatic Organisms] and **Section 6.5.3** [Fish]), terrestrial animals (for example, livestock and wild game), as well as plants. PFAAs, particularly PFOS, are typically the dominant PFAS detected in biota (**Houde et al. 2011**). **Section 5.5**, **5.6**, and **Section 16** provide detailed discussions of factors affecting the bioaccumulation potential of PFAS across a variety of organisms. The Priority Topics for Biosolids Land Application include information about plant uptake (see **Section 1.7.4**) and uptake by animals (see **Section 1.7.5**).

Figure 17-1 illustrates bioaccumulation pathways from sediment and surface water.

Section 6.5.3 (Fish) provides a detailed discussion of bioaccumulation of PFAS in fish. PFAS accumulation in fish has been documented, particularly for PFOS, longer chain PFCAs (with eight or more fluorinated carbons), and perfluorodecane sulfonate (PFDS) (**Houde et al. 2011**; **Martin et al. 2013**; **Conder et al. 2008**). In fish, PFOS tends to partition to the tissue of highest protein density, including the liver, blood serum, and kidney (**Falk et al. 2015**; **Ng and Hungerbühler 2013**). Available aquatic organism BCF and BAF data are presented in Table 5-1 (provided as a separate Excel file). Trophic level biomagnification in food webs (**Figure 17-1**) can occur for some PFAS (**Franklin 2016**; **Fang et al. 2014**) as discussed in further detail in **Section 5.5.3**.

Sections **5.6** and **6.5.1** discuss partitioning of PFAS to plants.

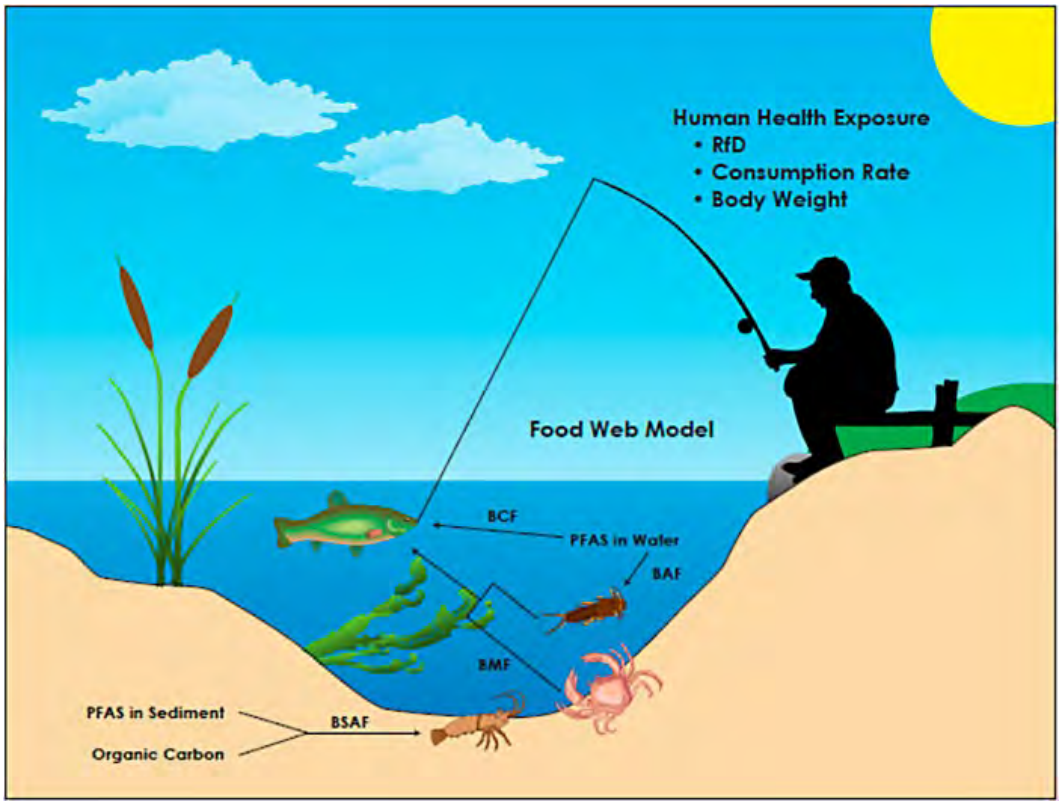

Figure 17-1. Bioaccumulation of PFAS from sediment and surface water. (BAF–bioaccumulation factor; BCF–bioconcentration factor; BSAF–biota-sediment accumulation factor; BMF–biomagnification factor; RfD–reference dose.

Source: J. Conder, Geosyntec. Used with permission.

Plant uptake, bioaccumulation, and partitioning within the plant appear to depend on PFAS chemical structure and the plant species. **Figure 17-2** illustrates bioaccumulation of PFAS in plants. Most studies report partitioning of PFAAs within plants, with longer chain PFAAs, especially PFSAs, partitioning to the roots and more soluble, shorter chain PFAAs, especially PFCAs, partitioning to other parts of the plant (**Lechner and Knapp 2011**; **Stahl et al. 2009**) Blaine (**Blaine et al. 2013**; **Blaine, Rich, Sedlacko, Hundal, et al. 2014**; **Yoo et al. 2011**; **Scher et al. 2018**; **Gobelius, Lewis, and Ahrens 2017**). Table 5-2 (provided as a separate Excel file) contains BCFs and BAFs for various PFAS in a variety of plant species. In general, most plant BCFs and BAFs fall between a range of 0.1 and 10.

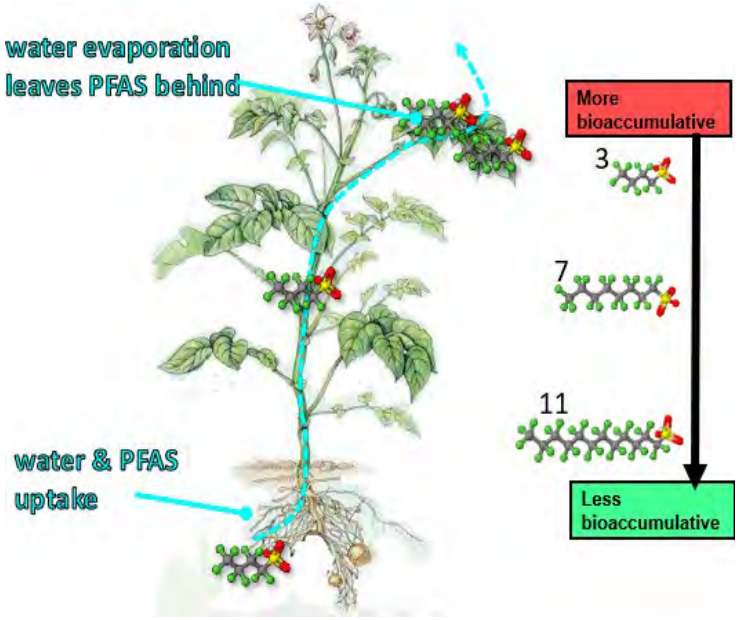

Figure 17-1. Bioaccumulation of PFAS in plants.

Source: J. Conder, Geosyntec. Used with permission.

As indicated in **Section 4.2.8** (Octanol/Water Partition Coefficient (K_{ow})) and **Section 5.5.2** (Bioaccumulation), it is difficult to measure K_{ow} for PFAS due to their complex chemistry, and because many PFAS have both hydrophilic and hydrophobic properties. Therefore, BAFs rely on calculations from empirical data instead of modeling (**Haukås et al. 2007**).

18 SORPTION-BASED TECHNOLOGIES FOR SEPARATION AND CONCENTRATION OF PFAS FROM WATER

The purpose of this section is to collate and summarize the current state of knowledge and practice for removal of PFAS from water by sorption-based technologies and provide a resource to assist regulators, consultants, and industry practitioners as they navigate the decision-making process. Topics addressed in this document include treatment objectives, characteristics of commonly treated waters, potential site-specific considerations, operation and testing of fixed-bed and fractionation-based treatment technologies, resources for decision-making, and outstanding challenges for treatment implementation.

ITRC already provides resources to help with issues related to treatment of PFAS in water in the PFAS-1 Guidance Document. **Section 12.2** includes a useful overview of the technologies discussed here (specifically, **Section 12.2.1** and **Section 12.2.3**), as well as several other effective PFAS treatment technologies that are not sorption-based, such as membrane processes. Readers are advised to familiarize themselves with the summaries and concepts in Section 12 to take maximum advantage of the information presented here. That said, exhaustive knowledge of the earlier text is not necessary for understanding this new Section 18, and relevant sections will be referenced or summarized as needed. Readers should note that **Section 12.2.1** is called "Sorption Technologies" and **Section 12.2.3** is titled "Foam Fractionation," but both fixed-bed adsorption by adsorbent media and adsorption to bubbles are considered "sorption-based" technologies in this Section. Readers specifically interested in point of use (POU) treatment or point of entry (POE) treatment (also referred to as POET) systems for treating drinking water, which are not specifically discussed in this new section, are advised to consult **Section 12.1.4.1**.

Section Number	Topic
18.1	**Introduction**
18.2	**Treatment Objectives and Considerations**
18.3	**Fixed-Bed Adsorbers**
18.4	**Foam Fractionation**
18.5	**Resources for Decision-Making**
18.6	**Barriers, Challenges, and Outlook**

18.1 Introduction

Removal of per- and polyfluoroalkyl substances (PFAS) from water has become an important concern for water utilities; landfill operators; industry professionals; and state, local, and tribal decision makers. One option for removal of PFAS from water is sorption-based technologies, which remove contaminants from the dissolved phase by adsorption to surfaces or absorption into bulk phases. Examples of sorption-based technologies include granular activated carbon (GAC), ion exchange (IX) resins, and foam fractionation. They have long-standing applications in water treatment and are recognized for their proven efficiency in removing PFAS. These technologies are frequently regarded as effective solutions due to their ability to target and remove a wide range of PFAS, especially longer chain PFAS (**Murray et al. 2023**; **Tajdini et al. 2025**), leveraging mechanisms that optimize contaminant capture and separation. Because of these characteristics, sorption-based technologies have planned or current deployment for PFAS treatment in more than half of US states (**ECOS 2025**). However, selecting the best treatment method or system configuration for removal of PFAS from water can be a daunting task, and PFAS-specific information on the topic is currently scattered across a variety of sources.

This section focuses on PFAS-specific concepts and practical considerations. It is not a nuts-and-bolts operational manual for water treatment systems, nor is it an exhaustive resource on the underlying

physical principles of adsorption and absorption. Readers interested in gaining deeper or broader knowledge than can be provided here are advised to consult general texts on IX resins (**Harland 1994**; **Helfferich 1995**; **Slater 2013**; **Zagorodni 2006**), GAC (**Worch 2012**), foam fractionation (**Lemlich 2012**; **Stevenson and Li 2014**), and water treatment (**Crittenden et al. 2012**; **Spellman 2008**) as appropriate.

Only adsorptive technologies considered "field-implemented" by the ITRC (defined in **Section 12.1**) as of September 2025 will be discussed in this document. Although novel media technology such as surface-modified clays, cyclodextrins, and many others may have demonstrated PFAS removal under pilot or bench-scale conditions, they have not yet (September 2025) demonstrated maturity in full-scale treatment systems. Accordingly, it is not possible to provide specialized information on testing and evaluation for these technologies in practice. However, the testing methodologies described in this document are still expected to provide a useful foundation for testing and evaluation of these novel sorbents as they become more technologically mature. Where applicable, some new or emerging technologies for regeneration of GAC and IX resins or destruction of treatment residuals are briefly discussed. Removal of PFAS from water in ex situ treatment systems by addition of powdered activated carbon (PAC) is not cost-effective except in some cases where modest PFAS removal (50% or less) is needed and a method for dealing with resulting sludge is available (**Ahrens et al. 2025**). Therefore, testing and evaluation of PAC are not examined here.

Ex situ treatment applications such as wastewater (industrial or municipal) treatment, treatment of extracted groundwater, and drinking water treatment, which are the focus of this document, have significant overlaps in site assessment, testing, and evaluation processes. In situ remediation methods, such as injection of colloidal activated carbon or other sorbents, differ significantly from ex situ methods in all these aspects and fall beyond the scope of this document.

18.1.1 Additional Resources

This section extends but is also distinct from content provided in the previously published PFAS-1 Document (**https://pfas-1.itrcweb.org**). Therefore, prior to continuing in this section, readers may find it useful to review and familiarize themselves with the following sections and external data tables:

- **Section 8: Basis of Regulations – PFAS – Per- and Polyfluoroalkyl Substances**
- **Section 8: PFAS Regulatory Programs Summary Excel File**
- **PFAS Environmental Media Values Table Excel File**
- **Section 10: Site Characterization**
- **Section 12.1.1: Factors Affecting Technology Selection**
- **Section 12.1.4: Considerations for Specific Environmental Media**

ITRC offers other resources covering in situ treatment technologies, including **Section 12.2.4** and **Section 15.2.3** and relevant slides in the **ITRC PFAS Beyond the Basics: PFAS Treatment Technologies Training**.

Some commonly asked questions about PFAS treatment methods are mapped to their respective sections in the section in **Figure 18-1**.

Information about Strategic Environmental Research and Development Program (SERDP) and Environmental Security Technology Certification Program (ESTCP) projects for sorption-based technologies can be found at **https://serdp-estcp.mil/**.

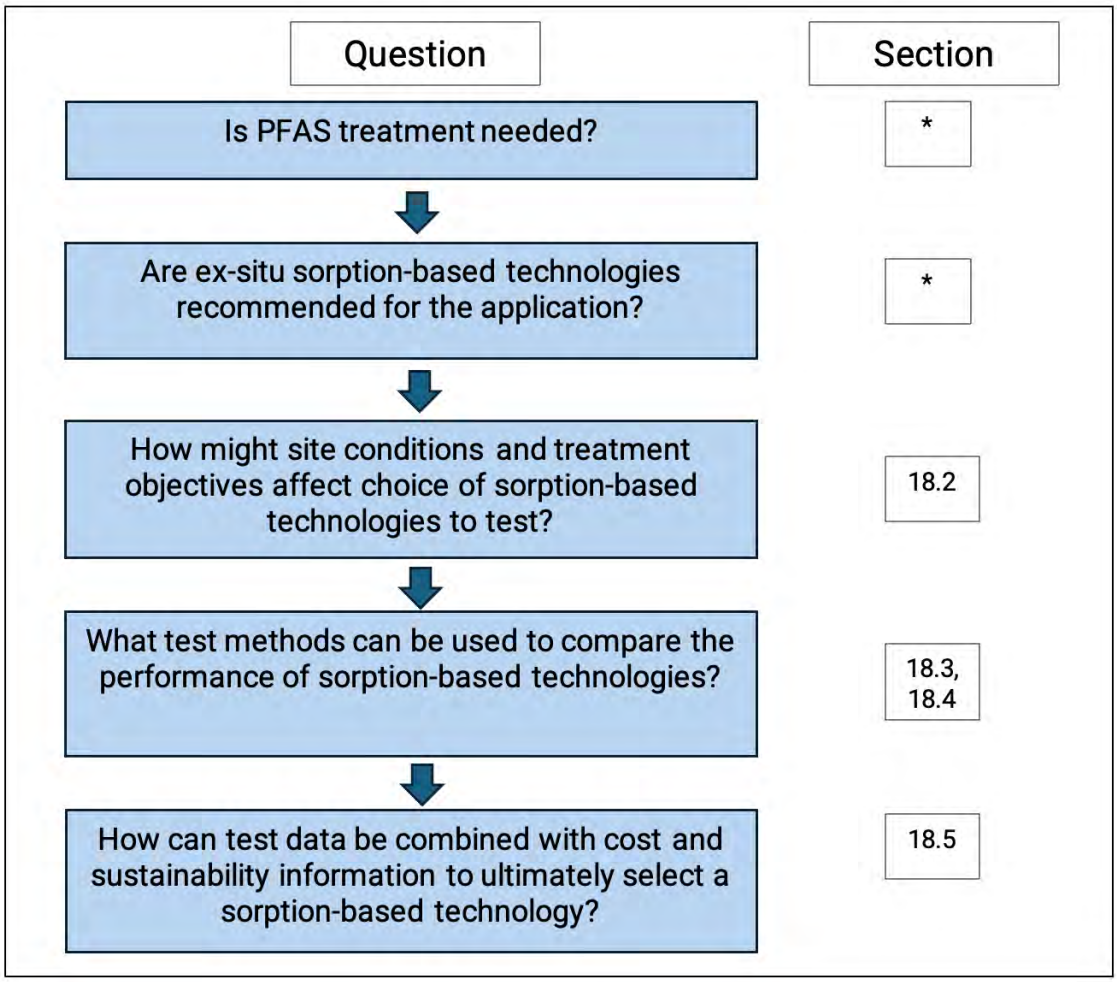

Figure 18-1. Diagram mapping document sections to pertinent questions for planning, testing, and evaluating sorption-based treatment options for PFAS in water. An (*) denotes questions answered before consulting this document using guidance from other resources, such as **Section 8** (Basis of Regulations) and **Section 12.1.1** (Factors Influencing Technology Selection).

18.2 Treatment Objectives and Considerations

18.2.1 Introduction

Location selection and sizing of sorption-based PFAS treatment facilities require a comprehensive evaluation of various factors, including PFAS treatment objectives, characterization of waters commonly treated and their influence in treatment process selection, and flow quantification. This section discusses these and other operational considerations. By thoroughly understanding these considerations, informed decisions can be made that balance efficiency, cost, and space constraints to develop an optimal PFAS treatment strategy.

18.2.2 Objectives

It is important to first recognize that the objective of sorption-based PFAS treatment is to remove PFAS from the water or liquid waste stream such that the treated water is made suitable for some consumptive

use or discharge. This is different from the objectives specific to remediation of a contamination site, but the use of such treatment may contribute to site remediation objectives. For the purposes of this guidance, all applications of treatment are ex situ. Treatment using GAC and IX resins achieves this objective by separating and concentrating PFAS onto the sorption media, while foam fractionation achieves this objective by separating and concentrating PFAS into a separate solution of reduced volume. Enhancing the concentration of separated PFAS allows it to be more efficiently and economically destroyed or properly disposed. Detailed discussion regarding the use of additional treatment for destruction of PFAS or technology for the containment/disposal of the separated PFAS is outside the scope of this guidance, but some factors regarding destruction and disposal are mentioned. Additional information on these destruction technologies is available in the following sections:

- **Section 12.4** Incineration
- **Section 12.6** Limited Application and Developing Liquids Treatment Technologies
    - **Section 12.6.3** Redox Manipulation
    - **Section 12.6.5** Alkaline Hydrothermal Reaction

The amount of removal needed will depend upon the concentration of PFAS in the source water or liquid waste stream and the intended end use or point of discharge and regulatory requirements. PFAS may be regulated individually, in combination with other PFAS or precursors, or both. Users can refer to the PFAS Environmental Media Values Table, and the Environmental Council of the States (ECOS) Compendium of State PFAS Actions, (**ECOS 2025**) for additional information regarding state- or country-specific regulatory information.

18.2.2.1 Consumptive Use Objectives

PFAS treatment of groundwaters or surface waters for consumption may include nonpotable uses but is more commonly associated with the production of drinking water. Treatment objectives to produce drinking water are related to public health, limiting the risk of potential health effects by limiting the concentrations of PFAS regulated in drinking water and thus limiting exposure to those contaminants. Concentrations may be established through primary standards, treatment techniques, goals, advisory levels, etc. There may be differences between concentrations associated with a regulatory goal and the minimum level of treatment established by a standard. These could be due to economic and technological limitations (for example, limits in the ability to practically quantitate the concentration of a particular PFAS). Despite such limitations, a drinking water supplier and its customers may establish treatment objectives that provide a level of service that goes beyond minimum regulatory requirements (for example, to produce water with no detectable levels of regulated PFAS, or to limit the concentration of certain unregulated PFAS). Achievement of PFAS treatment objectives for drinking water utilities is typically determined at the entry point into the distribution system, rather than at individual customer taps. Where PFAS treatment is provided for an individual household with a privately owned well, achievement of objectives may be determined either in the household after point of entry treatment for all uses, or at specific points of drinking water use.

18.2.2.2 Discharge Objectives

The objective of sorption-based PFAS treatment for the discharge of generated liquid waste streams is to reduce the concentration or mass loading, or both of regulated PFAS in the discharge to restore and maintain the chemical, physical, and biological integrity of the receiving water for the protection of public health, environmental, and designated uses. Wastewaters where sorption-based PFAS treatment may be used to meet discharge objectives may include but are not limited to municipal sewage, industrial process wastewaters, landfill leachates, contaminated groundwater, contaminated dewatering water, membrane reject concentrate, containment waters, and managed construction site water. Sorption-based

PFAS treatment may also be applied to industrial or municipal stormwater to achieve discharge objectives. Discharge objective criteria may be associated with:

- Regulated PFAS concentration or loading based on achieving certain water quality
- Regulated PFAS concentration or removal efficiency based on the treatment technology being applied
- Regulated PFAS concentration or loading established by a local publicly owned treatment works (POTW) based on contaminant loading to the POTW and ability to maintain its own discharge objectives
- Industry-specific guidelines
- Highest attainable conditions under standard variances or Pollutant Minimization Program goals where concentration reductions can occur over time with interim criteria
- Corporate or governmental environmental stewardship program goals

Objectives for discharges to groundwater may be associated with a specific use(s) of that groundwater for protection of human or ecological receptors, such as use as a source of drinking water by individual household private wells or public water utilities' wells. Discharge of some wastewaters to groundwater may be prohibited, depending on the nature of the liquid waste stream being generated, either categorically or in accordance with antidegradation requirements.

As listed above, discharges to a POTW may be subject to limitation of PFAS concentration and mass loading to the wastewater treatment plant to prevent pass-through of untreated PFAS and interference with the operation or performance of the treatment plant. This may include interference with the ability to land-apply biosolids or to provide other beneficial use. Because these limitations are established based on the needs of the individual wastewater treatment plant, they can vary widely, and individual POTWs should be consulted to verify requirements. Similarly, co-contaminants within the waste streams or additives used as part of the PFAS treatment process could also be subject to local limitation and could affect the efficiency of PFAS removal.

