Artifically induced changes such as the return of cooling water or the release of cool hypolimnetic waters from impoundments may alter indigenous aquatic ecosystems (Coutant, 1972). Entrained organisms may be damaged by temperature increases across cooling water condensers if the increase is sufficiently great or the exposure period sufficiently long. Impingement upon condenser screens, chlorination for slime control or other physical insults damage aquatic life (Raney, 1969; Patrick, 1969 (b)). However, Patrick (1969(a)) has shown that algae passing through condensers are not injured if the temperature of the outflowing water does not exceed 34°C to 34.5°C

In open waters elevated temperatures may affect periphyton, benthic invertebrates, and fish in addition to causing shifts in algal predominance. Trembley (1960) studied the Delaware River downstream from a power plant and concluded that the periphyton population was considerably altered by the discharge.

The number and distribution of bottom organisms decrease as water temperatures increase. The upper tolerance limit for a balanced benthic population structure is approximately 32°C. A large number of these invertebrate species are able to tolerate higher temperatures than those required for reproduction (FWPCA, 1967).

In order to define criteria for fresh waters, Coutant (1972) cited the following as currently defineable requirements:

"1. Maximum sustained temperatures that are consistent with maintaining desirable levels of productivity,

2. Maximum levels of metabolic acclimation to warm temperatures that will permit return to ambient winter temperatures should artificial sources of heat cease,

NMED Exhibit 83

3. Time dependent temperature limitations for survival of brief exposures to temperature extremes, both upper and lower,

4. Restricted temperature ranges for various states of reproduction including (for fish) gametogenesis, spawning migration, release of gametes, development of the embryo, commencement of independent feeding (and other activities) by juveniles, and temperatures required for metamorphosis, emergence or other activities of lower forms,
5. Thermal limits for diverse species compositions of aquatic communities, particularly where reduction in diversity creates nuisance growths of certain organisms, or where important food sources (food chains) are altered,
6. Thermal requirements of downstream aquatic life (in rivers) where upstream diminution of a cold water resource will adversely affect downstream temperature requirements."

The major portion of such information that is available, however, is for freshwater fish species rather than lower forms or marine aquatic life.

The temperature-time duration for short term exposures such that 50 percent of a given population will survive an extreme temperature frequently is expressed mathematically by fitting experimental data with a straight line on a semi-logarithmic plot with time on the logarithmic scale and temperature on the linear scale. (See Fig. 1). In equation form this 50 percent mortality relationship is:

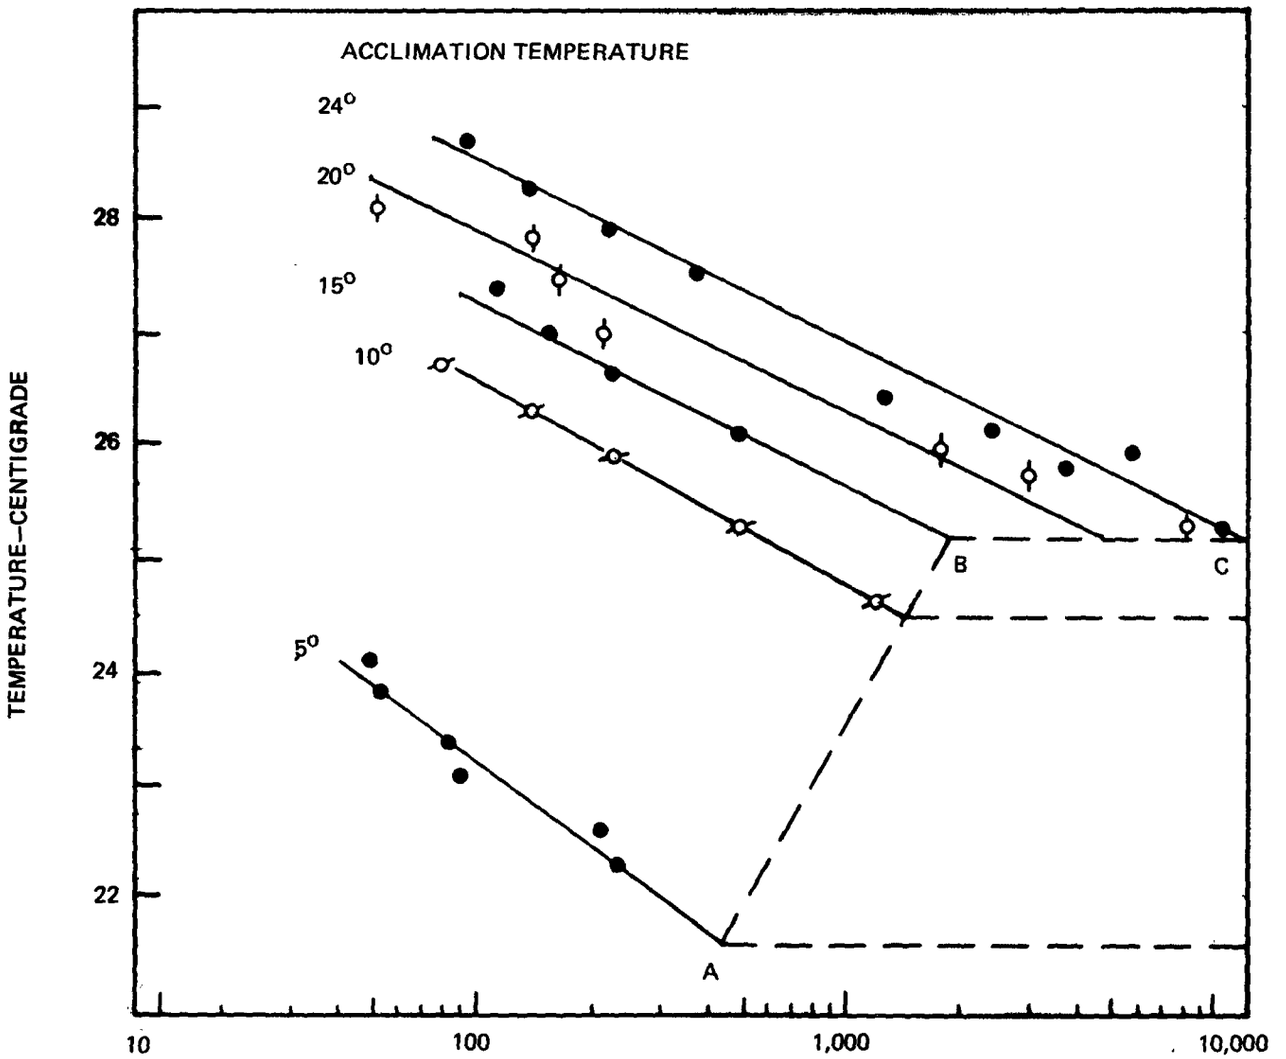
NMED Exhibit 83

$$\log_{10}(\text{time}_{(\text{minutes})}) = a + b\ (\text{Temperature}_{(^\circ C)})$$

where: $\log_{10}$ = logarithm to base 10 (common logarithm)

a = intercept on the "y" or logarithmic axis of the line fitted to experimental data and which is available from Appendix II-C, NAS, 1974 for some species.

b = slope of the line fitted to experimental data and which is available from Appendix II-C, NAS, 1974 for some species.



To provide a safety factor so that none or only a few organisms will perish, it has been found experimentally that a criterion of 2° C below maximum temperature is usually sufficient (Black, 1953). To provide safety for all the organisms, the temperature causing a median mortality for 50 percent of the population would be calculated and reduced by 2° C in the case of an elevated temperature. Available scientific information includes upper and lower incipient lethal temperatures, coefficients "a" and "b" for the thermal resistance equation, and information on size, life stage, and geographic source of the particular test species (Appendix II-C, NAS, 1974)

Maximum temperatures for an extensive exposure (e.g., more than 1 week) must be divided into those for warmer periods and winter. Other than for reproduction, the most temperature-sensitive life function appears to be growth (Coutant, 1972). Coutant (1972) has suggested that a satisfactory estimate of a limiting maximum weekly mean temperature* is an average of the optimum temperature for growth and the temperature for zero net growth.

---

* maximum weekly mean temperature - true mean temperature for a calendar week which is a higher value than for any other week. Can be determined from continuous measurements, hourly determinations, or some other non-biased statistical method of analyzing temperature data.

NMED Exhibit 83

AFTER BRETT 1952

Figure 1. MEDIAN RESISTANCE TIMES TO HIGH TEMPERATURES AMONG YOUNG CHINOOK (Oncorhynchus tshawytscha) ACCLIMATED TO TEMPERATURES INDICATED. LINE A-B DENOTES RISING LETHAL THRESHOLD (incipient lethal temperatures) WITH INCREASING ACCLIMATION TEMPERATURE. THIS RISE EVENTUALLY CEASES AT THE ULTIMATE LETHAL THRESHOLD (ultimate upper incipient lethal temperature), LINE B-C. (TAKEN FROM NAS, 1974)

Because of the difficulty in determining the temperature of zero net growth, essentially the same temperature can be derived by adding to the optimum temperature (for growth or other physiological functions) a factor calculated as 1/3 of the difference between the ultimate upper incipient lethal temperature and the optimum temperature (NAS, 1974). In equation form:

$$\begin{array}{l}\text{Maximum weekly} \\ \text{average} \\ \text{temperature}\end{array} = \begin{array}{l}\text{optimum} \\ \text{temperature}\end{array} + 1/3 \begin{array}{l}(\text{ultimate upper} \\ (\text{incipient lethal} \\ (\text{temperature}\end{array} - \begin{array}{l}\text{optimum} \\ \text{temperature}\end{array}\begin{array}{l}) \\ ) \\ )\end{array}$$

Since temperature tolerance varies with various states of development of a particular species, the criterion for a particular location would be calculated for the most important life form likely to be present during a particular month. One caveat in using the maximum weekly mean temperature is that the limit for short-term exposure must not be exceeded. Example calculations for predicting the summer maximum temperatures for short-term survival and for extensive exposure for various fish species are presented in Table 11. These calculations use the above equations and data from ERL-Duluth, 1976.

The winter maximum temperature must not exceed the ambient water temperature by more than the amount of change a specimen acclimated to the plume temperature can tolerate. Such a change could occur by a cessation of the source of heat or by the specimen being driven from an area by addition of biocides or other factors. However, there are inadequate data to estimate a safety factor for the "no stress" level from cold shocks (NAS, 1974). Figure 2 was developed from available data in the literature (ERL-Duluth, 1976) and can be used for estimating allowable winter temperature increases.

Coutant (1972) has reviewed the effects of temperature on aquatic life reproduction and development. Reproductive events are noted as perhaps the most thermally restricted of all life phases assuming other factors are at or

a - Calculated according to the equation (using optimum temperature for growth)

maximum weekly average temperature for growth = optimum temperature + 1/3 (ultimate incipient lethal temp. - optimum temperature

b - Based on temperature $(^{o}C) = 1/b\ (\log_{10}\ time_{(min.)} - a) - 2^{o}C$, acclimation at the maximum weekly average temperature for summer growth, and data in Appendix II-C of Water Quality Criteria, 1972 (NAS, 1973).

c - Based on data for larvae (ERL-Duluth, 1976).

NMED Exhibit 83

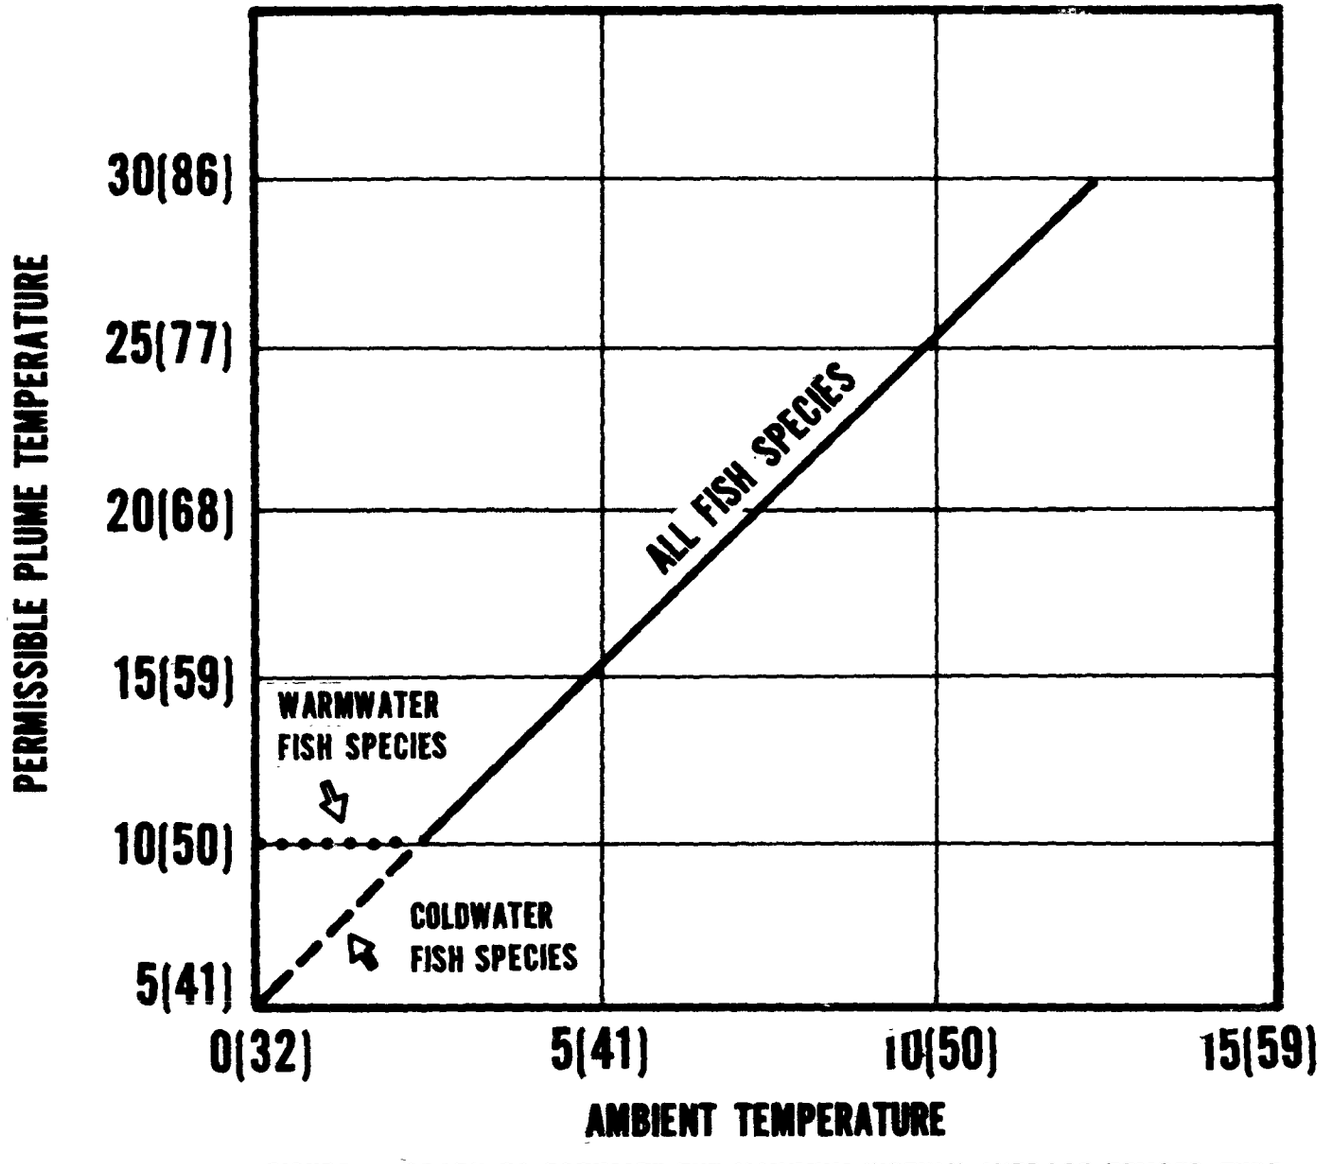

FIGURE 2. GRAPH TO ESTIMATE THE MAXIMUM WEEKLY AVERAGE TEMPERATURE OF PLUMES FOR VARIOUS AMBIENT TEMPERATURES, °C (°F)

near optimum levels. Unnatural short-term temperature fluctuations appear to cause reduced reproduction of fish and invertebrates. There are inadequate data available quantitating the most temperature-sensitive life stages among various aquatic species. Uniform elevation of temperature a few degrees, but still within the spawning range may lead to advanced spawning for spring spawning species and delays for fall spawners. Such changes may not be detrimental unless asynchrony occurs between newly hatched juveniles and their normal food source. Such asynchrony may be most pronounced among anadromous species or other migrants who pass from the warmed area to a normally chilled, unproductive area. Reported temperature data on maximum temperatures for spawning and embryo survival have been summarized in Table 12 (from ERL-Duluth 1976).

Although the limiting effects of thermal addition to estuarine and marine waters are not as conspicuous in the fall, winter and spring as during the summer season of maximum heat stress, nonetheless crucial thermal limitations do exist. Hence, it is important that the thermal additions to the receiving waters be minimized during all seasons of the year. Size of harvestable stocks of commercial fish and shellfish, particularly near geographic limits of the fishery, appear to be markedly influenced by slight changes in the long-term temperature regime (Dow, 1973).

Jefferies and Johnson (1974) studied the relationship between temperature and annual variation in 7-year catch data for winter flounder, Pseudopleuronectes americanus, in Narragansett Bay, Rhode Island. A 78 percent decrease in annual catch correlated closely with a 0.5°C increase in the average temperature over the 30-month period between spawning and recruitment into

a - the optimum or mean of the range of spawning temperatures reported for the species (ERL-Duluth, 1976).

b - the upper temperature for successful incubation and hatching reported for the species (ERL-Duluth, 1976).

c - upper temperature for spawning

NMED Exhibit 83

the fishery. Sissenwine's 1974 model predicts a 68 percent reduction of recruitment in yellowtail flounder, Limanda ferruginea, with a 1° C long-term elevation in southern New England waters.

Community balance can be influenced strongly by such temperature dependent factors as rates of reproduction, recruitment and growth of each component population. A few degrees elevation in average monthly temperature can appreciably alter a community through changes in inter-species relationships. A 50 percent reduction in the soft-shell clam fishery in Maine by the green crab, Carcinus maenus, illustrates how an increase in winter temperatures can establish new predator-prey relationships. Over a period of four years, there was a natural amelioration of temperature and the monthly mean for the coldest month of each year did not fall below 2° C. This apparently precluded appreciable ice formation and winter cold kill of the green crab and permitted a major expansion of its population, with increased predation of the soft-shell clam resulting (Glude, 1954; Welch, 1968).

Temperature is a primary factor controlling reproduction and can influence many events of the reproductive cycle from gametogenesis to spawning. Among marine invertebrates, initiation of reproduction (gametogenesis) is often triggered during late winter by attainment of a minimum environmental threshold temperature. In some species, availability of adequate food is also a requisite (Pearse, 1970; Sastry, 1975; deVlaming, 1971). Elevated temperature can limit gametogenesis by preventing accumulation of nutrients in the gonads. This problem could be acute during the winter if food availability and feeding activity is reduced. Most marine organisms spawn during the spring and summer; gametogenesis is usually initiated during the previous fall. It should also be noted that there are some species which

NMED Exhibit 83

spawn only during the fall (herring), while others spawn during the winter and very early spring. At the higher latitudes, winter breeders include such estuarine community dominants as acorn barnacles, Balanus balanus, and B. balanoides, the edible blue mussel Mytilus edulis, sea urchin, Strongylocentrotus drobachiensis, sculpin, and the winter flounder, Pseudopleuronectes americanus. The two boreal barnacles require temperatures below 10°C before egg production will be initiated (Crisp, 1957). It is clear that adaptations for reproduction exist which are dependent on temperature conditions close to the natural cycle.

Juvenile and adult fish usually thermoregulate behaviorally by moving to water having temperatures closest to their thermal preference. This provides a thermal environment which approximates the optimal temperature for many physiological functions, including growth (Neill and Magnuson, 1974). As a consequence, fishes usually are attracted to heated water during the fall, winter, and spring. Avoidance will occur as water temperature exceeds the preferendum by 1 to 3° C (Coutant, 1975). This response precludes problems of heat stress for juvenile and adult fishes during the summer, but several potential problems exist during the other seasons. The possibility of cold shock and death of plume-entrained fish due to winter plant shutdown is well recognized. Also, increased incidence of disease and a deterioration of physiological condition has been observed among plume-entrained fishes, perhaps due to insufficient food (Massengill, 1973). A weight loss of approximately 10% for each 1°C rise in water temperature has been observed in fish when food is absent (Phillips et al., 1960) There may also be indirect adverse effects on the indigenous community due to increased predation pressure if thermal addition leads to a concentration of fish which are dependent on this community for their food.

Fish migration is often linked to natural environmental temperature cycles. In early spring, fish employ temperature as their environmental cue to migrate northward (e.g., menhaden, bluefish) or to move inshore (winter

NMED Exhibit 83

flounder). Likewise, water temperature strongly influences timing of spawning runs of anadromous fish into rivers (Leggett and Whitney, 1972). In the autumn, a number of juvenile marine fishes and shrimp are dependent on a drop in temperature to trigger their migration from estuarine nursery grounds for oceanic dispersal or southward migration (Lund and Maltezos, 1970; Talbot, 1966).

Thermal discharges should not alter diurnal and tidal temperature variations normally experienced by marine communities. Laboratory studies show thermal tolerance to be enhanced when animals are maintained under a diurnally fluctuating temperature regime rather than at a constant temperature (Costlow and Bookhout, 1971; Furch, 1972; Hoss, et al., 1975). A daily cyclic regime can be protective additionally as it reduces duration of exposure to extreme temperatures (Pearce, 1969; Gonzalez, 1972).

Summer thermal maxima should be established to protect the various marine communities within each biogeographic region. During the summer, naturally elevated temperatures may be of sufficient magnitude to cause death or emigration (Chin, 1961; Glynn, 1968; Vaughn, 1918) This more commonly occurs in tropical and warm temperate zone waters, but has been reported for enclosed bays and shallow waters in other regions as well (Nichols, 1918). Summer heat stress also can contribute to increased incidence of disease or parasitism (Sinderman, 1965); reduce or block sexual maturation (Thorhaug, et al., 1971; deVlaming, 1972); inhibit or block embryonic cleavage of larval development (Calabrese, 1969); reduce feeding and growth of juveniles and adults (Olla and Studholme, 1971);

NMED Exhibit 83

result in increased predation (Gonzalez, 1972); and reduce productivity of macroalgae and seagrasses (South and Hill, 1970; Zieman, 1970). The general ceilings set forth here are derived from studies delineating limiting temperatures for the more thermally sensitive species or communities of a biogeographic region.

Thermal effects data are presently insufficient to set general temperature limits for all coastal biogeographic regions. The data enumerated in the Appendix, plus any additional data subsequently generated, should be utilized to develop thermal limits which specifically consider communities relevant to given water bodies.

Appendix

A Summary of the Thermal Effects Literature for the United States Estuarine and Coastal Biota

Recommended marine thermal criteria are based on scientific evaluation of available data. Representative thermal effects data are summarized here for an array of ecologically diverse marine organisms, grouped by biotic region. Since the summer temperature regime can provide "worst case" thermal conditions, studies dealing with warm-acclimated organisms are cited primarily. Findings of sublethal effects studies are listed also. Twenty-four-hour TLm (median tolerance limit) data have been adjusted by subtracting 2.2°C to estimate the upper thermal protection limit for the life history stage in question (Mihursky, 1969). Recognized biological variables such as recent environmental history, nutritional state, size, sex, and age have been considered for all thermal effects investigations. Likewise, contrasting methods of study were considered. Normally, thermal effects data derived in one biotic region should not be applied to another. Latitudinally separated populations of widely distributed species may exhibit significant genetic variability and usually have experienced different, recent environmental histories. Boundaries for regional ceilings are demarcated by biogeographic provinces. Species composition of the marine system, and most important, responses to elevated

NMED Exhibit 83

temperature, are generally similar within a region. Boundaries of a biotic province are characterized by significant thermal discontinuities. Boundary areas are maintained during summer or winter due to combined forces of current, wind, and coastal geomorphology. On the east coast, Cape Canaveral, Fla.; Cape Hatteras, North Carolina; and Cape Cod, Massachusetts, represent these boundaries. On the west coast, Point Conception in southern California marks the limit of warm and cold temperate zones.

Boreal Zone, Atlantic Coast: This region extends from Cape Cod, Mass., to the Gulf of Maine. Insufficient data are available for setting regional temperature limits. Upper limits should be determined on a case-by-case basis using best available data for the site and its environs.

In the boreal region, maintenance of a general temperature regime resembling natural conditions is particularly important during winter months. Some boreal species require periods of uninterrupted low water temperatures to fulfill environmental requirements for successful maturation of sexual products, spawning, and subsequent egg and larval survival. Winter flounder, Pseudopleuronectes americanus, have an upper limit for spawning of 5.5°C (Bigelow and Schroeder, 1953). Spawning occurs during the winter.

NMED Exhibit 83

Ten degrees centigrade is the upper thermal limit for Atlantic salmon, Salmo salar, smolt migration to the sea, which normally occurs in June. Twelve degrees centigrade inhibits maturation of sex products (DeCola, 1970). Development of winter flounder, Pseudopleuronectes americanus, eggs to hatching is reduced 50 percent at 13°C (Rogers, in press). Blood worm, Glycera americana, spawning is induced when temperatures reach 13°C (Creaser, 1973). Fifteen degrees centigrade is the upper limit for spawning Atlantic herring, Clupea harengus, (Hela and Laevastu, 1962) and of an amphipod, Psammonx nobilis, (Scott, 1975). In Atlantic herring, there is above normal incidence of a protozoan disease at 15°C (Sinderman, 1965) and at 16°C, there is a prevalence of erythrocyte degeneration (Sherburne, 1973). Field mortality of yellowtail flounder larvae, Limanda ferruginea, was observed at 17.8°C (Colton, 1959). The protection limit for yearling Atlantic herring, Clupea harengus, (48-hr. TLm - 2.2°C) is 19.0°C (Brawn, 1960). At 21°C, embryonic development ceases in the amphipod, Gammarus duebeni, (Steele and Steele, 1969). Above 21.2°C, spores are killed and growth is reduced in the macroalga, Chondrus crispus, which is commercially harvested as Irish moss (Prince and Kingsbury, 1973).