During the treatment method selection, the practitioner may evaluate more than one of the discharge options listed above where PFAS treatment objective criteria differ. Valuable insight on recommended practices for discharge of PFAS-contaminated treated water and liquid waste streams under the National Pollutant Discharge Elimination System (NPDES) program is provided in a December 5, 2022, US Environmental Protection Agency (USEPA) memorandum on "Addressing PFAS Discharges in NPDES Permits and Through the Pretreatment Program and Monitoring Programs" (**USEPA 2022**).

The USEPA has since published (draft as of December 2024) national recommended human health ambient water quality criteria for perfluorooctanoic acid (PFOA) (**USEPA 2024**), perfluorooctane sulfonate (PFOS) (**USEPA 2024**), and perfluorobutane sulfonate (PFBS) (**USEPA 2024**). The criteria provide recommendations as part of the development and adoption of water quality standards, but as stated in the associated USEPA Technical Fact Sheet, "National recommended human health ambient water quality criteria are not regulations, nor do they impose legally binding requirements." The USEPA has also published Final Recommended Aquatic Life Criteria and Benchmarks for Select PFAS (**USEPA 2024**; **USEPA 2024**; **USEPA 2024**).

In some circumstances where no existing regulations currently apply, but a reduction in PFAS is desired, PFAS treatment objectives may be determined by the responsible party.

18.2.2.3 Additional Objective Information

In addition to concentration, mass load, and removal efficiency components of PFAS treatment objectives are the components related to the location used to determine whether a PFAS treatment objective has been met, the treatment objective assessment frequency, and any calculation associated

with determining whether the PFAS treatment objective has been met. For PFAS treatment objectives associated with consumptive uses, such as drinking water, the location for determining whether a treatment objective has been met may be an entry point to where water is distributed, a specific point of entry, or a specific point or points of end use. Locations for determining whether PFAS treatment objectives associated with discharges have been met may include the point of effluent from the treatment system itself, the point of discharge (to a water body, a POTW, or groundwater), or monitoring wells. Reporting of monitoring at additional locations, such as influent or raw water, between stages of adsorptive media vessels or within media beds, may not be used to determine whether a PFAS objective has been met, but may inform the state of operational performance to help ensure a PFAS treatment objective will continue to be met. The assessment frequency for determining whether a PFAS treatment objective has been met may vary depending on the type of discharge or consumptive use or vary from location to location within the same treatment system. Assessment frequencies for PFAS treatment objectives can range from daily maxima to monthly averages to annual or running annual averages. Determinations may also be based on individual batch discharges. The PFAS treatment objective assessment frequency can factor in treatment design, redundancy, operation, and maintenance provisions.

It is also important to understand how qualified analytical results may be used in determining whether a PFAS treatment objective has been met. This includes the occurrence of estimated concentrations between method detection limits and a practical quantitation limit, or laboratory limit of quantitation, as well as when matrix interference causes the limit of quantitation to increase the concentration associated with reporting detections.

In some circumstances PFAS treatment objectives may be prescribed based on minimum operational conditions (**WI DNR 2022**). These may include minimum amounts of empty bed contact time (EBCT), maximum treated bed volumes between change-out of fixed-bed sorptive media, changing of lead/lag unit positions, or reporting of these tank rotation or media change-out conditions (**MI EGLE 2024**).

Although not directly tied to PFAS treatment objectives for consumption or discharge of waters, additional PFAS objectives may be associated with releases of air to the indoor environment or atmosphere that potentially contain PFAS associated with sorption-based PFAS treatment, or volatile co-contaminants. Pressure vessels used for fixed-bed adsorptive media include air vacuum/air release valves to allow for the flow of air in and out of the vessel. These air release valves are known to release small amounts of water as they close. Vapor-phase emissions from these vent valves in fixed-bed sorptive media vessels are assumed to be de minimis. Foam fractionation systems input air or gases into the treatment system that must also exit from the system. These releases of air or gas may include vapors or aerosols containing PFAS. There is ongoing research into the magnitude of these potential releases and several studies funded by the Environmental Security Technology Certification Program (ESTCP) are collecting samples to quantify PFAS in air emissions from foam fractionation (for example, **Sorenson 2023**; **Sorenson 2023**). The use of additional controls or air monitoring may be considered to meet objectives associated with these discharges of air.

It is important to determine PFAS treatment objectives at all levels of authority—federal, tribal, state/territory, and local—as one authority may have established objectives that are more restrictive than another. PFAS treatment objectives are expected to evolve as additional knowledge is accrued regarding the human health effects and toxicology associated with these contaminants, and as analytical method limits of quantitation are refined. By staying informed of proposed and future changes that could add or modify PFAS treatment objectives, the selected treatment can be evaluated in its ability to meet such

objectives or configured to allow for expanded PFAS treatment if needed in the future. These changes could include:

- Changes to regulated PFAS
- Changes to treatment objective concentrations or mass loading
- Changes to treatment removal efficiency objectives
- Changes to Pollutant Minimization Program goals or standard variance highest attainable condition target objectives

18.2.3 Characterization and Pretreatment Needs

The water to be treated must be adequately characterized to evaluate available treatment technologies. This includes characterizing the PFAS content of the water to be treated, the types of PFAS present and their respective concentrations, the concentration of co-occurring constituents, and other parameters. Both regulated and unregulated PFAS should be considered, including precursors. This information can be used to help understand competition for sorptive sites and to determine sorbent media loading capacity before saturation.

For industrial facilities, municipal wastewater treatment plants, and stormwater systems, making efforts to reduce or eliminate identified sources of PFAS to the extent practicable prior to determining the need for treatment can provide benefits such as reducing PFAS mass loading or the flow requiring treatment. These reductions can be achieved through industrial pretreatment programs, reducing or eliminating exposure to stormwater, industrial process and material changes, etc., and are normally more cost-effective in addressing PFAS than treatment of less concentrated and greater flow wastewaters and stormwaters at downstream points.

PFAS concentrations typically encountered in surface- and groundwaters across many different release sites, such as aqueous film-forming foam (AFFF) release sites, industrial facilities, and landfills, range from 0.1 to 10,000 parts per trillion (ppt) (**Section 6.3** and **Section 6.4**). PFAS concentrations in industrial wastewater discharges (**MI EGLE 2020**; **MI EGLE 2020**) and landfill leachates (**Sabba et al. 2025**), however, can be substantially higher—up to the low parts per million range. These potentially elevated concentrations can simply be due to the nature of the waste stream, such as in landfill leachate, or can be the result of a concentration step, such as reverse osmosis. Although all these sources have been treated with sorption-based technologies, highly concentrated sources require further evaluation of pretreatment needs, co-constituents, operation and maintenance (O&M) costs (for example, media change-out frequency).

Waters with highly complex background chemistry, such as landfill leachates, tend to have rapid PFAS breakthrough in sorptive media, as they often exhibit high total organic carbon (TOC, ~ 560 mg/L) and total dissolved solids (TDS) concentrations (~ 60,000 mg/L) (**Murray et al. 2023**; **Malovanyy et al. 2023**). These types of waters may be treated with minimal pretreatment with foam fractionation, depending on treatment objectives and type and concentration of co-constituents. Foam fractionation removal of PFAS is positively impacted by TDS, while TDS may deteriorate GAC and IX resin performance. Both GAC and IX resins may need pretreatment for organic carbon and metals removals while foam fractionation largely does not (**Buckley et al. 2022**).

For groundwaters and drinking waters with PFAS influent in the low-level ppt range, sorptive media are often the most cost-effective treatment option because the media will have a long lifetime, minimizing O&M. For media beds designed with typical EBCTs (see **Section 18.3.1.1** for IX and GAC), generally IX resins, including regenerable resins, provide a longer run time or total volume throughput to breakthrough for sulfonate PFAS compared to GAC (**Kassar and Boyer 2023**; **Liu et al. 2022**). More discussion about the relative efficacy of GAC and IX resins can be found in **Section 18.3.1.6**. The more frequently treatment media need to be replaced, the more economically favorable a reusable media or foam

fractionation approach may become (**Kempisty et al. 2024**). However, other factors, including removal efficiency, cost of maintenance and repair, and efficiency should be considered.

Solution characterization should also consider physical characteristics and the presence of co-contaminants—those that may interfere with treatment and those that are also regulated for simultaneous compliance considerations. Co-occurring organics, inorganics, and ions have all been demonstrated to affect PFAS treatment technologies and should be considered during the characterization of waters to be treated as different types of media might be needed (**Zeidabadi, Esfahani, and Mohseni 2023**). The presence of these water quality constituents may require pretreatment technologies to maintain effective PFAS treatment based on their concentration and the selected PFAS treatment method(s). Most adsorbents aside from gases are negatively impacted by organic compounds (for example, natural organic matter (NOM) in groundwater and surface water, as well as effluent organic matter in wastewater). Therefore, characterizing the organic matter by analyzing TOC or dissolved organic carbon (DOC) concentrations, or both is of critical importance. Total and dissolved fractions of iron and manganese should be analyzed due to their potential to foul media. Dissolved oxygen and oxidation/reduction potential also should be analyzed to determine natural or contaminant-induced redox conditions; microbial activity may impact treatment system fouling, especially for surface water and stormwater runoff treatment, and must be evaluated. The use of the Langelier Saturation Index (LSI) can be helpful in assessing the likelihood for calcium carbonate scale formation, which can also negatively impact adsorption media. Calculation of the LSI requires the following parameters: TDS concentration, pH, alkalinity, calcium concentration, and temperature. Depending on the source of the stream requiring treatment, characterization of volatile organic compounds (VOCs) and the oil and grease concentration may be important as well. Characterizing the nitrate, sulfate, and chloride concentrations is also important for applications using anion exchange IX resins.

Seasonal conditions can impact treatment. For example, nitrate from agricultural runoff and chloride salts from road de-icing can potentially interfere with the performance of IX resins treating ground or surface waters. Similarly, pH and organic matter, both of which can influence effectiveness of adsorption for several technologies, may also vary with seasonal conditions. Water sources impacted by industrial sources may experience high variability in PFAS concentrations, especially if operation of the industrial processes is seasonal or intermittent. Storm events and differences between dry weather and wet weather, including first-flush water quality conditions, should be evaluated to determine impacts to sorption-based treatment systems and pretreatment needs. This includes mobilized silt, sediment, turbid waters, and debris that can cause fouling.

Drinking water utilities may use multiple source waters of varying quantity and quality. If centralized

Table 18-1. Interference of water quality parameters with sorption-based PFAS treatments.

pH	X	X	
Total and Dissolved Silica	X	X	X

treatment is being planned, all sources should be characterized to understand worst-case conditions and variation of co-contaminants.

Various water sources have differing water chemistries, which create differing alleviations or stressors on adsorption-based solutions. For example, landfill leachate and wastewater typically contain high TOC, which may take up sorption spaces on some technologies and affect downstream destruction. Similar membrane concentrates and IX regeneration brines may have high salinity, which may affect sorption as well as downstream destruction. **Table 18-1** includes examples of co-contaminants and other water quality parameters that may interfere with sorption-based treatment technologies based on information in **Section 18.3** and **Section 18.4**. Interference by co-contaminants depends on composition and concentration. For instance, presence of VOCs does not necessarily mean that PFAS removal by GAC will be heavily degraded (**Haupert et al. 2023**). Also, IX resins with different morphologies and chemistries have differing resistance to attack by oxidants, with macroporous resins being more rugged than gel-type resins. More details on interference by co-contaminants can be found in **Section 18.3** and **Section 18.4**.

The need for pretreatment prior to PFAS treatment can be substantially different from treatment of other contaminants. Pretreatment needs are directly related to the specific water or liquid waste stream and its geochemical properties. Assessing pretreatment needs and options is an important part of bench and pilot testing. Co-contaminants and other water constituents, such as total organic matter, solids, metals (for example, iron and manganese **Speth 2022**), and turbidity, can adversely affect the removal efficiency (decreased), operational life (decreased lifespan, increased media replacement frequency), and effort (for example, staffed operational hours, complexity and difficulty of maintenance tasks).

18.2.3.1 Types of Pretreatment

The type and extent of pretreatment can vary based on the PFAS treatment technology(ies) used. GAC, IX resins, and foam fractionation all generally require water and liquid waste stream co-contaminants to be removed and geochemical conditions improved to operate effectively. **Table 18-2** presents information about pretreatment methods summarized from information in **Section 18.3** and **Section 18.4** and cited literature therein. Operational and maintenance practices such as backwashing GAC may also be beneficial in managing adverse effects of water quality parameters on PFAS treatment.

Further, changes of organic matter characteristics (for example, aromaticity, molecular weight) through emerging pretreatment strategies such as ozonation (O_3) and biologically active filtration (BAF) have been shown to substantially improve PFAS removal in subsequent sorption-based treatment technologies (**Tajdini et al. 2023**). **Vatankhah et al. (2022)** demonstrated that low-dose ozonation transforms high molecular weight organic compounds into smaller, more bioavailable assimilable organic carbon, which reduces pore blockage and decreases site competition with PFAS molecules, ultimately improving PFAS removal during subsequent sorption. **Dai et al. (2019)** demonstrated a pilot-scale ozonated air fractionation and combined UV/ozone treatment for PFAS. BAF is another pretreatment strategy used for biodegradation or biotransformation of organic matter that ultimately leads to improved PFAS removal in the subsequent sorption step. Both ozonation and BAF, whether applied individually or in combination as pretreatment, enhance PFAS sorption in the subsequent treatment stage, with the combined configuration demonstrating the greatest improvement in performance (**Vatankhah et al., 2022**). However, it is also important to recognize that oxidation conditions can alter transformation product distribution and the range of intermediates and PFAS produced. Unintended generation of nontargeted intermediates or ultrashort-chain PFAS (ultrashort PFAS) may also occur during oxidation. For example, nontargeted products can occur during oxidation of PFAS with ether functional groups (**Ateia et al. 2023**). Our understanding of PFAS oxidation and biotransformation processes is limited and use of these pretreatment systems should be thoroughly evaluated.

Table 18-2. Pretreatment methods, water quality parameters pretreated.

Pretreatment	Suspended Solids Removal (for example, bag, cartridge, sand filters)	Iron and Manganese Removal (for example, greensand, aeration, oxidation)	Chemical Addition (anti-scaling agents, pH control, sodium bisulfite)	Ion Exchange (for example, water softening, demineralization, organic scavenger resins)	Membrane Processes (for example, nanofiltration)	Oil-Water Separation (for example, oil-water separators, organoclay)	Air Stripping	Settling / Clarification Tank (with or without coagulant or polymer addition)	GAC (sacrificial)	Disinfection (for example, UV, chlorine, ozone, biocides)
Water Quality Parameter Addressed by Pretreatment

Disinfectants/Oxidants			X						X	

[1] Disinfection techniques using oxidants may also treat the indicated water quality parameters.

18.2.4 System Size

Estimates should be made regarding the rate of flow to be treated and the variability of that flow. Both present and future flow parameters should be considered over the expected design life of the treatment system. All of the sorption-based treatment systems presented in this guidance can be expanded with additional units to accommodate future flows using parallel treatment trains if needed, but this requires adequate planning. Examples of planning concepts to be considered are provided in this section.

Drinking water systems should be capable of meeting peak hour or instantaneous water demands. Existing or additional treated water storage volumes can be used to reduce the treatment flow capacity needed. The cost of additional treated water storage can be compared to the cost of treatment capacity. If treatment is centralized for multiple sources of water, flow rates and water quality associated with different source combinations should be considered when evaluating treatment capacity needs.

Municipal wastewater systems may need to consider diurnal flow conditions, the impact of inflow and infiltration, and combined sewer flow, along with flow and water quality from separately received materials, such as septage, hauled liquid wastes, and leachates, when evaluating treatment flow capacity needs. Industrial wastewater systems must consider what process flows will require treatment and how often those flows are generated. Landfills must consider the amount and quality of leachate generated from existing cells and the amount of leachate that will be generated from future cells. Landfills should also evaluate other flows for PFAS treatment, such as underdrain systems. Wastewater equalization storage capacity can be used to reduce the treatment flow capacity needed.

Scientists can measure dry weather flow conditions of stormwater systems and evaluate the volume of stormwater generated within PFAS-impacted catchment areas during various targeted storm events to select the desired treatment flow capacity and equalization storage capacity.

When treatment system effluents are beneficially reused (for example, on-site irrigation or dust control), the need for storage or alternative discharge/disposal methods can also affect system size needs. Such conditions can occur when on-site soils are saturated (for example, from storm events). The case study provided in **Section 15.2.4.1** provides an example of a foam fractionation treatment system with beneficial reuse of the treated water for on-site irrigation.

18.2.4.1 Footprint and Spacing Requirements

In addition to media selection, the size of PFAS treatment facilities is influenced by several factors, which determine the capacity and scalability of the treatment system. Before full-scale implementation, rapid small-scale column testing (RSSCT) and piloting are often important to validate the effectiveness of fixed-bed sorption media. The value of RSSCT and pilot testing depends on site-specific conditions such as PFAS type and concentration, the presence of adverse water quality parameters, treatment objectives, and permit requirements. For example, an RSSCT for a water stream with minimal potential fouling conditions and low PFAS concentrations may be of limited value compared to a water stream with significant potential fouling conditions, high PFAS concentrations, or both.

RSSCT involves using small-scale columns to simulate the performance of the treatment media under real-world conditions. This testing helps determine the optimal design parameters, such as appropriate contact time and the estimated number of bed volumes that can be treated before media replacement or regeneration is needed for each media being evaluated. Pilot studies involve deploying a smaller version of the treatment system to gather data on its performance, operational challenges, and efficiency. This step is crucial for refining the design and ensuring reliability before scaling up.

Residence time is the duration that a water or liquid waste stream must be processed within a treatment unit. For GAC, IX, and some pretreatment technologies (for example, sand filtration), this is commonly

referred to as empty bed contact time (EBCT). For foam fractionation and some pretreatment technologies (for example, solids coagulation, flocculation, and settling), this may be referred to as hydraulic residence time (HRT). PFAS residence times are generally highest in foam fractionation systems, followed by GAC, followed by regenerable IX resin, followed by single-use IX resin. Typical HRTs for foam fractionation range from 25 to 60 minutes (**We et al. 2024**). Typical ranges of EBCTs for GAC and IX are provided in **Section 18.3.1.1**. The specific residence time can vary between equipment design, media type, operating conditions, and the quality of the water or liquid waste stream treated. If there is limited space for PFAS treatment available, the sizing of equipment for any given flow rate and the corresponding treatment footprint is largely related to HRT or EBCT. Any required pretreatment or regeneration equipment would also add to the system footprint. The amount of fractional removal to meet PFAS treatment objectives may influence the treatment technology selection as well as the treatment system design. A system needing to achieve a 99.9% reduction in PFAS may need a more robust treatment design than one needing only a 50% reduction to meet the same concentration treatment objective. This could include more EBCT, longer batch times, or additional stages of treatment, or some combination of these.

As a hypothetical example, a containerized foam fractionation system may be able to treat 1,000 gallons of PFAS-contaminated groundwater over a 30-minute batch process in each of two primary fractionation tanks sized 6 feet in diameter with a water column 5 feet in height. Under this example, by alternating tank filling and processing, the system would be able to process 96,000 gallons operating 24 hours per day. However, if a municipal wastewater treatment plant that processes a higher flow of 1,000,000 gallons per day but with lower concentrations of PFAS needs a longer 60-minute batch processing time, the same containerized foam fractionation system would be able to treat only 48,000 gallons operating 24 hours per day, and 21 of these foam fractionation units would be needed to achieve a capacity of 1,000,000 gallons per day.

Under a hypothetical example for GAC, using 20 minutes of EBCT, two 8-foot diameter pressure vessels in a lead-lag configuration with a bed depth of 7 feet would be capable of treating a flow of 263 gallons per minute or 378,800 gallons per day under 24-hour operation. A municipal wastewater treatment plant needing to process 1,000,000 gallons per day would need to install at least three parallel treatment trains of these two-tank lead-lag systems. The pressure vessels alone would require approximately 400 square feet of spacing, along with more than 12 feet of ceiling height. This could be compared to a single-use IX system using 4 minutes of EBCT and two 3-foot-diameter pressure vessels in a lead-lag configuration with a bed depth of 5 feet, which would be capable of treating a flow of 132 gallons per minute or 190,250 gallons per day under 24-hour operation. The same municipal wastewater treatment plant needing to process 1,000, 000 gallons per day would need to install at least six parallel treatment trains of these two-tank lead-lag systems. However, the pressure vessel spacing requirements would be reduced to 108 square feet with a ceiling height of 10 feet.

18.2.5 Additional Site-Specific and Operational Considerations

Although PFAS treatment equipment and systems have many similarities to those used for treatment of other contaminants (for example, petroleum and chlorinated hydrocarbons, solids, and metals), there are operational considerations that are specific to or similar but significantly more critical to PFAS treatment for water and liquid waste streams.

18.2.5.1 Installation At Sites or Facilities with Existing Treatment

Treatment of existing water and liquid waste streams that were not previously treated for PFAS (for example, drinking water treatment plants, landfill leachates, industrial wastewater discharges, and contaminated groundwater treatment systems) is a growing need. Technologies used in existing treatment systems for conventional and other non-PFAS contaminants are typically unable or insufficient to effectively treat PFAS. For example, a treatment system for an industrial wastewater discharge may

include GAC, but the type of GAC and system design (for example, contact time, flow rate) currently in use are insufficient to remove the PFAS loading present. Some water and liquid waste streams may not have any treatment, such as some groundwater wells used to provide drinking water. These situations present challenges of incorporating PFAS treatment (and possibly pretreatment) within current space and utility constraints. Additionally, it may be necessary to implement immediate corrective actions while a longer term solution is developed.

Placement of sorption-based PFAS treatment for most existing municipal wastewater treatment plants and drinking water treatment plants will typically be as a tertiary process. For fixed-bed media systems, this reduces co-contaminant loading to the GAC or IX and helps limit the need for additional pretreatment. Foam fractionation systems may have more flexibility in their placement; however, placement as a tertiary process will limit the potential for generating odors. In municipal wastewater treatment plants, placement to treat a substream of plant flow, such as solids processing decant water recycle flow, may be considered depending on its PFAS load contribution. The placement of these sorption-based PFAS treatment systems in relation to disinfection processes must also be considered. The presence of chlorine or chloramines can cause degradation of anion resins. GAC will reduce or remove these disinfectants from the water. Similarly, the introduction of air or gases in foam fractionation can also reduce or remove disinfectant residuals. At the same time drinking water treatment plants and municipal wastewater treatment plants must maintain sufficient disinfectant contact time to meet their respective regulatory requirements. Non-PFAS co-contaminant simultaneous compliance treatment needs should also be evaluated. For example, because GAC can also be used to effectively reduce concentrations of disinfection byproducts, in a situation where the present value cost of a GAC system to address PFAS in drinking water is greater than other PFAS treatment technologies, the added benefit of disinfection byproduct removal may still make GAC treatment a preferable overall alternative.