Cold Temperate Zone, Atlantic Coast: Temperature ceilings are particularly critical in the southern portion of this region (south shore of Long Island to Cape Hatteras, N.C.) where enclosed sounds and large coastal-plain bays and rivers are

NMED Exhibit 83

prevalent. Maximum temperatures should not exceed 30.6°C. Were temperatures of 30°C to persist for over 4 to 6 hours, appreciable stress or direct mortality would occur among juvenile winter flounder, Pseudopleuronectes americanus; striped mullet larvae, Mugil cephalus; Atlantic silverside eggs and adults, Menidia menidia; adult northern puffer, Sphaeroides maculatus; adult blue mussel, Mytilus edulis; and adult soft shell clam, Mya arenaria. Specific critical temperatures for these species are detailed in Table 13 The adult protection limit (TLm - 2.2°C) is 28.8°C for sand shrimp, Crangon septemspinosa, and 30.8°C for opossum shrimp, Neomysis americanus. Both are important food organisms for fish (Mihursky and Kennedy, 1967). Respiration rate is depressed above 30°C in the mole crab, (Edwards and Irving, 1943). At 31.5°C, there is 67 percent mortality in coot clams when exposed for 6 hours (Kennedy, et al., 1974).

A true daily mean limit of 27.8°C approximates the upper limit for larval growth of the coot clam (27.5°C; Calabrese, 1969). Between 28°C and 30°C juvenile amphipods, Corophium insidiosum, leave their tubes and thereby lose natual protection from predation (Gonzalez, 197[illegible]). Such elevated temperatures may also have subtle sublethal effects, such as reducing feeding and growth. In the quahaug, Mercenaria mercenaria, growth is optimum at 20°C (Ansell, 1968). Growth is inhibited above 24°C in a rock weed, Ascophyllum nodosum, (South and Hill, 1970). Prolonged

NMED Exhibit 83

13

TABLE SELECTED THERMAL REQUIREMENTS & LIMITING TEMPERATURE DATA
COLD TEMPERATE ZONE, ATLANTIC COAST:
South of Long Island, N.Y. to Cape Hatteras, N.C.

Temperature °C	°F	Effect	Species	Seasonal Occurrence	Reference
30	86.0	Avoidance response breakdown (CTM)	Morone saxatilis (striped bass)	April-November	Gift & Westman, 1971
29.8	85.6	Behavior-reduced feeding and behavior altered	Pomatomus saltatrix (bluefish)	May-October	Olla, et al 1969
29.4	84.9	Survival-eggs (50% optimal survival)	Menidia menidia (Atlantic silverside)	May-June	Everich & Neves, 1973 (unpublished)
29.1	84.3	Survival-larvae (TLm)	Mugil cephalus (striped mullet)	January-April (coastal waters)	Cortenay & Roberts, 1973
29.0	84.2	Survival-adult protection limit (TLm - 2.2°C)	Sphaeroides maculatus (Northern puffer)	January-December	Hoff & Westman, 1966
29.0	84.2	Avoidance response	Brevoortia tyrannus (Atlantic menhaden)	April-October	Meldrim & Gift, 1971
29.2	82.7	Survival-adult protection limit (TLm - 2.2°C)	Menidia menidia (Atlantic silverside)	April-November	Hoff & Westman, 1966
28.0	82.4	Survival-adult limit	Mya arenaria (soft shell clam)	January-December	Pfitzenmeyer (pers comm)
27.5	81.5	Development-upper limit larval development	Mulinia lateralis (coot clam)	March-October	Calabrese, 1969
26.9	80.4	Survival-juvenile protection limit (TLm - 2.2°C)	Pseudopleuronectes americanus (winter flounder)	April-December	Hoff & Westman, 1966
26.5	79.7	Avoidance response	Cynoscian regalis (sea trout)	May-October	Gift & Westman, 1971
26.0	78.8	Survival-adult	Mytilus edulis (blue mussel)	January-December	Gonzalez, 1972
25.5	77.9	Avoidance response	Leiostomus xanthrus (spot)	January-December	Gift & Westman, 1971
24.8	76.7	Occurrence-maximum temperature for occurrence in Chesapeake Bay	Urophycis regius (spotted hake)	January-December	Barans, 1972
24.6	76.2	Survival-larvae (TLm)	Menidia menidia (Atlantic silverside)	May-June	Everich & Neves, 1973 (unpublished)

Compiled by ERL-Narragansett, 1976

151

locomotion is markedly reduced at 22°C in the Jonah crab, Cancer borealis; at 28°C in Cancer irroratus (Jeffries, 1967). An oyster pathogen, Democystidium marinum, readily proliferates above 25°C (Andrews, 1965).

High temperature usually will elicit avoidance response in fishes. Avoidance is triggered at 29°C in Atlantic menhaden, Brevoortia tyrannus, and at 26.5°C in sea trout, Cynoscion regalis, (Meldrin and Gift, 1971). Breakdown of the avoidance response in striped bass, Morone saxatilis, occurs at 30°C (Gift and Westman, 1971). Maximum reported temperature for capture of spotted hake, Urophycis regius, is 24.8°C in the Chesapeake Bay (Barans, 1972).

North of Long Island, a 1.0°C rise above summer ambient provides reasonable protection. For example, maximum short-term temperatures in Narragansett Bay, Rhode Island, usually would not exceed 23.4°C in August, judging from 15-year mean temperature data for Fox Island. Larval Atlantic silverside, juvenile winter flounder, and blue mussel should be protected by that thermal limitation. The thermal protection limit (TLm - 2.2°C) for juvenile winter flounder is 26.9°C (Gift and Westman, 1971).

NMED Exhibit 83

Repeated exposures to 25°C would stress the blue mussel, Mytilus edulis, by causing cessation of feeding (Gonzalez, 1972). Diurnal summer maxima exceeding 22°C can alter normal metabolic rates in embryonic tautog, Tautoga onitis, (Laurence, 1973) and cause feeding problems for adult winter flounder (Olla, 1969) and the sand-collar snail, Polinices duplicata, (Hanks, 1953).

Optimum for summer development of the rock crab, Cancer irroratus, and Jonah crab, C. borealis, larvae is 20°C; at 25°C, mortality precludes completion of larval development (Sastry and Vargo, in press). Between 15 and 20°C, activity of the amphipod, Gammarus oceanicus, is much reduced (Halcrow and Boyd, 1967). Initiation of spawning is often cued by temperature. Blue mussel spawning occurs when spring temperatures reach 12°C (Engle and Loosanoff, 1944). A minimum of 10°C is required for their embryonic development (Brenko and Calabrese, 1969) and spawning occurs at 15°C. Peak spawning runs of American shad, Alosa sapidissima, into rivers occurs at 19.5°C (15 year average, Connecticut River); downstream migration of juveniles occurs as temperature falls below 15.5°C (Leggett and Whitney, 1972). Menhaden migrate at 10°C (Bigelow and Schroeder, 1953); striped bass, Morone saxatilis, migrate into or leave rivers at 6 to 7.5°C (Merriman, 1941). In the fall and winter, fishes congregate in discharge plumes which exceed these temperatures. These fishes exhibit increased incidence of disease and a general loss of physiological condition (Mihursky, et al; 1970).

Warm Temperate Zone, Atlantic and Gulf Coasts: This region tends from Cape Hatteras, N.C., to Cape Canaveral, Florida, and

NMED Exhibit 83

on the Gulf Coast from Tampa, Florida, to Mexico. The recommended regional ceiling is a short-term maximum of 32.2°C . Prolonged exposures to temperatures near this level would adversely affect portions of the biota. At 33°C, bay anchovy, Anchoa mitchilli, embryonic development is reduced to 50 percent of optimum (Rebel, 1973). The upper limit for growth of juvenile white shrimp, Penaeus setiferus, is 32.5°C (Zein-Eldin and Griffith, 1969). A decline in field abundance of brown shrimp, Penaeus aztecus, at temperatures above 30°C was reported by Chin (1961).

Protection limits (50 percent of optimal survival) of two sardines, Harengula jaguana and Harengula pensacolae, for development of the yolk sac larval stage are 31.4°C and 32.2°C, respectively (Rebel, 1973; Sakensa, et al., 1972). Larval pinfish, Lagodon rhomboides, and spot, Leiostomus xanthurus, exhibit a breakdown in avoidance response mechanisms at 31.0°C and 31.1°C, respectively (Hoss, D.E., et al., 1974). The protection limit (TLm - 2.2°C) for young-of-the-year Atlantic menhaden is 30.8°C (Lewis and Hettler, 1968). Upper limit for adult growth of the quahaug, Mercenaria mercenaria, is 31°C (Ansell, 1968).

Daily mean temperatures continually exceeding 29°C would result in mortality of striped mullet eggs, Mugil cephalus.

NMED Exhibit 83

Their 96-hour TLm is 26.4°C (Courtenay and Roberts, 1973). Egg and yolk sac larval survival of sea bream, Archosargus rhomboidalis, is reduced to 50 percent of optimal at 29.1°C. For yellowfin menhaden, Brevoortia smithi, exposure to 29.8°C reduced survival of egg and yolk sac larvae to 50 percent of optimal (Rebel, 1973). Sublethal but potentially damaging ecological effects could occur at levels well below 29°C. For example, the upper limit for optimal growth of post-larval brown shrimp, Penaeus aztecus, is 27.5°C (Zein-Eldin and Alrich, 1965). Developing embryos and fry of striped bass cannot tolerate 26.7°C in fresh water (Shannon, 1969). This report may also apply to fry in waters at the head of estuaries. This species spawns in early spring. Elevation of winter temperatures above 20°C in St. Johns River, Florida, could interfere with upstream migration of American shad, Alosa sapidissima, (Leggett and Whitney, 1972).

Sub-Tropical Regions: Ceilings for sub-tropical regions such as south Florida (Cape Canaveral and Tampa southward), and Hawaii are an instantaneous maximum 32.2°C and a true daily mean not exceeding 29.4°C. Ceilings for true tropical sites should be developed from studies of indigenous populations of relevant communities. Physiological variation in thermal adaptations and tolerances have been reported for coral between sub-tropical (Hawaii, 19-22° Lat.) and true tropical sites (Eniwetok Atol, Marshall Islands, 11° Lat.) (Jokiel, et al., in press).

Much of the following thermal effects data represent southern Florida or Hawaiian biota. A review by Zieman and Wood (1975) suggests that the thermal optimum is 26-28°C for tropical marine systems, with chronic exposure to temperatures between 28°C and 30°C causing heat stress. Death of the biota is readily discernible between 30°C and 32°C. Mayer (1914) recognized that nearshore

NMED Exhibit 83

tropical marine biota normally live at temperatures only a few degrees below their upper lethal limit. A study of elevated temperature effects on the benthic community in Biscayne Bay, Florida, resulted in the following data (Roessler, 1974):

Phylum	Temperature for High Species Diversity (°C)	Temperature for 50 Percent Species Exclusion (°C)
Molluscs	26.7	31.4
Echinoderms	27.2	31.8
Coelenterates	25.9	29.5
Porifera	24.0	31.2

Other thermal data for tropical biota include a 25.4-27.8°C optimum for fouling community larval settlement (Roessler, 1974); 25°C optimum for larval development of Polyonyx gibbesi, a commensal crab (Gore, 1968); 27°C for growth and gonad development in sea urchins, Lytechinus variegatus, and for growth in a snail, Cantharus tinctus, (Albertson, 1973); 27 to 28°C optimum for larval development of pink shrimp, Penaeus duorarum, (Thorhaug, et al., 1971a); and 30°C optium for turtle grass, Thalassia testudinum, productivity (Zieman, 1970). Kuthalingham (1959) studied thermal tolerance of newly hatched larvae of ten tropical marine fishes in the laboratory. When held at a series of constant temperatures for 12 hours immediately following

NMED Exhibit 83

hatch, optimal survival for all species fell between 28°C to 30°C, but their tolerance limit ranged from 30°C to 32°C.

Thermal stress of the fouling community is seen in a 50 percent reduced settlement rate of larvae at 28°C (Roessler, 1974). Fifty percent reduction in gonadal volume of the sea urchin, Lytechinus variegatus, occurs at 29.9°C (Thorhaug, et al., 1971b). Irreversible plasmyolysis of the macroalga, Valonia ventricosa, at 29.9°C and of Valonia macrophysa at temperatures above 29.7°C has been reported. Survival of developing embryos to the yolk sac larval stage was reduced to 50 percent of optimal at 29.1°C among sea bream, Archosargus rhomboidalis. At 29.8°C, yellowfin menhaden, Brevoortia smithi, and at 31.4°C scaled sardines, Harengula jaguana, suffer similar mortalities during early development (Rebel, 1973). Temperatures in excess of 31°C to 33°C can interfere with embryonic development in six species of mangrove-associated nematodes, even though adults can tolerate an additional 2°C to 7°C (Hopper, et al., 1973). Upper limit for larval (naupliar) metamorphosis in pink shrimp, Penaeus duorarum, is 31.5°C (Thorhaug, et al., 1971b). Upper lethal temperatures include 31.5°C for five species of Valonia (Thorhaug, 1970); death in 3 to 8 hours for five Hawaiian corals at 31-32°C (Edmondson, 1928; Jokiel and Coles, 1974); 32°C Tlm (95-hour) for the sea squirt, Ascidia nigra, and sea urchin, Lytechinus variegatis, (Chesher, 1971). Average daily temperatures near 31°C

NMED Exhibit 83

for three to ten days result in decreased growth in seagrass, Thallassia testudinum and red macroalgae, Laurencia poitei. Between 32°C and 33°C, health and abundance of these species declines markedly (Thorhaug, 1971, 1973). Replacement of seagrass is slow, especially if rhizomes are damaged due to excessive consumption of stored starch during heat stress (Zieman, 1970). Recovery of Thallassia beds may take decades (Zieman and Wood, 1975).

Pacific Coast: Fewer thermal effects studies have been conducted on West Coast species. However, the concept of seasonal restrictions for temperature elevations above ambient are well supported in several East Coast provinces and is deemed applicable to the West Coast as a general biological principle. Data are not sufficient to develop general regional ceilings. These must be determined on a case-by-case basis until general principles emerge.

The Pacific Coast consists of two distinct biogeographical regions; the cold temperate province ranges north from Point Conception, California and the warm temperate region from Point Conception southward. Published data should provide a general indication of possible adverse effects of excessive thermal discharge on indigenous species.

NMED Exhibit 83

Pacific Cold Temperate Zone: Some winter and spring spawning temperature ranges include 3°C to 6°C for Pacific herring, Clupea pallasi, (McCauley and Hancock, 1971); 7°C to 8°C for English sole, Parophrys vetulus, (Alderdice and Forrester, 1968); 13°C for May and June spawning of razor clams, Siliqua patula, (McCauley and Hancock, 1971); and 12°C to 14°C for native little neck clams, Protothaca staminea, (Schink and Woelke, 1973). Optimal growth occurs at 10°C in the small filamentous red algae, Antithamnion spp., (West, 1968), and 12°C to 16°C is optimal for growth and reproduction of various red and brown algae, including kelp, Macrocystis pyrifera, (Druehl and Hisiao, 1969). Twelve to 16°C favors sea grasses, Zostera marina and Phyllospadix scouleri (McRoy, 1970). Spawning migration of striped bass, Morone saxatilis, occurs at 15°C to 18°C (Albrecht, 1964); in American shad, Alosa sapidissima, spawning runs occur at 16.0-19.5°C (Leggett & Whitney,1972). At Vancouver Island, B.C., distribution of a kelp, Laminaria groenlandica , is temperature influenced . The long stipe form is not found above 13°C; the short stipe form does not occur above 17°C . In the laboratory, elevation of temperature to 13°C produces abnormal sporophytes (Druehl, 1967). Dungeness crab, Cancer magister, larval development is optimal at 10 and 13.9°C, survival is reduced at 17.8°C, with no survival to megalops at 21.7°C (Reed, 1969). The Upper thermal limit for razor clam embryonic and larval development is 17°C (McCauley and Hancock, 1971). Upper growth limit

NMED Exhibit 83

for small filamentous red algae, Antithamnion spp, is 18°C (West, 1968). King salmon migration into the San Joaquin River may be delayed by estuarine temperatures in excess of 17.8°C (Dunham, 1968).

The sea grass, Phyllospadix scouleri, begins to die off (McRoy, 1970), and the pea pod borer, Botula fulcata, ceases to develop at 20°C (Fox and Corcoran, 1957). Twenty degrees centigrade also is the upper limit for embryonic and larval development of the summer-spawning horse clam, Tresus nuttalli, and native little neck clam, Protothaca staminea, (Schink and Woelke, 1973). Upper incipient lethal temperature for the mysid shrimp, Neomysis intermedia, is 21.7°C (Hair, 1971). This value is corroborated by reports of a drop in field populations of this important fish food organism above 22.2°C in the San Joaquin estuary (Heubach, 1969). Twenty-two degrees centigrade is the upper tolerance limit for embryological development of the wooly sculpin, Clinocottus analis, (Hubbs, 1966). A four-hour exposure to 23°C results in significant mortality of the adult razor clam, Siliqua patula, (Woelke, 1971) and the sockeye salmon, Oncorhynchus nerka, (Brett and Alderdice, 1958). Striped bass, Morone saxatilis, are believed to be stressed at temperatures above 23.9°C (Dunham, 1968). Sexual maturation in a gobiid fish, Gillicthys mirabilis, is blocked at high temperatures. Gonadal regression begins at 22°C in females; at 24°C in males.

NMED Exhibit 83

Gonadal recrudescence will not occur at 24°C or above, regardless of photoperiod (DeVlaming, 1972). The 36-hour TLm for red abalone adults is 23°C when acclimated to 15°C; for the embryos, 26°C, when exposed for 30 hours (Ebert, 1974). Sea urchin, Strongylocentrotus purpuratus, upper tolerance limit is 23.5°C for adults (Gonor, 1968); 25°C is lethal to embryos and renders adults limp and unresponsive after 4 hours (Farmanfarmaian and Giese, 1963).

Pacific Warm Temperate Zone: The thermal threshold for spawning in Pacific sardine, Sardinops caerulea, is 13°C (Marr, 1962). Reports of temperature optima for spawning include 15°C in a ctenophore, Pleurobranchia bachei, (Hirota, 1973); 16°C in the spring spawning wooly sculpin, Clinocottus analis, (Graham, 1970); 17.5°C for northern anchovy, Engraulis mordax; 19°C for opaleye fish, Girella nigricans, (Norris, 1963). Larval survival is best at 16 to 18°C in white abalone, Haliotis sorenseni, (Leighton, 1972).

Limiting effects of temperature include scarcity of the kelp isopod in the beds above 17.8°C (Jones, 1971). Upper limit for growth in Pleurobranchia bachei is 17°C; 20°C is the upper tolerance limit for the adult ctenophore (Hirota, 1973). Twenty degrees centigrade also causes limited survival in recently settled juvenile white abalone (Leighton, 1972). Limiting

NMED Exhibit 83

effects for wooly sculpin include the upper limit of optimal growth at 21°C; at 22°C, a 50 percent reduction in the successful development of eggs; at 24°C, the upper limit for embryonic development is reached (Hubbs, 1966). Sea Urchins, Strongylocentrotus sp. are weakened or killed at 24°C to 25°C (Leighton, 1971). At 25°C, partial osmoregulatory failure occurs in staghorn sculpin, Leptocottus armatus, at 37.6 o/oo (Morris, 1960). A maximum temperature of occurrence of 25°C is reported for top smelt, Atherinops affinis, by Doudoroff (1945) and northern anchovy, Engraulis mordax, (Baxter, 1967). For topsmelt, the upper limit at which larvae hatch is 26.8°C (Hubbs, 1965).

Natural summer temperatures are stressful to beds of giant kelp, Macrocystis pyrifera, in southern California. This precludes any summer thermal discharge in the vicinity of these beds. Deterioration of surface blades is evident from late June onward, due in part to reduced photosynthesis (Clendenning, 1971). Several weeks' exposure to 18.9°C is harmful to the beds (Jones, 1971), while temperatures over 20°C result in pronounced loss of kelp (North, 1964). Brandt (1923) reported that there was some 60 percent reduction of kelp harvest when the average temperature was 20.65°C and that a bacterial disease, black rot, thrives on kelp at 18-20°C. One-day exposure to 22°C is quite harmful to cultured gametophytes of giant kelp (North, 1972).

ZINC

CRITERIA:

5,000 ug/l for domestic water supplies (welfare);

For freshwater aquatic life, 0.01 of the 96-hour LC_{50} as determined through bioassay using a sensitive resident species.

INTRODUCTION:

Zinc usually is found in nature as the sulfide; it is often associated with sulfides of other metals, especially lead, copper cadmium, and iron. Most other zinc minerals probably have been formed as oxidation products of the sulfide; they represent only minor source of zinc. Nearly 3,000,000 short tons of recoverable zinc per year are mined in the world; about 500,000 tons of this come from the United States.

Zinc (as metal) is used in galvanizing, i.e., coating (hot dipping) of various iron and steel surfaces with a thin layer of zinc to retard corrosion of the coated metal. In contact with iron, zinc is oxidized preferentially, thus protecting the iron. The second most important use of zinc, reaching major proportions in the last quarter century, is in the preparation of alloys for dye casting. Zinc is used also in brass and bronze alloys, slush castings (in the rolled or extruded state), in the production of zinc oxide and other chemical products, and in photoengraving and printing plates.

NMED Exhibit 83

Kopp and Kroner (1967) report that in 1,207 positive tests for zinc on samples from U.S. waterways, the maximum observed value was 1,183 ug/l (Cuyahoga River at Cleveland, Ohio) and the mean was 64 ug/l. Dissolved zinc was measured in over 76 percent of all water samples tested. The highest mean zinc value, 205 ug/l, was found in the Lake Erie Basin, whereas the lowest mean zinc value, 16 ug/l, was observed in the California Basin. In seawater, zinc is found at a maximum concentration of about 10 ug/l.

RATIONALE:

Zinc is an essential and beneficial element in human metabolism (Vallee, 1957). The daily requirement of preschool-aged children is 0.3 mg Zn/kg body weight. The daily adult human intake averages 0 to 15 mg/ zinc; deficiency in children leads to growth retardation. Community water supplies have contained 11 to 27 mg/l without harmful effects (Anderson, et al., 1934; Bartow and Weigle, 1932). However, in tests performed by a taste panel, 5 percent of the observers were able to distinguish between water containing 4 mg/l zinc as $ZnSO_4$, which had a bitter or astringent taste, and water containing no zinc salts (Cohen, et al., 1960). Because zinc in water produces undesirable aesthetic effects, the concentration of zinc in domestic water supplies should be below 5 mg/l (5,000 ug/l).

The toxicity of zinc compounds to aquatic animals is modified by several environmental factors, particularly hardness, dissolved oxygen, and temperature. Skidmore (1964), in undertaking a review of the literature on the toxicity of zinc to fish, reported that salts of the

NMED Exhibit 83

alkaline-earth metals are antagonistic to the action of zinc salts, and salts of certain heavy metals are synergistic in soft water. Both an increase in temperature and a reduction in dissolved oxygen increase the toxicity of zinc. Toxic concentrations of zinc compounds cause adverse changes in the morphology and physiology of fish. Acutely toxic concentrations induce cellular breakdown of the gills, and possibly the clogging of the gills with mucous. Chronically toxic concentrations of zinc compounds, in contrast, cause general enfeeblement and widespread histological changes to many organs, but not to gills. Growth and maturation are retarded.

Using dilution water with calcium of 1.7 mg/l and magnesium of 1.0 mg/l, Affleck (1952) found a 54 percent mortality of rainbow trout fry in 28 days in a zinc concentration of 10 ug/l. Pickering and Henderson (1966) determined the 96-hour LC_{50} of zinc for fathead minnows, Pimephales promelas, and bluegills, Lepomis macrochirus, using static test conditions. For fathead minnows in soft water (20 mg/l $CaCO_3$) the LC_{50} was 870 ug/l, and in hard water (360 mg/l $CaCO_3$) it was 33,000 ug/l. Bluegills were more resistant in both waters. Similarly, the lethal threshold concentration was 3 or 4 times as high for coarse fish as for trout, Salvelinus fontinalis, (Ball, 1967).

The 24-hour LC_{50} of zinc for rainbow trout, Salmo gairdneri, was reduced only 20 percent when the fish were forced to swim at 85 percent of their maximum sustained swimming speed (Herbert and Shurben, 1964). The maximum effect of a reduction in dissolved oxygen from 6 to 7 mg/l to 2 mg/l on the acute toxicity of zinc was a 50-percent increase (Lloyd, 1961; Cairns and Scheier, 1958; Pickering, 1968).

NMED Exhibit 83

The Atlantic salmon, Salmo salar, was tested in a 168-hour continuous-flow bioassay at 17° C in water with a total hardness of 14 mg/l $CaCO_3$. The incipient lethal level, the level beyond which the organism can no longer survive, was 420 ug/l of zinc (Sprague and Ramsay, 1965).

Brungs (1969) found that in water with a total hardness of 200 mg/l $CaCO_3$, 180 ug/l zinc caused an 83 percent reduction in eggs produced by the fathead minnow, Pimephales promelas, in chronic tests. The tests lasted 10 months and the control test water contained 30 ug/l zinc. The 96-hour continuous-flow TLm was determined to be 9,200 ug/l zinc.

A number of short term fish toxicity data are detailed in Table 14. When referring to this table, the reader should consider the species tested, pH, alkalinity, and hardness (if alkalinity is not given (in most natural waters alkalinity parallels hardness). In general, the salmonids are most sensitive to elemental zinc in soft water; the rainbow trout Salmo gairdneri is the most sensitive in hard waters. The influence of the pH on solubility of zinc complexes, and the resulting toxicity of zinc, is clearly shown in the data presented on the fathead minnow, Pimephales promelas. The influence of pH and other factors on the solubility and form of the zinc preclude the recommendation of a freshwater or marine criteria based on acute toxicities alone.

NMED Exhibit 83

Wurtz (1962) performed bioassays on young pond snails, Physa heterostropha, in waters with a total hardness of 100 mg/l and 20 mg/l $CaCO_3$. In water with a temperature of 51° F, the soft water tests resulted in a 96-hour LC_{50} of 303 ug/l zinc, whereas the 96-hour LC_{50} in hard water was 434 ug/l zinc. The LC_{50} of a zinc sulfate solution in dilution water with a total hardness of 44 mg/l $CaCO_3$ for a 10-day test to a mayfly, Ephemerella subvaria, was 16,000 ug/l (Warnick and Bell, 1969). In such tests with several heavy metals, the immature insects seem to be less sensitive than many fishes that have been tested.

The 48-hour LC_{50} for Daphnia magna in soft water with a hardness of 45 mg/l $CaCO_3$ and an alkalinity of 42 mg/l has been found to be 100 ug/l; in 70 ug/l zinc, there was a 16 percent reproductive impairment in a 3-week chronic test (Biesinger and Christensen, 1972).

Toxicities of zinc in nutrient solutions have been demonstrated for a number of plants. Hewitt (1948) found that zinc at 16 to 20 mg/l produced iron deficiencies in sugar beets. Hunter and Vergnano (1953) found toxicity to oats at 25 mg/l. Millikan (1947) found that 2.5 mg/l produced iron deficiency in oats. Early (1943) found that the Peking variety of soybeans was killed at 0.4 mg/l, whereas the Manchu variety was killed at 1.6 mg/l zinc.

Although few data are available on the effects of zinc in the marine environment, it is accumulated by some species, and marine animals contain zinc in the range of 6 to 1,500 mg/kg (NTAC, 1968). As a goal, the marine environment should be protected to the same level as the fresh water environment.