Hydraulic evaluations should also be conducted at existing treatment systems to determine whether existing pumping equipment remains sufficient or requires modification, or if it should be used to meet the needs of the proposed PFAS treatment equipment to avoid the need for double pumping. GAC and IX media beds will create additional pressure head losses that must be overcome. The evaluation should consider the full range of pressure head loss increase over the fixed-bed media life cycle, including fouling potential. This type of planning may help avoid the need for premature media change-outs before full use of media sorption capacity can be achieved. The system must be able to maintain its rated treatment flow capacity.

18.2.5.2 Treatment Space Considerations

The following list of considerations should be evaluated when developing a treatment site layout:

- Sizes of treatment tanks, vessels, or containerized units
- Sizes of pretreatment equipment
- Space for pumps, piping, and other equipment
- Space for fixed-bed media storage, change-out, and delivery
- Space for chemical storage, feed systems, and delivery
- Space for control systems
- Sufficient space for operator access to repair and maintain equipment
- Equalization storage
- Treated water storage
- Backwash water storage
- Space for on-site monitoring and analytical equipment
- Space for mechanical, electrical, and plumbing equipment
- Space to allow for future treatment expansion or building addition
- Space for repair or replacement parts, particularly those with long lead times
- Heating and cooling needs, including freeze protection of exterior or unheated equipment

- Facilities for operator(s) (for example, restrooms, potable water, hot water)
- Space compliant with building, electrical, mechanical, and plumbing codes

18.2.5.3 Site Location Utilities

Selecting an optimal location for PFAS treatment facilities involves several logistic and regulatory factors. Adequate land availability is essential for the construction and operation of treatment facilities. Zoning regulations must be considered to ensure the site is suitable for industrial use and complies with local land-use policies. Locating the treatment facility close to the PFAS-contaminated water that will be treated minimizes the need for extensive piping and reduces potential to create or exacerbate contamination areas during water transportation. At the same time, the treatment system should be in an area that is easily accessible for maintenance, monitoring, and the delivery and removal of treatment materials.

Proximity to transportation infrastructure can help keep facility operations efficient. If access roads must be provided, ensure that they are sufficient for delivery vehicles with spacing provisions for delivery and pickup positions, and turnarounds. Determine whether seasonal weight restrictions on roads to and from the proposed treatment site may limit bulk delivery of consumables such as GAC, IX resin, or treatment chemicals to the site, or limit the off-site transport of spent media or foam concentrate for destruction or disposal.

Determine what source(s) of water are available at or near the proposed treatment site. The largest demands for water will generally be associated with any applicable fire protection needs, backwash operations for the specific media (**Section 18.3**), or safety equipment such as eyewashes or showers. If a source of backwash water is needed, it must be available at appropriate flow rates or stored in sufficient volumes for the duration of the backwash cycle. Consider whether the quality and quantity of treated effluent could be used for any of these water demands. Evaluate options for the disposal or treatment of backwash water. Although existing pretreatment processes such as coagulation/flocculation followed by clarification may be able to remove the solids loading from backwash recycled to the influent of the treatment system, some storage of the backwash may be necessary to limit the percentage of recycled backwash making up the influent flow to the treatment system. In some cases, it may be necessary to provide sufficient volumes of stored water on-site.

Determine the availability and capacity of electric and natural gas utilities and whether these resources are adequate to address the needs of the proposed treatment system. GAC and IX systems needs will depend largely on the total dynamic head loss that must be overcome by pumping systems. Head losses will depend on the media properties, vessel design (for example, media bed depth and underdrain design), EBCT requirements, and the number of stages used in the treatment process. Foam fractionation systems use several different pumping systems, including those used in the bubbling process, which make up a significant portion of the electrical capacity requirements. Pretreatment systems will also add to electrical demand considerations.

Any backup power requirements should be verified with the treatment system vendor(s) and any applicable regulatory authority. Some facilities are required to provide backup power for continuous operation. Some treatment equipment may need a limited supply of backup power to allow for a properly controlled shutdown of equipment, in accordance with the manufacturer/vendor requirements. If the facility has an existing source of backup power, it should be checked to determine whether it has enough remaining capacity to handle this additional load.

Security needs to prevent unauthorized access to treatment systems should be considered, including items such as fencing, video surveillance, intrusion alarms, and electronic fire walls. Higher security may be applied to certain areas of higher hazard. For example, some chemicals and equipment used in IX regeneration can be designated as hazardous classified locations where fire or explosion hazards exist.

Spill containment provisions should be determined along with the need for containment of stormwater in areas where potential exposures exist at the treatment site. Consider whether these containment waters can be processed by the proposed PFAS treatment system, or whether they must be transported off-site for disposal or destruction.

18.2.5.4 Separated PFAS Destruction and Disposal

System design should consider final fate of separated PFAS-laden wastes, which could include spent media, media regeneration residuals, or foamate. The project planner should consider whether PFAS destruction is a priority or whether sequestration in landfills or deep wells is acceptable. Detailed considerations for spent media and media regeneration residuals are presented in **Section 18.3.3**, and detailed considerations for PFAS-containing foams are presented in **Section 18.4.3**.

Thermal treatment, including hazardous waste incineration and GAC reactivation, are widely available, with about 22 hazardous waste combustors and 17 GAC reactivation facilities in the United States (**USEPA 2024**). Landfills and deep well injection are also currently available disposal methods but should be evaluated to consider acceptability of PFAS-containing wastes and tipping fees. Backup alternatives should also be determined in case the primary method of destruction or disposal becomes temporarily unavailable. Whichever option(s) are selected, dedicated space will be needed for these concentrate/media storage, media change-out, and treatment equipment operations. Thermal treatment, landfilling, and deep well injection are further described in **Section 10.3.4** and **Section 12** and as part of the Priority Topics for Treatment Technologies. The USEPA's Interim Guide for Destruction and Disposal Guidance for PFAS-Containing Wastes also provides context (**USEPA 2024**).

In addition to the commercially available PFAS disposal options listed above, emerging technologies are undergoing demonstration for PFAS destruction in multiple applications. One recent ESTCP project evaluated comparative performance and four liquid destruction technologies (hydrothermal alkaline treatment and multiple types of supercritical water oxidation) (see ESTCP projects ER23-8398, ER23-8435, ER23-8434, ER23-8400). Other developing technologies for disposal of liquid wastes include advanced reduction processes, nonthermal plasma, and electrochemical oxidation for PFAS destruction.

Some of these options are available for use on-site and should be compared with the long-term costs of available off-site options. In some areas destructive treatment systems may be set up as a regional hub, to serve multiple sites where spent media or PFAS liquid concentrates can be sent for processing. This may be a more economically viable destruction option if low volumes of materials are generated at the site.

The USEPA has also made changes to the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), which designated PFOA and PFOS as hazardous substances and became effective on July 8, 2024 (**USEPA 2024**). These changes may affect transport and disposal of PFAS-containing wastes. The management of that concentrated waste or residual can be done on-site, or it can be managed by transporting it to a specialized location where the destruction is achieved or it is disposed in a safe manner. Determine if on-site versus off-site management of residuals is appropriate for an application as part of project planning. Understanding cost, sustainability, and risk implications of the residuals management is important to make informed project decisions.

Off-site residuals management includes management or disposal by commonly owned facilities, privately owned specialized facilities, or other instances where management is not integrated into the same system as the sorption or fractionation technology. Off-site residuals management is generally advantageous for sites that generate residuals infrequently or at lesser volumes. Other reasons to consider management of residuals off-site are when there is proximity to off-site facilities that can accept the residuals, lack of on-site expertise to manage residuals, unreasonable potential risks associated with on-site use of a destruction or disposal technology, or more complicated or costly regulatory

requirements associated with residuals management on-site. Off-site management may also reduce facility liability, depending on contracting conditions.

On-site residuals management and minimization of waste volume are important to reduce the potential liability associated with ultimate disposal. On-site residuals management may be necessary for remote sites due to the logistics and costs associated with off-site alternatives. There may be cost advantages for sites with large volumes or frequent generation of residuals. On-site management may present opportunities to use destruction technologies with limited unit capacities where smaller volumes of residuals are generated. In addition, management on-site can streamline residual management to the site of origination.

18.2.5.5 Community Concerns

Concerns of the community should be identified, considered, adequately addressed, and communicated back to members of the community. The ITRC **Risk Communication Toolkit** RCT-1 (**ITRC 2020**) includes mechanisms to provide effective communication with the community. Their concerns may include:

- transportation of spent media or foamate containing concentrated PFAS
- truck traffic to and from the site
- hours of operation and noise pollution
- release of PFAS into the air and potential deposition
- hazards from other treatment chemicals or additives
- spills or runoff from the treatment facility
- impacts to water and sewer user rates
- remaining PFAS in effluent or drinking water, or contaminated groundwater

These concerns may play a role in the types of treatment considered and selected.

18.2.5.6 Operations Oversight

Determine what level of operations oversight is necessary for the treatment technologies being evaluated, including any additional pretreatment. Determine the types and levels of operator certification required for these treatments. Consider how many on-site worker hours are expected, and what activities will need to be carried out. Determine whether this workload be taken on by existing operations staff or whether additional staff will be needed. If operations are contracted out, ensure the contractor has the technical expertise and experience for the proposed treatment. Consider whether the treatment system can be operated remotely and under what conditions, if any, remote operation is allowed. Consider what types of alarms and notifications will be provided and how they are communicated. Consider the compatibility of any existing supervisory control and data acquisition systems with the proposed treatment.

18.2.5.7 Sample Collection and Analytical Support

The locations and frequency of PFAS monitoring that will be required, and an understanding of under what conditions it may be reduced, should be reviewed as analytical costs associated with PFAS sampling can have a significant impact on annual operation costs.

Confirm the expected turnaround time from sample collection to receipt and reporting of analytical results to meet data quality objectives. If analytical results must be obtained and provided before discharge can occur, storage of treated water may be necessary with sizing to adequately accommodate this timing and any potential delays or inability for treated water to meet the treatment performance objectives.

Although PFAS treatment objectives may apply to only a limited number of PFAS, analysis and reporting of all PFAS analytes available within a specific method may be requested or required—for example, all 40 PFAS associated with USEPA Method 1633A (**USEPA 2024**). Monitoring of PFAS that do not have regulatory limits or treatment objectives, especially short-chain PFAS, can help act as a surrogate to monitor breakthrough and the need for media change-outs while maintaining treatment objectives, and not relying on estimated bed volumes treated.

Even though multiple PFAS may have a treatment objective, it may be only one PFAS that drives the design of the treatment system and in the case of fixed-bed media, the need for change-out of the media. This can help in the evaluation of each alternative and selection of treatment(s).

18.2.5.8 Sustainability

Understand the influence of the treatment technology on the environmental, social, and economic aspects of the project. **Section 12.9** identifies environmental impacts as a consideration in technology selection and provides references to guidance documents that can aide in an evaluation. Each location and application are unique, so overarching statements about sustainability by technology may be inaccurate. Often, preliminary understanding of proposed application to obtain equipment sizing, materials change-out frequencies, and performance monitoring frequency is needed to perform an evaluation, especially if seeking to perform a side-by-side comparison. One recent study compared life cycle energy use rates of different management options for spent adsorption media, including energy needs for virgin media production (**Ling et al. 2025**).

When evaluating the sustainability of a technology application, it is common that a preliminary accounting is conducted to understand based on the planned application what would create the largest impacts and how they match with the priorities for the site based on stakeholder engagement. Based on site prioritization and concerns, the team could decide to seek improvement of the planned application based on the priorities (for example, greenhouse gas, waste creation, energy use). Best management practices (BMPs) should be consulted and innovative approaches can be developed to reduce these areas. The USEPA maintains recommendations of BMPs available through CLU-IN (**CLU-IN n.d.**). The analysis can then be revised to incorporate the reductions gained by integrating the BMPs. The implementation and maintenance (as applicable) of the BMPs should be tracked as part of remedial construction and remedial operations reporting. Additional tools and resources for including sustainability in decision-making are discussed in **Section 18.5**.

18.2.5.9 Centralized vs. Distributed Treatment

Many public water supply systems consist of multiple sources of water that are geographically separated (for example, multiple well fields, surface water intakes, or combinations). Treatment at these systems may be provided at a centralized water treatment plant (centralized treatment), or at individual wells/well fields that connect directly to the water distribution system (distributed treatment). When evaluating whether to provide centralized or distributed PFAS treatment, the following differences may be considered.

Centralized treatment at a single location may allow for simplified operations oversight, monitoring, and reporting, while each distributed treatment system may have its own operations oversight, monitoring, and reporting requirements. However, distributed treatment systems can be tailored to the specific source water quality and flow, while centralized treatment must be capable of addressing variable source water quality depending on the mixture of source waters in use. The location of a centralized system can potentially be tailored to reduce fluctuations in source water quality to sustain optimal conditions for high-volume treatment. Centralized treatment may need to process greater flows of lower PFAS concentration water, which can reduce operational efficiency of the treatment and thus may increase overall treatment cost.

18.3 Fixed-bed Adsorbers

This section is an extension of **Section 12.2.1.1** and **Section 12.2.1.2**. It provides a technical overview of GAC and IX systems, including descriptions of the selected fixed-bed adsorptive media; techniques used to evaluate adsorptive media using bench, RSSCT, and pilot studies; and various aspects of system design and how they impact the ability of the system to effectively treat the contaminated water. Constraints and limitations of the technology, such as pretreatment needs, competitive effects of co-contaminants, and feasibility of treating short-chain PFAS and precursors, are discussed. This document is not intended to be a technical or design manual but does describe the basic concepts and considerations when testing and selecting fixed-bed adsorbers for PFAS removal.

18.3.1 Technical Overview

Fixed-bed adsorbers contain sorbent media such as GAC and IX resins that need to be replaced, reactivated, or regenerated once treatment performance no longer meets the desired water quality. Vessels containing the media are typically totally enclosed and constructed of metal or fiberglass to withstand the pressures required to overcome the range of total dynamic head loss across the bed and convey the treated water to the next treatment process, ultimate treated water storage location, or discharge point. Vessels sometimes contain freeboard to accommodate backwashing and swelling of IX resins. Filter basins using sorbent media that are open to the atmosphere are sometimes used at drinking water and wastewater treatment plants and primarily for activated carbon. Once target PFAS are measured at or near treatment goals in the treated water, the sorbent media must be exchanged or regenerated. Single-use media types are commonly removed from the vessel and replaced with fresh media. **Section 12** contains additional background information on mechanisms of PFAS removal for GAC and IX.

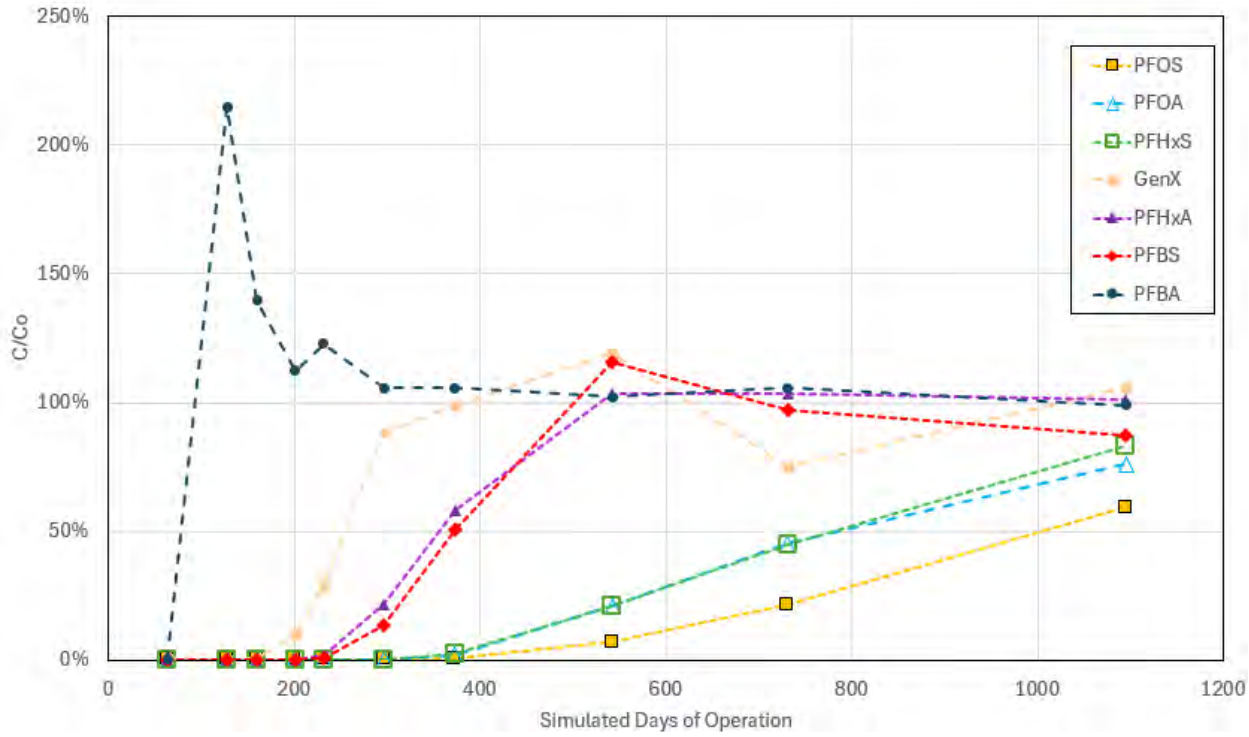

Figure 18-2. Example breakthrough curves for GAC (10-minute empty bed contact time).

Fixed beds containing sorbent media differ from treatment processes such as reverse osmosis in that the contaminant molecules adhere to the sorbent surface until the sorbent's capacity is exceeded. This means that the effluent will contain essentially no measurable contaminant until the initial breakthrough occurs, at which point an increase in the concentration will take place until it reaches a concentration equal to the influent concentration. The variation of a fixed-bed effluent contaminant concentration with time or volume treated is commonly referred to as a breakthrough curve. Breakthrough is calculated as the ratio of the effluent concentration to the influent concentration (C/C0). Each contaminant compound will move through the sorbent media at a different rate and will thus have a unique breakthrough curve as shown in the example curves in **Figure 18-2**. If contaminants are desorbed from the sorbent media either because higher affinity contaminants displace them or because contaminant concentration was higher earlier in the bed's service run, it is possible for concentrations leaving the media bed to exceed concentration in the feed (**Figure 18-2**, first breakthrough (C/C0) curve, perfluorobutanoic acid (PFBA)).

18.3.1.1 Process Parameters

Two critical concepts for the effective removal of any specific compound using fixed-bed adsorbers are the media's equilibrium loading capacity and the kinetics of adsorption for the system. The equilibrium loading capacity is the mass of contaminant the media can hold for a given unit mass of media at the contaminant's influent concentration given a sufficiently long contact time. This is the media's inherent affinity for the compound of interest. The higher the affinity for a particular compound (equilibrium loading capacity), the slower that compound will work its way through the media, leading to a longer bed life. Regardless of a media's affinity for a particular compound, it takes some time for a given molecule of the compound once it enters the top of the media to find an adsorption or exchange site. Even for contaminants with an affinity for the sorption media, the sorption rate can be limited by mass- or phase-transfer processes. The evaluation of these rate-limited processes is referred to as kinetics.

If the kinetics of adsorption were instantaneous, then a band of media saturated with a given contaminant would simply move through the bed until it reached the effluent. In such a system, the effluent contaminant concentration would sharply transition from zero to the influent concentration at the point of breakthrough. But the kinetics of reals systems are not instantaneous, so there is always a thickness of media called the mass transfer zone (MTZ) on the leading edge of the saturated band as it moves through the bed. The MTZ is where the adsorption is occurring. The presence of an MTZ can be seen as the gradual, rather than instantaneous, increase in effluent concentration at the initial breakthrough point (**Figure 18-2**).

Thus, designers of fixed-bed adsorbers must allow for sufficient contact time to account for the kinetics of adsorption (the MTZ) and to provide a bed depth that provides a reasonably long bed life. The convention in the industry is to call this empty bed contact time (EBCT), and it is the media volume divided by the flow rate. EBCTs vary depending on the media used, contaminants present and their influent concentrations, desired effluent concentrations, and levels of co-contaminants (for example, natural organic matter (NOM)) present. Although typical EBCTs per GAC and single-use IX vessel range from 10 to 20 minutes and 1.5 to 3 minutes, respectively, for PFAS removal in drinking water and groundwater pump and treat applications (**AWWA 2019**; **AWWA 2025**), bench or pilot testing may validate EBCTs outside of these ranges for specific applications. GAC and IX adsorbers have been used to polish landfill leachate and industrial wastewater effluents. These applications can require significantly longer EBCTs than drinking water or groundwater treatment systems due to higher PFAS and co-contaminant concentrations. **Section 18.3.1.3** provides strategies to achieve longer EBCTs.

The velocity of the fluid through the sorption media must be fast enough to avoid maldistribution (or channeling) but not so high as to cause excessive pressure drop. This velocity, often referred to as the linear velocity, superficial velocity, or hydraulic loading rate (HLR), is simply the volumetric flow divided by the vessel cross-sectional area. Typical linear velocities range from 2 to 10 gallons per minute per square foot (gpm/ft^2) (5—25 m/h) for GAC and 6 to 18 gpm/ft^2 (15—45 m/h) for IX resin (**Section 12**), but

recommended HLRs may vary from this range depending on the application or specific media. The linear velocity dictates the vessel diameter or cross-sectional area, while the EBCT dictates the depth of the media bed.

18.3.1.2 Operational Considerations

When employing adsorbents such as GAC or IX resins, it is critical to exercise caution regarding the potential leaching of unintended toxic constituents, particularly during the initial operational phase. Newly installed media can release trace amounts of contaminants such as arsenic (**Gandy and Maas 2004**) due to impurities in the raw materials, or nitrosamines, from amine functional groups (**Flowers and Singer 2013**). These leachates can compromise treated water quality and pose regulatory compliance risks. Procedures for mitigating these issues are discussed in **Section 18.3.1.4**. Further, during the operation, backwashing of IX resins used for PFAS removal can disturb the established MTZ within the column, potentially redistributing PFAS-laden particles and altering the contaminant concentration profile along the bed depth (**Woodard, Nickelsen, and Sinnett 2018**). Such disruption may cause breakthrough challenges, complicating the interpretation of monitoring data and masking early signs of adsorbent exhaustion. Furthermore, disturbance of the MTZ can result in transient spikes of PFAS in the effluent, challenging the accuracy of performance assessments and compliance monitoring, particularly for trace-level regulatory limits. Backwashing of GAC can be conducted with minimal impact provided a backwash is conducted on a newly installed bed to stratify it.

18.3.1.3 Adsorber System Configurations

A lead/lag (vessels in series) configuration is often employed for fixed-bed vessels to provide a margin of safety for complying with effluent limitations and to lower the overall media consumption rate. The use of multiple vessels in series permits the lead vessel(s) to become more heavily loaded with contaminants prior to exchanging the media, thus driving the overall media usage rate down. Each time a lead vessel becomes spent, its media is replaced, reactivated, or regenerated, and the vessel's flow position is moved furthest downstream. While the lead vessel is temporarily offline, flow often continues through the lag vessel(s). The vessel that was formerly furthest downstream is then moved one vessel position upstream in the order of flow. In this mode of operation, the vessel with the cleanest media is always the last vessel in the order of water flow. Provided that the MTZ is small enough to fit within a single vessel, lead/lag operation potentially permits media to be changed out on near complete exhaustion, rather than initial breakthrough, leading to more efficient use of media.

In some instances, a lower cost sorptive media to remove co-contaminants can be used in front of higher cost media specific to PFAS removal. If the required flows exceed what can be treated by a single train of vessels in series, then additional trains can be introduced in parallel to increase total flow rates. Sufficient flow paths and valves must be present in interconnecting piping between multiple vessels in series when the intent is to hard pipe the vessels together and allow any of the vessels to be in the lead position. Strategies to increase the EBCT for a fixed flow rate include increasing vessel size or increasing the number of vessels in series or parallel. Or, for a given treatment system, the EBCT can be increased by decreasing the flow rate. In cases where a single vessel of media is used, sample taps located at 25%, 50%, and 75% of the bed depth, which are widely used in vessels in PFAS service, can be used to assess the extent of breakthrough before PFAS are detected in the vessel effluent. Sample taps can be useful in individual lead/lag vessels as well, enabling better prediction of breakthrough and evaluation of performance upsets.

18.3.1.4 Media Conditioning and System Startup

Fixed-bed sorption media require preparation prior to use, and while specific media manufacturer guidelines should be followed, this section will cover the general steps for both GAC and IX media.

With respect to GAC media, the startup process can be broken down into three distinct steps: the loading and wetting step, the backwashing step, and the conditioning step. The first step, loading and wetting, involves the transfer of the media from the delivery vehicle to the vessel and the soaking of the installed media in clean water. The goal of this step is to displace the entrapped air in the media's pore structure by soaking the media in water (usually overnight). Once the media is properly degassed, the second step can begin—the backwash step. The goal of the backwash step is to remove the media fines and to stratify the bed by size, with the smaller granules at the top and the larger granules at the bottom. By removing the fines and stratifying the bed, the hydraulics of the system are optimized and the clean-bed pressure drop minimized. In addition, the stratification of the bed by size minimizes the impact to the MTZ a subsequent operational backwash may have. The last step in the process is the conditioning step, which is a slow forward rinse-to-waste process. The goal of the conditioning step is to stabilize the media bed's effluent pH and remove soluble metals from the finished water stream. Reviewing the manufacturer's startup procedure is important to understand the volume of water required to commission a GAC system. Note that most media manufacturers also have options available to reduce the volume of water required if there are site constraints.

With respect to IX media, the startup process consists of two steps: the loading step and the conditioning step. Unlike GAC media, degassing IX media is usually not required since it is typically already wetted. Furthermore, there is usually no backwash step for IX media because the risk of media washout is high due to the relatively low specific gravity of the media. There is a conditioning step, which, like GAC, means a slow forward rinse-to-waste of the media. The goal of this conditioning step is to rinse off any manufacturing byproducts, such as nitrosamines, prior to commissioning the system. The conditioning step for IX media typically uses less water than the GAC conditioning step. Like GAC, IX media manufacturers have options available to reduce the volume of water required if there are site constraints. Freshly installed IX columns may cause short-term disruptions in pH or corrosivity of effluent water (see **Section 12.2.1.2**).

18.3.1.5 Water Quality Impacts and Pretreatment Needs

The matrix of co-contaminants, background NOM, and other water quality parameters often significantly impacts fixed-bed media consumption and performance for PFAS removal applications. Thus, pretreatment of the water is sometimes necessary to mitigate media fouling to extend bed life, and pilot testing is often recommended to accurately account for these impacts. Fixed beds in these applications are designed to sorb dissolved constituents, so prefiltration with 5-micron or 10-micron filters to remove suspended solids is commonly recommended to ensure the most cost-effective use of the media. Precipitation of iron and manganese particles can foul sorption media and can lead to biofouling from iron bacteria. This problem can be mitigated by treatment to reduce iron and manganese concentrations to below the secondary Maximum Contaminant Level (MCL) of 0.3 mg/L (or lower, depending on piloting data). Biocides or sodium hypochlorite are sometimes used to reduce naturally occurring microbial activity upstream of sorbent media that would otherwise result in biofouling. Disinfectant residuals, however, may damage some sorbent media, so consulting the media manufacturer is recommended. Hard water with a positive LSI can result in precipitation of calcium carbonate within the media, which blocks access to sorption sites. Targeting a neutral or slightly negative LSI can mitigate these concerns. Addition of anti-scaling agents such as phosphonates can reduce the risk of scale formation, but it is possible that these anti-scaling agents could compete with PFAS for exchange sites on IX resins (**Haupert et al. 2023**). In some instances, GAC may provide more flexibility than IX for sites with significant fouling risk due to suspended solids or precipitated metals (for example, iron or manganese) and without a means to pretreat the water because GAC can be backwashed with minimal impact to performance. It is easier to wash out the media and to disrupt the MTZ when backwashing IX resin.

TOC, including NOM, can interfere with the performance of both GAC and IX adsorption of PFAS. Advanced oxidation approaches such as ozonation (**Vatankhah et al. 2022**) can be used to transform and reduce TOC. However, ozonation and AOP can also increase concentrations of PFAS through precursor

transformation, potentially leading to a performance tradeoff for some water compositions. Pretreatment media such as GAC is also used to remove TOC prior to the PFAS treatment media. GAC that is used to remove TOC may have different characteristics (for example, different mesoporosity) than the GAC used to treat PFAS and may be designed for a different EBCT. In general, the impact of NOM on PFAS removal by IX depends on the characteristics of the resin and NOM. For example, removal of PFAS by polystyrene-based strong base IX resins is typically less affected by DOC than polyacrylic-based strong base IX resins that have a higher selectivity for DOC (**Hu et al. 2016**). The properties of the NOM are important as well: removal of PFAS decreases as the charge density, molecular weight, and aromatic carbon content (hydrophobicity) increase (**Boyer et al. 2021**).

Many PFAS exist in anionic (soluble) form in the ambient pH conditions commonly encountered in surface and groundwater. Physical adsorption onto GAC of some short-chain PFCAs that have pKas above 3 would be expected to improve as the pH drops and the ionic fraction decreases. PFSAs and long-chain PFCAs have pKas below 2 and are not likely to be impacted by pH (**Section 4.3.2**). **Boyer et al. (2021)** summarized the impacts of pH, background inorganic ions, and NOM on the removal of PFAS by IX resins in a comprehensive review. Strong base IX commonly used to treat PFAS are typically robust with respect to direct pH effects, with fixed groups being ionized over pH ranges of most applications. Weak base IX resins, whose charge is sensitive to pH, have generally exhibited a lower capacity for PFAS than their strong base analogs (**Liu and Sun 2021**; **Kassar and Boyer 2023**). As noted with GAC, only the charge composition of very short-chain PFCAs is likely to be strongly influenced by pH. Changes in pH also theoretically change the adsorption strength of some NOM fractions. Overall, the potential benefit to manipulating the pH has not been demonstrated to outweigh the added cost and complexity; therefore, GAC and strong base IX systems are commonly employed at ambient pH conditions.

IX resin (specifically anion exchange resin) is most sensitive to the presence of dissolved anionic species, such as nitrate, sulfate, and chloride, which will compete with PFAS for capacity on the IX media (**Wahman et al. 2023**). Waters with high salinity may be particularly challenging to treat with IX, and practitioners may consider testing other media in such situations. Pretreatment to remove major inorganic anions (for example, high-pressure membranes or demineralization by IX) is not commonly practiced and would be unlikely to make IX treatment more cost-effective overall. However, knowing the concentrations of major anions in the water to be treated is still valuable because that knowledge can be used in conjunction with modeling (**Section 18.3.2.1**) to aid in planning and design of pilot systems.

18.3.1.6 Media Description and Properties

IX Resins

Polymer-based IX resins used for PFAS treatment morphologies can be divided into two classes based on pore structure: gel-type and macroporous. The pores of gel-type resins are small enough (usually 1–2 nm) that they do not scatter light, giving these resins a translucent appearance. Macroporous resins, by contrast, usually have pore sizes larger than 20 nm, and are opaque. Gel-type resins usually contain more functional IX sites by volume than otherwise equivalent macroporous resins, which may lead to higher PFAS adsorption capacity for some applications. However, the pore and crosslinking structures in macroporous resins make them more rugged than gel-type resins and lead to faster exchange rates under some conditions. Accordingly, macroporous resins are often considered for applications involving regeneration or challenging water conditions. For example, in waters where biofouling potential is high, the ability to chlorine shock macroporous resin is key to avoiding costly media replacements. If the feed water contains a low level of chlorine residual (for example, 0.2–0.7 ppm, on average, from greensand filters continuously), using a macroporous resin can avoid the addition of a dechlorination step (such as sodium bisulfite addition). Macroporous resins are also expected to be more resistant to iron and manganese fouling than the gel-type resins, which may reduce the need for oxidant-based pretreatment in the first place.

IX resins of different polymer compositions (polystyrene and polyacrylic), pore structures (gel or macroporous), and functional groups (quaternary ammonium, tertiary amine, complex amino) have been used to remove PFAS. Most studies comparing IX resins have been done on PFOS (**Boyer et al. 2021**) and have found that polyacrylic/gel/weak base or polyacrylic/macroporous/strong base (type I quaternary ammonium functional group) resins have the highest capacity (**Chularueangaksorn et al. 2013**; **Deng et al. 2010**; **Schuricht et al. 2017**; **Schuricht et al. 2014**; **Zaggia et al. 2016**). When considering the removal of short- and long-chain PFCAs and PFSAs, **del Moral et al. (2020)** found that a polystyrene/macroporous/strong base IX resin (triethyl functional group) outperformed a polyacrylic/macroporous/strong base IX resin (triethyl functional group).

GAC Media Properties

The raw materials used to manufacture commercially available GAC primarily consist of bituminous and sub-bituminous coals, wood, and coconut shells. The adsorption pore structure and certain physical properties such as abrasion and inorganic mineral content of an activated carbon product are inherited from the raw material used to make it. For example, bituminous coal and coconut shells yield harder and denser activated carbon with more microporous structure compared to wood or sub-bituminous coal.

Every activated carbon product has a distribution of pore sizes, often categorized into micro (<2 nm), meso (2–50 nm), and macro (>50 nm) fractions. Although most of the adsorption occurs within the micro- and mesopores, macro porosity is important because it serves as a conduit to transport contaminants to the adsorption sites. **McNamara et al. (2018)** demonstrated that re-agglomerated, bituminous coal–based activated carbon outperformed coconut-based activated carbon for PFAS removal due to an enhanced transport pore network. During the manufacturing process, the raw materials used are crushed and processed and the GAC is screened to meet certain mesh size specifications. Common GAC mesh sizes employed in water treatment and their respective (US Mesh) size distributions are 12 x 40 (0.43–1.7 mm) and 8 x 30 (0.60–2.36 mm). Specifications for GAC products used in the drinking water industry are provided in AWWA B604 (**AWWA 2018**).

GAC/IX Comparisons

Many studies have been conducted comparing the PFAS removal performance of GAC and IX resin (**Liu et al. 2022**; **Zeng et al. 2020**; **Murray et al. 2021**; **Tajdini et al. 2025**). Although most studies have concluded that PFAS adsorption capacities and media lives for IX are greater than equivalently sized GAC beds, pilot-scale testing with site water as well as an evaluation of the total capital and operating cost on a net present value (NPV) of cost basis is recommended to select the most cost-effective remedy for an application. Numerous studies have confirmed two common trends in the removal of PFAS using sorbent media (**Zeng et al. 2020**). First, the longer chain PFAS within the same class adsorb better than the shorter chain PFAS. For example, in the class of perfluoroalkyl sulfonates, PFOS (C8) adsorbs more strongly than PFBS (C4), and in the class of perfluoroalkyl carboxylates, PFOA (C8) adsorbs more strongly than PFBA (C4). Second, the sulfonates adsorb better than their corresponding carboxylates of the same chain length. For example, PFOS adsorbs better than PFOA. This trend is especially pronounced in PFAS-selective IX resins, which often have even higher affinity for PFBS than for PFOA. Although IX resins, including regenerable IX resins, have higher capacity for short-chain sulfonate PFAS than GAC, they are considerably more expensive on a unit basis. It is also possible that the use of varying media in series can extend media lifetime by removing competing co-contaminants or water constituents such as organic matter. Due to the complexities of assessing relative performance and cost of GAC and IX systems, a site-specific economic evaluation of both types of media is recommended. Additional information about mixed media treatment systems can be found in **Section 18.3.2.3**.

18.3.1.7 Media Reactivation and Regeneration

Thermal GAC Reactivation

Although the terms "regeneration" and "reactivation" are sometimes used synonymously, there is a distinction. GAC reactivation is a thermal process that returns the GAC to a near virgin state. GAC reactivation is commercially available at large-scale, with about 17 facilities currently operating in the US (**USEPA 2024**). When spent GAC is returned to a reactivation facility, it enters a furnace where residual moisture is driven off and volatile contaminants are vaporized as the first step. Calcination and pyrolysis then occur, which char organics not previously volatilized. In the final step, steam gasification removes some of the carbon atoms within the biochar to return the activity level of the carbon to a near virgin state. The bulk of the adsorbed organic mass is thermally destroyed within the furnace, and emission abatement systems are used to capture and destroy remaining organics, acid gases, and particulate matter. The fate of adsorbed PFAS through a reactivation facility has been studied (see **Section 18.3.3**). GAC reactivation consumes between 15% and 30% of the media mass (**USEPA 2024**) and requires this amount of virgin media makeup for each reactivation cycle.

Reactivated GAC has demonstrated similar PFAS removal efficacy when returned to the original facility, but lower PFAS removal efficiency when using general-pool reactivated carbon from unknown origin (**McNamara 2018**). General-pool reactivated carbon should not be used for drinking water applications due to potential contamination from non-drinking-water sources. Sites considering GAC reactivation for PFAS treatment should contact reactivation facilities to see if they merit a site-specific reactivation contract (typically at least 80,000 pounds per change-out as of 2023 communications) (**Barr Engineering and Hazen and Sawyer 2023**). Consult activated carbon reactivation vendors to confirm minimum required quantities, as batch quantities less than 80,000 pounds may be possible.

GAC reactivation offers a similar service to high-temperature incineration, with about 17 facilities operating in the US and lower costs than high-temperature incineration (**USEPA 2024**). GAC reactivation can be used as a disposal method if facilities are replacing carbon with virgin carbon and reactivated carbon is returned to a general pool for resale. Alternately, facilities can accept reactivated carbon back for reuse. Using reactivated GAC offers a significant environmental benefit: a reduction in global warming potential of up to 80% compared to virgin carbon (**Vilen, Laurell, and Vahala 2022**). Destruction efficiencies of greater than 99.99% of targeted PFAS have been demonstrated through GAC reactivation (**DiStefano et. al 2022**), though full defluorination is difficult to demonstrate due to analytical limitations in closing the fluorine mass balance. Relative to high-temperature incineration with virgin media replacement, GAC reactivation and reuse is estimated to use less than half as much energy and incur less than half the operational expense (**Ling et al. 2025**).

GAC Regeneration

Regeneration refers to the process of partially restoring the capacity of a spent GAC, typically within the vessel, and uses either thermal (for example, steam) or chemical means to desorb contaminants in liquid-phase applications. Contaminants desorbed from the GAC must then be captured and destroyed or disposed by other means. Regeneration processes have been largely unable to completely restore the adsorption capacity of GAC and, therefore, experience decreasing efficiencies as the regeneration cycles proceed (**Vakili et al. 2024**). In-vessel GAC regeneration uses a basic solvent solution (**Siriwardena et al. 2021**). The spent regenerant solution is distilled and the resulting PFAS extract is proposed for destruction with supercritical water oxidation (SCWO) (**Scheitlin et al. 2023**), but could also be destroyed using other liquid destruction technologies, as further discussed in **Section 18.3.3**. The number of regeneration cycles a single vessel of these media can undergo may be limited, in part due to media degradation. However, application of in-place chemical regeneration of standard, bituminous GAC media has not yet been demonstrated widely on a commercial scale.

Several other technologies are being evaluated at lab-scale and pilot-scale for GAC regeneration, including hydrothermal alkaline treatment (HALT) regeneration (**Soker et al. 2023**), microwave regeneration (**Gagliano et al. 2021**), and plasma reactivation (**Bailey 2021**).

IX Regeneration

In some treatment systems, the adsorptive treatment media is regenerated within the vessel to replenish capacity. In situ regeneration of IX media for PFAS treatment for non-drinking-water applications is commercially available and has been used in cases of high PFAS influent concentrations or treatment of short-chain or ultrashort PFAS that would otherwise require very frequent media exchanges (**Woodard, Berry, and Newman 2017**; **Woodard, Nickelsen, and Sinnett 2019**, **Kempisty et al. 2024**). The book chapter by **Woodard, Nickelsen, and Sinnett (2019)** offers a comprehensive overview of regenerable IX resins for PFAS removal, including mechanisms of removal, importance of water quality analysis, key design parameters, loading and regeneration cycle data sets, and economic considerations. A case study demonstrating the use of regenerable IX resins, including a system diagram, is available in **Section 15.2.2.2**. Regenerable resins tend to be macroporous, rather than gel-type, because of the importance of ruggedness and fast kinetics during regeneration (**Liu and Sun 2021**). Some regenerable resins have lower capacities (**Ellis et al. 2022**) or require a longer EBCT to achieve similar capacity to single-use PFAS-selective resins, but this could be offset by O&M cost savings associated with on-site regeneration over off-site disposal (**Ling et al. 2025**).

Strong base IX regeneration involves the desorption of PFAS from the resin with a solvent brine solution that breaks both the hydrophobic and anionic interaction of the PFAS with the media. Multiple trials of regeneration using various combinations and concentrations of salts and solvents were conducted in (**Crimi et al. 2023**). These trials concluded high concentrations of alcohol solvents, for example, 75% by volume, and sodium chloride at 2% resulted in the most efficient and complete desorption of PFAS from the media. Research studies have also shown that even IX resins that are typically considered to be "single-use" resins can also be regenerated using 90% methanol brines (**Ellis et al. 2025**). After regeneration, the solvent is distilled for continued regeneration cycles and a PFAS concentrate known as a "still bottom" is the residual waste product of the process that can be further handled. Management of spent residuals is discussed further in **Section 18.3.3**.

Currently, no state agencies permit solvent regenerated IX (or GAC) systems for PFAS treatment of drinking water (**Ling et al. 2025**). Regenerable IX has been reused in full-scale PFAS remediation systems since 2018. Five years of performance data from a full-scale system demonstrated continuous use of IX resins without performance deterioration (**Kempisty et al. 2024**). Potential application scenarios for media regeneration include on-site regeneration and solvent recovery, on-site regeneration with off-site solvent recovery, and off-site regeneration of spent media vessels. Advantages of regenerable IX systems include reuse of the resin, reduced waste generation and associated liabilities, reduced size requirement of PFAS destruction technology, and lower operating costs, particularly when short-chain or ultrashort PFAS removals are required. An important consideration for life cycle cost is that high concentration solvents trigger the need for fire protection and intrinsically safe equipment. Moreover, the regeneration equipment itself represents important additional capital costs. The opportunity over time is cost savings associated with nonregenerable media replacement. Life cycle cost assessment (LCA) in **Hagelin et al. (2022)** suggested an expected return on those capital investments may occur during the time-horizon of a typical groundwater remediation system.

On-site or mobile regeneration of resin, typically using brines and/or solvents, provides the benefit of not having to physically remove and change out spent resin. Concentrated liquid produced during regeneration requires disposal. The primary waste product evolved from regenerable IX or GAC systems is the still bottom which contains high concentrations of PFAS and the regenerant salt. This material can be further concentrated with media in a process known as super-loading, which exposes the still bottoms to a mixed media bed with long contact times to achieve equilibrium isotherm conditions (case study

provided in **Section 15.2.2.2**; SERDP ER23-8391; **Haeglin et al. 2022**). Alternatively, the resulting still bottoms can be disposed of via traditional high-temperature incineration, SCWO, or an emerging destruction method such as HALT, plasma, or electrochemical treatment (**Singh et al. 2020**; **Maldonado et al. 2021**; **Liang et al. 2022**; **Pinkard et al. 2024**; **Higgins et al. 2025**), depending on the treatment equipment's ability to handle the still bottom salt content. Large-scale implementation could leverage a "hub-and-spoke" model with a regional regeneration and PFAS destruction facility servicing multiple facilities using IX resins, where vessels or media are sent to centralized facilities for regeneration and PFAS destruction (**Kempisty et al. 2024**). The additional capital costs associated with IX regeneration should be evaluated with an LCA; the payback period can be as little as 2 years or can be determined not to be feasible if the conditions do not provide an acceptable payback (for example, low flow rates, infrequent change-outs, or easily obtained treatment objectives). Similar approaches are being used for the regeneration of GAC and novel adsorbents (ESTCP Projects ER23-8379, ER23-8391), although the number of regeneration cycles these media can undergo may be limited. On-site or mobile electrochemical oxidation has also been used for the regeneration of GAC treating landfill leachate. As an example, one vendor uses an on-site solvent-based GAC regeneration process with a regional hub to process spent solvent for recovery reuse while separating desorbed PFAS for destruction at the hub using SCWO (**DiGuiseppi et al. 2024**). Hubs may be set up as centralized waste treatment facilities(**USEPA 2025**). Where regeneration solutions (additives) are used, the ability to demonstrate their removal from the media/vessel prior to reinstallation for treatment should be evaluated. Destruction of regeneration brines is further discussion in **Section 18.3.3**.