NMED Exhibit 83

GLOSSARY

Acutely toxic: Causing death or severe damage to an organism by poisoning during a brief exposure period, normally ninety-six hours or less, although there is no clear line of demarcation between acute and chronic toxicity.

Chronically toxic: Causing death or damage to an organism by poisoning during prolonged exposure, which, depending on the organism tested and the test conditions and purposes, may range from several days, to weeks, months, or years.

Dose equivalent: The product of the absorbed dose from ionizing radiation and such factors to account for differences in biological effectiveness due to the type of radiation and its distribution in the body as specified by the International Commission on Radiological Units and Measurements (ICRU).

EC50: The concentration at which a specified effect is observed under the test conditions in a specified time in fifty percent of the organisms tested. Examples of specified effects are hemorrhaging, decreased feeding, dilation of pupils, and altered swimming patterns.

Gross alpha particle activity: The total radioactivity due to alpha particle emission as inferred from measurements on a dry sample exclusive of the contribution, if any, due to radon and uranium.

NMED Exhibit 83

Gross beta particle activity: The total radioactivity due to beta particle emission as inferred from measurements on a dry sample exclusive of the contribution, if any, due to potassium-40 and other naturally occurring radionuclides.

LC25: The concentration of a toxicant that is lethal (fatal) to twenty-five percent of the organisms tested under the test conditions in a specified time.

LC50: The concentration of a toxicant which is lethal (fatal) to fifty percent of the organisms tested under the test conditions in a specified time.

LD50: The dose of a toxicant that is lethal (fatal) to fifty percent of the organisms tested under the test conditions in a specified time. A dose is the quantity actually administered to the organism and is not identical with a concentration, which is the amount of toxicant in a unit of test medium rather than the amount ingested by or administered to the organism.

Liter (l): The volume occupied by one kilogram of water at a pressure of 760 mm of mercury and a temperature of 4 C. A liter is 0.9463 quart.

Man-made beta particle and photon emitters: All radionuclides emitting beta particles and/or photons listed in Maximum Permissible Body Burdens and Maximum Permissible Concentrations of Radionuclides in Air or Water for Occupational Exposure, NBS Handbook 69, except the daughter products of thorium-232, uranium-235, and uranium-238.

NMED Exhibit 83

Microgram per liter (ug/l): The concentration at which one millionth of a gram (10^{-6}g) is contained in a volume of one liter. There are 453.59 grams in a pound.

Microgram per kilogram (ug/kg): The concentration at which one millionth of a gram (one microgram) is contained in a mass of one kilogram. A kilogram is 2.2046 pounds.

Milligram per kilogram (mg/kg): The concentration at which one thousandth of a gram (one milligram) is contained in a mass of one kilogram. A gram contains 1000 milligrams.

Milligram per liter (mg/l): The concentration at which one milligram (10^{-3}g) is contained in a volume of one liter.

Milliliter (ml): A volume equal to one thousandth of a liter.

Most Probable Number (MPN): The statistically determined number which represents the number of individuals most likely present in a given sample or aliquot, based on test data.

Nanogram per liter (ng/l): The concentration at which one billionth of a gram (10^{-9}g) is contained in a volume of one liter.

NMED Exhibit 83

Part per million (ppm): A concentration at which one unit is contained in a total of a million units. Any units may be used (e.g., weight, volume) but in any given application identical units should be used (e.g., grams per million grams or liters per million liters).

Parts per thousand (o /oo): A concentration at which one unit is contained in a total of a thousand units. The rules for using this term are the same as those for parts per million. Normally, this term is used to specify the salinity of estuarine or sea waters.

Picocurie (pCi): That quantity of radioactive material producing 2.22 nuclear transformations per minute.

Rem: The unit of dose equivalent from ionizing radiation to the total body or any internal organ or organ system. A millirem (mrem) is 1/1000 of a rem (0.001 rem).

TL50: - Median Tolerance Limit: The concentration of a test material at which just fifty percent of the test animals are able to survive under test conditions for a specified period of exposure.

TLm : Synonymous with TL_{50}.

NOTICE

The policies and procedures set forth in this document are intended solely to describe EPA methods for developing or revising ambient water quality criteria to protect human health, pursuant to Section 304(a) of the Clean Water Act, and to serve as guidance to States and authorized Tribes for developing their own water quality criteria. This guidance does not substitute for the Clean Water Act or EPA's regulations; nor is it a regulation itself. Thus, it does not impose legally-binding requirements on EPA, States, Tribes or the regulated community, and may not apply to a particular situation based upon the circumstances.

This document has been reviewed in accordance with U.S. Environmental Protection Agency policy and approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

NMED Exhibit 84

FOREWORD

This document presents EPA's recommended Methodology for developing ambient water quality criteria as required under Section 304(a) of the Clean Water Act (CWA). The Methodology is guidance for scientific human health assessments used by EPA to develop, publish, and from time to time revise, recommended criteria for water quality accurately reflecting the latest scientific knowledge. The recommended criteria serve States and Tribes' needs in their development of water quality standards under Section 303(c) of the CWA.

The term "water quality criteria" is used in two sections of the Clean Water Act, Section 304(a)(1) and Section 303(c)(2). The term has a different program impact in each section. In Section 304, the term represents a scientific assessment of ecological and human health effects that EPA recommends to States and authorized Tribes for establishing water quality standards that ultimately provide a basis for controlling discharges or releases of pollutants. Ambient water quality criteria associated with specific stream uses when adopted as State or Tribal water quality standards under Section 303 define the maximum levels of a pollutant necessary to protect designated uses in ambient waters. The water quality criteria adopted in the State or Tribal water quality standards could have the same numerical limits as the criteria developed under Section 304. However, in many situations States and authorized Tribes may want to adjust water quality criteria developed under Section 304 to reflect local environmental conditions and human exposure patterns before incorporation into water quality standards. When adopting their water quality criteria, States and authorized Tribes have four options: (1) adopt EPA's 304(a) recommendations; (2) adopt 304(a) criteria modified to reflect site-specific conditions; (3) develop criteria based on other scientifically defensible methods; or (4) establish narrative criteria where numeric criteria cannot be determined.

EPA will use this Methodology to develop new ambient water quality criteria and to revise existing recommended water quality criteria. It also provides States and authorized Tribes the necessary guidance to adjust water quality criteria developed under Section 304 to reflect local conditions or to develop their own water quality criteria using scientifically defensible methods consistent with this Methodology. EPA encourages States and authorized Tribes to use this Methodology to develop or revise water quality criteria to appropriately reflect local conditions. EPA believes that ambient water quality criteria inherently require several risk management decisions that are, in many cases, better made at the State, Tribal, or regional level. Additional guidance to assist States and authorized Tribes in the modification of criteria based on the Methodology will accompany this document in the form of three companion Technical Support Documents on Risk Assessment, Exposure Assessment, and Bioaccumulation Assessment.

1. INTRODUCTION

1.1 WATER QUALITY CRITERIA AND STANDARDS

Pursuant to Section 304(a)(1) of the Clean Water Act (CWA), the U.S. Environmental Protection Agency (EPA) is required to publish, and from time to time thereafter revise, criteria for water quality accurately reflecting the latest scientific knowledge on the kind and extent of all identifiable effects on human health which may be expected from the presence of pollutants in any body of water.

Historically, the ambient water quality criteria (AWQC or 304(a) criteria) provided two essential types of information: (1) discussions of available scientific data on the effects of the pollutants on public health and welfare, aquatic life, and recreation; and (2) quantitative concentrations or qualitative assessments of the levels of pollutants in water which, if not exceeded, will generally ensure adequate water quality for a specified water use. Water quality criteria developed under Section 304(a) are based solely on data and scientific judgments on the relationship between pollutant concentrations and environmental and human health effects. The 304(a) criteria do not reflect consideration of economic impacts or the technological feasibility of meeting the criteria in ambient water. These 304(a) criteria may be used as guidance by States and authorized Tribes to establish water quality standards, which ultimately provide a basis for controlling discharges or releases of pollutants into ambient waters.

In 1980, AWQC were derived for 64 pollutants using guidelines developed by the Agency for calculating the impact of waterborne pollutants on aquatic organisms and on human health. Those guidelines consisted of systematic procedures for assessing valid and appropriate data concerning a pollutant's acute and chronic adverse effects on aquatic organisms, nonhuman mammals, and humans.

1.2 PURPOSE OF THIS DOCUMENT

The *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (2000)* (hereafter the "2000 Human Health Methodology") addresses the development of AWQC to protect human health. The Agency intends to use the 2000 Human Health Methodology both to develop new AWQC for additional pollutants and to revise existing AWQC. Within the next several years, EPA intends to focus on deriving AWQC for chemicals of high priority (including, but not limited to, mercury, arsenic, PCBs, and dioxin). Furthermore, EPA anticipates that 304(a) criteria development in the future will be for bioaccumulative chemicals and pollutants considered highest priority by the Agency. The 2000 Human Health Methodology is also intended to provide States and authorized Tribes flexibility in establishing water quality standards by providing scientifically valid options for developing their own water quality criteria that consider local conditions. States and authorized Tribes are strongly encouraged to use this Methodology to derive their own AWQC. However, the 2000 Human Health Methodology also defines the default factors EPA intends to use in evaluating and determining consistency of State water quality standards with the requirements of the CWA. The Agency intends to use these default factors to calculate national water quality criteria under

NMED Exhibit 84

Section 304(a) of the Act. EPA will also use this Methodology as guidance when promulgating water quality standards for a State or Tribe under Section 303(c) of the CWA.

This Methodology does not substitute for the CWA or EPA's regulations; nor is it a regulation itself. Thus, the 2000 Human Health Methodology cannot impose legally-binding requirements on EPA, States, Tribes or the regulated community, and may not apply to a particular situation based upon the circumstances. EPA and State/Tribal decision-makers retain the discretion to use different, scientifically defensible, methodologies to develop human health criteria on a case-by-case basis that differ from this Methodology where appropriate. EPA may change the Methodology in the future through intermittent refinements as advances in science or changes in Agency policy occur.

The 2000 Human Health Methodology incorporates scientific advancements made over the past two decades. The use of this Methodology is an important component of the Agency's efforts to improve the quality of the Nation's waters. EPA believes the Methodology will enhance the overall scientific basis of water quality criteria. Further, the Methodology should help States and Tribes address their unique water quality issues and risk management decisions, and afford them greater flexibility in developing their water quality programs.

There are three companion Technical Support Document (TSD) volumes for the 2000 Human Health Methodology: a Risk Assessment TSD; an Exposure Assessment TSD; and a Bioaccumulation TSD. These documents are intended to further support States and Tribes in developing AWQC to reflect local conditions. The Risk Assessment TSD (USEPA, 2000) is being published concurrently with this Methodology. Publication of the Exposure Assessment and Bioaccumulation TSDs are anticipated in 2001.

1.3 HISTORY OF THE AMBIENT WATER QUALITY CRITERIA (AWQC) METHODOLOGY

In 1980, EPA published AWQC for 64 pollutants/pollutant classes identified in Section 307(a) of the CWA and provided a methodology for deriving the criteria (USEPA, 1980). These 1980 AWQC National Guidelines (or the "1980 Methodology") for developing AWQC for the protection of human health addressed three types of endpoints: noncancer, cancer, and organoleptic (taste and odor) effects. Criteria for protection against noncancer and cancer effects were estimated by using risk assessment-based procedures, including extrapolation from animal toxicity or human epidemiological studies. Basic human exposure assumptions were applied to the criterion equation.

The risk assessment-based procedures used to derive the AWQC to protect human health were specific to whether the endpoint was cancer or noncancer. When using cancer as the critical risk assessment endpoint (which had been assumed not to have a threshold), the AWQC were presented as a range of concentrations associated with specified incremental lifetime risk

NMED Exhibit 84

levels[1]. When using noncancer effects as the critical endpoint, the AWQC reflected an assessment of a "no-effect" level, since noncancer effects were assumed to have a threshold. The key features of each procedure are described briefly in the following paragraphs.

Cancer effects. If human or animal studies on a contaminant indicated that it induced a statistically significant carcinogenic response, the 1980 AWQC National Guidelines treated the contaminant as a carcinogen and derived a low-dose cancer potency factor from available animal data using the linearized multistage model (LMS). The LMS, which uses a linear, nonthreshold assumption for low-dose risk, was used by the Agency as a science policy choice in protecting public health, and represented a plausible upper limit for low-dose risk. The cancer potency factor, which expresses incremental, lifetime risk as a function of the rate of intake of the contaminant, was then combined with exposure assumptions to express that risk in terms of an ambient water concentration. In the 1980 AWQC National Guidelines, the Agency presented a range of contaminant concentrations corresponding to incremental cancer risks of 10^{-7} to 10^{-5} (that is, a risk of one additional case of cancer in a population of ten million to one additional cancer case in a population of one hundred thousand, respectively).

Noncancer effects. If the pollutant was not considered to have the potential for causing cancer in humans (later defined as a known, probable, or possible human carcinogen by the 1986 *Guidelines for Carcinogen Risk Assessment,* USEPA, 1986d), the 1980 AWQC National Guidelines treated the contaminant as a noncarcinogen; a criterion was derived using a threshold concentration for noncancer adverse effects. The criteria derived from noncancer data were based on the Acceptable Daily Intake (ADI) (now termed the reference dose [RfD]). ADI values were generally derived using a no-observed-adverse-effect level (NOAEL) from animal studies, although human data were used whenever available. The ADI was calculated by dividing the NOAEL by an uncertainty factor to account for uncertainties inherent in extrapolating limited toxicological data to humans. In accordance with the National Research Council recommendations of 1977 (NRC, 1977), safety factors (SFs) (later redefined as uncertainty factors) of 10, 100, or 1,000 were used, depending on the quality of the data.

Organoleptic effects. Organoleptic characteristics were also used in developing criteria for some contaminants to control undesirable taste and/or odor imparted by them to ambient water. In some cases, a water quality criterion based on organoleptic effects would be more stringent than a criterion based on toxicologic endpoints. The 1980 AWQC National Guidelines emphasized that criteria derived for organoleptic endpoints are not based on toxicological information, have no direct relationship to adverse human health effects and, therefore, do not necessarily represent approximations of acceptable risk levels for humans.

[1]Throughout this document, the term "risk level" regarding a cancer assessment using linear approach refers to an upper-bound estimate of excess lifetime cancer risk.

NMED Exhibit 84

1.4 RELATIONSHIP OF WATER QUALITY STANDARDS TO AWQC

Under Section 303(c) of the CWA, States have the primary responsibility for establishing water quality standards, defined under the Act as designated beneficial uses of a water segment and the water quality criteria necessary to support those uses. Additionally, Native American Tribes authorized to administer the water quality standards program under 40 CFR 131.8 establish water quality standards for waters within their jurisdictions. This statutory framework allows States and authorized Tribes to work with local communities to adopt appropriate designated uses and to adopt criteria to protect those designated uses. Section 303(c) provides for EPA review of water quality standards and for promulgation of a superseding Federal rule in cases where State or Tribal standards are not consistent with the applicable requirements of the CWA and the implementing Federal regulations, or where the Agency determines Federal standards are necessary to meet the requirements of the Act. Section 303(c)(2)(B) specifically requires States and authorized Tribes to adopt water quality criteria for toxics for which EPA has published criteria under Section 304(a) and for which the discharge or presence could reasonably be expected to interfere with the designated use adopted by the State or Tribe. In adopting such criteria, States and authorized Tribes must establish numerical values based on one of the following: (1) 304(a) criteria; (2) 304(a) criteria modified to reflect site-specific conditions; or, (3) other scientifically defensible methods. In addition, States and authorized Tribes can establish narrative criteria where numeric criteria cannot be determined.

It must be recognized that the Act uses the term "criteria" in two different ways. In Section 303(c), the term is part of the definition of a water quality standard. Specifically, a water quality standard is composed of designated uses and the criteria necessary to protect those uses. Thus, States and authorized Tribes are required to adopt regulations which contain legally enforceable criteria. However, in Section 304(a) the term criteria is used to describe the scientific information that EPA develops to be used as guidance by States, authorized Tribes and EPA when establishing water quality standards pursuant to 303(c). Thus, two distinct purposes are served by the 304(a) criteria. The first is as guidance to the States and authorized Tribes in the development and adoption of water quality criteria which will protect designated uses, and the second is as the basis for promulgation of a superseding Federal rule when such action is necessary.

1.5 NEED FOR THE AWQC METHODOLOGY REVISIONS

Since 1980, EPA risk assessment practices have evolved significantly in all of the major Methodology areas: that is, cancer and noncancer risk assessments, exposure assessments, and bioaccumulation. When the 1980 Methodology was developed, EPA had not yet developed formal cancer or noncancer risk assessment guidelines. Since then, EPA has published several risk assessment guidelines. In cancer risk assessment, there have been advances in the use of mode of action (MOA) information to support both the identification of potential human carcinogens and the selection of procedures to characterize risk at low, environmentally relevant exposure levels. EPA published *Proposed Guidelines for Carcinogen Risk Assessment* (USEPA, 1996a, hereafter the "1996 proposed cancer guidelines"). These guidelines presented revised procedures to quantify cancer risk at low doses, replacing the current default use of the LMS model. Following review by the Agency's Science Advisory Board (SAB), EPA published the

NMED Exhibit 84

revised *Guidelines for Carcinogen Risk Assessment–Review Draft* in July 1999 (USEPA, 1999a, hereafter the "1999 draft revised cancer guidelines"). In noncancer risk assessment, the Agency is moving toward the use of the benchmark dose (BMD) and other dose-response approaches in place of the traditional NOAEL approach to estimate an RfD or Reference Concentration (RfC). *Guidelines for Mutagenicity Risk Assessment* were published in 1986 (USEPA, 1986b). In 1991, the Agency published *Guidelines for Developmental Toxicity Risk Assessment* (USEPA, 1991), and it issued *Guidelines for Reproductive Toxicity Risk Assessment* in 1996 (USEPA, 1996b). In 1998, EPA published final *Guidelines for Neurotoxicity Risk Assessment* (USEPA, 1998), and in 1999 it issued the draft *Guidance for Conducting Health Risk Assessment of Chemical Mixtures* (USEPA, 1999b).

In 1986, the Agency made available to the public the Integrated Risk Information System (IRIS). IRIS is a database that contains risk information on the cancer and noncancer effects of chemicals. The IRIS assessments are peer reviewed and represent EPA consensus positions across the Agency's program and regional offices.

New studies have addressed water consumption and fish tissue consumption. These studies provide a more current and comprehensive description of national, regional, and special-population consumption patterns that EPA has reflected in the 2000 Human Health Methodology. In addition, more formalized procedures are now available to account for human exposure from multiple sources when setting health goals such as AWQC that address only one exposure source. In 1986, the Agency published the *Total Exposure Assessment Methodology (TEAM) Study: Summary and Analysis, Volume I, Final Report* (USEPA, 1986c), which presents a process for conducting comprehensive evaluation of human exposures. In 1992, EPA published the revised *Guidelines for Exposure Assessment* (USEPA, 1992), which describe general concepts of exposure assessment, including definitions and associated units, and provide guidance on planning and conducting an exposure assessment. The *Exposure Factors Handbook* was updated in 1997 (USEPA, 1997a). Also in 1997, EPA developed *Guiding Principles for Monte Carlo Analysis* (USEPA, 1997b) and published its *Policy for Use of Probabilistic Analysis in Risk Assessment* (see http://www.epa.gov/ncea/mcpolicy.htm). The Monte Carlo guidance can be applied to exposure assessments and risk assessments. The Agency has recently developed the Relative Source Contribution (RSC) Policy for assessing total human exposure to a contaminant and apportioning the RfD among the media of concern, published for the first time in this Methodology.

The Agency has moved toward the use of a bioaccumulation factor (BAF) to reflect the uptake of a contaminant from all sources (e.g., ingestion, sediment) by fish and shellfish, rather than just from the water column as reflected by the use of a bioconcentration factor (BCF) in the 1980 Methodology. The Agency has also developed detailed procedures and guidelines for estimating BAF values.

Another reason for the 2000 Human Health Methodology is the need to bridge the gap between the differences in the risk assessment and risk management approaches used by EPA's Office of Water for the derivation of AWQC under the authority of the CWA and Maximum Contaminant Level Goals (MCLGs) under the Safe Drinking Water Act (SDWA). Three notable differences are the treatment of chemicals designated as Group C, possible human carcinogens

NMED Exhibit 84

under the 1996 proposed cancer guidelines, the consideration of non-water sources of exposure when setting an AWQC or MCLG for a noncarcinogen, and cancer risk ranges. Those three differences are described in the three subsections below, respectively.

1.5.1 Group C Chemicals

Chemicals were typically classified as Group C–i.e., possible human carcinogens–under the existing (1986) EPA cancer classification scheme for any of the following reasons:

1) Carcinogenicity has been documented in only one test species and/or only one cancer bioassay and the results do not meet the requirements of "sufficient evidence."

2) Tumor response is of marginal statistical significance due to inadequate design or reporting.

3) Benign, but not malignant, tumors occur with an agent showing no response in a variety of short-term tests for mutagenicity.

4) There are responses of marginal statistical significance in a tissue known to have a high or variable background rate.

The 1986 *Guidelines for Carcinogen Risk Assessment* (hereafter the "1986 cancer guidelines") specifically recognized the need for flexibility with respect to quantifying the risk of Group C, possible human carcinogens. The 1986 cancer guidelines noted that agents judged to be in Group C, possible human carcinogens, may generally be regarded as suitable for quantitative risk assessment, but that case-by-case judgments may be made in this regard.

The EPA Office of Water has historically treated Group C chemicals differently under the CWA and the SDWA. It is important to note that the 1980 AWQC National Guidelines for setting AWQC under the CWA predated EPA's carcinogen classification system, which was proposed in 1984 (USEPA, 1984) and finalized in 1986 (USEPA, 1986a). The 1980 AWQC National Guidelines did not explicitly differentiate among agents with respect to the weight of evidence for characterizing them as likely to be carcinogenic to humans. For all pollutants judged as having adequate data for quantifying carcinogenic risk–including those now classified as Group C–AWQC were derived based on data on cancer incidence. In the1980 AWQC National Guidelines, EPA emphasized that the AWQC for carcinogens should state that the recommended concentration for maximum protection of human health is zero. At the same time, the criteria published for specific carcinogens presented water concentrations for these pollutants corresponding to individual lifetime excess cancer risk levels in the range of 10^{-7} to 10^{-5}.

In the development of national primary drinking water regulations under the SDWA, EPA is required to promulgate a health-based MCLG for each contaminant. The Agency policy has been to set the MCLG at zero for chemicals with strong evidence of carcinogenicity associated with exposure from water. For chemicals with limited evidence of carcinogenicity, including many Group C agents, the MCLG was usually obtained using an RfD based on the

NMED Exhibit 84

pollutant's noncancer effects with the application of an additional uncertainty factor of 1 to 10 to account for carcinogenic potential of the chemical. If valid noncancer data for a Group C agent were not available to establish an RfD but adequate data are available to quantify the cancer risk, then the MCLG was based upon a nominal lifetime excess cancer risk in the range of 10^{-6} to10^{-5} (ranging from one case in a population of one million to one case in a population of one hundred thousand). Even in those cases where the RfD approach has been used for the derivation of the MCLG for a Group C agent, the drinking water concentrations associated with excess cancer risks in the range of 10^{-6} to 10^{-5} were also provided for comparison.

It should also be noted that EPA's pesticides program has applied both of the previously described methods for addressing Group C chemicals in actions taken under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and finds both methods applicable on a case-by-case basis. Unlike the drinking water program, however, the pesticides program does not add an extra uncertainty factor to account for potential carcinogenicity when using the RfD approach.

In the 1999 draft revised cancer guidelines, there are no more alphanumeric categories. Instead, there will be longer narratives for hazard characterization that will use consistent descriptive terms when assessing cancer risk.

1.5.2 Consideration of Non-water Sources of Exposure

The 1980 AWQC National Guidelines recommended that contributions from non-water sources, namely air and non-fish dietary intake, be subtracted from the Acceptable Daily Intake (ADI), thus reducing the amount of the ADI "available" for water-related sources of intake. In practice, however, when calculating human health criteria, these other exposures were generally not considered because reliable data on these exposure pathways were not available. Consequently, the AWQC were usually derived such that drinking water and fish ingestion accounted for the entire ADI (now called RfD).

In the drinking water program, a similar "subtraction" method was used in the derivation of MCLGs proposed and promulgated in drinking water regulations through the mid-1980s. More recently, the drinking water program has used a "percentage" method in the derivation of MCLGs for noncarcinogens. In this approach, the percentage of total exposure typically accounted for by drinking water, referred to as the relative source contribution (RSC), is applied to the RfD to determine the maximum amount of the RfD "apportioned" to drinking water reflected by the MCLG value. In using this percentage procedure, the drinking water program also applies a ceiling level of 80 percent of the RfD and a floor level of 20 percent of the RfD. That is, the MCLG cannot account for more than 80 percent of the RfD, nor less than 20 percent of the RfD.

The drinking water program usually takes a conservative approach to public health by applying an RSC factor of 20 percent to the RfD when adequate exposure data do not exist, assuming that the major portion (80 percent) of the total exposure comes from other sources, such as diet.

NMED Exhibit 84

In the 2000 Human Health Methodology, guidance for the routine consideration of non-water sources of exposure [both ingestion exposures (e.g., food) and exposures other than the oral route (e.g., inhalation)] is presented. The approach is called the Exposure Decision Tree. Relative source contribution estimates will be made by EPA using this approach, which allows for use of either the subtraction or percentage methods, depending on chemical-specific circumstances, within the 20 to 80 percent range described above.

1.5.3 Cancer Risk Ranges

In addition to the different risk assessment approaches discussed above for deriving AWQC and MCLGs for Group C agents, there have been different risk management approaches by the drinking water and surface water programs on lifetime excess risk values when setting health-based criteria for carcinogens. The surface water program has derived AWQC for carcinogens that generally corresponded to lifetime excess cancer risk levels of 10^{-7} to 10^{-5}. The drinking water program has set MCLGs for Group C agents based on a slightly less stringent risk range of 10^{-6} to 10^{-5}, while MCLGs for chemicals with strong evidence of carcinogenicity (that is, classified as Group A, known, or B probable, human carcinogen) are set at zero. The drinking water program is now following the principles of the 1999 draft revised cancer guidelines to determine the type of low-dose extrapolation based on mode of action.

It is also important to note that under the drinking water program, for those substances having an MCLG of zero, enforceable Maximum Contaminant Levels (MCLs) have generally been promulgated to correspond with cancer risk levels ranging from 10^{-6} to 10^{-4}. Unlike AWQC and MCLGs which are strictly health-based criteria, MCLs are developed with consideration given to the costs and technological feasibility of reducing contaminant levels in water to meet those standards.

With the 2000 Human Health Methodology, EPA will publish its national 304(a) water quality criteria at a 10^{-6} risk level, which EPA considers appropriate for the general population. EPA is increasing the degree of consistency between the drinking water and ambient water programs, given the somewhat different requirements of the CWA and SDWA.