18.3.2 Performance Evaluation

18.3.2.1 Fixed-Bed Adsorption Models

The most accurate way to predict the breakthrough behavior of PFAS in fixed-bed adsorbers is to conduct bench- or pilot-scale column tests using water from a particular site. Conducting these tests, however, can be time-consuming and expensive. A faster, although often less accurate, method of assessing fixed-bed performance is to use modeling. A publicly available model from the USEPA's "Water Treatment Models" GitHub site (**USEPA 2021**) using the pore and surface diffusion model can incorporate the effects of fouling and predict performance of GAC. This model is based on the AdDesignS (Michigan Technological University, Houghton, MI) adsorption design software that was released into the public domain as part of the USEPA's Environmental Technologies Design Option Tool (ETDOT) (**USEPA 2023**). The challenge in using models such as this is that many of the model inputs parameters are not widely available and are quite difficult to determine (**Burkhardt et al. 2022**). Ideally, model inputs would include single solute Freundlich isotherm values of K and 1/n, external mass-transfer coefficients, internal diffusion coefficients, parameters for background NOM, and fouling factors for equilibrium capacity and kinetics (**Burkhardt et al. 2022**). PFAS isotherm parameters are sparse in the literature, however, some theoretical methods can estimate K and 1/n for PFAS with some success (**Burkhardt et al. 2023]**). **Burkhardt et al. (2022)** fit a pore and surface diffusion model to RSSCT breakthrough curves and then used the model to predict the impacts of changing fixed-bed parameters such as bed diameter, flow rate, and influent concentrations. Some activated carbon vendors have their own predictive models and databases. However, these vendor-specific tools are generally proprietary and not available to decision makers outside of consultation with vendors. The advent of machine learning methods has yielded novel approaches to estimating GAC performance in PFAS applications. For example, **Koyama et al. (2024)** compiled a data set of published PFAS breakthrough curves on GAC adsorbers and developed machine learning models using GAC characteristics, PFAS properties, and water quality parameters to predict throughput to 10% breakthrough (BV10). Although the machine learning model developed by Koyama et al. had mean errors of roughly 32% on BV10 and does not produce whole breakthrough curves, it is still a potentially useful tool for estimating the duration of GAC pilot studies.

Modeling tools for predicting the performance of IX resins for PFAS removal are few and far between—especially freely available or open-source models. As with GAC, various media vendors and consultants

have proprietary IX models for use internally, but these models are not typically published in peer-reviewed literature. It is accordingly difficult to comment on them because the underlying theory of their operation is unknown.

Use of empirical breakthrough curve models is common practice in literature and can be quite useful for interpolating data and comparing breakthrough curves among competing adsorbents. However, breakthrough curve models that neglect mass transport mechanisms or use purely empirical isotherms have difficulty correctly predicting the effects of changing system EBCT or variability in PFAS concentrations (**Haupert, et al. 2021**; **Haupert et al. 2023**), which are common concerns when interpreting pilot data and designing full-scale systems.

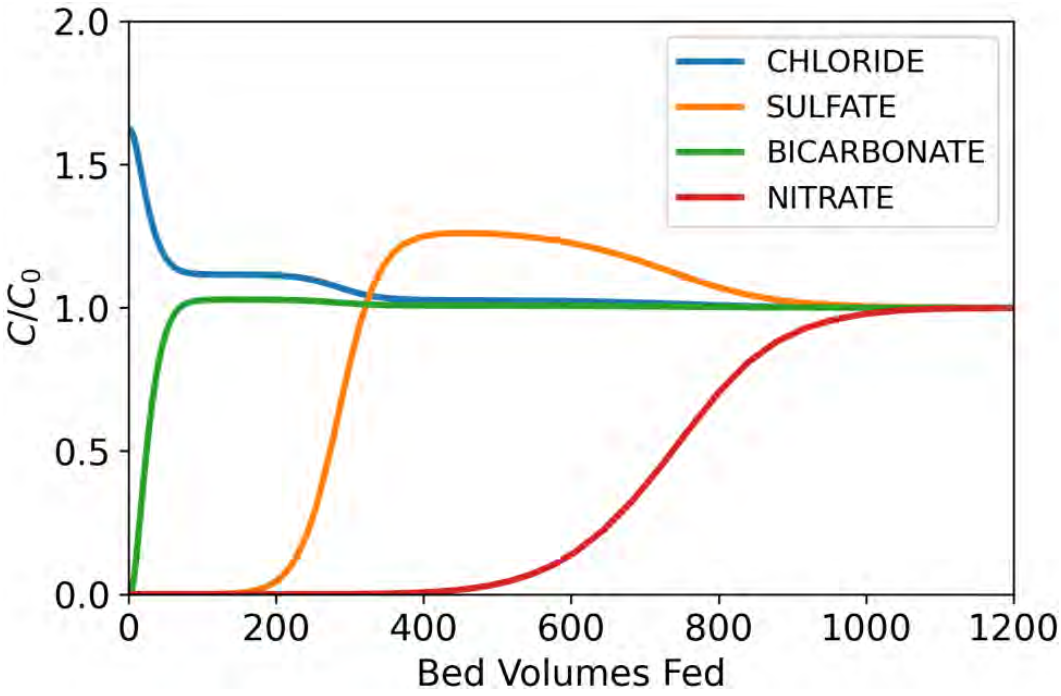

Figure 18-3. Example output of USEPA's IX model (USEPA 2021) showing influent-normalized effluent concentrations of commonly occurring anions in drinking water for an example system (Haupert et al. 2023). This output demonstrates the model's ability to predict chromatographic effects from displacement.

The USEPA has developed an IX performance model that closely follows the mechanistic conventions of the GAC model in AdDesignS, incorporating mass transfer resistances and combining them with multicomponent IX isotherms (**Smith et al. 2023**; **USEPA 2021**). This model explicitly includes competition effects from multiple ions in solution (**Figure 18-3**). Using IX isotherm parameters from the literature (**Fang et al. 2021**; **Wahman et al. 2023**), it is possible to make predictions about the impact of changes in commonly occurring anions (such as chloride, sulfate, and nitrate) on expected PFAS treatment performance. Unlike the GAC models, the IX models developed by USEPA do not currently have well developed methods for handling competition from NOM. Although the model can be used to estimate NOM impacts on performance in pilot data (**Haupert et al. 2023**), prediction is not yet rigorously possible. Some empirical, quantitative structure-property relationships (QSPRs) and pseudo-single solute models for estimating NOM effects on PFAS adsorption on IX systems have been developed for specific waters using AdDesignS (**Cheng et al. 2025**), but NOM is difficult to characterize and waters with similar TOC/DOC levels can have very different IX performance impacts (**Tajdini et al. 2023**). It is possible that additional research with carefully controlled water quality—for instance, with the use of lyophilized NOM in laboratory column studies (**Abulikemu et al. 2022**)—will shed light on the underlying mechanisms of

NOM interference on ion exchangers. Despite this limitation, it is still possible to use these models to make predictions about the effects of changing PFAS concentrations and changing operational parameters such as EBCT.

18.3.2.2 Summary of Testing Methods

As discussed in **Section 18.3.1**, general guidelines exist to help engineers design adsorption-based systems for PFAS removal. The media's performance and change-out frequency, however, cannot be generalized, as it is dependent on each site's water quality and proposed design. As a result, performance testing or evaluation of historical treatment data from analogous applications should be completed at each site to select the most cost-effective adsorptive media, including consideration of reactivation/regeneration, disposal, and/or replacement costs. Testing allows owners to make data-driven decisions regarding which technology is optimal for their scenario by looking at both performance and expected life cycle costs.

When it comes to adsorptive media, feed-water quality can have a significant impact on both operability and performance with respect to PFAS removal. For example, water sources with elevated levels of anions, such as sulfate and nitrate, tend to reduce media lifetime for IX resins. Similarly, water sources with elevated levels of TOC tend to be challenging for GAC media. Furthermore, sources with steady water quality (for example, groundwater) are usually well suited for lab tests. On the other hand, surface waters used for drinking water, which tend to see seasonal changes to their water quality, are not well suited for lab tests. These are some of the factors that need to be considered when evaluating different adsorptive media technologies and performance test options.

Table 18-3. Summary of performance test options for evaluating adsorption-based technologies.

Test Type	Relative Time to Completion	Relative Cost	Ability to Compare Media?	Predictability of Full-Scale Performance
Isotherm	Shortest	Least	Yes	Poor
Rapid Small-Scale Column Test	Moderate-low	Moderate-low	Yes[1]	Moderate[2]
Pilot	Moderate-high	Moderate-high	Yes	High[3]
Full-Scale Demonstration	Longest	Highest	No[4]	Best

[1] The RSSCT method has historically been used to compare the performance of GAC media. Although work is currently being done to modify the test for IX media, an industry consensus on the method has not been reached.
[2] GAC media RSSCTs for evaluating PFAS removal have been shown to either underpredict or overpredict the full-scale performance (**Cheng and Knappe 2024**; **Hopkins and Knappe 2024**; **Liu, Liu, and Sun 2024**). This issue is discussed in more detail in **Section 18.3.2.4**.
[3] The pilot study design plays a major role in the scalability of the results.
[4] Due to the scale of these tests, typically only one media is evaluated.

It is important to note that the term "feed water" does not necessarily mean the site's "raw water." PFAS treatment by fixed beds in wastewater and drinking water systems tends to be tertiary processes, within those systems, they are downstream of conventional treatment. Where the PFAS system is tied into the process can have a significant impact on the performance of the adsorptive media. For example, antiscalant from an upstream air stripper process may interfere with PFAS adsorption in downstream IX unit operations (**Haupert et al. 2023**). The same study found that low levels of VOCs in the feed water did not have a measurable impact on the performance of the GAC with respect to PFAS removal. Therefore, understanding the feed water quality to the future PFAS removal system can help owners select which adsorptive media to evaluate in their performance tests, and it is important to conduct testing on water that has already been subject to all intended pretreatment. More detail about applicable pretreatment strategies can be found in **Section 18.2.3**.

There are four main performance test options an owner can pursue when investigating different adsorptive media technologies for PFAS removal. The first two are lab-based tests—the isotherm test and the RSSCT. The other two are field-based tests—the pilot test and the full-scale demonstration test. As shown in **Table 18-3**, each option has advantages and disadvantages that will be discussed in more detail in the following subsections.

18.3.2.3 Isotherm Tests

One way to evaluate adsorbent media is via batch mode bench-scale experiment, whereby a known volume and concentration of PFAS-containing water is mixed for a set exposure time with a measured mass of adsorbent media to determine changes in the water's PFAS concentration. Typically, these batch tests are repeated with the same influent water (concentration and volume) but using varying doses of the adsorbent media. The data are then analyzed using an appropriate adsorption mathematical model (for example, Freundlich, Langmuir,) to develop an isotherm curve—a mathematical function relating the amount of PFAS adsorbed on the media to the remaining concentration of PFAS in the water at equilibrium.

In practice, it is common to use isotherm results as a means of identifying media that can remove the target contaminant for an application. Adsorbents showing the best performance can then be selected for further testing by RSSCTs or pilot tests. Batch isotherm tests using carefully controlled, synthetic waters have been used to obtain relative affinities for PFAS and common inorganic ions on some common IX resins (**Wahman et al. 2023**). These relative affinities can be used in conjunction with isotherm tests to make predictions about the effects changing concentrations of PFAS or common inorganic ions (for example, chloride, sulfate) have on IX performance. However, because NOM impacts on IX isotherms are still not well understood, the isotherm test is not able to rigorously predict PFAS breakthrough curves in practice. This limitation, along with the time, expense, and expertise needed to conduct such detailed batch experiments, means that these efforts are typically conducted by researchers rather than practitioners.

It is important to note that isotherm results provide an adsorbent media's capacity for PFAS at equilibrium. Notably the appropriate time to reach equilibrium in isotherm batch testing can vary with different media and different adsorbent doses (**Wahman et al. 2023**) and should be considered during experimental design. It is therefore important to confirm that bottle isotherm tests have reached equilibrium for proper interpretation of results. It is important to note that the kinetics of adsorption in bottle isotherm tests do not necessarily reflect the kinetics in column process. For this reason, isotherm results should not be used by themselves to extrapolate full-scale performance.

In situations where owners have time or budget constraints precluding further testing, isotherm results can be used with column performance models (for example, AdDesignS (**USEPA 2023**)) to obtain high level, estimated time to breakthrough for PFAS of interest. Although this approach is not the most accurate, it can provide a rough initial method of comparing adsorbent media performance to assist in planning. If the owners find themselves in this situation, they should keep three things in mind. First is to make sure they use their site's actual water, rather than synthetic water, for their testing to increase the representativeness of their results. If the site's water source is highly variable, the owner may want to run two isotherms (for example, winter and summer) to understand how the changes in water quality impact the adsorbent media's performance. Second, during the batch tests, any co-contaminants of interest also in the test water can be monitored. This allows owners to understand any potential added water quality benefits associated with adsorbent media. Last, water quality impacts (for example, fouling) and operational complexities (for example, backwash frequency) cannot be assessed in a batch test. Visiting a facility that already uses the adsorbent media(s) being evaluated can provide some operational knowledge to assist with this limitation of the isotherm test.

18.3.2.4 Rapid Small-scale Column Tests (RSSCTs)

A second lab-scale performance test available is the RSSCT. Originally developed around GAC media, the procedure for this test can be found in ASTM D6586-03, though it has not seen significant updates for PFAS applications (**ASTM 2021**). Due to the lack of industry consensus with respect to the IX RSSCT, some vendors and consultants recommend using the ASTM RSSCT method only with GAC media. With that said, it is imperative that practitioners understand that small errors in the test setup can lead to significant impacts on the results and conclusions of the test. To aid utilities in obtaining representative and accurate media performance relative comparison from RSSCT tests, here are some general guidelines to follow:

- The calculations in the ASTM D6586 RSSCT method should be followed.
- Ground media must be analyzed using sieve analysis (for example, alpine air jet sieve) to confirm size before testing; scaling should be recalculated based on results for each media.
- Full-scale mean particle diameter assumptions should be acquired from the media manufacturers.
- Small-scale column fill weight and volume should agree with the full-scale apparent density of the material tested.

Assumptions concerning the relationship between intraparticle diffusivity and carbon particle size can have a significant impact on the accuracy of RSSCTs to predict full-scale breakthrough (**Hopkins and Knappe 2024**). **Hopkins and Knappe (2024)** concluded that RSSCTs assuming constant diffusivity (CD) have shorter run times and are more accurate than proportional diffusivity (PD) at predicting the onset of PFAS breakthrough, but the shape of the breakthrough curve needs to be adjusted using the pore and surface diffusion model. An alternative presented by **Hopkins and Knappe (2024)** is to use a proportionality constant somewhere between CD and PD. In contrast to PD-RSSCTs, neither **Hopkins and Knappe's (2024)** method nor CD-RSSCTs need further adjustments to the breakthrough data need to be made to account for the effects of fouling.

RSSCTs provide a more accurate representation of adsorptive media performance, because they are operated under a scaled down HLR and EBCT, unlike the isotherm tests. As such, this is a great option for utilities that are evaluating multiple adsorbent media and want to select the best performing one(s) for further testing. Like the isotherm test, RSSCTs rely on a grab sample of water for completing the test. This means that results are tied to the water quality of that specific grab sample, which may or may not be representative of the water source as a whole or for every season. For this reason, the same grab water sample should be used as the feed water to each media RSSCT column being evaluated to minimize variables during the assessment. RSSCT run times and sample water volumes will vary depending on multiple factors, and typically range from 5 to 90 days and 25 to 55 gallons.

Results of the RSSCT can be applied directly to draw qualitative comparisons between media performance but should not be used in lieu of pilot testing for direct scale-up. RSSCTs capture performance on only a small sample of water from the affected site and may not be representative of long-term trends in water quality. RSSCT theory assumes similitude between the full-size and reduced-size adsorptive media to predict full-scale performance. From a morphological standpoint, this seems a reasonable assumption for GAC because both full-size and reduced-size GAC have been milled and have irregular particle shapes. However, **Abulikemu et al. (2023)** noted differences in specific surface area and surface oxygen content between GACs milled with different grinding methods. Differences in these properties were also observed in different size fractions even with a consistent milling method. Variability in PFAS adsorption in bottle isotherm tests has also been reported to depend on the size of milled GAC particles (**Abulikemu et al. 2025**). The effects of milling might be even more important for IX resins. Full-size IX resin beads are typically smooth, uniform spheres, but milling resin beads changes the morphology to irregular shapes. It is not yet clear how this change in morphology might affect

correspondence between RSSCTs results and pilot-scale IX behavior, though this is being actively studied in academia today.

Many studies have shown discrepancies between RSSCT predictions and pilot or full-scale performance, whereby sometimes they underpredict and sometimes overpredict performance (**Cheng and Knappe 2024**; **Hopkins and Knappe 2024**; **Liu, Liu, and Sun 2024**). This is especially true for IX RSSCTs. The current usefulness of this performance test for IX mostly lies in supporting media selection for pilot studies, rather than in substituting for them. This situation may change in the future as researchers and the water industry continue to research IX RSSCT methods and adsorption mathematical models.

GAC RSSCT test results can be used in tandem with column performance models (for example, AdDesignS) to obtain midrange full-scale bed life predictions for PFAS of interest. This option should be explored for utilities that lack the time or resources to pursue pilot testing. For sites with variable water quality, conducting two RSSCTs (for example, winter versus summer, or wet versus dry) is recommended to capture seasonal variations in testing. Although the accuracy of these RSSCT data–calibrated mathematical models is not as high as pilot testing, it can still provide good information for operations budgeting purposes.

18.3.2.5 Pilot Tests

Unlike the previous two performance tests discussed, pilot testing can provide both media performance comparisons and full-scale bed life predictions accurately for adsorption media. Although more time- and labor-intensive, pilot tests can capture water quality fluctuations, operational complexities such as fouling and backwash frequency, and PFAS removal performance simultaneously. It is important to note that the accuracy of the results will heavily depend on the pilot's design as compared to the proposed full-scale system.

The first step in the pilot testing process is to develop a robust test plan that considers the site's water quality, the media manufacturer's recommendations, and the pilot equipment's limitations. There are six main components to a good pilot test plan: feed-water considerations, media selection, column design, monitoring plan, project timeline, and data analysis. **Table 18-4** summarizes some of the common questions that should be addressed for each component.

As previously mentioned, the accuracy of the results of the pilot test depends heavily on the design of the pilot column, namely the selected HLR and EBCT. For GAC media, there are two main paths for sizing the column—targeting the full-scale HLR or targeting the full-scale EBCT. Both parameters are important in adsorption, with the MTZ length and shape being more strongly impacted by the selected HLR. Although the ideal pilot would match both full-scale parameters, this is usually not feasible in practice due to the larger sized pilot systems and resulting long testing durations required. Note that pilot-scale evaluations are typically scaled using the design or permitted flow for the facility rather than the average day flow.

When the pilot column is designed to mimic the full-scale EBCT, run time to breakthrough tends to be extended and the resulting HLR is usually significantly less than what the full-scale system would experience. This setup may lead to results that overpredict performance. Alternatively, when the pilot column is designed to mimic the full-scale HLR and the pilot column length is less than the full-scale bed depth, run time to breakthrough tends to be minimized and the resulting EBCT is usually a fraction of the full-scale system. Essentially, the media in the pilot column would be representative of a core sample taken from a fraction of the full-scale bed depth (for example, first 3 ft of media of a 12 ft bed depth). Under this scenario, the results may underpredict performance (more conservative) because the column essentially represents a cross-section of the full-scale bed. Although both options can provide good results, it is important to remember that the goal of a pilot test is to achieve contaminant breakthrough (at least 50%) in a reasonable amount of time. Thus, the recommended setup for pilot tests is to size the column matching the full-scale HLR.

Table 18-4. Components of a good pilot test plan[1].

Component	Topics/Questions
Feed Water	• What are the target contaminants for this site? • Are there co-contaminants to consider, and how do variations in type and concentration over time impact performance? • What are the treatment/effluent goals?
Media Selection	• Do you want to test multiple media? • Will different media be used for different contaminants? • Do you want to test multiple flow conditions?
Column Design	• What are the site's design and average flows? • What does the media manufacturer recommend for their media?
Monitoring Plan	• What discharge criteria need to be met, and what limitations apply under various conditional discharge scenarios (for example, irrigation, receiving water body, on-site dust suppression, sanitary sewer)? • What is the analytical budget? • What influent and effluent parameters will be monitored? • What operational parameters will be measured (for example, total flow, pressure drop)?
Project Timeline	• How long will the study last? • Do you need to test under multiple conditions (for example, seasons)?
Data Analysis	• Do you need specialized software to analyze the results? • Have you identified resources for troubleshooting?

[1] Note that this list is not exhaustive and is meant as a general guideline.

Equally important to the column design is selecting the locations and parameters to monitor during the pilot test. For GAC columns, it is recommended to monitor PFAS, as well any co-contaminants or water quality parameters of concern, such as TOC or VOCs. For IX columns, it is recommended to monitor PFAS alongside anions (for example, chloride, sulfate, nitrate) and metals (for example, iron, manganese). If the feed water contains an oxidant or turbidity, those can also be monitored through the study. Pilot-scale columns are typically anywhere between 2 and 6 inches in diameter, meaning the risk of channeling while sampling can be significant. To minimize risk of channeling, remember to collect samples using low flows through the bottom tap of a column. Ensuring that the column diameter is greater than eight times the average particle diameter of the media is also important for reducing channeling and wall effects (**Knappe et al. 1999**). If a pilot test consists of a single column, collecting samples from intermediate points along the column depth would be appropriate provided the column length is sufficiently long to contain the MTZ. Weekly PFAS sampling is recommended, alongside twice a week or weekly water quality monitoring samples. Samples should be collected from both the influent and effluent for proper analysis at the end of the study, and care should be taken to minimize sources of external contamination while collecting samples. Consider collecting samples in the opposite direction of flow for columns installed in series to avoid or minimize cross-contamination.