NMED Exhibit 84

1.6 OVERVIEW OF THE AWQC METHODOLOGY REVISIONS

The following equations for deriving AWQC include toxicological and exposure assessment parameters which are derived from scientific analysis, science policy, and risk management decisions. For example, values for parameters such as a field-measured BAF or a point of departure from an animal study [in the form of a lowest-observed-adverse-effect level (LOAEL)/no-observed -adverse-effect level (NOAEL)/lower 95 percent confidence limit on a dose associated with a 10 percent extra risk (LED_{10})] are empirically measured using scientific methods. By contrast, the decision to use animal effects as surrogates for human effects involves judgment on the part of the EPA (and similarly, by other agencies) as to the best practice to follow when human data are lacking. Such a decision is, therefore, a matter of science policy. The choice of default fish consumption rates for protection of a certain percentage (i.e., the 90th percentile) of the general population is clearly a risk management decision. In many cases, the Agency has selected parameter values using its best judgment regarding the overall protection afforded by the resulting AWQC when all parameters are combined. For a longer discussion of the differences between science, science policy, and risk management, please refer to Section 2 of this document. Section 2 also provides further details with regard to risk characterization for this Methodology, with emphasis placed on explaining the uncertainties in the overall risk assessment.

The generalized equations for deriving AWQC based on noncancer effects are:

Noncancer Effects[2]

$$AWQC = RfD \cdot RSC \cdot \left(\frac{BW}{DI + \sum_{i=2}^{4} (FI_i \cdot BAF_i)} \right) \qquad \text{(Equation 1-1)}$$

Cancer Effects: Nonlinear Low-Dose Extrapolation

$$AWQC = \frac{POD}{UF} \cdot RSC \cdot \left(\frac{BW}{DI + \sum_{i=2}^{4} (FI_i \cdot BAF_i)} \right) \qquad \text{(Equation 1-2)}$$

[2] Although appearing in this equation as a factor to be multiplied, the RSC can also be an amount subtracted. Refer to the explanation key below the equations.

NMED Exhibit 84

Cancer Effects: Linear Low-Dose Extrapolation

$$AWQC = RSD \cdot \left(\frac{BW}{DI + \sum_{i=2}^{4} (FI_i \cdot BAF_i)} \right) \qquad \text{(Equation 1-3)}$$

where:

AWQC	=	Ambient Water Quality Criterion (mg/L)
RfD	=	Reference dose for noncancer effects (mg/kg-day)
POD	=	Point of departure for carcinogens based on a nonlinear low-dose extrapolation (mg/kg-day), usually a LOAEL, NOAEL, or LED_{10}
UF	=	Uncertainty Factor for carcinogens based on a nonlinear low-dose extrapolation (unitless)
RSD	=	Risk-specific dose for carcinogens based on a linear low-dose extrapolation (mg/kg-day) (dose associated with a target risk, such as 10^{-6})
RSC	=	Relative source contribution factor to account for non-water sources of exposure. (Not used for linear carcinogens.) May be either a percentage (multiplied) or amount subtracted, depending on whether multiple criteria are relevant to the chemical.
BW	=	Human body weight (default = 70 kg for adults)
DI	=	Drinking water intake (default = 2 L/day for adults)
FI_i	=	Fish intake at trophic level (TL) I (I = 2, 3, and 4) (defaults for total intake = 0.0175 kg/day for general adult population and sport anglers, and 0.1424 kg/day for subsistence fishers). Trophic level breakouts for the general adult population and sport anglers are: TL2 = 0.0038 kg/day; TL3 = 0.0080 kg/day; and TL4 = 0.0057 kg/day.
BAF_i	=	Bioaccumulation factor at trophic level I (I=2, 3 and 4), lipid normalized (L/kg)

For highly bioaccumulative chemicals where ingestion from water might be considered negligible, EPA is currently evaluating the feasibility of developing and implementing AWQCs that are expressed in terms of concentrations in tissues of aquatic organisms. Such tissue residue criteria might be used as an alternative to AWQCs which are expressed as concentrations in water, particularly in situations where AWQCs are at or below the practical limits for quantifying a chemical in water. Even though tissue residue criteria would not require the use of a BAF in their derivation, implementing such criteria would still require a mechanism for relating chemical loads and concentrations in water and sediment to concentrations in tissues of appropriate fish and shellfish (e.g., a BAF or bioaccumulation model). At this time, no revisions are planned to the Methodology to provide specific guidance on developing fish tissue-based water quality criteria. However, guidance may be provided in the future either as a separate document or integrated in a specific 304(a) water quality criteria document for a chemical that warrants such an approach.

NMED Exhibit 84

AWQC for the protection of human health are designed to minimize the risk of adverse effects occurring to humans from chronic (lifetime) exposure to substances through the ingestion of drinking water and consumption of fish obtained from surface waters. The Agency is not recommending the development of additional water quality criteria similar to the "drinking water health advisories" that focus on acute or short-term effects; these are not seen as routinely having a meaningful role in the water quality criteria and standards program. However, as discussed below, there may be some instances where the consideration of acute or short-term toxicity and exposure in the derivation of AWQC is warranted.

Although the AWQC are based on chronic health effects data (both cancer and noncancer effects), the criteria are intended to also be protective against adverse effects that may reasonably be expected to occur as a result of elevated acute or short-term exposures. That is, through the use of conservative assumptions with respect to both toxicity and exposure parameters, the resulting AWQC should provide adequate protection not only for the general population over a lifetime of exposure, but also for special subpopulations who, because of high water- or fish-intake rates, or because of biological sensitivities, have an increased risk of receiving a dose that would elicit adverse effects. The Agency recognizes that there may be some cases where the AWQC based on chronic toxicity may not provide adequate protection for a subpopulation at special risk from shorter-term exposures. The Agency encourages States, Tribes, and others employing the 2000 Human Health Methodology to give consideration to such circumstances in deriving criteria to ensure that adequate protection is afforded to all identifiable subpopulations. (See Section 4.3, Factors Used in the AWQC Computation, for additional discussion of these subpopulations.)

The EPA is in the process of revising its cancer guidelines, including its descriptions of human carcinogenic potential. Once final guidelines are published, they will be the basis for assessment under this methodology. In the meanwhile, the 1986 guidelines are used and extended with principles discussed in EPA's 1999 *Guidelines for Carcinogen Risk Assessment - Review Draft* (hereafter "1999 draft revised cancer guidelines"). These principles arise from new science about cancer discovered in the last 15 years and from EPA policy of recent years supporting full characterization of hazard and risk both for the general population and potentially sensitive groups such as children. These principles are incorporated in recent and ongoing assessments such as the reassessment of dioxin, consistent with the 1986 guidelines. Until final guidelines are published, information is presented to describe risk under both the old guidelines and draft revisions. Dose-response assessment under the 1986 guidelines employs a linearized multistage model to extrapolate tumor dose-response observed in animal or human studies down to zero dose, zero extra risk. The dose-response assessment under EPA's 1999 draft revised cancer guidelines is a two-step process. In the first step, the response data are modeled in the range of empirical observation. Modeling in the observed range is done with biologically based or appropriate curve-fitting modeling. In the second step, extrapolation below the range of observation is accomplished by biologically based modeling if there are sufficient data or by a default procedure (linear, nonlinear, or both). A point of departure (POD) for extrapolation is estimated from modeling observed data. The lower 95 percent confidence limit on a dose associated with 10 percent extra risk (LED_{10}) is the standard POD for low-dose extrapolation. The linear default procedure is a straight line extrapolation to the origin (i.e., zero dose, zero extra risk) from the POD, which is the LED_{10} identified in the observable response

NMED Exhibit 84

range. The result of this procedure is generally comparable (within 2-fold) to that of using a linearized multistage model under existing, 1986 guidelines. The linear low-dose extrapolation applies to agents that are best characterized by the assumption of linearity (e.g., direct DNA reactive mutagens) for their MOA. A linear approach would also be applied when inadequate or no information is available to explain the carcinogenic MOA; this is a science policy choice in the interest of public health. If it is determined that the MOA understanding fully supports a nonlinear extrapolation, the AWQC is derived using the nonlinear default which is based on a margin of exposure (MOE) analysis using the LED_{10} as the POD and applying uncertainty factors (UFs) to arrive at an acceptable MOE. There may be situations where it is appropriate to apply both the linear and nonlinear default procedures (e.g., for an agent that is both DNA reactive and active as a promoter at higher doses).

For substances that are carcinogenic, particularly those for which the MOA suggests nonlinearity at low doses, the Agency recommends that an integrated approach be taken in looking at cancer and noncancer effects. If one effect does not predominate, AWQC values should be determined for both carcinogenic and noncarcinogenic endpoints. The lower of the resulting values should be used for the AWQC.

When deriving AWQC for noncarcinogens and carcinogens based on a nonlinear low-dose extrapolation, a factor is included to account for other non-water exposure sources [both ingestion exposures (e.g., food) and exposures other than the oral route (e.g., inhalation)] so that the entire RfD, or POD/UF, is not apportioned to drinking water and fish consumption alone. Guidance is provided in the 2000 Human Health Methodology for determining the factor (i.e., the RSC) to be used for a particular chemical. The Agency is recommending the use of an Exposure Decision Tree procedure to support the determination of the appropriate RSC value for a given water contaminant. In the absence of data, the Agency intends to use 20 percent of the RfD (or POD/UF) as the default RSC in calculating 304(a) criteria or promulgating State or Tribal water quality standards under Section 303(c).

With AWQC derived for carcinogens based on a linear low-dose extrapolation, the Agency will publish recommended criteria values at a 10^{-6} risk level. States and authorized Tribes can always choose a more stringent risk level, such as 10^{-7}. EPA also believes that criteria based on a 10^{-5} risk level are acceptable for the general population as long as States and authorized Tribes ensure that the risk to more highly exposed subgroups (sportfishers or subsistence fishers) does not exceed the 10^{-4} level. Clarification on this risk management decision is provided in Section 2 of this document.

The default fish consumption value for the general adult population in the 2000 Human Health Methodology is 17.5 grams/day, which represents an estimate of the 90th percentile consumption rate for the U.S. adult population based on the U.S. Department of Agriculture's (USDA's) Continuing Survey of Food Intake by Individuals (CSFII) 1994-96 data (USDA, 1998). EPA will use this default intake rate with future national 304(a) criteria derivations or revisions. This default value is chosen to be protective of the majority of the general population. However, States and authorized Tribes are urged to use a fish intake level derived from local data on fish consumption in place of this default value when deriving AWQC, ensuring that the fish intake level chosen is protective of highly exposed individuals in the population. EPA has

NMED Exhibit 84

provided default values for States and authorized Tribes that do not have adequate information on local or regional consumption patterns, based on numerous studies that EPA has reviewed on sport anglers and subsistence fishers. EPA's defaults for these population groups are estimates of their average consumption. EPA recommends a default of 17.5 grams/day for sport anglers as an approximation of their average consumption and 142.4 grams/day for subsistence fishers, which falls within the range of averages for this group. Consumption rates for women of childbearing age and children younger than 14 are also provided to maximize protection in those cases where these subpopulations may be at greatest risk.

In the 2000 Human Health Methodology, criteria are derived using a BAF rather than a BCF. To derive the BAF, States and authorized Tribes may use EPA's Methodology or any method consistent with this Methodology. EPA's highest preference in developing BAFs are BAFs based on field-measured data from local/regional fish.

NMED Exhibit 84

2. CLARIFICATIONS ON THE METHODOLOGY, RISK CHARACTERIZATION, AND OTHER ISSUES FOR DEVELOPING CRITERIA

2.1 IDENTIFYING THE POPULATION SUBGROUP THAT THE AWQC SHOULD PROTECT

Water quality criteria are derived to establish ambient concentrations of pollutants which, if not exceeded, will protect the general population from adverse health impacts from those pollutants due to consumption of aquatic organisms and water, including incidental water consumption related to recreational activities. For each pollutant, chronic criteria are derived to reflect long-term consumption of food and water. An important decision to make when setting AWQC is the choice of the particular population to protect. For instance, criteria could be set to protect those individuals who have average or "typical" exposures, or the criteria could be set so that they offer greater protection to those individuals who are more highly exposed. EPA has selected default parameter values that are representative of several defined populations: adults in the general population; sport (recreational) fishers; subsistence fishers; women of childbearing age (defined as ages 15-44); and children (up to the age of 14). In deciding on default parameter values, EPA is aware that multiple parameters are used in combination when calculating AWQC (e.g., intake rates and body weight). EPA describes the estimated population percentiles that are represented by each of the default exposure parameter values in Section 4.

EPA's national 304(a) criteria are usually derived to protect the majority of the general population from chronic adverse health effects. EPA has used a combination of median values, mean values, and percentile estimates for the parameter value defaults to calculate its national 304(a) criteria. EPA believes that its assumptions afford an overall level of protection targeted at the high end of the general population (i.e., the target population or the criteria-basis population). EPA also believes that this is reasonably conservative and appropriate to meet the goals of the CWA and the 304(a) criteria program. EPA considers that its target protection goal is satisfied if the population as a whole will be adequately protected by the human health criteria when the criteria are met in ambient water. However, associating the derived criteria with a specific population percentile is far more difficult, and such a quantitative descriptor typically requires detailed distributional exposure and dose information. EPA's *Guidelines For Exposure Assessment* (USEPA, 1992) describes the extreme difficulty in making accurate estimates of exposures and indicates that uncertainties at the more extreme ends of the distribution increase greatly. On quantifying population exposures/risks, the guidelines specifically state:

> *In practice, it is difficult even to establish an accurate mean health effect risk for a population. This is due to many complications, including uncertainties in using animal data for human dose-response relationships, nonlinearities in the dose-response curve, projecting incidence data from one group to another dissimilar group, etc. Although it has been common practice to estimate the number of cases of disease, especially cancer, for populations exposed to chemicals, it should be understood that these estimates are not meant to be accurate estimates of real (or actuarial) cases of disease. The estimate's value lies in framing*

NMED Exhibit 84

hypothetical risk in an understandable way rather than in any literal interpretation of the term "cases."

Although it is not possible to subject the estimates to such a rigorous analysis (say, for example, to determine what criterion value provides protection of exactly the 90th percentile of the population), EPA believes that the combination of parameter value assumptions achieves its target goal, without being inordinately conservative. The standard assumptions made for the national 304(a) criteria are as follows. The assumed body weight value used is an arithmetic mean, as are the RSC intake estimates of other exposures (e.g., non-fish dietary), when data are available. The BAF component data (e.g., for lipid values, for particulate and dissolved organic carbon) are based on median (i.e., 50th percentile) values. The drinking water intake values are approximately 90th percentile estimates and fish intake values are 90th percentile estimates. EPA believes the use of these values will result in 304(a) criteria that are protective of a majority of the population; this is EPA's goal.

However, EPA also strongly believes that States and authorized Tribes should have the flexibility to develop criteria, on a site-specific basis, that provide additional protection appropriate for highly exposed populations. EPA is aware that exposure patterns in general, and fish consumption in particular, vary substantially. EPA understands that highly exposed populations may be widely distributed geographically throughout a given State or Tribal area. EPA recommends that priority be given to identifying and adequately protecting the most highly exposed population. Thus, if the State or Tribe determines that a highly exposed population is at greater risk and would not be adequately protected by criteria based on the general population, and by the national 304(a) criteria in particular, EPA recommends that the State or Tribe adopt more stringent criteria using alternative exposure assumptions.

EPA has provided recommended default intake rates for various population groups for State and Tribal consideration. EPA does not intend for these alternative default values to be prescriptive. EPA strongly emphasizes its preference that States and Tribes use local or regional data over EPA's defaults, if they so choose, as being more representative of their population groups of concern.

In the course of updating the 2000 Human Health Methodology, EPA received some questions regarding the population groups for which the criteria would be developed. EPA does not intend to derive multiple 304(a) criteria for all subpopulation groups for every chemical. As stated above, criteria that address chronic adverse health effects are most applicable to the CWA Section 304(a) criteria program and the chemicals evaluated for this program. If EPA determined that pregnant women/fetuses or young children were the target population (or criteria basis population) of a chemical's RfD or POD/UF, then the 304(a) criteria would be developed using exposure parameters for that subgroup. This would only be relevant for acute or subchronic toxicity situations. This does not conflict with the fact that chronic health effects potentially reflect a person's exposure during both childhood and adult years.

For RfD-based and POD/UF-based chemicals, EPA's policy is that, in general, the RfD (or POD/UF) should not be exceeded and the exposure assumptions used should reflect the population of concern. It is recommended that when a State or authorized Tribe sets a

NMED Exhibit 84

waterbody-specific AWQC, they consider the populations most exposed via water and fish. EPA's policy on cancer risk management goals is discussed in Section 2.4.

Health Risks to Children

In recognition that children have a special vulnerability to many toxic substances, EPA's Administrator directed the Agency in 1995 to explicitly and consistently take into account environmental health risks to infants and children in all risk assessments, risk characterizations, and public health standards set for the United States. In April 1997, President Clinton signed Executive Order 13045 on the protection of children from environmental health risks, which assigned a high priority to addressing risks to children. In May 1997, EPA established the Office of Children's Health Protection to ensure the implementation of the President's Executive Order. EPA has increased efforts to ensure its guidance and regulations take into account risks to children. Circumstances where risks to children should be considered in the context of the 2000 Human Health Methodology are discussed in the Section 3.2, Noncancer Effects (in terms of developmental and reproductive toxicity) and in Section 4, Exposure (for appropriate exposure intake parameters).

Details on risk characterization and the guiding principles stated above are included in EPA's March 21, 1995 policy statement and the discussion of risk characterization (USEPA, 1995) and the 1999 *Guidelines for Carcinogen Risk Assessment. Review Draft* (USEPA, 1999a) and the *Reproductive and Toxicity Risk Assessment Guidelines* of 1996 (USEPA, 1996b).

2.2 SCIENCE, SCIENCE POLICY, AND RISK MANAGEMENT

An important part of risk characterization, as described later in Section 2.7, is to make risk assessments transparent. This means that conclusions drawn from the science are identified separately from policy judgments and risk management decisions, and that the use of default values or methods, as well as the use of assumptions in risk assessments, are clearly articulated. In this Methodology, EPA has attempted to separate scientific analysis from science policy and risk management decisions for clarity. This should allow States and Tribes (who are also prospective users of this Methodology) to understand the elements of the Methodology accurately and clearly, and to easily separate out the scientific decisions from the science policy and risk management decisions. This is important so that when questions are asked regarding the scientific merit, validity, or apparent stringency or leniency of AWQC, the implementer of the criteria can clearly explain what judgments were made to develop the criterion in question and to what degree these judgments were based on science, science policy, or risk management. To some extent this process will also be displayed in future AWQC documents.

When EPA speaks of science or scientific analysis, it is referring to the extraction of data from toxicological or exposure studies and surveys with a minimum of judgment being used to make inferences from the available evidence. For example, if EPA is describing a POD from an animal study (e.g., a LOAEL), this is usually determined as a lowest dose that produces an observable adverse effect. This would constitute a scientific determination. Judgments applying science policy, however, may enter this determination. For example, several scientists may differ in their opinion of what is adverse, and this in turn can influence the selection of a LOAEL

NMED Exhibit 84

in a given study. The use of an animal study to predict effects in a human in the absence of human data is an inherent science policy decision. The selection of specific UFs when developing an RfD is another example of science policy. In any risk assessment, a number of decision points occur where risk to humans can only be inferred from the available evidence. Both scientific judgments and policy choices may be involved in selecting from among several possible inferences when conducting a risk assessment.

Risk management is the process of selecting the most appropriate guidance or regulatory actions by integrating the results of risk assessment with engineering data and with social, economic, and political concerns to reach a decision. In this Methodology, the choice of a default fish consumption rate which is protective of 90 percent of the general population is a risk management decision. The choice of an acceptable cancer risk by a State or Tribe is a risk management decision.

Many of the components in the 2000 Human Health Methodology are an amalgam of science, science policy, and/or risk management. For example, most of the default values chosen by EPA are based on examination of scientific data and application of either science policy or risk management. This includes the default assumption of 2 liters a day of drinking water; the assumption of 70 kilograms for an adult body weight; the use of default percent lipid and particulate organic carbon/dissolved organic carbon (POC/DOC) for developing national BAFs; the default fish consumption rates for the general population and sport and subsistence anglers; and the choice of a default cancer risk level. Some decisions are more grounded in science and science policy (such as the choice of default BAFs) and others are more obviously risk management decisions (such as the determination of default fish consumption rates and cancer risk levels). Throughout the 2000 Human Health Methodology, EPA has identified the kind of decision necessary to develop defaults and what the basis for the decision was. More details on the concepts of science analysis, science policy, risk management, and how they are introduced into risk assessments are included in *Risk Assessment in the Federal Government: Managing the Process* (NRC, 1983).

2.3 SETTING CRITERIA TO PROTECT AGAINST MULTIPLE EXPOSURES FROM MULTIPLE CHEMICALS (CUMULATIVE RISK)

EPA is very much aware of the complex issues and implications of cumulative risk and has endeavored to begin developing an overall approach at the Agency-wide level. Assuming that multiple exposures to multiple chemicals are additive is scientifically sound if they exhibit the same toxic endpoints and modes of action. There are numerous publications relevant to cumulative risk that can assist States and Tribes in understanding the complex issues associated with cumulative risk. These include the following:

- Durkin, P.R., R.C. Hertzberg, W. Stiteler, and M. Mumtaz. 1995. The identification and testing of interaction patterns. *Toxicol. Letters* 79:251-264.

The Agency's program offices are also engaged in on-going discussions of the great complexities, methodological challenges, data adequacy needs and other information gaps, as well as the science policy and risk management decisions that will need to be made, as they pursue developing a sound strategy and, eventually, specific guidance for addressing cumulative

NMED Exhibit 84

risks. As a matter of internal policy, EPA is committed to refining the Methodology as advances in relevant aspects of the science improve, as part of the water quality criteria program.

2.4 CANCER RISK RANGE

For deriving 304(a) criteria or promulgating water quality criteria for States and Tribes under Section 303(c) based on the 2000 Human Health Methodology, EPA intends to use the 10^{-6} risk level, which the Agency believes reflects an appropriate risk for the general population. EPA's program office guidance and regulatory actions have evolved in recent years to target a 10^{-6} risk level as an appropriate risk for the general population. EPA has recently reviewed the policies and regulatory language of other Agency mandates (e.g., the Clean Air Act Amendments of 1990, the Food Quality Protection Act) and believes the target of a 10^{-6} risk level is consistent with Agency-wide practice.

EPA believes that both 10^{-6} and 10^{-5} may be acceptable for the general population and that highly exposed populations should not exceed a 10^{-4} risk level. States or Tribes that have adopted standards based on criteria at the 10^{-5} risk level can continue to do so, if the highly exposed groups would at least be protected at the 10^{-4} risk level. However, EPA is not automatically assuming that 10^{-5} will protect "the highest consumers" at the 10^{-4} risk level. Nor is EPA advocating that States and Tribes automatically set criteria based on assumptions for highly exposed population groups at the 10^{-4} risk level. The Agency is simply endeavoring to add that a specific determination should be made to ensure that highly exposed groups do not exceed a 10^{-4} risk level. EPA understands that fish consumption rates vary considerably, especially among subsistence populations, and it is such great variation among these population groups that may make either 10^{-6} or 10^{-5} protective of those groups at a 10^{-4} risk level. Therefore, depending on the consumption patterns in a given State or Tribal jurisdiction, a 10^{-6} or 10^{-5} risk level could be appropriate. In cases where fish consumption among highly exposed population groups is of a magnitude that a 10^{-4} risk level would be exceeded, a more protective risk level should be chosen. Such determinations should be made by the State or Tribal authorities and are subject to EPA's review and approval or disapproval under Section 303(c) of the CWA.

Adoption of a 10^{-6} or 10^{-5} risk level, both of which States and authorized Tribes have chosen in adopting water quality standards to date, represents a generally acceptable risk management decision, and EPA intends to continue providing this flexibility to States and Tribes. EPA believes that such State or Tribal decisions are consistent with Section 303(c) if the State or authorized Tribe has identified the most highly exposed subpopulation, has demonstrated that the chosen risk level is adequately protective of the most highly exposed subpopulation, and has completed all necessary public participation. States and authorized Tribes also have flexibility in how they demonstrate this protectiveness and obtain such information. A State or authorized Tribe may use existing information as well as collect new information in making this determination. In addition, if a State or authorized Tribe does not believe that the 10^{-6} risk level adequately protects the exposed subpopulations, water quality criteria based on a more stringent risk level may be adopted. This discretion includes combining the 10^{-6} risk level with fish consumption rates for highly exposed population groups.

NMED Exhibit 84

It is important to understand that criteria for carcinogens are based on chosen risk levels that inherently reflect, in part, the exposure parameters used to derive those values. Therefore, changing the exposure parameters also changes the risk. Specifically, the incremental cancer risk levels are *relative*, meaning that any given criterion associated with a particular cancer risk level is also associated with specific exposure parameter assumptions (e.g., intake rates, body weights). When these exposure parameter values change, so does the relative risk. For a criterion derived on the basis of a cancer risk level of 10^{-6}, individuals consuming up to 10 times the assumed fish intake rate would not exceed a 10^{-5} risk level. Similarly, individuals consuming up to 100 times the assumed rate would not exceed a 10^{-4} risk level. Thus, for a criterion based on EPA's default fish intake rate (17.5 gm/day) and a risk level of 10^{-6}, those consuming a pound per day (i.e., 454 grams/day) would potentially experience between a 10^{-5} and a 10^{-4} risk level (closer to a 10^{-5} risk level). (Note: Fish consumers of up to 1,750 gm/day would not exceed the 10^{-4} risk level.) If a criterion were based on high-end intake rates and the relative risk of 10^{-6}, then an average fish consumer would be protected at a cancer risk level of approximately 10^{-8}. The point is that the risks for different population groups are not the same.

2.5 MICROBIOLOGICAL AMBIENT WATER QUALITY CRITERIA

Guidance for deriving microbiological AWQC is not a part of this Methodology. In 1986, EPA published *Ambient Water Quality Criteria for Bacteria - 1986* (USEPA, 1986a), which updated and revised bacteriological criteria previously published in 1976 in *Quality Criteria for Water* (USEPA, 1976). The inclusion of guidance for deriving microbiological AWQC was considered in the 1992 national workshop that initiated the effort to revise the 1980 Methodology and was recommended by the SAB in 1993. Since that time, however, efforts separate from these Methodology revisions have addressed microbiological AWQC concerns. The purpose of this section is to briefly describe EPA's current recommendations and activities.

EPA's *Ambient Water Quality Criteria for Bacteria - 1986* recommends the use of *Escherichia coli* and enterococci rather than fecal coliforms (USEPA, 1986a). EPA's criteria recommendations are:

- Fresh water: *E. coli* not to exceed 126/100 ml or enterococci not to exceed 33/100 ml; and

- Marine water: enterococci not to exceed 35/100 ml.

These criteria should be calculated as the geometric mean based on five equally spaced samples taken over a 30-day period.