Once a robust test plan is developed, the next step is to procure the necessary equipment and media for the test. A few media manufacturers can provide piloting equipment, and most will provide their media for testing at little to no cost provided the results for their media are shared. The media manufacturer's recommended loading and startup procedures should be followed to minimize the risk of issues either with pilot operations or data analysis later. Once the system is online, it is important to track the column pressure or pressure drop, flow rate, and throughput daily. Additionally, the column is recommended to be operated to at least 50% breakthrough, because the shape of the breakthrough curve along with the operating parameters monitored daily are essential for determining media performance and scaling up the results.

At the end of the study, the PFAS and operations data should be compiled and used to create breakthrough curves (**Figure 18-2**). When comparing media performance across multiple types of media, it is recommended to modify the breakthrough curves prior to analysis. Instead of using operation time or bed volumes processed in the x-axis, use gallons treated or days in operation instead. The modified breakthrough curves can then be used to accurately compare the performance of tested media.

When the full-scale HLR is matched, this means that there is similitude between the number of bed volumes to initial and 50% breakthrough between the pilot column and the full-scale system. What changes is what one bed volume represents at each scale. For example, 1 bed volume in a 4-inch diameter pilot column with 3 ft of GAC media is approximately 2 gallons of water treated. In a 12 ft diameter, 40,000 lb vessel running at the same HLR, one bed volume is approximately 10,000 gallons of water treated. Therefore, if at the pilot-scale initial detection was at 30,000 bed volumes and 50% breakthrough at 45,000 bed volumes, then those same bed volume values are expected for the full-scale system. The change is that while the pilot treated only 60,000 gallons of water to initial detection (2 gal x 30,000 bed volumes), the full-scale system would instead treat 300 million gallons of water (10,000 gal x 30,000 bed volumes). Care should be taken when trying to compare performance between different sorption media with respect to the number of bed volumes treated before reaching an established breakthrough criterion. An example would be comparing IX and GAC, which typically have significantly different bed volumes. In this case, it is advisable to compare the performance based on a normalized measure such as pounds of media per million gallons treated.

For GAC media, the pilot test results can be combined with mathematical modeling software (for example, AdDesignS) to improve the accuracy of the pilot results and evaluate different flow conditions not investigated at the pilot scale. A few GAC media manufacturers offer this service if the pilot data are shared. Looking at AdDesignS as an example, the modeling software can be calibrated to the site's pilot results using a combination of influent data (which may be variable in time) and x and y points, where x is days in operation and y is percent breakthrough. Once the model is calibrated to the pilot results, it can then be used to simulate full-scale performance for a more accurate estimate to minimize the impact of the pilot design not matching both the HLR and EBCT at full-scale. Additionally, the model can also be used to predict performance at other flow conditions such as minimum day flow, average daily flow, and peak hourly flow. These additional simulations can provide important information regarding yearly carbon usage for a more well-rounded life cycle costs assessment. Note that the media manufacturers who supplied the media for pilot testing can provide budgetary price for media disposal, which should be considered during the LCA. Other items that should be considered when comparing pilot test results are operability (for example, frequency of backwashing), site requirements (for example, footprint), and complexity (for example, operator training), among others.

18.3.2.6 Multi-media Pilot Tests

New multi-media treatment processes are being considered now for PFAS applications. One such novel approach is GAC followed by IX resin. The idea behind this combination is for the GAC media to protect the downstream IX media (for example, oxidants, metals, organic compounds, biofouling), thus extending the life of the more expensive IX media with respect to PFAS. In these full-scale systems, the GAC media is exchanged at a predetermined breakthrough point, and the IX resin is kept as a polisher vessel rather than rotate vessel positions. The operation of these dual media systems is complex, because it requires more monitoring and more care when operating the system. Pilot testing these novel configurations can provide some insights into full-scale performance but typically cannot be properly scaled up. This is because the pilot test would require the GAC media column to be replaced at the predetermined breakthrough point each time it is reached to truly evaluate the bed life for the IX media. Because fresh GAC media is placed online at regular intervals, the timeline for these projects typically exceeds the available time a site has. So, while the pilot may not directly yield the expected bed life for the IX media within the project timeline, it can provide confirmation that the IX system works as intended along with a

conservative estimate of the minimum expected bed life. It can also provide information on how well the GAC protects the IX media, and how often the GAC media may need to be exchanged.

18.3.2.7 Full-Scale Demonstration Tests

Although rare, full-scale demonstration tests can be conducted to determine the effectiveness of an adsorptive media for PFAS removal. This style of testing is typically used after one adsorptive media has been selected and installed and is more commonly seen with GAC media. Remediation systems commonly go through an initial startup process to verify treatment system performance and to monitor the impact of geochemical parameters on the operation of the system. During this process, more thorough monitoring and testing is commonly conducted than during the long-term operational program. For example, sorption beds that have multiple sample taps along their depths can be sampled initially to gauge how quickly the bed is exhausting. After the media usage rate has been adequately characterized, the number of sample locations within a sorption bed and sampling frequency may be reduced.

The two most popular types of full-scale demonstration tests in drinking water treatment are gravity filters and potable reuse demonstration pilots. Usually located at drinking water treatment plants that use surface water sources, gravity filters remove turbidity through physical means and are usually filled with a mix of gravel, sand, and anthracite. Sites with taste and odor issues or elevated disinfection byproducts may have already made the transition to replacing the anthracite layer with a GAC layer. With the new PFAS MCLs and the fact that GAC can simultaneously remove multiple contaminants, these utilities are now evaluating the performance of their gravity filters for PFAS removal. If the plant has the redundancy to run without one filter, then a full-scale demonstration test can be conducted to determine the effectiveness of the GAC media for PFAS removal (**Prein & Newhof 2019**). The redundant filter can be retrofitted with GAC media and run in parallel with existing gravity filters (control) to compare performance and estimate bed life.

Gravity filter tests need to be designed with the understanding that there will be inherent limitations that will impact the variables able to be modified. One is the space available for the GAC media—the design must maintain enough freeboard between the top of the expanded bed (backwash) and the bottom of the trough. Another is any hydraulic constraints (for example, pressure drop, run time) for the system that may be impacted by a change in media type, media depth, or media mesh size. Although HLR tends to be low in gravity filter applications, the main limitation in these filters is the limited EBCT. Thus, gravity filter test plans should be reviewed and the media manufacturer consulted prior to determining the maximum bed depth and media type that can be used for the study.

Once the media type and bed depth are decided and the media is loaded and backwashed, the test can begin. Like with pilot testing, both sampling and operations data are key to a successful performance analysis in the end. Throughout the study, influent and effluent PFAS (and other constituents of concern) should be monitored frequently (for example, twice a week). Because one of the main goals of filtration in the drinking water treatment process is turbidity reduction, turbidity is another parameter that should be monitored throughout the test. The operating parameters to monitor are flow rate, throughput, and pressure drop. Alongside pressure drop, the frequency of backwashing or filter run time should also be noted and compared to the existing gravity filters.

Because the gravity filter is already full-scale size, the results of the test do not need to be scaled up. However, the data from the test can also be analyzed using AdDesignS to estimate the performance at other set points for the media tested. Note that while the modeling software can provide breakthrough estimates under different scenarios (for example, flows, bed depths), it cannot predict any operability impacts (for example, run time, turbidity). Thus, it is recommended that the design that is selected for the demonstration test be the one that may produce the greatest impact on the operability of the filter. That way, both impacts on operability and PFAS removal performance can be captured and any subsequent

modeling for PFAS will be for scenarios whose operability impacts are minimized. Note that when it comes to PFAS treatment, gravity filter retrofits may not be an economical solution for the site.

The other type of full-scale demonstration test to be discussed in this section is potable reuse pilots, which may use any of the discussed adsorptive media in the market. These pilots tend to use large-scale systems, and sometimes even involve entire setups or buildings where stakeholders can tour the facility and learn about the study. In these situations, large-scale sorptive media beds may be used as tertiary treatment processes that are in part targeting PFAS removal from wastewater effluent. The media manufacturer's guidelines for recommended HLR and EBCT should be followed when designing these demonstration pilots. Once in operation, the same parameters listed for gravity filter demonstrations should be monitored in these systems. The results may or may not need to be scaled up, depending on the size of the system selected for the test. Similarly to gravity filter tests, the results can be coupled with AdDesignS for further analysis.

In exceptional cases, it may be possible to use existing GAC adsorbers already in place for VOC removal to test PFAS removal efficacy at scale. However, this is usually not practical because of issues such as differences in needed EBCT and media change-out frequency.

It is important to note that full-scale systems, once online, should be routinely monitored not just for compliance, but to verify that the system is operating as designed. Changes in water demand that required higher flow rates through the filter or changing water quality (for example, PFAS species change, chemical spill, spikes in TOC) can impact the performance of the system. Therefore, keeping track of operations data (for example, flow rate, throughput, pressure drop) and influent and effluent sampling results is important. Media manufacturers should be able to provide guidance and troubleshooting help should the water quality or flow rate change, provided there is data available for them to review and analyze.

18.3.3 Fate of Spent Media and Treatment Residuals

The 2024 USEPA disposal and destruction guidance for PFAS-containing wastes lists landfilling and thermal treatment as established options for managing PFAS-laden waste streams (**USEPA 2024**). However, with an anticipated upcoming increase in GAC and IX resins use in municipal drinking water and industrial wastewater systems, additional disposal options may be warranted. Off-site GAC reactivation and on-site IX or GAC regeneration can reduce demand for virgin media, as well as operating costs and energy usage. Media reactivation and regeneration is addressed in more detail in **Section 18.3.1.7**.

Landfilling of PFAS-laden waste streams sequesters PFAS for a limited time, and landfills can serve as a short-term or medium-term source of PFAS to the environment through landfill gas and leachate (**Lin et al. 2024**). Costs vary depending on the type of landfill used. Municipal solid waste landfills have tipping fees of $40–$80 per ton (**USEPA 2024**). Costs for disposal in hazardous waste landfills is in the range of thousands of dollars per ton, similar to costs for hazardous waste incineration (**USEPA 2024**). For GAC containing PFAS, reactivation may be more economical depending on the distance between the source and the nearest GAC reactivation facility. The type of landfill used depends on regional requirements by landfill operators, with some municipal solid waste landfills choosing to not accept PFAS-laden spent media.

High-temperature incineration can be used to destroy PFAS-laden spent media, with about 20 facilities operating in the US. These facilities primarily operate as hazardous waste incinerators or cement kilns (**USEPA 2024**). A temperature of 1,100°C is typically considered high enough for PFAS mineralization, but lower temperatures may be sufficient under certain operational strategies and retention times (**Winchell et al. 2024**; **Wang et al. 2022**). PFAS destruction also depends on the contact time at these temperatures and the amount of turbulence within the incineration unit. Disposal fees for these facilities are typically in the range of $1,300–$1,900 per ton (**USEPA 2024**). Uncertainties remain regarding the final fate of all

PFAS given the lack of analytical capabilities to fully close the fluorine mass balance (**Wang et al. 2022**). In addition, some jurisdictions have limited incineration of PFAS-containing wastes (Illinois, New York, and the Department of Defense), leading to regulatory uncertainty around this disposal option.

Although SCWO is a field-implemented destruction technology, a new application for direct disposal of spent GAC and IX resin is being pilot tested. SCWO has the potential to be energy-neutral or energy-positive because of the high energy content in spent media. Lab tests to date have demonstrated over 99% removal efficiency of targeted PFAS (**Chiang et al. 2023**). Piezoelectric ball-milling has also been shown to destroy PFAS on spent IX resins (**Zhu et al. 2025**), but application of this technology is still in an early stage of development.

Spent regenerant from GAC and IX regeneration can undergo liquid treatment technologies to achieve PFAS destruction. The process concentration factors achieved by regeneration of IX resins depend upon treatment goals and matrix but can be as high as 30,000 (**Higgins et al. 2025**). Because of the high degree of concentration achieved via the adsorption and regeneration processes and the very high PFAS concentrations that result (mg/L range), still bottoms represent a low volume, high strength waste stream that can be treated via a PFAS destruction process. A high degree of PFAS destruction (>99%) has been demonstrated when applying PFAS destruction technologies, including electrochemical oxidation (**Liang et al. 2022**) and nonthermal plasma (**Singh et al. 2020**; **Higgins et al. 2025**), to the concentrated still bottoms matrix. High salt and organic matter content of the still bottom can limit the reaction kinetics of some destruction technologies, including plasma, electrochemical oxidation, and UV-based reduction systems (**Liang et al. 2022**). HALT treatment of PFAS in high ionic strength solutions similar to still bottoms has shown efficient and complete degradation of PFAS (**Pinkard et al. 2024**). There are ESTCP and Defense Innovation Unit Projects currently evaluating destruction of PFAS with HALT and SCWO in still bottoms (for example, ER23-8400, ER23-8434, ER23-8398, ER23-8435) with final reports expected in 2026. **Hagelin et al. (2022)** investigated distilling the alcohol from the spent regenerant with very little PFAS carryover. Other technologies being evaluated at lab-scale and pilot-scale for IX regeneration and PFAS destruction include using advanced reduction processes (**Cui and Deng 2023**). However, a study by **Liu et al. (2025)** applied advanced reduction processes to solutions containing highly PFAS-selective IX resins. They noted less effective PFAS destruction than was observed by **Cui and Deng (2023)**, suggesting that direct use of advanced reduction process on solutions containing PFAS-selective IX might be less efficient than using the advanced reduction process on regenerant solution.

18.4 Foam Fractionation

This section is an extension of **Section 12.2.3** and the case studies presented in **Section 15.2.4**. It is recommended that readers who are not familiar with foam fractionation familiarize themselves with that material before proceeding with the material presented in this section. Foam fractionation for the separation of PFAS can be applied either in situ or ex situ. However, as mentioned in **Section 18.1**, this guidance is focused on ex situ applications of sorption-based treatment. Although some of the material presented may also be applicable to in situ foam fractionation, this section is intended to cover only ex situ foam fractionation. Additional information on the progress to field-demonstrate and validate in situ foam fractionation is available under the ESTCP research project ER21-5124 and **Reynolds, Nelson, and Danko (2024)**.

In this document, foam fractionation means any adsorptive bubble separation technique in which amphiphilic substances (in this case PFAS) are adsorbed onto a gas-water interface that is then separated from the bulk liquid. Despite the name “foam fractionation,” this can be accomplished with and without the presence of a stable foam. There are several commercially available methods of foam fractionation using a variety of gases (for example, air, ozone) and flow-through configurations (for example, batch, countercurrent flow). This section is not intended to provide details of all foam fractionation configurations but to provide a general overview of factors to consider and tools to assess performance.

Foam fractionation may be used for a variety of liquid media. Below are some applicable/nonapplicable matrixes based on currently available systems. Advances in foam fractionation may enable treatment of nonapplicable matrixes in the future.

Applicable:

- Groundwater and surface water. When targeting these matrixes, water may not readily foam upon aeration, and additional foaming additives may be needed. Foam fractionation should be considered for waters, such as those impacted by AFFF, or water with substantial concentrations of organics or ions that may affect other sorptive technologies. Foam fractionation vendors may have typical PFAS concentration thresholds for cost-effectiveness in comparison with fixed-bed sorption media.

- Landfill leachate. Leachate typically foams readily due to other constituents and may be an ideal matrix for foam fractionation. It typically contains high concentrations of organics and salts that impede other separation technologies.

- Process water. There are various process waters from a variety of sources with disparate characteristics. Foam fractionation is well suited to process waters with high PFAS concentrations, those that foam readily, or those containing co-contaminants that affect other sorptive technologies.

- Soil wash water. Foam fractionation has been used to remove PFAS from soil wash water. Depending on the concentrations and the source of the wash water, foaming additives may be needed to enhance PFAS removal. After foam fractionation, wash water can be reused for subsequent washes or discharged.

- Reverse osmosis (RO) reject water. Foam fractionation is well suited to RO reject water, because it typically has higher PFAS and salt concentrations than the RO feed water, both of which can improve the efficiency of foam fractionation for PFAS removal. The preconcentration of salts can reduce the efficiency of other sorptive technologies but has been shown to assist in PFAS removal by foam fractionation.

- Drinking water. Although it may not be cost-effective for low PFAS influent streams, there are other considerations (such as media disposal and site access) that may make it suitable for some drinking water sources. These waters may not readily foam and additives may be needed. As with any drinking water system components and treatment chemical additives, foam fractionation system materials of construction and foaming additives should be selected carefully to ensure compliance with drinking water regulations such as National Sanitation Foundation (NSF)/American National Standards Institute (ANSI) standards certification requirements.

- Pretreatment to remove bulk PFAS. As discussed below, foam fractionation can be useful as a component of a treatment train to cost-effectively remove high concentrations of PFAS prior to a downstream polish using other sorptive media.

- Sewerage water. Due to the high concentrations of solids and organics, PFAS are difficult to remove from sewerage without significant pretreatment. Foam fractionation can remove PFAS from this matrix with minimal pretreatment, but high solids and biological loading may increase maintenance requirements.

- Oily waters (with pretreatment to remove oils).

Nonapplicable:

- High AFFF solution (>10 ppm PFAS). AFFF solutions with a high proportion of AFFF generate too much foam to effectively concentrate PFAS through foam fractionation. These waters are typically sufficiently enriched in PFAS for direct disposal or destruction without the need for concentration through foam fractionation.

- Liquids with densities greater than 1.15 (sludges with percent solids of 1% or greater). Dense liquids make it difficult to introduce air and generate sufficient foam to remove PFAS. Pretreatment would likely be required to remove solids prior to foam fractionation.

- Oily waters (without pretreatment to remove oils). The presence of nonaqueous phase liquid (NAPL) can impede PFAS removal by foam fractionation. NAPL creates a multiphase system with water and air that prevents PFAS from readily sorbing to the surface of air bubbles, limiting removal. Pretreatment to remove oils and grease (for example, an oil-water separator) is needed prior to foam fractionation.

There are several advantages and disadvantages to foam fractionation when compared to other sorptive technologies (for example, GAC and IX resin), and these should be considered when evaluating implementation of a sorptive-based remedy for PFAS treatment. In contrast to other sorptive technologies, foam fractionation does not require a solid adsorptive media; the PFAS sorb to rising air bubbles, which produces a PFAS-enriched liquid waste. This is a particular advantage for sites with limited capacity for managing large volumes of solids, or other logistic challenges. Because there is no physical sorptive media to be spent during PFAS removal, foam fractionation can be advantageous for aqueous matrixes with high PFAS concentrations that would rapidly break through other forms of sorptive media. This can provide cost savings even if GAC/IX resin are used downstream of foam fractionation. Foam fractionation is further advantaged over media systems for water sources with complex matrixes due to minimal pretreatment requirements for many co-constituents, potentially lowering cost and footprint required to address PFAS treatment needs. Foam fractionation systems can have a smaller footprint than comparable GAC or IX resin systems due to the lack of physical media. However, current commercial offerings tend to have limited throughput capacities and cannot be scaled as easily as media-based sorption technologies. Overall, foam fractionation is usually considered for sites with PFAS concentrations greater than 100 ng/L and flow rates less than 0.2 million gallons per day, or for waters with high co-contaminant loadings and projects where the logistics of handling spent physical media are of concern. Higher flow rates are currently achievable by installing multiple units in parallel. Advances in foam fractionation, including larger vessels, are expected to be available soon, enabling higher throughput systems.

18.4.1 Technical Overview

18.4.1.1 Bubble PFAS Adsorption

Foam fractionation and its derivative approaches (for example, bubble fractionation and aerosol fractionation) use the amphiphilic nature of PFAS typically comprising a hydrophilic functional head group and a hydrophobic tail group. The adsorption coefficient necessary for uptake onto a gas-liquid interface, such as a swarm of rising bubbles generated most economically from ambient air, is influenced by several factors.

Different PFAS are adsorbed by air bubbles at different rates and through different mechanisms (**We et al. 2024**). For example, long-chain PFAS are removed rapidly in the process of foam fractionation because of their greater adsorption coefficients. In contrast, short-chain PFAS are less readily removed due to their lower affinity and adsorption coefficient for gas/liquid interfaces, such as air-water surfaces provided by gas bubbles (**Burns, Stevenson, and Murphy 2021**; **Wang et al. 2023**; **Smith et al. 2022**; **Dai et**

al. 2019). See **Table 2-3** for the definition of long- and short-chain PFAS. Various gases can be used in foam fractionation. Air is typically used due to its low cost, but ozone and nitrogen have also been used as gas streams for foam fractionation (**Dai et al. 2019**; **Vo et al. 2024**; **Burghoff 2012**). The use of ozone may offer some benefits such as reductions in waste volumes, smaller bubble sizes, and the oxidation of precursor PFAS and/or organic co-contaminants. However, using ozone also has drawbacks, such as higher costs, production of byproducts (for example, bromate), lower total PFAS removal, and production of additional PFAS degradation products (for example, perfluorobutane sulfonamide [FBSA]) (**Vo et al. 2024**; **Dai et al. 2019**). There is limited information available on the use of nitrogen in foam fractionation for PFAS removal, but it has been used in other applications to prevent oxidation of metals or precursor PFAS (**Burghoff 2012**).

18.4.1.2 Bubble Separation

During foam fractionation, bubbles, along with adsorbed PFAS, rise to the surface of the bulk aerated water column and may be separated/concentrated in a single process step from the original contaminated water matrix with or without added co-surfactant to assist in removal of PFAS molecules with low adsorption coefficients (**Stevenson and Karakashev 2024**; **Lee and Venkatesan 2024**). Foam fractionation, contrary to its name, does not always require foam. In some cases, a stable foam is not produced but PFAS can still be accumulated and captured in an aqueous layer or as aerosols at the top of the column or vessel (**Nguyen et al. 2024**; **Stevenson and Karakashev 2024**).

While the column is being aerated to generate bubbles, the highly aerated liquid or foam concentrate is harvested from the foam fractionation vessel by a spillover weir, a real-time vacuum, displacement by clean water, or other means to collect the separated PFAS (**We et al. 2024**). The harvested foam containing concentrated PFAS is called foamate or concentrate. Once harvested, the foamate/concentrate can be collapsed into a liquid concentrate for enrichment, additional treatment, or disposal. Destructive treatment and disposal of foam concentrate is covered in **Section 18.4.3**.

18.4.1.3 Fractionation Enhancement

Additives, such as co-surfactants, can enhance the removal of PFAS during foam fractionation, with substantial improvement in the removal of short-chain PFAS (**Stevenson and Karakashev 2024**; **Lee and Venkatesan 2024**; **Buckley et al. 2023**). Because most regulated PFAS are anionic, cationic surfactants can associate with these PFAS to form complexes that are more readily removed. Surfactants can also help stabilize the foam layer to increase PFAS removal during foam harvesting and reduce the amount of water in the foamate. Nonionic and biologically derived surfactants have also been shown to improve PFAS removal and may be more biodegradable and have lower threshold ecological toxicity values (**Malovanyy, Forsén, and Lihammer et al. 2025**; **Ziaee, Ziaee, and Taseidifar 2021]**). Polymers, metals, and electrolytes have also been examined as potential foam fractionation additives (**Buckley et al. 2023**; **Buckley et al. 2022**; **Ziaee, Ziaee, and Taseidifar 2021**). Most foaming additives (for example, surfactants) are typically removed during the foam fractionation process and are concentrated in the foamate. However, residual co-surfactant additives may be present in the treated water and evaluated for acceptance with applicable limits. Low dosages (1 mg/L or less) of co-surfactants have been shown to enhance removal of four-carbon-chain-length PFAS, with removal rates greater than 98% for some waters (**Lee and Venkatesan 2024**; **Buckley et al. 2023**). Research (SERDP Project ER23-7892) is being conducted on the use of colloidal gas aphrons (microbubbles encapsulated by surfactant multilayers) to increase the surface area of supplied air-water interfaces, targeting both long- and short-chain PFAS. This method requires substantial amounts of co-surfactants to function effectively, and the process has challenges achieving trace-level removal criteria, which may be due to aphron bubble size (**Kulkarni et al. 2022**).

18.4.1.4 Operational Modes & Multistage Concentration

Some operational method variations among foam fractionation vendors are important to understand and consider, and all modes may not be applicable to every vendor. Foam fractionation has been implemented in batch, semibatch, and continuous configurations (**Figure 18-4**) (**Buckley et al. 2021**; **Burns, Stevenson, and Murphy 2021**; **Malovanyy, Forsén, and Lihammer 2025**). Continuous configuration may be either co-current or countercurrent (**Smith et al. 2022**; **McCleaf, Kjellgren, Ahrens 2021**). Under a continuous countercurrent configuration, a portion of the foam generated in a downstream column can be transferred into the upstream column to increase PFAS concentration, mass transport, and net PFAS removal efficiency. The last stage acts as a polishing step to achieve treated water concentration requirements. Foam fractionation may also be designed in single fractionation, twin fractionation, triple fractionation, or multifractionation stages in series, in parallel, and a variety of other configurations. Designs may include a primary stripping stage (does not require the formation of foam) to reduce PFAS to satisfy adopted criteria, followed by subsequent stages that enrich the primary fractionation waste stream to minimize waste destruction volumes. In other configurations, multiple enrichment stages are applied in series to gradually remove successive amounts of PFAS and enrich the waste volume. Additional stages of foam fractionation columns can be used to process the foamate and further concentrate PFAS to a desired level. Effluent water from secondary and tertiary stages can be recirculated back to prior stages for additional removal. For smaller volumes of water, it is also possible to operate a single column or vessel in a batch mode as either a primary or secondary stage.

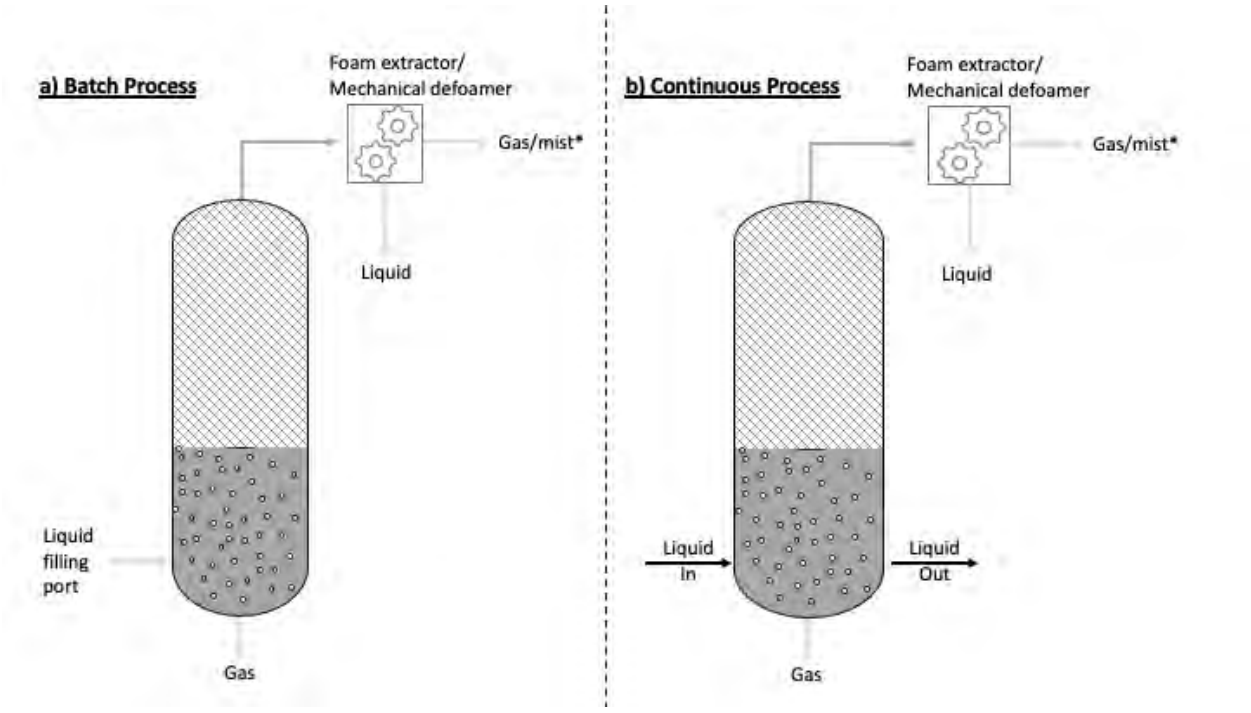

Figure 18-4. Diagram comparing batch (a) and continuous (b) foam fractionation processes. (*) Gas/mist may require monitoring or additional treatment for VOCs or PFAS.

Source: Drawing by Dr. Pradeep R Shukla, Aquarise Innovations.

Batch and semibatch foam fractionation takes place in a vessel that is filled with the water to be treated. Gas is introduced in the bottom for the duration of the treatment batch, and after the foamate is recovered, the treated water is discharged from the vessel (**Burns, Stevenson, and Murphy 2021**; **Malovanyy, Forsén, and Lihammer et al. 2025**). Continuous foam fractionation typically uses a vertical

column with water flowing countercurrent to the air stream. PFAS are removed by the bubbles into a foamate while the treated water is continually discharged (**Smith et al. 2022**; **McCleaf, Kjellgren, Ahrens 2021**). Management of foamate is presented in **Section 18.4.3**.

Most foam fractionation vendors operate traditional systems requiring the creation of a foam. When the feed-water chemistry lacks sufficient amphiphilic substances such as medium/high PFAS concentrations or other non-PFAS surfactants, the vendor's foam fractionation solutions typically add several foaming additives (for example, surfactants) to prevent depletion of amphiphilic substance during foam fractionation to maintain foam generation (**Buckley et al. 2022**; **Malovanyy, Forsén, and Lihammer et al. 2025**; **Klevan et al. 2025**). Alternatively, countercurrent operation can be used to increase foamability by transfer of foam generated in a downstream column into the upstream column, increasing the steady state concentration of surface-active species in the initial treatment stages (**McCleaf, Kjellgren, and Ahrens 2021**). Other commercialized foam fractionation systems have demonstrated effective removal of legacy PFAS without any froth/foam creation where the vendor system operates in either bubble fractionation mode or aerosol fractionation mode (**McCleaf, Kjellgren, and Ahrens 2021**; **Morrison et al. 2023**; **Nguyen et al. 2024**). Application of bubble separation techniques allows high levels of PFAS removal from nonfoaming waters.

For example, if the concentration of PFAS in the water to be treated is high and readily foams, then foam fractionation with normal aeration and vessel fill volumes is typically applied. If the subject water excessively foams, then reduced aeration or mixing various waste streams can be considered to bring the foaming range into the optimal operation range to remove the PFAS from treated water. Either way, the objective is to create a column of aerated water underneath a foaming phase on top. In bubble fractionation, the vessel fill volume is typically higher than with less foaming water. The nature of low-foaming waters prevents bubbly liquid from forming a froth/wet foam or dry foam via interstitial drainage, but higher vessel fill volumes (lower air/water ratios) result in very little frothing but removal of PFAS as bubbly liquid collected from the fractionation vessel (for example, by spilling over the primary fractionation weir). Bubble fractionation typically achieves lower treatment results compared to traditional foam fractionation because bubble fractionation does not provide an opportunity for froth to climb a froth/foam chimney (air gap) to drain interstitial liquid, which may carry residual PFAS, back into the aerated bulk subject water. Bubble fractionation also results in a wetter foamate, resulting in lower volumetric concentration factors. The lower volumetric concentration factor is not necessarily an indicator of PFAS removal but does increase the volume of foamate that needs to be treated or disposed of. The foamate volume generated is variable and depends on the foamability of the water being treated.

PFAS removal mechanisms during foam fractionation vary, and multiple mechanisms may contribute to PFAS removal depending on the water being treated and the specific foam fractionation equipment used. For example, some waters may exhibit significantly reduced bubble formation at the top of the aerated water column when treated in the usual manner. In such cases, aerosol fractionation may be the primary PFAS removal mechanism while bubble fractionation or foam formation may be less important. To enhance aerosol fractionation, vessel fill volume can be set low in a wide-body primary fractionator, reducing aeration and creating smaller bubbles that burst, forming aerosol fragments for condensing back into a liquid foamate. This method has been shown to remove long-chain PFAS if the fractionator can be operated to avoid creating a foam blanket that would capture aerosols before they can be condensed.

18.4.1.5 Pretreatment Considerations

For most waste streams, foam fractionation can be operated with little or no pretreatment and used as a stand-alone PFAS removal technology or incorporated into a treatment train (**Burns, Stevenson, and Murphy 2021**; **Sochacki, Michorczyk, and Vogt 2025**). Because there is little pretreatment required, a foam fractionation treatment process can be placed nearly anywhere in a treatment train. Ideally, foam fractionation placement prior to the generation of organic solids would be of great benefit as the

separation of PFAS during foam fractionation may limit the amount of PFAS that sorbs onto settleable solids. However, in some circumstances this may be problematic. For example, using foam fractionation to treat raw sanitary sewage may result in the generation of odors, and placement as a tertiary process after secondary treatment may be warranted. If odor is the only concern for the placement of the foam fractionation system, it can be mitigated by the design of off-gas recirculation or treatment as discussed below.

Most co-contaminants or impurities that affect solid phase sorption-based treatments (for example, metals, salts, and organic carbon) do not affect the efficiency of PFAS removal by foam fractionation, and in some cases, may enhance foaming and/or PFAS removal (**Buckley et al 2022,**; **Smith et al. 2023**; **Wang et al. 2023**). However, there are exceptions. The presence of suspended solids in the liquid sometime hinders complete PFAS removal. Suspended solids, especially carbonaceous materials, tend to adsorb PFAS to achieve an equilibrium between the PFAS concentration in the liquid and solid phase. These trapped PFAS are not removed during the foam partitioning and get carried over in the treated liquid (**We et al. 2025**). Operational strategies, including air injection rate modification and chemical addition, may be used to enhance the capture of suspended solids within the foamate to alleviate this concern. Another exception is measurable oil and grease or NAPL due to interactions between the air-water and NAPL-water interfaces (**Brusseau 2021**). Where oil and grease are present, an oil-water separator or other pretreatment is recommended prior to foam fractionation to bring the total oil and grease (TOG) concentration below 100 ppm. Dissolved air flotation may also be used for pretreatment to remove oils and grease (**Al-Shamrani, James, and Xiao 2002**).

Certain pollutants such as benzene, mercury, and other VOCs in the influent liquid will trigger the emissions impact assessment. The air or gases emitted from the treatment process could contain high levels of volatile pollutants due to the partitioning of these pollutants from the liquid phase to gas phase. Hence, a complete assessment of the influent liquid chemistry needs to be undertaken to ensure a proper design of the emissions management process. The foam fractionation process can also generate mist in the exhaust air, which can emit pollutants, including PFAS, into the atmosphere. Effective mist elimination, treatment, or recirculation systems should be evaluated and could include the use of demisting pads, a cyclonic demister system, and/or sorbent beds or canisters.

Although metals are unlikely to impact PFAS removal during foam fractionation, the aeration of water during treatment may affect redox-sensitive metals (for example, iron and manganese), which may precipitate as solids. The buildup of solids from precipitated metals, salts, and carbonates may increase the maintenance of foam fractionation equipment so the cost and benefits of additional pretreatment should be considered.

Foam fractionation aeration rates are not usually sufficient to replace other treatment (for example, air stripping) for the removal of volatile constituents from the aqueous stream, but the potential for these contaminants to be present in air emissions should be considered. Pretreatment or treatment of gaseous emissions can mitigate the release of volatiles.

18.4.1.6 Operational Considerations

During the design and operation of foam fractionation systems, there are numerous factors to consider that may affect PFAS removal and waste generation for a particular water stream. Some factors are applicable when selecting a particular piece of equipment while others can be adjusted during operations. When selecting equipment, there is a tradeoff between flexibility and capital cost that should be considered. Adjustable operating parameters may be proprietary, but they generally include:

- Batch vs. semicontinuous batch vs. continuous flow operation
- If batch or semicontinuous batch, the batch duration

- If continuous or semicontinuous, the flow direction (countercurrent or co-current), effluent location (for example, top, middle, or bottom), and overhead pressure
- Liquid level in the vessel
- Influent and effluent flow rate
- Type of gas used
- Volume of gas, velocity and turbulence of gas, size of the subsequent bubble once introduced to liquid
- Method of removing and handling PFAS concentrate within the system
- Number of active treatment stages in the multistage process with bypass feature
- Co-surfactant chemical feed dosage for enhanced PFAS removal, if used
- Additive chemical feed dosage to increase unit process flow, if used
- Off-gas treatment (if needed)

There is sometimes a tradeoff between concentration/enrichment factor and PFAS removal efficiency: Higher gas flow rates and additive dosing can increase PFAS recovery, but lower enrichment, leading to larger waste volumes (**Sochacki, Michorczyk, and Vogt 2025**; **Comfort et al. 2025**; **Klevan et al. 2025**; **Klevan et al. 2025**).

When selecting and optimizing a foam fractionation system, it is important to consider the feed water being supplied. If the feed water is seasonal or intermittent, batch or semibatch systems may provide flexibility if sufficient storage is available to equilibrate flow during high flow periods. Generally, these systems are not negatively impacted by downtime and can be restarted when feed water is available. As with any water treatment equipment, certain parts (for example, pumps, valves, and seals) should be regularly exercised or maintained during prolonged shutdowns.

When starting a foam fractionation system, there is typically a period of optimization during which there may be inconsistencies in treatment and, potentially, lower PFAS removal (**Burns, Stevenson, and Murphy 2021**; **Malovanyy, Forsén, and Lihammer et al. 2025**). Depending on the purpose of treatment and the requirements for discharge/use, it may be necessary to temporarily store treated water during optimization. This water can then be reprocessed after the system has been optimized and its capability to meet discharge requirements has been documented.

Like all water treatment equipment, foam fractionation systems require periodic cleaning and maintenance and may need to be fully drained for long-term storage or relocation. These activities may require storage and disposal of PFAS-impacted waters if there is not available alternative treatment on-site. If the shutdown is temporary, these waters may be stored and processed through foam fractionation when the system is restarted.

Seasonal variations in air and water temperatures are unlikely to affect foam fractionation performance. **We et al. (2024)** found no significant impact of temperature on long-chain PFAS removal, although there may be a slight improvement in short-chain PFAS removal at lower temperatures, but there have been limited studies on this subject.

18.4.1.7 Air Emissions

Releases of PFAS to the atmosphere from the foam fractionation process through volatilization or aerosolization are a concern but may be controlled. Volatile PFAS can be stripped from water and transferred to the vapor phase. Most PFAS of interest have low volatility, so minimal volatilization is expected. Vapor phase controls (for example, vapor-phase GAC) can be included to reduce emissions. Other volatiles (for example, VOCs) can also be stripped during foam fractionation and may require additional vapor phase controls. PFAS in air emissions can also be adsorbed to particulates or entrained in aerosols (**Smith et al. 2023**; **Lee and Venkatesan 2024**; **Nguyen et al. 2024**). These can be mitigated by the design of the system or additional controls such as filters, moisture traps, or knockout pots with

consideration for humid fractionation reactor conditions. Additional information regarding air treatment methods can be found in **Section 12.5** . Some systems have been configured so gases from fractionation vessels are reintroduced into the system. This could lead to the buildup of volatiles in the system if they are present in the water to be treated. The use of monitoring and controls to mitigate any associated risks may be needed. Some systems have been configured so gases from fractionation vessels are reintroduced into the system. This could lead to the buildup of volatiles in the system if they are present in the water to be treated. The use of monitoring and controls to mitigate any associated risks may be needed.

Long-chain PFAS (for example, PFOS, PFOA, PFHxS) can also be generated as aerosols, where small micro/nano bubbles (including macro bubbles) are allowed to burst at the top of the bulk aerated foam fractionation column in the absence of any froth/foam blanket or other mechanical/physical blanket, which would serve to entrap such aerosols (**Lee and Venkatesan 2024**; **Nguyen et al. 2024**).

Air toxics regulations and analytical methods should be evaluated and considered. The ITRC PFAS Air Criteria Table (**PFAS Environmental Media Values Table Excel File)** can be referred to for applicable standards and guidance values for PFAS in air.

In the United States in August 2024, New Jersey, New Mexico, and North Carolina petitioned the USEPA to designate PFOS, PFOA, PFNA, and HFPO-DA (GenX) as hazardous air pollutants, to be regulated under Section 112 of the Clean Air Act.

Section 11.1.7.12 provides sampling procedures for air emissions to air and ambient air, and **Section 11.2** provides additional information regarding USEPA Other Test Method 45 (OTM-45), *Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources, Revision 1* (**USEPA 2024**), and Other Test Method 50 (OTM-50), *Sampling and Analysis of Volatile Fluorinated Compounds from Stationary Sources* (**USEPA 2024**). These could become a future cost driver or consideration as USEPA is increasing testing and developing new methods. For smaller emissions sources, such as the currently available foam fractionation systems, the sample collection protocols in OTM-45 may not be practical or cost-effective. Alternative, non-isokinetic sampling methods, such as those based on USEPA Method TO-13A (**USEPA 1999**), have been independently developed for some applications.

18.4.2 Performance Evaluation

Because PFAS adsorption mechanisms may vary for different water types and foam fractionation equipment, bench and pilot testing are recommended to assess potential performance and optimal operating parameters, which may include:

- The performance of different gas types (air, ozone, nitrogen)
- Bubble sizing
- Air flow rates
- Batch treatment times or hydraulic residence times
- The use and dosage of co-foaming additive(s)

Table 18-5 and subsequent sections describe some of the performance testing that can be completed to aid in the selection and design of foam fractionation systems. When evaluating foam fractionation, practitioners should consider these key questions and their purpose:

1. Is the liquid material to be treated listed as “applicable” or “non-applicable” in **Section 18.4**? This will help set the expectations for the potential to remove PFAS and determine treatment objectives; greater PFAS removal would be expected in applicable liquids.

2. Is there excessive foaming, insufficient foaming, or lack of bubble formation of site water upon conducting lab bench-scale feasibility testing? The foaming characteristics of the water will help determine the predominant PFAS removal mechanisms and corresponding foam fractionation equipment selection and operating settings. They can also determine the need for foam management/suppression systems or indicate the need for non-PFAS-containing foaming additives to enhance PFAS removal.

3. Is there a site history of anti-foaming agent usage (for example, to wastewater or leachate) or use of foam application to manage offensive odors (for example, landfill odor management)? This information will help clarify the expected quality and quantity of foam formed and the considerations in item 2 above (for example, anti-foaming agent presence in the liquid may hinder effective foaming rates, and conversely, the same may be true where foaming agents were used for odor or mist suppression.

4. How stable is the foam (for example, what is the foam collapse rate, such as millimeters of foam height drop over 2 minutes, measured during lab bench-scale feasibility testing, or the concentration of methylene blue–active substances in the liquid)? This can be used to determine whether the foam is stable or transient and can affect how foamate is managed after foam fractionation.

5. What is the optimal liquid height in the foam fractionation column? This will affect PFAS removal rates and overall system throughput.

6. What is the optimal aeration rate and pattern? The pattern of aeration and overall aeration rate can affect PFAS removal rates and the overall quantity of foamate generated. By tuning the system to optimal aeration rates and patterns, including pulsing or stepwise approaches, the PFAS removal rates may be optimized.

7. Should we use aerosol, bubble, or foam fractionation setup? The setup will affect the operating parameters (for example, fill height, aeration rate, foam collection method) that will yield the optimal PFAS removal rate.

8. Which foamate removal system should be applied (for example, weir or vacuum)? The foamate removal configuration can affect both PFAS removal rates and waste volume produced.

9. If short chains need removal, which foam booster of co-surfactant addition should be used, how much, and do these foam boosters transfer into foamate (waste) with PFAS or remain in treated water for recycling in a soil washing batch process? Foaming additives can add cost and complexity to systems and may have their own toxicity that should be considered and balanced against enhanced PFAS removal. Additional discharge permitting considerations should be weighed before deploying field-scale systems.

10. Is the addition of salt needed? High salt concentrations may improve foam fractionation performance, but the benefit must be considered against the additional cost, complexity, and maintenance.

11. What impact does altitude or environmental conditions, such as liquid temperatures, air temperatures, and humidity, have on stripping and enrichment performance? Although there is little evidence that these factors affect foam fractionation performance, difference between bench/pilot test conditions and field conditions should be considered when interpreting data.

12. If hard water is to be treated, how should it be managed (for example, pre-aeration plus filtration plus auto acid dosing to control pH post–foam fractionation at 6.8–7.6, anti-scaling chemical) to

prevent post-foam fractionation scaling and fouling polishing systems and/or aquifer reinjection? Scaling in water treatment equipment can increase maintenance costs and downtime. The potential for scale formation and solids precipitation should be considered and weighed against the cost of additional pretreatment.