In addition, EPA recommends that States adopt a single sample maximum, based on the expected frequency of use. No sample taken should exceed this value. EPA specifies appropriate single sample maximum values in the 1986 criteria document.

<u>Current Activities and Plans for Future Work</u>

NMED Exhibit 84

EPA has identified development of microbial water quality criteria as part of its strategy to control waterborne microbial disease, by controlling pathogens in waterbodies and by protecting designated uses, such as recreation and public water supplies. The program fosters an integrated approach to protect both ground-water and surface water sources. EPA plans to conduct additional monitoring for *Cryptosporidium parvum* and *E. coli*, and determine action plans in accordance with the results of this monitoring.

EPA recommends no change at this time in the stringency of its bacterial criteria for recreational waters; existing criteria and methodologies from 1986 will still apply. The recommended methods for *E. coli* and enterococci have been improved. As outlined in the *Action Plan for Beaches and Recreational Waters* (Beach Action Plan, see below), the Agency plans to conduct national studies on improving indicators together with epidemiology studies for new criteria development (USEPA, 1999b). The Agency is also planning to establish improved temporal and spatial monitoring protocols.

In the Beach Action Plan, EPA identifies a multi-year strategy for monitoring recreational water quality and communicating public health risks associated with potentially pathogen-contaminated recreational rivers, lakes, and ocean beaches. It articulates the Agency's rationale and goals in addressing specific problems and integrates all associated program, policy, and research needs and directions. The Beach Action Plan also provides information on timing, products and lead organization for each activity. These include activities and products in the areas of program development, risk communication, water quality indicator research, modeling and monitoring research, and exposure and health effects research.

Recently, EPA approved new 24-hour *E. coli* and enterococcus tests for recreational waters that may be used as an alternative to the 48-hour test (USEPA, 1997). EPA anticipates proposing these methods for inclusion in the 40 CRF 136 in the Fall of 2000. EPA has also published a video with accompanying manual on the original and newer methods for enterococci and *E. coli* (USEPA, 2000).

As part of the Beach Action Plan, EPA made the following recommendations for further Agency study:

- Future criteria development should consider the risk of diseases other than gastroenteritis. EPA intends to consider and evaluate such water-related exposure routes as inhalation and dermal absorption when addressing microbial health effects. The nature and significance of other than the classical waterborne pathogens are to some degree tied to the particular type of waste sources.

- A new set of indicator organisms may need to be developed for tropical water if it is proven that the current fecal indicators can maintain viable cell populations in the soil and water for significant periods of time in uniform tropical conditions. Some potential alternative indicators to be fully explored are coliphage, other bacteriophage, and *Clostridium perfringens*.

NMED Exhibit 84

- Because animal sources of pathogens of concern for human infection such as *Giardia lamblia*, *Cryptosporidium parvum*, and *Escherichia coli* 0157:H7 may be waterborne or washed into water and thus become a potential source for infection, they should not be ignored in risk assessment. A likely approach would be phylogenetic differentiation; that is, indicators that are specific to, or can discriminate among, animal sources.

- EPA intends to develop additional data on secondary infection routes and infection rates from prospective epidemiology studies and outbreaks from various types of exposure (e.g., shellfish consumption, drinking water, recreational exposure).

- EPA needs to improve sampling strategies for recreational water monitoring including consideration of rainfall and pollution events to trigger sampling.

2.6 RISK CHARACTERIZATION CONSIDERATIONS

On March 21, 1995, EPA's Administrator issued the *EPA Risk Characterization Policy and Guidance* (USEPA, 1995). This policy and guidance is intended to ensure that characterization information from each stage of a risk assessment is used in forming conclusions about risk and that this information is communicated from risk assessors to risk managers, and from EPA to the public. The policy also provides the basis for greater clarity, transparency, reasonableness, and consistency in risk assessments across EPA programs. The fundamental principles which form the basis for a risk characterization are as follows:

- Risk assessments should be transparent, in that the conclusions drawn from the science are identified separately from policy judgments, and the use of default values or methods and the use of assumptions in the risk assessment are clearly articulated.

- Risk characterizations should include a summary of the key issues and conclusions of each of the other components of the risk assessments, as well as describe the likelihood of harm. The summary should include a description of the overall strengths and limitations (including uncertainties) of the assessment and conclusions.

- Risk characterizations should be consistent in general format, but recognize the unique characteristics of each specific situation.

- Risk characterizations should include, at least in a qualitative sense, a discussion of how a specific risk and its context compares with similar risks. This may be accomplished by comparisons with other pollutants or situations on which the Agency has decided to act, or other situations with which the public may be familiar. The discussion should highlight the limitations of such comparisons.

- Risk characterization is a key component of risk communication, which is an interactive process involving exchange of information and expert opinion among individuals, groups, and institutions.

Additional guiding principles include:

NMED Exhibit 84

- The risk characterization integrates the information from the hazard identification, dose-response, and exposure assessments, using a combination of qualitative information, quantitative information, and information regarding uncertainties.

- The risk characterization includes a discussion of uncertainty and variability in the risk assessment.

- Well-balanced risk characterizations present conclusions and information regarding the strengths and limitations of the assessment for other risk assessors, EPA decision-makers, and the public.

In developing the methodology presented here, EPA has closely followed the risk characterization guiding principles listed above. As States and Tribes adopt criteria using the 2000 Human Health Methodology, they are strongly encouraged to follow EPA's risk characterization guidance. There are a number of areas within the Methodology and criteria development process where risk characterization principles apply:

- Integration of cancer and noncancer assessments with exposure assessments, including bioaccumulation potential determinations, in essence, weighing the strengths and weaknesses of the risk assessment as a whole when developing a criterion.

- Selecting a fish consumption rate, either locally derived or the national default value, within the context of a target population (e.g., sensitive subpopulations) as compared to the general population.

- Presenting cancer and/or noncancer risk assessment options.

- Describing the uncertainty and variability in the hazard identification, the dose-response, and the exposure assessment.

2.7 DISCUSSION OF UNCERTAINTY

2.7.1 Observed Range of Toxicity Versus Range of Environmental Exposure

When characterizing a risk assessment, an important distinction to make is between the observed range of adverse effects (from an epidemiology or animal study) and the environmentally observed range of exposure (or anticipated human exposure) to the contaminant. In many cases, EPA intends to apply default factors to account for uncertainties or incomplete knowledge in developing RfDs or cancer risk assessments using nonlinear low-dose extrapolation to provide a margin of protection. In reality, the actual effect level and the environmental exposure levels may be separated by several orders of magnitude. The difference between the dose causing some observed response and the anticipated human exposure should be described by risk assessors and managers, especially when comparing criteria to environmental levels of a contaminant.

2.7.2 Continuum of Preferred Data/Use of Defaults

NMED Exhibit 84

In both toxicological and exposure assessments, EPA has defined a continuum of preferred data for toxicological assessments ranging from a highest preference for chronic human data (e.g., studies that examine a long-term exposure of humans to a chemical, usually from occupational and/or residential exposure) and actual field data for many of the exposure parameter values (e.g., locally derived fish consumption rates, waterbody-specific bioaccumulation rates), to default values which are at the lower end of the preference continuum. EPA has supplied default values for all of the risk assessment parameters in the 2000 Human Health Methodology; however, it is important to note that when default values are used, the uncertainty in the final risk assessment may be higher, and the final resulting criterion may not be as applicable to local conditions, than is a risk assessment derived from human/field data. Using defaults assumes generalized conditions and may not capture the actual variability in the population (e.g., sensitive subpopulations/high-end consumers). If defaults are chosen as the basis for criteria, these inherent uncertainties should be communicated to the risk manager and the public. While this continuum is an expression of preference on the part of EPA, it does not imply in any way that any of the choices are unacceptable or scientifically indefensible.

2.7.3 Significant Figures

The number of significant figures in a numeric value is the number of certain digits plus one estimated digit. Digits should not be confused with decimal places. For example, 15.1, 0.0151, and 0.0150 all have 3 significant figures. Decimal places may have been used to maintain the correct number of significant figures, but in themselves they do not indicate significant figures (Brinker, 1984). Since the number of significant figures must include only one estimated digit, the sources of input parameters (e.g., fish consumption and water consumption rates) should be checked to determine the number of significant figures associated with data they provide. However, the original measured values may not be available to determine the number of significant figures in the input parameters. In these situations, EPA recommends utilizing the data as presented.

When developing criteria, EPA recommends rounding the number of significant figures at the end of the criterion calculation to the same number of significant figures in the least precise parameter. This is a generally accepted practice which can be found described in greater detail in APHA (1992) and Brinker (1984). The general rule is that for multiplication or division, the resulting value should not possess any more significant figures than is associated with the factor in the calculation with the least precision. When numbers are added or subtracted, the number that has the fewest decimal places, not necessarily the fewest significant figures, puts the limit on the number of places that justifiably may be carried in the sum or difference. Rounding off a number is the process of dropping one or more digits so that the value contains only those digits that are significant or necessary in subsequent computations (Brinker, 1984). The following rounding procedures are recommended: (1) if the digit 6, 7, 8, or 9 is dropped, increase the preceding digit by one unit; (2) if the digit 0, 1, 2, 3, or 4 is dropped, do not alter the preceding digit; and (3) if the digit 5 is dropped, round off the preceding digit to the nearest even number (e.g., 2.25 becomes 2.2 and 2.35 becomes 2.4) (APHA, 1992; Brinker, 1984).

NMED Exhibit 84

EPA recommends that calculations of water quality criteria be performed without rounding of intermediate step values. The resulting criterion may be rounded to a manageable number of decimal places. However, in no case should the number of digits presented exceed the number of significant figures implied in the data and calculations performed on them. The term "intermediate step values" refers to values of the parameters in Equations 1-1 through 1-3. The final step is considered the resulting AWQC. Although AWQC are, in turn, used for purposes of establishing water quality-based effluent limits (WQBELs) in National Pollutant Discharge Elimination System (NPDES) permits, calculating total maximum daily loads (TMDLs), and applicable or relevant and appropriate requirements (ARARs) for Superfund, they are considered the final step of this Methodology and, for the purpose of this discussion, where the rounding should occur.

The determination of appropriate significant figures inevitably involves some judgment given that some of the equation parameters are adopted default exposure values. Specifically, the default drinking water intake rate of 2 L/day is a value adopted to represent a majority of the population over the course of a lifetime. Although supported by drinking water consumption survey data, this value was adopted as a policy decision and, as such, does not have to be considered in determining the parameter with the least precision. That is, the resulting AWQC need not always be reduced to one significant digit. Similarly, the 70-kg adult body weight has been adopted Agency-wide and represents a default policy decision.

The following example with a simplified AWQC equation illustrates the rule described above. The example is for hexachlorobutadiene (HCBD), which EPA used to demonstrate the 1998 draft Methodology revisions (USEPA, 1998b). The parameters that were calculated (i.e., not policy adopted values) include values with significant figures of two (the POD and RSC), three (the UF), and four (the FI and BAF). Based on the 2000 Human Health Methodology, the final criterion should be rounded to two significant figures. The bold numbers in parentheses indicate the number of significant figures and those with asterisks also indicate Agency adopted policy values.

$$AWQC = \frac{POD}{UF} \cdot RSC \cdot \left(\frac{BW}{DI + (FI \cdot BAF)} \right) \qquad \text{(Equation 2-1)}$$

Example [Refer to draft HCBD document for details on the POD/UF, RSC and BAF data (EPA 822-R-98-004). Also note that the fish intake rate in this example is the revised value.]:

$$AWQC = \left(\frac{0.054\mathbf{(2)}}{300\mathbf{(3)}} - 1.2 \times 10^{-4}\mathbf{(2)} \right) \times \left(\frac{70\mathbf{(2^*)}}{2\mathbf{(1^*)} + (0.01750\mathbf{(4)} \times 3{,}180\mathbf{(4)})} \right)$$

NMED Exhibit 84

AWQC = 7.3×10^{-5} mg/L (0.073 µg/L, rounded from 7.285×10^{-2} µg/L)
* represents Agency adopted policy value

A number of the values used in the equation may result in intermediate step values that have more than four figures past the decimal place and may be carried throughout the calculation. However, carrying more than four figures past the decimal place (equivalent to the most precise parameter) is unnecessary as it has no effect on the resulting criterion value.

2.8 OTHER CONSIDERATIONS

2.8.1 Minimum Data Considerations

For many of the preceding technical areas, considerations have been presented for data quality in developing toxicological and exposure assessments. For greater detail and discussion of minimum data recommendations, the reader is referred to the specific sections in the Methodology on cancer and noncancer risk assessments (and especially to the referenced EPA risk assessment guidelines documents), exposure assessment, and bioaccumulation assessment, in addition to the TSD volumes for each.

2.8.2 Site-Specific Criterion Calculation

The 2000 Human Health Methodology allows for site-specific modifications by States and Tribes to reflect local environmental conditions and human exposure patterns. "Local" may refer to any appropriate geographic area where common aquatic environmental or exposure patterns exist. Thus "local" may signify Statewide, regional, a river reach, or an entire river.

Such site-specific criteria may be developed as long as the site-specific data, either toxicological or exposure-related, is justifiable. For example, when using a site-specific fish consumption rate, a State should use a value that represents at least the central tendency of the population surveyed (either sport or subsistence, or both). If a site-specific fish consumption rate for sport anglers or subsistence anglers is lower than an EPA default value, it may be used in calculating AWQC. However, to justify such a level (either higher or lower than EPA defaults), the State should assemble appropriate survey data to arrive at a defensible site-specific fish consumption rate.

Such data must also be submitted to EPA for its review when approving or disapproving State or Tribal water quality standards under Section 303(c). The same conditions apply to site-specific calculations of BAF, percent fish lipid, or the RSC. In the case of deviations from toxicological values (i.e., IRIS values: verified noncancer and cancer assessments), EPA strongly recommends that the data upon which the deviation is based be presented to and approved by the Agency before a criterion is developed.

Additional guidance on site-specific modifications to the 2000 Human Health Methodology is provided in each of the three TSD volumes.

2.8.3 Organoleptic Criteria

NMED Exhibit 84

Organoleptic criteria define concentrations of chemicals or materials which impart undesirable taste and/or odor to water. Organoleptic effects, while significant from an aesthetic standpoint, are not a significant health concern. In developing and utilizing such criteria, two factors must be appreciated: (1) the limitations of most organoleptic data; and (2) the human health significance of organoleptic properties. In the past, EPA has developed organoleptic criteria if organoleptic data were available for a specific contaminant. The 1980 AWQC National Guidelines made a clear distinction that organoleptic criteria and toxicity-based criteria are derived from completely different endpoints, and that organoleptic criteria have no demonstrated relationship to potential adverse human health effects because there is no toxicological basis. EPA acknowledges that if organoleptic effects (i.e., objectionable taste and odor) cause people to reject the water and its designated uses, then the public is effectively deprived of the natural resource. It is also possible that intense organoleptic characteristics could result in depressed fluid intake which, in turn, might lead to an indirect human health effect via decreased fluid consumption. Although EPA has developed organoleptic criteria in the past and may potentially do so in the future, this will not be a significant part of the water quality criteria program. EPA encourages the development of organoleptic criteria when States and Tribes believe they are needed. However, EPA cautions States and Tribes that the quality of organoleptic data is often significantly less than that of toxicologic data used in establishing health-based criteria. Therefore, a comprehensive evaluation of available organoleptic data should be made, and the selection of the most appropriate database for the criterion should be based on sound scientific judgment.

In 1980, EPA provided recommended criteria summary language when both types of data are available. The following format was used and is repeated here:

> *For comparison purposes, two approaches were used to derive criterion levels for ____. Based on available toxicity data, for the protection of public health the derived level is ____. Using available organoleptic data, for controlling undesirable taste and odor quality of ambient water the estimated level is ____. It should be recognized that organoleptic data as a basis for establishing a water quality criteria have no demonstrated relationship to potential adverse human health effects.*

Similarly, the 1980 Methodology recommended that in those instances where a level to limit toxicity cannot be derived, the following statement should be provided:

> *Sufficient data are not available for ____ to derive a level which would protect against the potential toxicity of this compound.*

2.8.4 Criteria for Chemical Classes

The 2000 Human Health Methodology also allows for the development of a criterion for classes of chemicals, as long as a justification is provided through the analysis of mechanistic data, toxicokinetic data, structure-activity relationship data, and limited acute and chronic toxicity data. When potency differences between members of a class is great (such as in the case

NMED Exhibit 84

of chlorinated dioxins and furans), toxicity equivalency factors (TEFs) may be more appropriately developed than one class criterion.

A chemical class is defined as any group of chemical compounds which are similar in chemical structure and biological activity, and which frequently occur together in the environment usually because they are generated by the same commercial process. In criterion development, isomers should be regarded as part of a chemical class rather than as a single compound. A class criterion, therefore, is an estimate of risk/safety which applies to more than one member of a class. It involves the use of available data on one or more chemicals of a class to derive criteria for other compounds of the same class in the event that there are insufficient data available to derive compound-specific criteria. The health-based criterion may apply to the water concentration of each member of the class, or may apply to the sum of the water concentrations of the compounds within the class. Because relatively minor structural changes within the class of compounds can have pronounced effects on their biological activities, reliance on class criteria should be minimized depending on the data available.

The following guidance should also be followed when considering the development of a class criterion.

- A detailed review of the chemical and physical properties of the chemicals within the group should be made. A close relationship within the class with respect to chemical activity would suggest a similar potential to reach common biological sites within tissues. Likewise, similar lipid solubilities would suggest the possibility of comparable absorption and distribution.

- Qualitative and quantitative toxicological data for chemicals within the group should be examined. Adequate toxicological data on a number of compounds within a group provides a more reasonable basis for extrapolation to other chemicals of the same class than minimal data on one chemical or a few chemicals within the group.

- Similarities in the nature of the toxicological response to chemicals in the class provides additional support for the prediction that the response to other members of the class may be similar. In contrast, where the biological response has been shown to differ markedly on a qualitative and quantitative basis for chemicals within a class, the extrapolation of a criterion to other members is not appropriate.

- Additional support for the validity of extrapolation of a criterion to other members of a class could be provided by evidence of similar metabolic and toxicokinetic data for some members of the class.

Additional guidance is described in the *Technical Support Document on Health Risk Assessment of Chemical Mixtures* (USEPA, 1990).

NMED Exhibit 84

2.9.5 Criteria for Essential Elements

Developing criteria for essential elements, particularly metals, must be a balancing act between toxicity and the requirement for good health. The AWQC must consider essentiality and cannot be established at levels that would result in deficiency of the element in the human population. The difference between the recommended daily allowance (RDA) and the daily doses causing a specified risk level for carcinogens or the RfDs for noncarcinogens defines the spread of daily doses within which the criterion may be derived. Because errors are inherent in defining both essential and adverse-effect levels, the criterion is derived from a dose level near the center of such dose ranges.

The process for developing criteria for essential elements should be similar to that used for any other chemical with minor modifications. The RfD represents concern for one end of the exposure spectrum (toxicity), whereas the RDA represents the other end (minimum essentiality). While the RDA and RfD values might occasionally appear to be similar in magnitude to one another, it does not imply incompatibility of the two methodological approaches, nor does it imply inaccuracy or error in either calculation.

3. RISK ASSESSMENT

This section describes the methods used to estimate ambient water quality criteria (AWQC) for the protection of human health for carcinogenic chemicals (Section 3.1) and for noncarcinogenic chemicals (Section 3.2).

3.1 CANCER EFFECTS

3.1.1 Background on EPA Cancer Risk Assessment Guidelines

The current EPA *Guidelines for Carcinogen Risk Assessment* were published in 1986 (USEPA, 1986a, hereafter the "1986 cancer guidelines"). The 1986 cancer guidelines categorize chemicals into alpha-numerical Groups: A, known human carcinogen (sufficient evidence from epidemiological studies or other human studies); B, probable human carcinogen (sufficient evidence in animals and limited or inadequate evidence in humans); C, possible human carcinogen (limited evidence of carcinogenicity in animals in the absence of human data); D, not classifiable (inadequate or no animal evidence of carcinogenicity); and E, evidence of noncarcinogenicity for humans (no evidence of carcinogenicity in at least two adequate animal tests in different species or in both adequate epidemiological and animal studies). Within Group B there are two subgroups, Groups B1 and B2. Group B1 is reserved for agents for which there is limited evidence of carcinogenicity from epidemiological studies. Group B2 is generally for agents for which there is sufficient evidence from animal studies and for which there is inadequate evidence or no data from epidemiological studies (USEPA, 1986). The system was similar to that used by the International Agency for Research on Cancer (IARC).

The 1986 cancer guidelines include guidance on what constitutes sufficient, limited, or inadequate evidence. In epidemiological studies, sufficient evidence indicates a causal relationship between the agent and human cancer; limited evidence indicates that a causal relationship is credible, but that alternative explanations, such as chance, bias, or confounding, could not adequately be excluded; inadequate evidence indicates either lack of pertinent data, or a causal interpretation is not credible. In general, although a single study may be indicative of a cause-effect relationship, confidence in inferring a causal association is increased when several independent studies are concordant in showing the association. In animal studies, sufficient evidence includes an increased incidence of malignant tumors or combined malignant and benign tumors:

- In multiple species or strains;
- In multiple experiments (e.g., with different routes of administration or using different dose levels);
- To an unusual degree in a single experiment with regard to high incidence, unusual site or type of tumor, or early age at onset;
- Additional data on dose-response, short-term tests, or structural activity relationships.

NMED Exhibit 84

In the 1986 cancer guidelines, hazard identification and the weight-of-evidence process focus on tumor findings. The weight-of-evidence approach for making judgments about cancer hazard analyzes human and animal tumor data separately, then combines them to make the overall conclusion about potential human carcinogenicity. The next step of the hazard analysis is an evaluation of supporting evidence (e.g., mutagenicity, cell transformation) to determine whether the overall weight-of-evidence conclusion should be modified.

For cancer risk quantification, the 1986 cancer guidelines recommend the use of linearized multistage model (LMS) as the only default approach. The 1986 cancer guidelines also mention that a low-dose extrapolation model other than the LMS might be considered more appropriate based on biological grounds. However, no guidance is given in choosing other approaches. The 1986 cancer guidelines recommended the use of body weight raised to the 2/3 power ($BW^{2/3}$) as a dose scaling factor between species.

3.1.2 EPA's Proposed Guidelines for Carcinogen Risk Assessment and the Subsequent July, 1999 Draft Revised Cancer Guidelines

In 1996, EPA published *Proposed Guidelines for Carcinogen Risk Assessment* (USEPA, 1996a, hereafter the "1996 proposed cancer guidelines"). After the publication of the 1996 proposed cancer guidelines and a February, 1997 and January, 1999 Science Advisory Board (SAB) review, a revision was made in July, 1999 *Guidelines for Carcinogen Risk Assessment - Review Draft* (hereafter the "1999 draft revised cancer guidelines"; USEPA, 1999a), and an SAB meeting was convened to review this revised document. When final guidelines are published, they will replace the 1986 cancer guidelines. These revisions are designed to ensure that the Agency's cancer risk assessment methods reflect the most current scientific information and advances in risk assessment methodology.

In the meanwhile, the 1986 guidelines are used and extended with principles discussed in the 1999 draft revised cancer guidelines. These principles arise from scientific discoveries concerning cancer made in the last 15 years and from EPA policy of recent years supporting full characterization of hazard and risk both for the general population and potentially sensitive groups such as children. These principles are incorporated in recent and ongoing assessments such as the reassessment of dioxin, consistent with the 1986 guidelines. Until final guidelines are published, information is presented to describe risk under both the 1986 guidelines and 1999 draft revisions.

The 1999 draft revised cancer guidelines call for the full use of all relevant information to convey the circumstances or conditions under which a particular hazard is expressed (e.g., route, duration, pattern, or magnitude of exposure). They emphasize understanding the mode of action (MOA) whereby the agent induces tumors. The MOA underlies the hazard assessment and provides the rationale for dose-response assessments.

The key principles in the 1999 draft revised cancer guidelines include:

NMED Exhibit 84

a) Hazard assessment is based on the analysis of all biological information rather than just tumor findings.

b) An agent's MOA in causing tumors is emphasized to reduce the uncertainty in describing the likelihood of harm and in determining the dose-response approach(es).

c) The 1999 draft revised cancer guidelines emphasize the conditions under which the hazard may be expressed (e.g., route, pattern, duration and magnitude of exposure). Further, the guidelines call for a *hazard characterization* to integrate the data analysis of all relevant studies into a weight-of-evidence conclusion of hazard and to develop a working conclusion regarding the agent's mode of action in leading to tumor development.

d) A weight-of-evidence narrative with accompanying descriptors (listed in Section 3.1.3.1 below) would replace the current alphanumeric classification system. The narrative summarizes the key evidence for carcinogenicity, describes the agent's MOA, characterizes the conditions of hazard expression, including route of exposure, describes any disproportionate effects on subgroups of the human population (e.g., children), and recommends appropriate dose-response approach(es). Significant strengths, weaknesses, and uncertainties of contributing evidence are also highlighted.

e) Biologically based extrapolation models are the preferred approach for quantifying risk. These models integrate data and conclusions about events in the carcinogenic process throughout the dose-response range from high to low doses. It is anticipated, however, that the necessary data for the parameters used in such models will not be available for most chemicals. The 1999 draft revised cancer guidelines allow for alternative quantitative methods, including several default approaches.

f) Dose-response assessment is a two-step process. In the first step, response data are modeled in the observable range of data and a determination is made of the point of departure (POD) from the observed range to extrapolate to low doses. The second step is extrapolation from the POD to estimate dose-response at lower doses. In addition to modeling tumor data, the 1999 draft revised cancer guidelines call for the use and modeling of other kinds of responses if they are considered to be more informed measures of carcinogenic risk. Nominally, these responses reflect key events in the carcinogenic process integral to the MOA of the agent.

g) Three default approaches are provided–linear, nonlinear, or both when adequate data are unavailable to generate a biologically based model. As the first step for all approaches, curve fitting in the observed range is used to determine a POD. A standard POD is the effective dose corresponding to the lower 95 percent limit on

NMED Exhibit 84

a dose associated with 10 percent extra risk (LED_{10}).[3] *Linear*: The linear default is a straight line extrapolation from the response at LED_{10} to the origin (zero dose, zero extra risk). *Nonlinear*: The nonlinear default begins with the identified POD and provides a margin of exposure (MOE) analysis rather than estimating the probability of effects at low doses. The MOE analysis is used to determine the appropriate margin between the POD and the exposure level of interest, in this Methodology, the AWQC. The key objective of the MOE analysis is to describe for the risk manager how rapidly responses may decline with dose. Other factors are also considered in the MOE analysis (i.e., nature of the response, slope of the dose-response curve, human sensitivity compared with experimental animals, nature and extent of human variability in sensitivity and human exposure). *Linear and nonlinear*: Section 3.1.3.4E describes the situations when both linear and nonlinear defaults are used.

h) The approach used to calculate an oral human equivalent dose when assessments are based on animal bioassays has been refined and includes a change in the default assumption for interspecies dose scaling. The 1999 draft revised cancer guidelines use body weight raised to the 3/4 power.