13. If co-contaminants are present in the liquid, how might they affect system fouling or performance, either positively or negatively? Knowing the co-contaminant removal potential, such as organics that may increase cleaning frequency or volatile co-contaminants that may necessitate more frequent vapor treatment change-outs, may benefit the overall decision to deploy foam fractionation.

Additional site-specific considerations for foam fractionation include availability of suitable power, location of influent connections, location and type of discharge, location of safe temporary storage of concentrated PFAS waste, and the need for a level surface that can withstand the heavy loads of the treatment equipment (hardstand).

Table 18-5. Summary of performance test options for evaluating foam fractionation.

Test Type	Relative Time to Completion	Relative Cost	Ability to Assess PFAS Removal?	Predictability of Full-Scale Performance
Shake and Foamability Tests	Shortest	Least	No	Poor
Modeling	Short	Low	Maybe	Low[1]
Bench-scale Testing	Moderate-low	Moderate-low	Yes	Moderate[2]
Pilot	Moderate-high	Moderate-high	Yes	High[2]
Full-scale Demonstration	Longest	Highest	Yes	Best

[1] Current models are mostly empirical and are based on past performance. Limited data are available on comparisons among model, pilot, and full-scale foam fractionation systems.
[2] The size and scale of bench- and pilot-test equipment is typically smaller than the full-scale equipment and may provide only an approximation to full-scale operations. The nature and magnitude of uncertainties should be determined in conversations with vendors or consultants and included in interpretation of results.

18.4.2.1 Shake and Foamability Tests

Although not scientifically rigorous, simple shake tests may be used in screening tests to assess whether a specific water will generate foam without the addition of foaming agent (note: the presence/volume of foam created is not necessarily indicative of PFAS removal by foam fractionation). To obtain measurable results, a foamability test is recommended, in which a standard column 0.5 meter in height and 10 centimeters in diameter is used for generating foam in the liquid and the rates of foam formation and collapse are measured.

18.4.2.2 Bench-scale Testing

Bench-scale units can be used to treat a small volume of water using foam fractionation to assess potential PFAS removal rates, the quantity of foamate generated, and concentration factors. Bench-scale tests typically generate insufficient foamate volumes to test additional concentration or destruction steps, so field pilot testing is often used. Removal rates at bench scale may differ from those in full-scale optimized foam fractionation systems due to the limited volumes available for optimization. Aeration rates, fill volumes, treatment times, and surfactant addition (type, dose, rate) can all be tested during

bench or field pilot tests. Descriptions of bench-scale testing are provided in several published articles (**Buckley et al. 2023**; **Buckley et al. 2023**; **Buckley et al. 2022**).

18.4.2.3 Field Pilot Testing

Field pilot testing is the recommended way to assess the suitability of foam fractionation for a particular water (**Klevan et al. 2025**). A foam fractionation pilot test plan should include similar considerations to adsorptive media pilot test plans described in **Section 18.3.2.5**. Foam fractionation pilot tests can be completed using full-scale equipment or smaller equipment designed specifically for pilot testing (**Burns et al. 2022**; **Smith et al. 2022**). Although smaller equipment may decrease the costs of pilot testing, there may be some uncertainty in directly translating results to larger, scaled-up systems. One significant advantage of pilot testing is the ability to test multiple fractionation conditions over the course of the test, including different treatment times, fill volumes, aeration rates, and additive doses, without being limited by the volume of water available in a bench-scale test. The duration of the pilot test can be longer or shorter depending on the conditions to be tested, site-specific objectives, and variability of the source water. Influent and effluent samples are typically collected for each test condition to assess performance. In addition to analyzing samples for PFAS concentration, it may be useful to measure additional parameters such as metals (to assess changes due to oxidation), foaming additives (to measure removal), VOCs (to assess removal), and other parameters that may be useful for a particular application. Emissions control and testing may also be necessary to evaluate evolution of vapors (PFAS or other co-contaminants).

Pilot testing also provides an opportunity to evaluate integration of foam fractionation with existing infrastructure and as part of a treatment train and may be combined with testing additional PFAS removal technologies, such as downstream adsorptive media. Pilot tests should be performed with sufficient duration and treatment volumes to generate a representative volume of PFAS concentrate. Depending on the number of fractionation steps performed, a large volume of water may need to be treated to generate sufficient foamate for evaluation. The volume of final foamate generated can be compared with the volume of water treated to determine a concentration factor, which is useful for full-scale planning and estimating long-term operations and maintenance costs. Larger scale pilot testing can also be useful to generate sufficient foamate to test and evaluate destruction and disposal technologies.

18.4.2.4 Modeling

Laboratory, bench, and pilot testing are currently the best tools to predict performance. Pilot testing is typically the most accurate method for optimizing the design of a foam fractionation system, but has higher costs, especially when scaling up or evaluating multiple process parameters or system configurations. Ideally, process modeling could offer a cost-effective means to use testing data to optimize process parameters and down-select system configurations, reducing the need for extensive experimental trials. However, due to the complex and chaotic nature of the process, there are no known mechanistic models that can generally predict performance across fractionation applications. For instance, researchers have recently developed mechanistic models of varying complexity for protein enrichment applications (**Keshavarzi et al. 2022**; **Grassia 2023**), but so far, no similar model has been translated into a tool used by practitioners in the environmental remediation field. Several scientific publications have investigated the adsorption models and associated parameters for PFAS on bubbles and aerosols (**Buckley et al. 2023**; **Schaefer et al. 2019**; **Brusseau and Van Glubt 2019**; **Brusseau and Van Glubt 2021**; **Sha et al. 2021**; **Wang et al. 2023**), but to date, none of these efforts has been incorporated into publicly available process models for PFAS removal from water. Foam fractionation providers have developed empirical models that can be used to estimate removal of specific PFAS. The performance of these models has not been independently verified, but additional work is ongoing to gather performance data to improve predictive performance based on influent water chemistry. As foam fractionation evolves, further data are collected, and a greater understanding of water chemistry effects is obtained, algorithms may be improved, or empirical models developed.

18.4.3 Fate of PFAS-containing Foams

The objective of foam fractionation is to concentrate large volumes of water with dilute PFAS concentrations into small volumes with high PFAS concentration. Separated foam, bubbles, or aerosols from the initial fractionation stage can be processed through additional stages to provide further volume reduction and increasing PFAS concentration. Depending on the liquid matrix type (for example, groundwater, landfill leachate), volumetric concentration factors of 10 times to 1,000,000 times have been achieved, such that the processing of 1,000,000 gallons of influent results in the generation of 1 gallon of foam concentrate or foamate as the foam eventually condenses back to an aqueous solution (**Burns, Stevenson and Murphy 2021**; **Smith et al. 2022**; **Wang et al. 2023**). The volumetric concentration factor is unique for each water and foam fractionation process and cannot be easily predicted without bench and/or pilot testing. This foamate is then more economical and efficient for consideration to be processed by various field-implemented or emerging destructive treatment technologies or disposal methods, including, but not limited to, those listed below. When considering the economics of destruction and disposal, it is important to consider trade-offs between volumetric concentration, PFAS removal, and system throughput.

- Sorption and Stabilization/Solidification (**Section 12.7.1**)
- Supercritical Water Oxidation (SCWO) (**Section 12.6.3.12** and **Section 1.6.2**)
- Alkaline Hydrothermal Reaction (**Section 12.6.5**)
- Electrochemical Treatment (**Section 12.6.3.6**)
- Plasma Technology (**Section 12.6.3.8**)
- Photolysis/Photochemical Oxidation (**Section 12.6.3.5**)
- Incineration (**Section 12.4**)
- Deep Well Injection (**Section 12.6.6**)

18.5 Resources for Decision-Making

Many factors should be considered when identifying a PFAS solution, including the treatment objectives and site-specific factors discussed in **Section 18.2**. Competing cost drivers, environmental impacts, and life cycle sustainability considerations (**Section 12.9**) also factor into these decisions. Several resources are available to develop preliminary cost estimates.

USEPA has published example applications of their own cost models of PFAS treatment of drinking water for GAC, IX, and membrane systems (**USEPA 2023**). Although capital costs for adsorption-based technologies are somewhat transferable across applications, O&M costs will heavily depend on project specifics, including influent water quality, influent PFAS types and concentrations, and targeted effluent PFAS types and concentrations. Costs may also vary significantly based on the degree of pretreatment required prior to adsorptive treatment. A study commissioned by the Minnesota Pollution Control Agency (MPCA) provided cost curves for treating liquid waste streams using multiple adsorptive technology configurations, including GAC, IX, RO with GAC+IX treatment of concentrate, and foam fractionation (**Barr Engineering Co. & Hazen and Sawyer 2023**). In the MPCA study, pretreatment of wastewater effluent prior to adsorption accounted for one-third to one-half of 20-year costs, depending on facility size and characteristics. All costs presented included high-temperature incineration of treatment residuals. Cost curves included wastewater effluent for facilities treating between 0.1 million gallons per day (MGD) and

10 MGD and landfill leachate and compost contact water for facilities managing between 1 gpm and 100 gpm (**Barr Engineering Co. & Hazen and Sawyer 2023**). The costs developed for aqueous solutions were associated with individual treatment targets (objectives) to reduce concentrations to 5 ng/L each for PFOS, PFOA, PFHxA, PFBS, PFBA, and 6:2 FTS, with N-EtFOSAA included only for landfill leachate. Most notable were the targets of 5 ng/L associated with short-chain PFAS (PFBS and PFBA). For municipal wastewater treatment plant effluent, the cost study generally estimated 10,000 bed volumes treated before change-out using GAC, and 20,000 bed volumes using IX resins, with a 67% removal rate for each of PFBS and PFBA.

Consideration of social and environmental externalities may also drive decision-making for adsorption-based technology adoption. These can be positive externalities such as reduction in health impacts or improved community resources or negative externalities such as greenhouse gas emissions, ecotoxicity, or degradation of community resources. Social impacts may be difficult to quantify, but planners should engage with community stakeholders early in the project to align interests and communicate project goals. The **USEPA (2024)** has developed the Clean Water Act Financial Capability Assessment Guidance as a tool that can be used to consider economic impacts to a community and its capability to implement controls such as sorption-based PFAS treatment to meet PFAS treatment objectives. Environmental impacts can be evaluated using several different approaches. LCA tools have been used to compare environmental impacts of single-use media use versus IX regeneration and GAC reactivation (**Boyer et al. 2021**; **Ellis et al. 2023**). LCA considers ongoing use of chemicals, water, and energy across use, treatment, and residuals disposal and can be estimated using simple calculation-based models or more complex software such as OpenLCA or SimaPro. The USEPA provides a broader list of tools for environmental impact assessment applicable to remediation projects, many of which can be adapted to water treatment projects (**CLU-IN n.d.**). Additional sustainability evaluation resources are also available through USEPA (**USEPA 2025**).

An example decision matrix for assessment of GAC, IX resins (usually anion exchange resins), and foam fractionation can be found in **Table 18-6**. The example decision matrix compares three different adsorption treatments and provides an evaluation based on several decision-making criteria. For this example, all three treatments are assumed to be able to meet treatment goals. However, each treatment has different advantages and disadvantages depending on site-specific factors. General pros include (1) GAC generally has lower unit costs than IX resin, (2) IX may have a smaller footprint and higher mass loadings, and (3) foam fractionation has a high concentration factor and low pretreatment. This example table provides a comprehensive comparison of these three treatments based on various criteria to help in the decision-making process. Some states have also published decision-making tools for PFAS treatment selection. For instance, Arizona has published a set of decision trees to aid in selection between GAC, IX, and high-pressure membranes for PFAS treatment in drinking water (**AZ DEQ 2024**). This example matrix helps evaluate options and make informed choices by comparing them against specific criteria (effectiveness under varying conditions, capital and operational expenses, and other factors). Judgments in this table were derived from information presented in the PFAS-1 Document (**https://pfas-1.itrcweb.org**) and available literature (**Burns, Stevenson, and Murphy 2021**; **DiGuiseppi et al. 2024**; **Ellis et al. 2022**; **Grieco et al. 2021**; **Liu and Sun 2021**; **Murray et al. 2021**; **Murray et al. 2023**; **USEPA 2024**; **We et al. 2024**). This decision matrix table is provided as an example. Actual selection of technologies may vary depending on site-specific conditions.

When evaluating water containing PFAS to be treated, understanding the basic pros, cons, and limitations of available treatment technologies can assist decision-making. However, different states, counties, and industries are starting to create their own PFAS guidelines and, as a widespread emerging class of contaminants, PFAS and PFAS technologies are rapidly evolving. These challenges are discussed in greater detail in **Section 18.6**.

Table 18-6. Example decision matrix comparing foam fractionation, GAC, and IX resin.

Adsorption Treatment	Foam Fractionation[1] (FF)	Granular Activated Carbon (GAC)	IX Resin (IX)
Decision-Making Criteria			
Ability to Treat High Concentration (>1 ppm) PFAS Influent	Up to ~10 ppm limit, depends on mix of PFAS	Limited by size/cost	Limited by size/cost
Treatment of Short-Chains (<6C)	Low removal without foaming additives	Typically low efficiency but depends on specific PFAS and design EBCT	Moderate to slightly more efficient than GAC
End Waste Product Mass/Volume	Liquid PFAS waste 500–1,000,000x Volumetric concentration factor	ug/g to mg/g sorptive capacities possible, ~85% sorbent reuse with reactivation	ug/g to mg/g sorptive capacities possible; regeneration and reuse are possible but may not be economical
TOC, Ion, Metal Interference	Little to none	TOC competes for adsorption site and reduces PFAS adsorption capacity, increases of 0.1 to 1 mg/L can drop the bed volumes to breakthrough by an order of magnitude. Precipitation and clogging can increase backwashing frequency	Ions and organic acids can outcompete PFAS for exchange sites on the beads
Solids	Above 2% requires filtration	Suspended solids may clog access to surface area, requiring backwashing and potentially reduced adsorption capacity when fouled	Similar solids concern to GAC
Pretreatment Requirement	Oily water, very high solids	Oily water, solids, high TOC, high Fe/Mn	Oily water, solids, high TOC, salinity, and other anions
Capital Expenditure[2]	Medium	Low to medium, depends on pretreatment requirements	Low to medium, depends on pretreatment requirements
Operational Expenditure[2]	Low, generally less reoccurring costs than sorbents due to lack of media. Concentrate disposal is a consideration. Higher electric demand for low concentrations.	Medium, reoccurring cost of GAC and reactivation or disposal	Higher unit cost of sorbent than GAC
General Pros	High concentration factor/low pretreatment. Small liquid waste volumes. No sorptive media.	Reactivation possibility, generally stakeholder acceptable, generally lower unit cost than resin	May be a smaller footprint. Potentially for higher mass loadings and selectivity
General Cons	Most applicable to long chains/new developments still occurring. Limited throughput in current commercially available systems (<500 gpm). Not typically effective at low concentrations	Complex geochemistry interferes with PFAS removal. Perpetual change-outs and often more frequent than piloted change-outs	Higher unit cost of the sorbent, perpetual change-outs though frequency may be lower than with GAC

[1] Note that though this example decision matrix table evaluates technologies individually, foam fractionation can be combined with GAC/IX resin depending on site-specific concentrations and conditions.
[2] Capital and operational expenditures can vary depending on vendor-specific equipment.

18.6 Barriers, Challenges, and Outlook

Although adsorption-based technologies have proven successful at treating PFAS-impacted water in an array of applications and situations, and the state of knowledge and practice has matured significantly in recent years, practitioners and decision makers may still face challenges and barriers when selecting or implementing these technologies. Performance problems associated with poorly adsorbing PFAS or especially challenging matrixes have already been discussed in previous sections. Therefore, this section will instead focus on regulatory issues, knowledge gaps, and practical resource limitations.

The quickly evolving discovery and research regarding PFAS toxicology and impacts to human health and the environment, and the development and improvement of PFAS analytical techniques, will continue to drive regulatory changes that impact treatment objectives or the transport and disposal of treatment residuals. Although uncertainty exists, the potential for these changes should be considered in evaluating and selecting a PFAS treatment process because the expected lifespan of the treatment equipment may span multiple decades. Consider to what extent PFAS separation can be achieved by the proposed treatment. Consider whether treatment can be expanded in the future or whether other treatment(s) could be added to the treatment train expansion to meet future requirements. Consider the potential for other PFAS to become regulated or for existing PFAS regulatory standards to become more stringent. Depending on locality and application, practitioners and decision makers may encounter overlapping regulations, permitting requirements, and guidance. However, difficulties in this area will likely abate as rules and regulations are finalized and practitioners gain more familiarity with them as the number of full-scale treatment systems in operation increases.

Financial challenges, difficulty purchasing equipment, and lack of operator/maintenance availability can be particularly difficult for small drinking water systems or utilities in remote locations. The **USEPA (2024)** Small and Rural Systems Fact Sheet summarizes resources available for implementation, funding, and technical assistance to help utilities face these challenges.

Supply chain issues may lead to shortages of media and equipment due to dramatically increased demand. Also, capacity of related services such as analytical laboratory capacity for PFAS may be limiting. However, both issues are likely temporary and will lessen as manufacturers and labs expand operations to meet the increased demands. In addition to the laboratory capacity issues already noted, the lack of rapid, on-site quantitation techniques can present challenges for some applications. Also, quantification of PFAS in challenging matrices, such as waters containing high levels of non-target PFAS, can make quantitation of target PFAS challenging. Advances in techniques or technology may be needed to fully address these challenges.

Utilities, especially potable water utilities, may face challenges with communication issues regarding treatment decisions. For instance, customers may have questions about health risks or why only some PFAS are being treated. This challenge and some strategies for addressing it are discussed in more detail in **Section 14**. Furthermore, these issues are not necessarily unique to PFAS, and many utilities already confront similar issues for other water contaminants, such as disinfection byproducts. Utilities and remediation specialists are encouraged to work with state, tribal, and federal partners to develop communication plans to address these issues.

Performance modeling for adsorptive processes, which can be used to maximize utility of testing data and inform cost analysis, faces several challenges. Very few open-source, transparent models are available. USEPA has open-source tools for modeling GAC and IX columns, but parameters for only a few IX resins are published and the effects of background organic matter are difficult to model. A large contributor to these challenges has been the lack of useful laboratory and field data collected with modeling specifically in mind. It can be reasonably expected that additional laboratory studies and increasing availability of pilot data will enable further performance model development.

Along with performance modeling development, wider adoption of lab-scale test procedures such as RSSCTs could potentially increase productivity or reduce the cost of pilot testing and permitting. However, several knowledge gaps remain in this area, and protocols and practice are not yet standardized, especially for IX resins. There are still some basic questions about mechanisms of adsorption of PFAS on GAC and IX resins and the effects of grinding on IX resins that, if answered, would provide additional confidence in conclusions and predictions developed using RSSCTs and other lab-scale tests.

When designing and implementing treatment systems, practitioners often fall back on internal institutional knowledge or standards and design documents that were not designed for the challenges and unique behaviors of PFAS. As such, there is an important opportunity for development of consensus and industry standards of practice to reduce time and cost of designing, reviewing, and optimizing treatment systems.

Current foam fractionation methods can effectively remove long-chain PFAS, including most USEPA-regulated compounds, but struggle with shorter chain PFAS, including PFBS, which is also USEPA-regulated in drinking water. Cationic and non-ionic surfactants have shown promise in removing short-chain PFAS, including PFBS. However, the use of these additives faces challenges with approval and permitting due to knowledge gaps. For instance, analytical methods and detection limits for measuring additive discharge (especially if additives are proprietary) make studying them challenging. Additional research efforts, including toxicity and biodegradation studies, are likely needed before processes using these additives see wide adoption. Scale up of foam fractionation may also be a barrier for some applications. Current commercially available foam fractionation systems typically have flow rate limitations. Although they can be scaled by installing additional treatment units in parallel, this may reach a point of diminishing returns. Research and testing of larger scale foam fractionation systems, capable of treating millions of gallons per day, are ongoing but have not been demonstrated commercially.

Although many barriers and challenges have been discussed here, there is cause for optimism. In general, most of these challenges are expected to lessen as regulatory rules are finalized, regulators and practitioners reach consensus on best practices, and standards are established. Future advances in research and technology of novel sorbents, sorbent regeneration, and PFAS destruction technologies will bring more options for adsorbent and process selection and will potentially make adsorption-based technologies viable for a wider range of waters and site conditions.

ACKNOWLEDGMENTS

The members of the Interstate Technology & Regulatory Council (ITRC) PFAS Team wish to acknowledge and thank the individuals, organizations, and agencies that contributed to this online document (from 2017 through 2025) that includes the PFAS Technical and Regulatory Guidance Document, the 2025 Priority Topics, Sorption-based Treatment Technologies Guidance, PFAS Fact Sheets, training resources, and external tables of data and information prepared by the ITRC PFAS Team.

The PFAS Team was led by: Bob Mueller, New Jersey Department of Environmental Protection (2017 - 2021); Ginny Yingling, Minnesota Department of Health (2017 - 2020); Kate Emma Schlosser, New Hampshire Department of Environmental Services (2020 - 2022); Sandra Goodrow, New Jersey Department of Environmental Protection (2020 - 2023); Kristi Herzer, Vermont Department of Environmental Conservation (2022 - 2025); Jeff Wenzel, Missouri Department of Health and Senior Services (2024 - 2025); and Ted Campbell, North Carolina Department of Environmental Quality (2024 - 2025).

The team leaders were assisted by Program Advisors: Lesley Hay Wilson and Jim Rocco of Sage Risk Solutions LLC. Josh Criss of GDIT provided video support for the training video modules. Tadbir Singh, ITRC/ECOS Project Associate; Evan Madden, ITRC Project Manager; Marguerite Bennett, ITRC Project Associate; and Sabrina Heivilin, ITRC Project Manager provided support to the team. Bobbilynne Koepke and Susan Cummins of Environmental Works, Inc. provided support for the collaborative PFAS and Vapor Intrusion Teams' Fact Sheet.

During the development and updating of the fact sheets, technical and regulatory guidance document, priority topics, sorption-based treatment technologies guidance, external tables, and training resources the team received many comments and reviews from experts across U.S. EPA, U.S. DoD, U.S. DOE, state agencies, academic institutions, industry, and consulting. This input was invaluable to the development of these ITRC products. The team greatly appreciates those who offered advice, suggestions, reviews, and comments.

Specifically, the team wishes to thank and recognize the efforts and important contributions of the team members.