EPA health risk assessment practices for both cancer and noncancer endpoints are beginning to come together with recent proposals to emphasize MOA understanding in risk assessment and to model response data in the observable range to derive PODs for data sets and benchmark doses (BMDs) for individual studies. The modeling of observed response data to identify PODs in a standard way will help to harmonize cancer and noncancer dose-response approaches and permit comparisons of cancer and noncancer risk estimates.

3.1.3 Methodology for Deriving AWQC[4] by the 1999 Draft Revised Cancer Guidelines

Following the publication of the *Draft Water Quality Criteria Methodology: Human Health* (USEPA, 1998a) and the accompanying TSD (USEPA, 1998b), EPA received comments from the public. EPA also held an external peer review of the draft Methodology. Both the peer reviewers and the public recommended that EPA incorporate the new approaches into the AWQC Methodology.

Until new guidelines are published, the 1986 cancer guidelines will be used along with principles of the 1999 draft revised cancer guidelines. The 1986 guidelines are the basis for IRIS risk numbers which were used to derive the current AWQC. Each new assessment applying the principles of the 1999 draft revised cancer guidelines will be subject to peer review before being used as the basis of AWQC.

---

[3] Use of the LED_{10} as the point of departure is recommended with this Methodology, as it is with the 1999 draft revised cancer guidelines.

[4] Additional information regarding the revised method for assessing carcinogens may be found in the *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (2000). Technical Support Document, Volume 1: Risk Assessment* (USEPA, 2000).

NMED Exhibit 84

The remainder of Section 3 illustrates the methodology for deriving numerical AWQC for carcinogens applying the 1999 draft revised cancer guidelines (USEPA, 1999a). This discussion of the revised methodology for carcinogens focuses primarily on the quantitative aspects of deriving numerical AWQC values. It is important to note that the cancer risk assessment process outlined in the 1999 draft revised cancer guidelines is not limited to the quantitative aspects. A numerical AWQC value derived for a carcinogen is to be based on appropriate hazard characterization and accompanied by risk characterization information.

This section contains a discussion of the weight-of-evidence narrative, that describes all information relevant to a cancer risk evaluation, followed by a discussion of the quantitative aspects of deriving numerical AWQC values for carcinogens. It is assumed that data from an appropriately conducted animal bioassay or human epidemiological study provide the underlying basis for deriving the AWQC value. The discussion focuses on the following: (1) the weight-of-evidence narrative; (2) general considerations and framework for analysis of the MOA; (3) dose estimation; (4) characterizing dose-response relationships in the range of observation and at low, environmentally relevant doses; (5) calculating the AWQC value; (6) risk characterization; and (7) use of Toxicity Equivalent Factors (TEF) and Relative Potency Estimates. The first three topics encompass the quantitative aspects of deriving AWQC for carcinogens.

3.1.3.1 Weight-of-Evidence Narrative[5]

The 1999 draft revised cancer guidelines include a weight-of-evidence narrative that is based on an overall judgment of biological and chemical/physical considerations. Hazard assessment information accompanying an AWQC value for a carcinogen in the form of a weight-of-evidence narrative is described in the footnote. Of particular importance is that the weight-of-evidence narrative explicitly provides adequate support based on human studies, animal bioassays, and other key evidence for the conclusion whether the substance is or is likely to be carcinogenic to humans from exposures through drinking water and/or fish ingestion. The Agency emphasizes the importance of providing an explicit discussion of the MOA for the substance in the weight-of-evidence narrative if data are available, including a discussion that relates the MOA to the quantitative procedures used in the derivation of the AWQC.

3.1.3.2 Mode of Action - General Considerations and Framework for Analysis

[5] The weight-of-evidence narrative is intended for the risk manager, and thus explains in nontechnical language the key data and conclusions, as well as the conditions for hazard expression. Conclusions about potential human carcinogenicity are presented by route of exposure. Contained within this narrative are simple likelihood descriptors that essentially distinguish whether there is enough evidence to make a projection about human hazard (i.e., Carcinogenic to humans; Likely to be carcinogenic to humans; Suggestive evidence of carcinogenicity but not sufficient to assess human carcinogenic potential; Data are inadequate for an assessment of human carcinogenic potential; and Not likely to be carcinogenic to humans). Because one encounters a variety of data sets on agents, these descriptors are not meant to stand alone; rather, the context of the weight-of-evidence narrative is intended to provide a transparent explanation of the biological evidence and how the conclusions were derived. Moreover, these descriptors should not be viewed as classification categories (like the alphameric system), which often obscure key scientific differences among chemicals. The new weight-of-evidence narrative also presents conclusions about how the agent induces tumors and the relevance of the mode of action to humans, and recommends a dose-response approach based on the MOA understanding (USEPA, 1996a, 1999a).

NMED Exhibit 84

An MOA is composed of key events and processes starting with the interaction of an agent with a cell, through operational and anatomical changes, resulting in cancer formation. "Mode" of action is contrasted with "mechanism" of action, which implies a more detailed, molecular description of events than is meant by MOA.

Mode of action analysis is based on physical, chemical, and biological information that helps to explain key events[6] in an agent's influence on development of tumors. Inputs to MOA analysis include tumor data in humans, animals, and among structural analogues as well as the other key data.

There are many examples of possible modes of carcinogenic action, such as mutagenicity, mitogenesis, inhibition of cell death, cytotoxicity with reparative cell proliferation, and immune suppression. All pertinent studies are reviewed in analyzing an MOA, and an overall weighing of evidence is performed, laying out the strengths, weaknesses, and uncertainties of the case as well as potential alternative positions and rationales. Identifying data gaps and research needs is also part of the assessment.

Mode of action conclusions are used to address the question of human relevance of animal tumor responses, to address differences in anticipated response among humans such as between children and adults or men and women, and as the basis of decisions about the anticipated shape of the dose-response relationship.

In reaching conclusions, the question of "general acceptance" of an MOA will be tested as part of the independent peer review that EPA obtains for its assessment and conclusions.

Framework for Evaluating a Postulated Carcinogenic Mode(s) of Action

The framework is intended to be an analytic tool for judging whether available data support a mode of carcinogenic action postulated for an agent and includes nine elements:

1. Summary description of postulated MOA
2. Identification of key events
3. Strength, consistency, specificity of association
4. Dose-response relationship
5. Temporal relationship
6. Biological plausibility and coherence
7. Other modes of action
8. Conclusion
9. Human relevance, including subpopulations

3.1.3.3 Dose Estimation

[6]A "key event" is an empirically observable, precursor step that is itself a necessary element of the mode of action, or is a marker for such an element.

NMED Exhibit 84

A. Determining the Human Equivalent Dose by the Oral Route

An important objective in the dose-response assessment is to use a measure of internal or delivered dose at the target site where possible. This is particularly important in those cases where the carcinogenic response information is being extrapolated to humans from animal studies. Generally, by the oral exposure route, the measure of a dose provided in the underlying human studies or animal bioassays is the applied dose, typically given in terms of unit mass per unit body weight per unit time, (e.g., mg/kg-day). When animal bioassay data are used, it is necessary to make adjustments to the applied dose values to account for differences in toxicokinetics between animals and humans that affect the relationship between applied dose and delivered dose at the target organ.

In the estimation of a human equivalent dose, the 1999 draft revised cancer guidelines recommend that when adequate data are available, the doses used in animal studies can be adjusted to equivalent human doses using toxicokinetic information on the particular agent. However, in most cases, there are insufficient data available to compare dose between species. In these cases, the estimate of a human equivalent dose is based on science policy default assumptions. To derive an equivalent human oral dose from animal data, the default procedure in the 1999 draft revised cancer guidelines is to scale daily applied oral doses experienced for a lifetime in proportion to body weight raised to the 3/4 power ($BW^{3/4}$). The adjustment factor is used because metabolic rates, as well as most rates of physiological processes that determine the disposition of dose, scale this way. Thus, the rationale for this factor rests on the empirical observation that rates of physiological processes consistently tend to maintain proportionality with body weight raised to 3/4 power (USEPA, 1992a, 1999a).

The use of $BW^{3/4}$ is a departure from the scaling factor of $BW^{2/3}$ that was based on surface area adjustment and was included in the 1980 AWQC National Guidelines as well as the 1986 cancer guidelines.

B. Dose-Response Analysis

If data on the agent are sufficient to support the parameters of a biologically based model and the purpose of the assessment is such as to justify investing resources supporting its use, this is the preferred approach for both the observed tumor and related response data and for extrapolation below the range of observed data in either animal or human studies.

3.1.3.4 Characterizing Dose-Response Relationships in the Range of Observation and at Low Environmentally Relevant Doses

The first quantitative component in the derivation of AWQC for carcinogens is the dose-response assessment in the range of observation. For most agents, in the absence of adequate data to generate a biologically based model, dose-response relationships in the observed range can be addressed through curve-fitting procedures for response data. It should be noted that the 1999 draft revised cancer guidelines call for modeling of not only tumor data in the observable range, but also other responses thought to be important events preceding tumor development (e.g., DNA adducts, cellular proliferation, receptor binding, hormonal changes). The modeling of

NMED Exhibit 84

these data is intended to better inform the dose-response assessment by providing insights into the relationships of exposure (or dose) below the observable range for tumor response. These non-tumor response data can only play a role in the dose-response assessment if the agent's carcinogenic mode of action is reasonably understood, as well as the role of that precursor event.

The 1999 draft revised cancer guidelines recommend calculating the lower 95 percent confidence limit on a dose associated with an estimated 10 percent increased tumor or relevant non-tumor response (LED_{10}) for quantitative modeling of dose-response relationships in the observed range. The estimate of the LED_{10} is used as the POD for low-dose extrapolations discussed below. This standard point of departure (LED_{10}) is adopted as a matter of science policy to remain as consistent and comparable from case to case as possible. It is also a convenient comparison point for noncancer endpoints. The rationale supporting use of the LED_{10} is that a 10 percent response is at or just below the limit of sensitivity for discerning a statistically significant tumor response in most long-term rodent studies and is within the observed range for other toxicity studies. Use of lower limit takes experimental variability and sample size into account. The ED_{10} (central estimate) is also presented as a reference for comparison uses, especially for use in relative hazard/potency ranking among agents for priority setting.

For some data sets, a choice of the POD other than the LED_{10} may be appropriate. The objective is to determine the lowest reliable part of the dose-response curve for the beginning of the second step of the dose-response assessment—determine the extrapolation range. Therefore, if the observed response is below the LED_{10}, then a lower point may be a better choice (e.g., LED_5). Human studies more often support a lower POD than animal studies because of greater sample size.

The POD may be a NOAEL when a margin of exposure analysis is the nonlinear dose-response approach. The kinds of data available and the circumstances of the assessment both contribute to deciding to use a NOAEL or LOAEL which is not as rigorous or as ideal as curve fitting, but can be appropriate. If several data sets for key events and tumor response are available for an agent, and they are a mixture of continuous and incidence data, the most practicable way to assess them together is often through a NOAEL/LOAEL approach.

When an LED value estimated from animal data is used as the POD, it is adjusted to the human equivalent dose using an interspecies dose adjustment or a toxicokinetic analysis as described in Section 3.1.3.3.

Analysis of human studies in the observed range is designed on a case-by-case basis depending on the type of study and how dose and response are measured in the study.

A. Extrapolation to Low, Environmentally Relevant Doses

In most cases, the derivation of an AWQC will require an evaluation of carcinogenic risk at environmental exposure levels substantially lower than those used in the underlying study. Various approaches are used to extrapolate risk outside the range of observed experimental data. In the 1999 draft revised cancer guidelines, the choice of extrapolation method is largely

NMED Exhibit 84

dependent on the mode of action. It should be noted that the term "mode of action" (MOA) is deliberately chosen in the 1999 draft revised cancer guidelines in lieu of the term "mechanism" to indicate using knowledge that is sufficient to draw a reasonable working conclusion without having to know the processes in detail as the term mechanism might imply. The 1999 draft revised cancer guidelines favor the choice of a biologically based model, if the parameters of such models can be calculated from data sources independent of tumor data. It is anticipated that the necessary data for such parameters will not be available for most chemicals. Thus, the 1999 draft revised cancer guidelines allow for several default extrapolation approaches (low-dose linear, nonlinear, or both).

B. Biologically Based Modeling Approaches

If a biologically based approach has been used to characterize the dose-response relationships in the observed range, and the confidence in the model is high, it may be used to extrapolate the dose-response relationship to environmentally relevant doses. For the purposes of deriving AWQC, the environmentally relevant dose would be the risk-specific dose (RSD) associated with incremental lifetime cancer risks in the 10^{-6} to 10^{-4} range for carcinogens for which a linear extrapolation approach is applied.[7] The use of the RSD and the POD/UF to compute the AWQC is presented in Section 3.1.3.5, below. Although biologically-based approaches are appropriate both for characterizing observed dose-response relationships and extrapolating to environmentally relevant doses, it is not expected that adequate data will be available to support the use of such approaches for most substances. In the absence of such data, the default linear approach, the nonlinear (MOE) approach, or both linear and nonlinear approaches will be used.

[7] For discussion of the cancer risk range, see Section 2.4.

NMED Exhibit 84

C. Default Linear Extrapolation Approach

The default linear approach replaces the LMS approach that has served as the default for EPA cancer risk assessments. Any of the following conclusions leads to selection of a linear dose-response assessment approach:

- There is an absence of sufficient tumor MOA information.
- The chemical has direct DNA mutagenic reactivity or other indications of DNA effects that are consistent with linearity.
- Human exposure or body burden is high and near doses associated with key events in the carcinogenic process (e.g., 2,3,7,8-tetrachlorodibenzo-p-dioxin).
- Mode of action analysis does not support direct DNA effects, but the dose-response relationship is expected to be linear (e.g., certain receptor-mediated effects).

The procedures for implementing the default linear approach begin with the estimation of a POD as described above. The point of departure, LED_{10}, reflects the interspecies conversion to the human equivalent dose and the other adjustments for less-than-lifetime experimental duration. In most cases, the extrapolation for estimating response rates at low, environmentally relevant exposures is accomplished by drawing a straight line between the POD and the origin (i.e., zero dose, zero extra risk). This is mathematically represented as:

$$y = mx + b \qquad \text{(Equation 3-1)}$$
$$b = 0$$

where:

y	=	Response or incidence
m	=	Slope of the line (cancer potency factor) = $\Delta y/\Delta x$
x	=	Dose
b	=	Slope intercept

The slope of the line, "m" (the estimated cancer potency factor at low doses), is computed as:

$$m = \frac{0.10}{LED_{10}} \qquad \text{(Equation 3-2)}$$

The RSD is then calculated for a specific incremental targeted lifetime cancer risk (in the range of 10^{-6} to 10^{-4}) as:

NMED Exhibit 84

$$RSD = \frac{\text{Target Incremental Cancer Risk}}{m} \qquad \text{(Equation 3-3)}$$

where:

RSD	=	Risk-specific dose (mg/kg-day)
Target Incremental Cancer Risk[8]	=	Value in the range of 10^{-6} to10^{-4}
m	=	Cancer potency factor $(mg/kg\text{-}day)^{-1}$

The use of the RSD to compute the AWQC is described in Section 3.1.3.5 below.

D. Default Nonlinear Approach

As discussed in the 1999 draft revised cancer guidelines, any of the following conclusions leads to a selection of a nonlinear (MOE) approach to dose-response assessment:

- A tumor MOA supporting nonlinearity applies (e.g., some cytotoxic and hormonal agents such as disruptors of hormonal homeostasis), and the chemical does not demonstrate mutagenic effects consistent with linearity.

- An MOA supporting nonlinearity has been demonstrated, and the chemical has some indication of mutagenic activity, but it is judged not to play a significant role in tumor causation.

Thus, a default assumption of nonlinearity is appropriate when there is no evidence for linearity and sufficient evidence to support an assumption of nonlinearity. The MOA may lead to a dose-response relationship that is nonlinear, with response falling much more quickly than linearly with dose, or being most influenced by individual differences in sensitivity. Alternatively, the MOA may theoretically have a threshold (e.g., the carcinogenicity may be a secondary effect of toxicity or of an induced physiological change that is itself a threshold phenomenon).

The nonlinear approach may be used, for instance, in the case of a bladder tumor inducer, where the chemical is not mutagenic and causes only stone formation in male rat bladders at high doses. This dynamic leads to tumor formation only at the high doses. Stone and subsequent tumor formation are not expected to occur at doses lower than those that induce the physiological changes that lead to stone formation. (More detail on this chemical is provided in the cancer section of the Risk Assessment TSD; USEPA, 2000). EPA does not generally try to distinguish between modes of action that might imply a “true threshold” from others with a

[8]In 1980, the target lifetime cancer risk range was set at 10-7 to 10-5. However, both the expert panel for the AWQC workshop (USEPA, 1993) and the peer review workshop experts (USEPA,1999c) recommended that EPA change the risk range to 10-6 to 10-4, to be consistent with SDWA program decisions. See Section 2.4 for more details.

NMED Exhibit 84

nonlinear dose-response relationship, because there is usually not sufficient information to distinguish between those possibilities empirically.

The nonlinear MOE approach in the 1986 proposed cancer guidelines compares an observed response rate such as the LED_{10}, NOAEL, or LOAEL with actual or nominal environmental exposures of interest by computing the ratio between the two. In the context of deriving AWQC, the environmentally relevant exposures are nominal targets rather than actual exposures.

If the evidence for an agent indicates nonlinearity (e.g., when carcinogenicity is secondary to another toxicity for which there is a threshold), the MOE analysis for the toxicity is similar to what is done for a noncancer endpoint, and an RfD or RfC for that toxicity may also be estimated and considered in the cancer assessment. However, a threshold of carcinogenic response is not necessarily assumed. It should be noted that for cancer assessment, the MOE analysis begins from a POD that is adjusted for toxicokinetic differences between species to give a human equivalent dose.

To support the use of the MOE approach, risk assessment information provides evaluation of the current understanding of the phenomena that may be occurring as dose (exposure) decreases substantially below the observed data. This gives information about the risk reduction that is expected to accompany a lowering of exposure. The various factors that influence the selection of the UF in an MOE approach are also discussed below.

There are two main steps in the MOE approach. The first step is the selection of a POD. The POD may be the LED_{10} for tumor incidence or a precursor, or in some cases, it may also be appropriate to use a NOAEL or LOAEL value. When animal data are used, the POD is a human equivalent dose or concentration arrived at by interspecies dose adjustment (as discussed in Section 3.1.3.3) or toxicokinetic analysis.

The second step in using MOE analysis to establish AWQC is the selection of an appropriate margin or UF to apply to the POD. This is supported by analyses in the MOE discussion in the risk assessment. The following issues should be considered when establishing the overall UF for the derivation of AWQC using the MOE approach (others may be found appropriate in specific cases):

- The nature of the response used for the dose-response assessment, for instance, whether it is a precursor effect or a tumor response. The latter may support a greater MOE.

- The slope of the observed dose-response relationship at the POD and its uncertainties and implications for risk reduction associated with exposure reduction. (A steeper slope implies a greater reduction in risk as exposure decreases. This may support a smaller MOE).

- Human sensitivity compared with that of experimental animals.

- Nature and extent of human variability and sensitivity.

NMED Exhibit 84

- Human exposure. The MOE evaluation also takes into account the magnitude, frequency, and duration of exposure. If the population exposed in a particular scenario is wholly or largely composed of a subpopulation of special concern (e.g., children) for whom evidence indicates a special sensitivity to the agent's MOA, an adequate MOE would be larger than for general population exposure.

E. Both Linear and Nonlinear Approaches

Any of the following conclusions leads to selection of both a linear and nonlinear approach to dose-response assessment. Relative support for each dose-response method and advice on the use of that information needs to be documented for the AWQC. In some cases, evidence for one MOA is stronger than for the other, allowing emphasis to be placed on that dose-response approach. In other cases, both modes of action are equally possible, and both dose-response approaches should be emphasized.

- Modes of action for a single tumor type support both linear and nonlinear dose response in different parts of the dose-response curve (e.g., 4,4' methylene chloride).

- A tumor mode of action supports different approaches at high and low doses; e.g., at high dose, nonlinearity, but, at low dose, linearity (e.g., formaldehyde).

- The agent is not DNA-reactive and all plausible modes of action are consistent with nonlinearity, but not fully established.

- Modes of action for different tumor types support differing approaches, e.g., nonlinear for one tumor type and linear for another due to lack of MOA information (e.g., trichloroethylene).

3.1.3.5 <u>AWQC Calculation</u>

A. Linear Approach

The following equation is used for the calculation of the AWQC for carcinogens where an RSD is obtained from the linear approach:

$$AWQC = RSD \cdot \left(\frac{BW}{DI + \sum_{i=2}^{4} (FI_i \cdot BAF_i)} \right) \qquad \text{(Equation 3-4)}$$

AWQC	=	Ambient water quality criterion (mg/L)
RSD	=	Risk-specific dose (mg/kg-day)
BW	=	Human body weight (kg)
DI	=	Drinking water intake (L/day)

NMED Exhibit 84

FI_i	=	Fish intake at trophic level I (I = 2, 3, and 4) (kg/day)
BAF_i	=	Bioaccumulation factor for trophic level I (I = 2, 3, and 4), lipid normalized (L/kg)

B. Nonlinear Approach

In those cases where the nonlinear, MOE approach is used, a similar equation is used to calculate the AWQC [9]

$$AWQC = \frac{POD}{UF} \cdot RSC \cdot \left(\frac{BW}{DI + \sum_{i=2}^{4} (FI_i \cdot BAF_i)} \right) \qquad \text{(Equation 3-5)}$$

where variables are defined as for Equation 3-4 and:

POD	=	Point of departure (mg/kg-day)
UF	=	Uncertainty factor (unitless)
RSC	=	Relative source contribution (percentage or subtraction)

Differences between the AWQC values obtained using the linear and nonlinear approaches should be noted. First, the AWQC value obtained using the default linear approach corresponds to a specific estimated incremental lifetime cancer risk level in the range of 10^{-4} to 10^{-6}. In contrast, the AWQC obtained using the nonlinear approach does not describe a specific cancer risk. The AWQC calculations shown above are appropriate for waterbodies that are used as sources of drinking water.

The actual AWQC chosen for the protection of human health is based on a review of all relevant information, including cancer and noncancer data. The AWQC may, or may not, utilize the value obtained from the cancer analysis in the final AWQC value. The endpoint selected for the AWQC will be based on consideration of the weight of evidence and a complete analysis of all toxicity endpoints.

3.1.3.6 Risk Characterization

Risk assessment is an integrative process that is documented in a risk characterization summary. Risk characterization is the final step of the risk assessment process in which all preceding analyses (i.e., hazard, dose-response, and exposure assessments) are tied together to convey the overall conclusions about potential human risk. This component of the risk assessment process characterizes the data in nontechnical terms, explaining the extent and weight of evidence, major points of interpretation and rationale, and strengths and weaknesses of

[9] Although appearing in this equation as a factor to be multiplied, the RSC can also be an amount subtracted.

NMED Exhibit 84

the evidence, and discussing alternative approaches, conclusions, uncertainties, and variability that deserve serious consideration.

Risk characterization information accompanies the numerical AWQC value and addresses the major strengths and weaknesses of the assessment arising from the availability of data and the current limits of understanding the process of cancer causation. Key issues relating to the confidence in the hazard assessment and the dose-response analysis (including the low-dose extrapolation procedure used) are discussed. Whenever more than one interpretation of the weight of evidence for carcinogenicity or the dose-response characterization can be supported, and when choosing among them is difficult, the alternative views are provided along with the rationale for the interpretation chosen in the derivation of the AWQC value. Where possible, quantitative uncertainty analyses of the data are provided; at a minimum, a qualitative discussion of the important uncertainties is presented.

3.1.3.7 Use of Toxicity Equivalence Factors and Relative Potency Estimates

The 1999 draft revised cancer guidelines state:

> *A toxicity equivalence factor (TEF) procedure is one used to derive quantitative dose-response estimates for agents that are members of a category or class of agents. TEFs are based on shared characteristics that can be used to order the class members by carcinogenic potency when cancer bioassay data are inadequate for this purpose. The ordering is by reference to the characteristics and potency of a well-studied member or members of the class. Other class members are indexed to the reference agent(s) by one or more shared characteristics to generate their TEFs.*

In addition, the 1999 draft revised cancer guidelines state that TEFs are generated and used for the limited purpose of assessment of agents or mixtures of agents in environmental media when better data are not available. When better data become available for an agent, the TEF should be replaced or revised. To date, adequate data to support use of TEFs have been found only for dibenzofurans (dioxins) and coplanar polychlorinated biphenyls (PCBs) (USEPA, 1989, 1999b).

The uncertainties associated with TEFs must be described when this approach is used. This is a default approach to be used when tumor data are not available for individual components in a mixture. Relative potency factors (RPFs) can be similarly derived and used for agents with carcinogenicity or other supporting data. The RPF is conceptually similar to TEFs, but does not have the same level of data to support it and thus has a less rigorous definition compared with the TEF. TEFs and RPFs are used only when there is no better alternative. When they are used, assumptions and uncertainties associated with them are discussed. As of today, there are only three classes of compounds for which relative potency approaches have been examined by EPA: dibenzofurans (dioxins), polychlorinated biphenyls (PCBs), and polycyclic aromatic hydrocarbons (PAHs). There are limitations to the use of TEF and RFP approaches, and caution should be exercised when using them. More guidance can be found in the draft document for conducting health risk assessment of chemical mixtures, published by the EPA Risk Assessment Forum (USEPA,1999b).

3.2 NONCANCER EFFECTS

3.2.1 1980 AWQC National Guidelines for Noncancer Effects

In the 1980 AWQC National Guidelines, the Agency evaluated noncancer human health effects from exposure to chemical contaminants using Acceptable Daily Intake (ADI) levels. ADIs were calculated by dividing NOAELs by safety factors (SFs) to obtain estimates of doses of chemicals that would not be expected to cause adverse effects over a lifetime of exposure. In accordance with the National Research Council report of 1977 (NRC, 1977), EPA used SFs of 10, 100, or 1,000, depending on the quality and quantity of the overall database. In general, a factor of 10 was suggested when good-quality data identifying a NOAEL from human studies were available. A factor of 100 was suggested if no human data were available, but the database contained valid chronic animal data. For chemicals with no human data and scant animal data, a factor of 1,000 was recommended. Intermediate SFs could also be used for databases that fell between these categories.

AWQC were calculated using the ADI levels together with standard exposure assumptions about the rates of human ingestion of water and fish, and also accounting for intake from other sources (see Equation 1-1 in the Introduction). Surface water concentrations at or below the calculated criteria concentrations would be expected to result in human exposure levels at or below the ADI. Inherent in these calculations is the assumption that, generally, adverse effects from noncarcinogens exhibit a threshold.

3.2.2 Noncancer Risk Assessment Developments Since 1980

Since 1980, the risk assessment of noncarcinogenic chemicals has changed. To remove the value judgments implied by the words “acceptable” and “safety,” the ADI and SF terms have been replaced with the terms RfD and UF/modifying factor (MF), respectively.

For the risk assessment of general systemic toxicity, the Agency currently uses the guidelines contained in the IRIS background document entitled *Reference Dose (RfD): Description and Use in Health Risk Assessments* (hereafter the “IRIS background document”. That document defines an RfD as “an estimate (with uncertainty spanning approximately an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects over a lifetime” (USEPA,

NMED Exhibit 84

1993a). The most common approach for deriving the RfD does not involve dose-response modeling. Instead, an RfD for a given chemical is usually derived by first identifying the NOAEL for the most sensitive known toxicity endpoint, that is, the toxic effect that occurs at the lowest dose. This effect is called the critical effect. Factors such as the study protocol, the species of experimental animal, the nature of the toxicity endpoint assessed and its relevance to human effects, the route of exposure, and exposure duration are critically evaluated in order to select the most appropriate NOAEL from among all available studies in the chemical's database. If no appropriate NOAEL can be identified from any study, then the LOAEL for the critical effect endpoint is used and an uncertainly factor for LOAEL-to-NOAEL extrapolation is applied. Using this approach, the RfD is equal to the NOAEL (or LOAEL) divided by the product of UFs and, occasionally, an MF:

$$\text{RfD (mg/kg/day)} = \frac{\text{NOAEL (or LOAEL)}}{\text{UF} \cdot \text{MF}} \qquad \text{(Equation 3-6)}$$

The definitions and guidance for use of the UFs and the MFs are provided in the IRIS background document and are repeated in Table 3-1.

The IRIS background document on the RfD (USEPA, 1993a) provides guidance for critically assessing noncarcinogenic effects of chemicals and for deriving the RfD. Another reference on this topic is Dourson (1994). Furthermore, the Agency has also published separate guidelines for assessing specific toxic endpoints, such as developmental toxicity (USEPA, 1991a), reproductive toxicity (USEPA, 1996a), and neurotoxicity risk assessment (USEPA, 1995). These endpoint-specific guidelines will be used for their respective areas in the hazard assessment step and will complement the overall toxicological assessment. It should be noted, however, that an RfD, derived using the most sensitive known endpoint, is considered protective against all noncarcinogenic effects.

NMED Exhibit 84

TABLE 3-1. UNCERTAINTY FACTORS AND THE MODIFYING FACTOR

Uncertainty Factor	Definition
UF_H	Use a 1, 3, or 10-fold factor when extrapolating from valid data in studies using long-term exposure to average healthy humans. This factor is intended to account for the variation in sensitivity (intraspecies variation) among the members of the human population.
UF_A	Use an additional factor of 1, 3, or 10 when extrapolating from valid results of long-term studies on experimental animals when results of studies of human exposure are not available or are inadequate. This factor is intended to account for the uncertainty involved in extrapolating from animal data to humans (interspecies variation).
UF_S	Use an additional factor of 1, 3, or 10 when extrapolating from less-than-chronic results on experimental animals when there are no useful long-term human data. This factor is intended to account for the uncertainty involved in extrapolating from less-than-chronic NOAELs to chronic NOAELs.
UF_L	Use an additional factor of 1, 3, or 10 when deriving an RfD from a LOAEL, instead of a NOAEL. This factor is intended to account for the uncertainty involved in extrapolating from LOAELs to NOAELs.
UF_D	Use an additional 3- or 10-fold factor when deriving an RfD from an "incomplete" database. This factor is meant to account for the inability of any single type of study to consider all toxic endpoints. The intermediate factor of 3 (approximately ½ $\log_{10}$ unit, i.e., the square root of 10) is often used when there is a single data gap exclusive of chronic data. It is often designated as UF_D.

Modifying Factor

Use professional judgment to determine the MF, which is an additional uncertainty factor that is greater than zero and less than or equal to 10. The magnitude of the MF depends upon the professional assessment of scientific uncertainties of the study and database not explicitly treated above (e.g., the number of species tested). The default value for the MF is 1.

Note: With each UF or MF assignment, it is recognized that professional scientific judgment must be used. The total product of the uncertainty factors and modifying factor should not exceed 3,000.

NMED Exhibit 84

Similar to the procedure used in the 1980 AWQC National Guidelines, the revised method of deriving AWQC for noncarcinogens uses the RfD together with various assumptions concerning intake of the contaminant from both water and non-water sources of exposure. The objective of an AWQC for noncarcinogens is to ensure that human exposure to a substance related to its presence in surface water, combined with exposure from other sources, does not exceed the RfD. The algorithm for deriving AWQC for noncarcinogens using the RfD is presented as Equation 1-1 in the Introduction.

3.2.3 Issues and Recommendations Concerning the Derivation of AWQC for Noncarcinogens

During a review of the 1980 AWQC National Guidelines (USEPA, 1993b), the Agency identified several issues that must be resolved in order to develop a final revised methodology for deriving AWQC based on noncancer effects. These issues, as discussed below, mainly concern the derivation of the RfD as the basis for such an AWQC. Foremost among these issues is whether the Agency should revise the present method or adopt entirely new procedures that use quantitative dose-response modeling for the derivation of the RfD. Other issues include the following:

- Presenting the RfD as a single point value or as a range to reflect the inherent imprecision of the RfD;
- Selecting specific guidance documents for derivation of noncancer health effect levels;
- Considering severity of effect in the development of the RfD;
- Using less-than-90-day studies as the basis for RfDs;
- Integrating reproductive/developmental, immunotoxicity, and neurotoxicity data into the RfD calculation;
- Applying toxicokinetic data in risk assessments; and
- Considering the possibility that some noncarcinogenic effects do not exhibit a threshold.

3.2.3.1 Using the Current NOAEL/UF-Based RfD Approach or Adopting More Quantitative Approaches for Noncancer Risk Assessment

The current NOAEL/UF-based RfD methodology, or its predecessor ADI/SF methodology, have been used since 1980. This approach assumes that there is a threshold exposure below which adverse noncancer health effects are not expected to occur. Exposures above this threshold are believed to pose some risk to exposed individuals; however, the current approach does not address the nature and magnitude of the risk above the threshold level (i.e., the shape of the dose-response curve above the threshold). The NOAEL/UF-based RfD approach is intended primarily to ensure that the RfD value derived from the available data falls below the population effects threshold. However, the NOAEL/UF-based RfD procedure has

NMED Exhibit 84

limitations. In particular, this method requires that one of the actual experimental doses used by the researchers in the critical study be selected as the NOAEL or LOAEL value. The determination that a dose is a NOAEL or LOAEL will depend on the biological endpoints used and the statistical significance of the data. Statistical significance will depend on the number and spacing of dose groups and the numbers of animals used in each dose group. Studies using a small number of animals can limit the ability to distinguish statistically significant differences among measurable responses seen in dose groups and control groups. Furthermore, the determination of the NOAEL or LOAEL also depends on the dose spacing of the study. Doses are often widely spaced, typically differing by factors of three to ten. A study can identify a NOAEL and a LOAEL from among the doses studied, but the "true" effects threshold cannot be determined from those results. The study size and dose spacing limitations also limit the ability to characterize the nature of the expected response to exposures between the observed NOAEL and LOAEL values.

The limitations of the NOAEL/UF approach have prompted development of alternative approaches that incorporate more quantitative dose-response information. The traditional NOAEL approach for noncancer risk assessment has often been a source of controversy and has been criticized in several ways. For example, experiments involving fewer animals tend to produce higher NOAELs and, as a consequence, may produce higher RfDs. Larger sample sizes, on the other hand, should provide greater experimental sensitivity and lower NOAELs. The focus of the NOAEL approach is only on the dose that is the NOAEL, and the NOAEL must be one of the experimental doses. It also ignores the shape of the dose-response curve. Thus, the slope of the dose-response plays little role in determining acceptable exposures for human beings. Therefore, in addition to the NOAEL/UF-based RfD approach described above, EPA will accept other approaches that incorporate more quantitative dose-response information in appropriate situations for the evaluation of noncancer effects and the derivation of RfDs. However, the Agency wishes to emphasize that it still believes the NOAEL/UF RfD methodology is valid and can continue to be used to develop RfDs.

Two alternative approaches that may have relevance in assisting in the derivation of the RfD for a chemical are the BMD and the categorical regression approaches. These alternative approaches may overcome some of the inherent limitations in the NOAEL/UF approach. For example, the BMD analyses for developmental effects show that NOAELs from studies correlate well with a 5 percent response level (Allen et al., 1994). The BMD and the categorical regression approaches usually have greater data requirements than the RfD approach. Thus, it is unlikely that any one approach will apply to every circumstance; in some cases, different approaches may be needed to accommodate the varying databases for the range of chemicals for which water quality criteria must be developed. Acceptable approaches will satisfy the following criteria: (1) meet the appropriate risk assessment goal; (2) adequately describe the toxicity database and its quality; (3) characterize the endpoints properly; (4) provide a measure of the quality of the "fit" of the model when a model is used for dose-response analysis; and (5) describe the key assumptions and uncertainties.

NMED Exhibit 84

A. The Benchmark Dose

The BMD is defined as the dose estimated to produce a predetermined level of change in response (the Benchmark Response level, or BMR) relative to control. The BMDL is defined as the statistical lower confidence limit on the BMD. In the derivation of an RfD, the BMDL is used as the dose to which uncertainty factors are applied instead of the NOAEL. The BMD approach first models a dose-response curve for the critical effect(s) using available experimental data. Several mathematical algorithms can be used to model the dose-response curve, such as polynomial or Weibull functions. To define a BMD from the modeled curve for quantal data, the assessor first selects the BMR. The choice of the BMR is critical. For quantal endpoints, a particular level of response is chosen (e.g., 1 percent, 5 percent, or 10 percent). For continuous endpoints, the BMR is the degree of change from controls and is based on what is considered a biologically significant change. The BMD is derived from the BMR dose by applying the desired confidence limit calculation. The RfD is obtained by dividing the BMD by one or more uncertainty factors, similar to the NOAEL approach. Because the BMD is used like the NOAEL to obtain the RfD, the BMR should be selected at or near the low end of the range of increased risks that can be detected in a study of typical size. Generally, this falls in the range between the ED_{01} and the ED_{10}.

The Agency will accept use of a BMD approach to derive RfDs for those agents for which there is an adequate database. There are a number of technical decisions associated with the application of the BMD technique. These include the following:

- The definition of an adverse response;
- Selection of response data to model;
- The form of the data used (continuous versus quantal);
- The choice of the measures of increased risk (extra risk versus additional risk);
- The choice of mathematical model (including use of nonstandard models for unusual data sets);
- The selection of the BMR;
- Methods for calculating the confidence interval;
- Selection of the appropriate BMD as the basis for the RfD (when multiple endpoints are modeled from a single study, when multiple models are applied to a single response, and when multiple BMDs are calculated from different studies); and
- The use of uncertainty factors with the BMD approach.

These topics are discussed in detail in Crump et al. (1995) and in the Risk Assessment TSD Volume (USEPA, 2000). The use of the BMD approach has been discussed in general terms by several authors (Gaylor, 1983; Crump, 1984; Dourson et al., 1985; Kimmel and Gaylor, 1988; Brown and Erdreich, 1989; Kimmel, 1990). The International Life Sciences Institute

NMED Exhibit 84

(ILSI) also held a major workshop on the BMD in September 1993; the workshop proceedings are summarized in ILSI (1993) and in Barnes et al. (1995). For further information on these technical issues, the reader is referred to the publications referenced above.

The BMD approach addresses several of the quantitative or statistical criticisms of the NOAEL approach. These are discussed at greater length in Crump et al. (1995) and are summarized here. First, the BMD approach uses all the dose-response information in the selected study rather than just a single data point, such as the NOAEL or LOAEL. By using response data from all of the dose groups to model a dose-response curve, the BMD approach allows for consideration of the steepness of the slope of the curve when estimating the ED_{10}. The use of the full data set also makes the BMD approach less sensitive to small changes in data than the NOAEL approach, which relies on the statistical comparison of individual dose groups. The BMD approach also allows consistency in the consideration of the level of effect (e.g., a 10 percent response rate) across endpoints.

The BMD approach accounts more appropriately for the size of each dose group than the NOAEL approach. Laboratory tests with fewer animals per dose group tend to yield higher NOAELs, and thus higher RfDs, because statistically significant differences in response rates are harder to detect. Therefore, in the NOAEL approach, dose groups with fewer animals lead to a higher (less conservative) RfD. In contrast, with the BMD approach, smaller dose groups will tend to have the effect of extending the confidence interval around the ED_{10}; therefore, the lower confidence limit on the ED_{10} (the BMD) will be lower. With the BMD approach, greater uncertainty (smaller test groups) leads to a lower (more conservative) RfD.

There are some issues to be resolved before the BMD approach is used routinely. These were identified in a 1996 Peer Consultation Workshop (USEPA, 1996b). Methods for routine use of the BMD are currently under development by EPA. Several RfCs and RfDs based on the BMD approach are included in EPA's IRIS database. These include reference values for methylmercury based on delayed postnatal development in humans; carbon disulfide based on neurotoxicity; 1,1,1,2-tetrafluoroethane based on testicular effects in rats; and antimony trioxide based on chronic pulmonary interstitial inflammation in female rats.

Various mathematical approaches have been proposed for modeling developmental toxicity data (e.g., Crump, 1984; Kimmel and Gaylor, 1988; Rai and Van Ryzin, 1985; Faustman et al., 1989), which could be used to calculate a BMD. Similar methods can be used to model other types of toxicity data, such as neurotoxicity data (Gaylor and Slikker, 1990, 1992; Glowa and MacPhail, 1995). The choice of the mathematical model may not be critical, as long as estimation is within the observed dose range. Since the model fits a mathematical equation to the observed data, the assumptions in a particular model regarding the existence or absence of a threshold for the effect may not be pertinent (USEPA, 1997). Thus, any model that suitably fits the empirical data is likely to provide a reasonable estimate of a BMD. However, research has shown that flexible models that are nonsymmetric (e.g., the Weibull) are superior to symmetric models (e.g., the probit) in estimating the BMD because the data points at the higher doses have less influence on the shape of the curve than at low doses. In addition, models should incorporate fundamental biological factors where such factors are known (e.g., intralitter correlation for developmental toxicity data) in order to account for as much variability in the

NMED Exhibit 84

data as possible. The Agency is currently using the BMD approach in risk assessments where the data support its use. Draft guidelines for application of the BMD approach also are being developed by the Agency.

Use of BMD methods involves fitting mathematical models to dose-response data obtained primarily from toxicology studies. When considering available models to use for a BMD analysis, it is important to select the model that fits the data the best and is the most biologically appropriate. EPA has developed software following several years of research and development, expert peer review, public comment, subsequent revision, and quality assurance testing. The software (BMDS, Version 1.2) can be downloaded from http://www.epa.gov/ncea/bmds.htm. BMDS facilitates these operations by providing simple data-management tools, a comprehensive help manual, an online help system, and an easy-to-use interface to run multiple models on the same dose-response data.

As part of this software package, EPA has included sixteen (16) different models that are appropriate for the analysis of dichotomous (quantal) data (Gamma, Logistic, Log-Logistic, Multistage, Probit, Log-Probit, Quantal-Linear, Quantal-Quadratic, Weibull), continuous data (Linear, Polynomial, Power, Hill), and nested developmental toxicology data (NLogistic, NCTR, Rai & Van Ryzin). Results from all models include a reiteration of the model formula and model run options chosen by the user, goodness-of-fit information, the BMD, and the estimate of the lower-bound confidence limit on the benchmark dose (BMDL). Model results are presented in textual and graphical output files which can be printed or saved and incorporated into other documents.

B. Categorical Regression

Categorical regression is an emerging technique that may have relevance for the derivation of RfDs or for estimating risk above the RfD (Dourson et al., 1997; Guth et al., 1997). The categorical regression approach, like the BMD approach, can be used to estimate a dose that corresponds to a given probability of adverse effects. This dose would then be divided by UFs to establish an RfD. However, unlike the BMD approach, the Categorical regression approach can incorporate information on different health endpoints in a single dose-response analysis. For those health effects for which studies exist, responses to the substance in question are grouped into severity categories; for example (1) no effect, (2) no adverse effect, (3) mild-to-moderate adverse effect, and (4) frank effect. These categories correspond to the dose categories currently used in setting the RfD, namely, the no-observed-effect level (NOEL), NOAEL, LOAEL, and frank-effect level (FEL), respectively. Logistic transformation or other applicable mathematical operations are used to model the probability of experiencing effects in a certain category as a function of dose (Harrell, 1986; Hertzberg, 1989). The "acceptability" of the fit of the model to the data can be judged using several statistical measures, including the χ^2 statistic, correlation coefficients, and the statistical significance of its model parameter estimates.

The resulting mathematical equation can be used to find a dose (or the lower confidence bound on the dose) at which the probability of experiencing adverse effects does not exceed a selected level, e.g., 10 percent. This dose (like the NOAEL or BMD) would then be divided by

NMED Exhibit 84

relevant UFs to calculate an RfD. For more detail on how to employ the categorical regression approach, see the discussion in the Risk Assessment TSD (USEPA, 2000).

As with the BMD approach, the categorical regression approach has the advantage of using more of the available dose-response data to account for response variability as well as accounting for uncertainty due to sample size through the use of confidence intervals. Additional advantages of categorical regression include the combining of data sets prior to modeling, thus allowing the calculation of the slope of a dose-response curve for multiple adverse effects rather than only one effect at a time. Another advantage is the ability to estimate risks for different levels of severity from exposures above the RfD.

On the other hand, as with BMD, opinions differ over the amount and adequacy of data necessary to implement the method. The categorical regression approach also requires judgments regarding combining data sets, judging goodness-of-fit, and assigning severity to a particular effect. Furthermore, this approach is still in the developmental stage. It is not recommended for routine use, but may be used when data are available and justify the extensive analyses required.

C. Summary

Whether a NOAEL/UF-based methodology, a BMD, a categorical regression model, or other approach is used to develop the RfD, the dose-response-evaluation step of a risk assessment process should include additional discussion about the nature of the toxicity data and its applicability to human exposure and toxicity. The discussion should present the range of doses that are effective in producing toxicity for a given agent; the route, timing, and duration of exposure; species specificity of effects; and any toxicokinetic or other considerations relevant to extrapolation from the toxicity data to human-health-based AWQC. This information should always accompany the characterization of the adequacy of the data.

3.2.3.2 Presenting the RfD as a Single Point or as a Range for Deriving AWQC

Although the RfD has traditionally been presented and used as a single point, its definition contains the phrase ". . . an estimate (with uncertainty spanning perhaps an order of magnitude) . . ." (USEPA, 1993a). Underlying this concept is the reasoning that the selection of the critical effect and the total uncertainty factor used in the derivation of the RfD is based on the "best" scientific judgment, and that competent scientists examining the same database could derive RfDs which varied within an order of magnitude.

In one instance, IRIS presented the RfD as a point value within an accompanying range. EPA derived a single number as the RfD for arsenic (0.3 μg/kg-day), but added that "strong scientific arguments can be made for various values within a factor of 2 or 3 of the currently recommended RfD value, i.e., 0.1 to 0.8 μg/kg/day" (USEPA, 1993c). EPA noted that regulatory managers should be aware of the flexibility afforded them through this action.

There are situations in which the risk manager can select an alternative value to use in place of the RfD in the AWQC calculations. The domain from which this alternative value can

NMED Exhibit 84

be selected is restricted to a defined range around the point estimate. As explained further below, the Agency is recommending that sometimes the use of a value other than the calculated RfD point estimate is appropriate in characterizing risk. The selection of an alternative value within an appropriate range must be determined for each individual situation, since several factors affect the selection of the alternative value. Observing similar effects in several animal species, including humans, can increase confidence in the selection of the critical effect and thereby narrow the range of uncertainty. There are other factors that can affect the precision. These include the slope of the dose-response curve, seriousness of the observed effect, dose spacing, and possibly the route for the experimental doses. Dose spacing and the number of animals in the study groups used in the experiment can also affect the confidence in the RfD.

To derive the AWQC, the calculated point estimate of the RfD is the default. Based on consideration of the available data, the use of another number within the range defined by the product of the UF(s) (and MF, if used) could be justified in some specific situations. This means that there are risk considerations which indicate that some value in the range other than the point estimate may be more appropriate, based on human health or environmental fate considerations. For example, the bioavailability of the contaminant in fish tissues is one factor to consider. If bioavailability from fish tissues is much lower than that from water and the RfD was derived from a study in which the contaminant exposure was from drinking water, the alternative to the calculated RfD could be selected from the high end of the range and justified using the quantitative difference in bioavailability.

Most inorganic contaminants, particularly divalent cations, have bioavailability values of 20 percent or less from a food matrix, but are much more available (about 80 percent or higher) from drinking water. Accordingly, the external dose necessary to produce a toxic internal dose would likely be higher for a study where the exposure occurred through the diet rather than the drinking water. As a result, the RfD from a dietary study would likely be higher than that for the drinking water study if equivalent external doses had been used. Conversely, in cases where the NOAEL that was the basis for the RfD came from a dietary study, the alternative value could be slightly lower than the calculated RfD.

Because the uncertainty around the dose-response relationship increases as extrapolation below the observed data increases, the use of an alternative point within the range may be more appropriate in characterizing the risk than the use of the calculated RfD, especially in situations when the uncertainty is high. Therefore, as a matter of policy, the 2000 Human Health Methodology permits the selection of a single point within a range about the calculated RfD to be used as the basis of the AWQC if an adequate justification of the alternative point is provided. More complete discussion of this option, including limitations on the span of the range, is provided in the Risk Assessment TSD (USEPA, 2000).

3.2.3.3 Guidelines to be Adopted for Derivation of Noncancer Health Effects Values

The Agency currently is using the IRIS background document as the general basis for the risk assessment of noncarcinogenic effects of chemicals (USEPA, 1993a). EPA recommends continued use of this document for this purpose. However, it should be noted that the process for evaluating chemicals for inclusion in IRIS is undergoing revision (USEPA, 1996c). The

NMED Exhibit 84

revised assessments for many chemicals are now available on IRIS and can be consulted as examples of the RfD development process and required supporting documentation.

3.2.3.4 Treatment of Uncertainty Factors/Severity of Effects During the RfD Derivation and Verification Process

During the RfD derivation and toxicology review process, EPA considers the uncertainty in extrapolating between animal species and within individuals of a species, as well as specific uncertainties associated with the completeness of the database. The Agency's RfD Work Group has always considered the severity of the observed effects induced by the chemical under review when choosing the value of the UF with a LOAEL. For example, during the derivation and verification of the RfD for zinc (USEPA, 1992), an uncertainty factor less than the standard factor of 10 (UF of 3) was assigned to the relatively mild decrease in erythrocyte superoxide dismutase activity in human subjects. EPA recommends that the severity of the critical effect be assessed when deriving an RfD and that risk managers be made aware of the severity of the effect and the weight placed on this attribute of the effect when the RfD was derived.

3.2.3.5 Use of Less-Than-90-Day Studies to Derive RfDs

Generally, less-than-90-day experimental studies are not used to derive an RfD. This is based on the rationale that studies lasting for less than 90 days may be too short to detect various toxic effects. However, EPA, has in certain circumstances, derived an RfD based on a less-than-90-day study. For example, the RfD for nonradioactive effects of uranium is based on a 30-day rabbit study (USEPA, 1989). The short-term exposure period was used, because it was adequate for determining doses that cause chronic toxicity. In other cases, it may be appropriate to use a less-than-90-day study because the critical effect is expressed in less than 90 days. For example, the RfD for nitrate was derived and verified using studies that were less than 3-months in duration (USEPA, 1991b). For nitrate, the critical effect of methemoglobinemia in infants occurs in less than 90 days. When it can be demonstrated from other data in the toxicological database that the critical adverse effect is expressed within the study period and that a longer exposure duration would not exacerbate the observed effect or cause the appearance of some other adverse effect, the Agency may choose to use less-than-90-day studies as the basis of the RfD. Such values would have to be used with care because of the uncertainty in determining if other effects might be expressed if exposure was of greater duration than 90 days.

3.2.3.6 Use of Reproductive/Developmental, Immunotoxicity, and Neurotoxicity Data as the Basis for Deriving RfDs

All relevant toxicity data have some bearing on the RfD derivation and verification and are considered by EPA. The "critical" effect is the adverse effect most relevant to humans or, in the absence of an effect known to be relevant to humans, the adverse effect that occurs at the lowest dose in animal studies. If the critical effect is neurotoxicity, EPA will use that endpoint as the basis for the derivation and verification of an RfD, as it did for the RfD for acrylamide. Moreover, the Agency is continually revising its procedures for noncancer risk assessment. For example, EPA has released guidelines for deriving developmental RfDs (RfD_{DT}, USEPA, 1991a), for using reproductive toxicity (USEPA, 1996a), and neurotoxicity (USEPA, 1995) data

NMED Exhibit 84

in risk assessments. The Agency is currently working on guidelines for using immunotoxicity data to derive RfDs. In addition, the Agency is proceeding with the process of generating acceptable emergency health levels for hazardous substances in acute exposure situations based on established guidelines (NRC, 1993).

3.2.3.7 Applicability of Toxicokinetic Data in Risk Assessment

All pertinent toxicity data should be used in the risk assessment process, including toxicokinetic and mechanistic data. The Agency has used toxicokinetic data in deriving the RfD for cadmium and other compounds and currently is using toxicokinetic data to better characterize human inhalation exposures from animal inhalation experiments during derivation/verification of RfCs. In analogy to the RfD, the RfC is considered to be an estimate of a concentration in the air that is not anticipated to cause adverse noncancer effects over a lifetime of inhalation exposure (USEPA, 1994; Jarabek, 1995a). For RfCs, different dosimetry adjustments are made to account for the differences between laboratory animals and humans in gas uptake and disposition or in particle clearance and retention. This procedure results in calculation of a "human equivalent concentration." Based on the use of these procedures, an interspecies UF of 3 (i.e., approximately $10^{0.5}$), instead of the standard factor of 10, is used in the RfC derivation (Jarabek, 1995b).

Toxicokinetics and toxicodynamics of a chemical each contribute to a chemical's observed toxicity, and specifically, to observed differences among species in sensitivity. Toxicokinetics describes the disposition (i.e., deposition, absorption, distribution, metabolism, and elimination of chemicals in the body) and can be approximated using toxicokinetic models. Toxicodynamics describes the toxic interaction of the agent with the target cell. In the absence of specific data on their relative contributions to the toxic effects observed in species, each is considered to account for approximately one-half of the difference in observed effects for humans compared with laboratory animals. The implication of this assumption is that an interspecies uncertainty factor of 3 rather than 10 could be used for deriving an RfD when valid toxicokinetic data and models can be applied to obtain an oral "human equivalent applied dose" (Jarabek, 1995b). If specific data exist on the relative contribution of either element to observed effects, that proportion will be used. The role exposure duration may play, and whether or not the chemical or its damage may accumulate over time in a particular scenario, also requires careful consideration (Jarabek, 1995c).

3.2.3.8 Consideration of Linearity (or Lack of a Threshold) for Noncarcinogenic Chemicals

It is quite possible that there are chemicals with noncarcinogenic endpoints that have no threshold for effects. For example, in the case of lead, it has not been possible to identify a threshold for effects on neurological development. Other examples could include genotoxic teratogens and germline mutagens. Genotoxic teratogens act by causing mutational events during organogenesis, histogenesis, or other stages of development. Germline mutagens interact with germ cells to produce mutations which may be transmitted to the zygote and expressed during one or more stages of development. However, there are few chemicals which currently have sufficient mechanistic information about these possible modes of action. It should be recognized that although an MOA consistent with linearity is possible (especially for agents

NMED Exhibit 84

known to be mutagenic), this has yet to be reasonably demonstrated for most toxic endpoints other than cancer.

EPA has recognized the potential for nonthreshold noncarcinogenic endpoints and discussed this issue in the *Guidelines for Developmental Toxicity Risk Assessment* (USEPA, 1991a) and in the 1986 *Guidelines for Mutagenicity Risk Assessment* (USEPA, 1986). An awareness of the potential for such teratogenic/mutagenic effects should be established in order to deal with such data. However, without adequate data to support a genetic or mutational basis for developmental or reproductive effects, the default becomes a UF or MOA approach, which are procedures utilized for noncarcinogens assumed to have a threshold. Therefore, genotoxic teratogens and germline mutagens should be considered an exception while the traditional uncertainty factor approach is the general rule for calculating criteria or values for chemicals demonstrating developmental/reproductive effects. For the exceptional cases, since there is no well-established mechanism for calculating criteria protective of human health from the effects of these agents, criteria will be established on a case-by-case basis. Other types of nonthreshold noncarcinogens must also be handled on a case-by-case basis.

3.2.3.9 Minimum Data Guidance

For details on minimum data guidance for RfD development, see the Risk Assessment TSD (USEPA, 2000).

4. EXPOSURE

The derivation of AWQC for the protection of human health requires information about both the toxicological endpoints of concern for water pollutants and the pathways of human exposure to those pollutants. The two primary pathways of human exposure to pollutants present in a particular ambient waterbody that have been considered in deriving AWQC are direct ingestion of drinking water obtained from that waterbody and the consumption of fish/shellfish obtained from that waterbody. The water pathway also includes other exposures from household uses (e.g., showering). The derivation of an AWQC involves the calculation of the maximum water concentration for a pollutant (i.e., the water quality criteria level) that ensures drinking water and/or fish ingestion exposures will not result in human intake of that pollutant in amounts that exceed a specified level based upon the toxicological endpoint of concern.

The equation for noncancer effects is presented again here, in simplified form, to emphasize the exposure-related parameters (in bold). [Note: the RSC parameter also applies to nonlinear low-dose extrapolation for cancer effects and the other exposure parameters apply to all three of the equations (see Section 1.6).]

$$AWQC = RfD \bullet \boldsymbol{RSC} \bullet \frac{(\boldsymbol{BW})}{\left[\boldsymbol{DI} + (\boldsymbol{FI} \bullet BAF)\right]} \qquad \text{(Equation 4-1)}$$

where:

AWQC	=	Ambient Water Quality Criterion (mg/L)
RfD	=	Reference dose for noncancer effects (mg/kg-day)
RSC	=	Relative source contribution factor to account for non-water sources of exposure
BW	=	Human body weight (kg)
DI	=	Drinking water intake (L/day)
FI	=	Fish intake (kg/day)
BAF	=	Bioaccumulation factor (L/kg)

The following subsections discuss exposure issues relevant to the 2000 Human Health Methodology: exposure policy issues; consideration of non-water sources of exposure (the Relative Source Contribution approach); and the factors used in AWQC computation. In relevant sections, science policy and risk management decisions made by EPA are discussed.

4.1 EXPOSURE POLICY ISSUES

This section discusses broad policy issues related to exposure concerning the major objectives that the Agency believes should be met in setting AWQC.

NMED Exhibit 84

An Exposure Assessment TSD provides greater detail on numerous topics discussed in this guidance: suggested sources of contaminant concentration and exposure intake information; suggestions of survey methods for obtaining and analyzing exposure data necessary for deriving AWQC; summaries of studies on fish consumption among sport fishers and subsistence fishers; more detailed presentation of parameter values (e.g., fish consumption rates, body weights); and additional guidance on the application of the RSC approach.

4.1.1 Sources of Exposure Associated With Ambient Water

4.1.1.1 Appropriateness of Including the Drinking Water Pathway in AWQC

EPA intends to continue including the drinking water exposure pathway in the derivation of its national default human health criteria (AWQC), as has been done since the 1980 AWQC National Guidelines were first published.

EPA recommends inclusion of the drinking water exposure pathway where drinking water is a designated use for the following reasons: (1) Drinking water is a designated use for surface waters under the CWA and, therefore, criteria are needed to assure that this designated use can be protected and maintained. (2) Although rare, there are some public water supplies that provide drinking water from surface water sources without treatment. (3) Even among the majority of water supplies that do treat surface waters, existing treatments may not necessarily be effective for reducing levels of particular contaminants. (4) In consideration of the Agency's goals of pollution prevention, ambient waters should not be contaminated to a level where the burden of achieving health objectives is shifted away from those responsible for pollutant discharges and placed on downstream users to bear the costs of upgraded or supplemental water treatment.

This policy decision has been supported by the States, most of the public stakeholders, and by external peer reviewers. As with the other exposure parameters, States and authorized Tribes have the flexibility to use alternative intake rates if they believe that drinking water consumption is substantively different than EPA's recommended default assumptions of 2 L/day for adults and 1 L/day for children. EPA recommends that States and authorized Tribes use an intake rate that would be protective of a majority of consumers and will consider whether an alternative assumption is adequately protective of a State's or Tribe's population based on the information or rationale provided at the time EPA reviews State and Tribal water quality standards submissions.

4.1.1.2 Setting Separate AWQC for Drinking Water and Fish Consumption

In conjunction with the issue of the appropriateness of including the drinking water pathway explicitly in the derivation of AWQC for the protection of human health, EPA intends to continue its practice of setting a single AWQC for both drinking water and fish/shellfish consumption, and a separate AWQC based on ingestion of fish/shellfish alone. This latter criterion applies in those cases where the designated uses of a waterbody include supporting fishable uses under Section 101(a) of the CWA and, thus, fish or shellfish for human consumption, but not as a drinking water supply source (e.g., non-potable estuarine waters).

NMED Exhibit 84

EPA does not believe that national water quality criteria for protection of drinking water uses only are particularly useful for two reasons. First, State and Tribal standards for human health are set to protect Section 101(a) uses (e.g., "fishable, swimmable uses") under the CWA. Second, most waters have multiple designated uses. Additionally, the water quality standards program protects aquatic life. The 2000 Human Health Methodology revisions do not change EPA's policy to apply aquatic life criteria to protect aquatic species where they are more sensitive (i.e., when human health criteria would not be protective enough) or where human health via fish or water ingestion is not an issue.

4.1.1.3 Incidental Ingestion from Ambient Surface Waters

The 2000 Human Health Methodology does not routinely include criteria to address incidental ingestion of water from recreational uses. EPA has considered whether there are cases where water quality criteria for the protection of human health based only on fish ingestion (or only criteria for the protection of aquatic life) may not adequately protect recreational users from health effects resulting from incidental water ingestion.

EPA reviewed information that provided estimates of incidental water ingestion rates averaged over time. EPA generally believes that the averaged amount is negligible and will not have any impact on the chemical criteria values representative of both drinking water and fish ingestion. A lack of impact on the criteria values would likely also be true for chemical criteria based on fish consumption only, unless the chemical exhibits no bioaccumulation potential. However, EPA also believes that incidental/accidental water ingestion could be important for the development of microbial contaminant water quality criteria, and for either chemical or microbial criteria for States where recreational uses such as swimming and boating are substantially higher than the national average. EPA also notes that some States have indicated they already have established incidental ingestion rates for use in developing criteria. Therefore, although EPA will not use this intake parameter when deriving its national 304(a) chemical criteria, limited guidance is provided in the Exposure Assessment TSD volume in order to assist States and authorized Tribes that face situations where this intake parameter could be of significance.

4.2 CONSIDERATION OF NON-WATER SOURCES OF EXPOSURE WHEN SETTING AWQC

4.2.1 Policy Background

The 2000 Human Health Methodology uses different approaches for addressing non-water exposure pathways in setting AWQC for the protection of human health depending upon the toxicological endpoint of concern. With those substances for which the appropriate toxic endpoint is carcinogenicity based on a linear low-dose extrapolation, only the two water sources (i.e., drinking water and fish ingestion) are considered in the derivation of the AWQC. Non-water sources are not considered explicitly. In the case of carcinogens based on linear low-dose extrapolation, the AWQC is being determined with respect to the *incremental* lifetime risk posed by a substance's presence in water, and is not being set with regard to an individual's total risk from all sources of exposure. Thus, the AWQC represents the water concentration that would be

NMED Exhibit 84

expected to increase an individual's lifetime risk of carcinogenicity from exposure to the particular pollutant by no more than one chance in one million, regardless of the additional lifetime cancer risk due to exposure, if any, to that particular substance from other sources.

Furthermore, health-based criteria values for one medium based on linear low-dose extrapolation typically vary from values for other media in terms of the concentration value, and often the associated risk level. Therefore, the RSC concept could not even theoretically apply unless all risk assessments for a particular carcinogen based on linear low-dose extrapolation resulted in the same concentration value and same risk level; that is, an apportionment would need to be based on a single risk value and level.

In the case of substances for which the AWQC is set on the basis of a carcinogen based on a nonlinear low-dose extrapolation or for a noncancer endpoint where a threshold is assumed to exist, non-water exposures are considered when deriving the AWQC using the RSC approach. The rationale for this approach is that for pollutants exhibiting threshold effects, the objective of the AWQC is to ensure that an individual's total exposure does not exceed that threshold level.

There has been some discussion of whether it is, in fact, necessary in most cases to explicitly account for other sources of exposure when computing the AWQC for pollutants exhibiting threshold effects. It has been argued that because of the conservative assumptions generally incorporated in the calculation of RfDs (or POD/UF values) used as the basis for the AWQC derivation, total exposures slightly exceeding the RfD are unlikely to produce adverse effects.

EPA emphasizes that the purpose of the RSC is to ensure that the level of a chemical allowed by a criterion or multiple criteria, when combined with other identified sources of exposure common to the population of concern, will not result in exposures that exceed the RfD or the POD/UF. The policy of considering multiple sources of exposure when deriving health-based criteria has become common in EPA's program office risk characterizations and criteria and standard-setting actions. Numerous EPA workgroups have evaluated the appropriateness of factoring in such exposures, and the Agency concludes that it is important for adequately protecting human health. Consequently, EPA risk management policy has evolved significantly over the last six years. Various EPA program initiatives and policy documents regarding aggregate exposure and cumulative risk have been developed, including the consideration of inhalation and dermal exposures. Additionally, accounting for other exposures has been included in recent mandates (e.g., the Food Quality Protection Act) and, thus, is becoming a requirement for the Agency. The Exposure Decision Tree approach has been shared with other EPA offices, and efforts to coordinate policies on aggregate exposure, where appropriate, have begun. EPA intends to continue developing policy guidance on the RSC issue and guidance to address the concern that human health may not be adequately protected if criteria allow for higher levels of exposure that, combined, may exceed the RfD or POD/UF. EPA also intends to refine the 2000 Human Health Methodology in the future to incorporate additional guidance on inhalation and dermal exposures. As stated previously, EPA is required to derive national water quality criteria under Section 304(a) of the CWA and does not intend to derive site-specific criteria. However, States and authorized Tribes have the flexibility to make alternative exposure and RSC estimates based on local data, and EPA strongly encourages this.

NMED Exhibit 84

Uncertainty factors used in the derivation of the RfD (or POD/UF) to account for intra- and interspecies variability and the incompleteness of the toxicity data set(s)/animal studies are specifically relevant to the chemical's internal toxicological action, irrespective of the sources of exposure that humans may be experiencing. The Agency's policy is to consider and account for other sources of exposure in order to set protective health criteria. EPA believes that multiple route exposures may be particularly important when uncertainty factors associated with the RfD are small. Although EPA is well aware that RfDs are not all equivalent in their derivation, EPA does not believe that uncertainty in the toxicological data should result in less stringent criteria by ignoring exposure sources. However, the RSC policy approach does allow less stringent assumptions when multiple sources of exposure are not anticipated.

The AWQC are designed to be protective criteria, generally applicable to the waters of the United States. While EPA cannot quantitatively predict the actual human health risk associated with combined exposures above the RfD or POD/UF, a combination of health criteria for multiple media exceeding the RfD or POD/UF may not be sufficiently protective. Therefore, EPA's policy is to routinely account for all sources and routes of non-occupational exposure when setting AWQC for noncarcinogens and for carcinogens based on nonlinear low-dose extrapolations. EPA believes that maintaining total exposure below the RfD (or POD/UF) is a reasonable health goal and that there are circumstances where health-based criteria for a chemical should not exceed the RfD (or POD/UF), either alone (if only one criterion is relevant, along with other intake sources considered as background exposures) or in combination. EPA believes its RSC policy ensures this goal.

Also, given the inability to reasonably predict future changes in exposure patterns, the uncertainties in the exposure estimates due to typical data inadequacy, possible unknown sources of exposure, and the potential for some populations to experience greater exposures than indicated by the available data, EPA believes that utilizing the entire RfD (or POD/UF) does not ensure adequate protection.

4.2.2 The Exposure Decision Tree Approach

As indicated in Section 1, EPA has, in the past, used a "subtraction" method to account for multiple sources of exposure to pollutants. In the subtraction method, other sources of exposure (i.e., those other than the drinking water and fish exposures) are subtracted from the RfD (or POD/UF). However, EPA also previously used a "percentage" method for the same purpose. In this approach, the percentage of total exposure typically accounted for by the exposure source for which the criterion is being determined, referred to as the relative source contribution (RSC), is applied to the RfD to determine the maximum amount of the RfD "apportioned" to that source. With both procedures, a "ceiling" level of 80 percent of the RfD and a "floor level" of 20 percent of the RfD are applied.

The subtraction method is considered acceptable when only one criterion is relevant for a particular chemical. The percentage method is recommended in the context of the above goals when multiple media criteria are at issue. The percentage method does not simply depend on the amount of a contaminant in the prospective criterion source only. It is intended to reflect health considerations, the relative portions of other sources, and the likelihood for ever-changing levels

NMED Exhibit 84

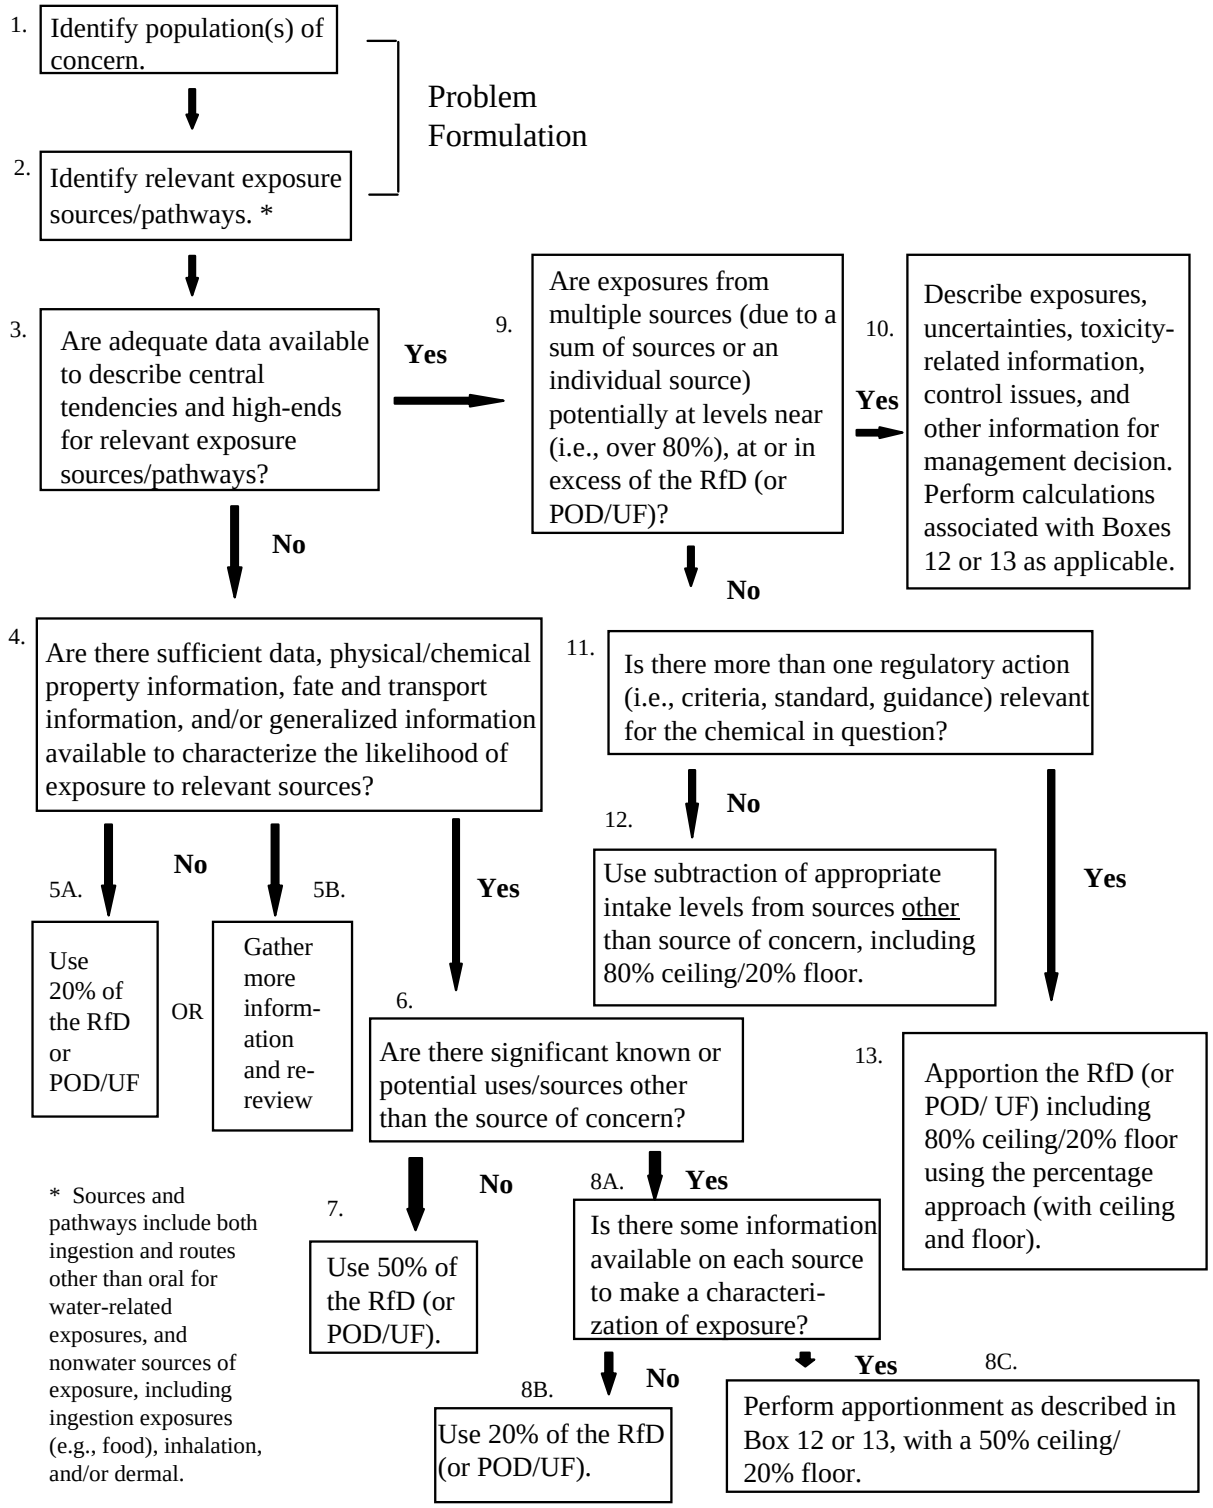
in each of those multiple sources (due to ever-changing sources of emissions and discharges). Rather than simply defaulting in every instance, the Agency attempts to compare multiple source exposures with one another to estimate their relative contribution to the total–given that understanding the degree to which their concentrations vary, or making any distributional analysis, is often not possible. The criteria levels, when multiple criteria are at issue, are based on the actual levels, with an assumption that there may be enough relative variability such that an apportionment (relating that percentage to the RfD) is a reasonable way of accounting for the uncertainty regarding that variability.

The specific RSC approach recommended by EPA, which we will use for the derivation of AWQC for noncarcinogens and carcinogens assessed using nonlinear low-dose extrapolation, is called the Exposure Decision Tree and is described below. To account for exposures from other media when setting an AWQC (i.e., non-drinking water/non-fish ingestion exposures, and inhalation or dermal exposures), the Exposure Decision Tree for determining proposed RfD or POD/UF apportionments represents a method of comprehensively assessing a chemical for water quality criteria development. This method considers the adequacy of available exposure data, levels of exposure, relevant sources/media of exposure, and regulatory agendas (i.e., whether there are multiple health-based criteria or regulatory standards for the same chemical). The Decision Tree addresses most of the disadvantages associated with the exclusive use of either the percentage or subtraction approaches, because they are not arbitrarily chosen prior to determining the following: specific population(s) of concern, whether these populations are relevant to multiple-source exposures for the chemical in question (i.e., whether the population is actually or potentially experiencing exposure from multiple sources), and whether levels of exposure, regulatory agendas, or other circumstances make apportionment of the RfD or POD/UF desirable. Both subtraction and percentage methods are potentially utilized under different circumstances with the Exposure Decision Tree approach, and the Decision Tree is recommended with the idea that there is enough flexibility to use other procedures if information on the contaminant in question suggests it is not appropriate to follow the Decision Tree. EPA recognizes that there may be other valid approaches in addition to the Exposure Decision Tree.

The Exposure Decision Tree approach allows flexibility in the RfD (or POD/UF) apportionment among sources of exposure. When adequate data are available, they are used to make protective exposure estimates for the population(s) of concern. When other sources or routes of exposure are anticipated but data are not adequate, there is an even greater need to make sure that public health protection is achieved. For these circumstances, a series of qualitative alternatives is used (with the less adequate data or default assumptions) that allow for the inadequacies of the data while protecting human health. Specifically, the Decision Tree makes use of chemical information when actual monitoring data are inadequate. It considers information on the chemical/physical properties, uses of the chemical, and environmental fate and transformation, as well as the likelihood of occurrence in various media. Review of such information, when available, and determination of a reasonable exposure characterization for the chemical will result in a water quality criterion that more accurately reflects exposures than automatically using a default value. Although the 20 percent default will still generally be used when information is not adequate, the need for using it should be reduced. There may also be some situations where EPA would consider the use of an 80 percent default (see Section 4.2.3).

NMED Exhibit 84

The Decision Tree also allows for use of either the subtraction or percentage method to account for other exposures, depending on whether one or more health-based criterion is relevant for the chemical in question. The subtraction method is considered acceptable when only one criterion is relevant for a particular chemical. In these cases, other sources of exposure can be considered "background" and can be subtracted from the RfD (or POD/UF).



EPA cautions States and Tribes when using the subtraction method in these circumstances. The subtraction method results in a criterion allowing the maximum possible chemical concentration in water after subtracting other sources. As such, it removes any cushion between pre-criteria levels (i.e., actual "current" levels) and the RfD, thereby setting criteria at the highest levels short of exceeding the RfD. It is somewhat counter to the goals of the CWA for maintaining and restoring the nation's waters. It is also directly counter to Agency policies, explicitly stated in numerous programs, regarding pollution prevention. EPA has advocated that it is good health policy to set criteria such that exposures are kept low when current levels are already low. The subtraction method generally results in criteria levels of a contaminant in a particular medium at significantly higher levels than the percentage method and, in this respect, is contradictory to such goals. In fact, many chemicals have pre-criteria levels in environmental media substantially lower (compared to the RfD) than the resulting criteria allow.

When more than one criterion is relevant to a particular chemical, apportioning the RfD (or POD/UF) via the percentage method is considered appropriate to ensure that the combination of criteria and, thus, the potential for resulting exposures do not exceed the RfD (or POD/UF). The Exposure Decision Tree (with numbered boxes) is shown in Figure 4-1. The explanation in the text on the following pages must be read in tandem with the Decision Tree figure; the text in each box of the figure only nominally identifies the process and conditions for determining the outcome for that step of the Decision Tree. The underlying objective is to maintain total exposure below the RfD (or POD/UF) while generally avoiding an extremely low limit in a single medium that represents just a nominal fraction of the total exposure. To meet this objective, all proposed numeric limits lie between 80 percent and 20 percent of the RfD (or POD/UF). Again, EPA will use the Exposure Decision Tree approach when deriving its AWQC but also recognizes that departures from the approach may be appropriate in certain cases. EPA understands that there may be situations where the Decision Tree procedure is not practicable or

NMED Exhibit 84

Figure 4-1

Exposure Decision Tree for Defining Proposed RfD (or POD/UF) Apportionment

NMED Exhibit 84

may be simply irrelevant after considering the properties, uses, and sources of the chemical in question. EPA endorses such flexibility by States and authorized Tribes when developing alternative water quality criteria in order to choose other procedures that are more appropriate for setting health-based criteria and, perhaps, apportioning the RfD or POD/UF, as long as reasons are given as to why it is not appropriate to follow the Exposure Decision Tree approach and as long as the steps taken to evaluate the potential sources and levels of exposure are clearly described. Often, however, the common situation of multiple exposure sources for a chemical is likely to merit a Decision Tree evaluation for the purpose of developing human health water quality criteria for a given chemical.

It is clear that this will be an interactive process; input by exposure assessors will be provided to, and received from, risk managers throughout the process, given that there may be significant implications regarding control issues (i.e., cost/feasibility), environmental justice issues, etc. In cases where the Decision Tree is not chosen, communication and concurrence about the decision rationale and the alternative water quality criteria are of great importance.

Descriptions of the boxes within the Decision Tree are separated by the following process headings to facilitate an understanding of the major considerations involved. The decision to perform, or not to perform, an apportionment could actually be made at several points during the Decision Tree process. Working through the process is most helpful for identifying possible exposure sources and the potential for exposure, determining the relevancy of the Decision Tree to developing an AWQC for a particular chemical and, possibly, determining the appropriateness of using an alternative approach to account for overall exposure. "Relevancy" here means determining whether more than one criterion, standard, or other guidance is being planned or is in existence for the chemical in question. Additional guidance for States and Tribes that wish to use the Exposure Decision Tree is provided in the Exposure Assessment TSD.

4.2.2.1 Problem Formulation

Initial Decision Tree discussion centers around the first two boxes: identification of population(s) of concern (Box 1) and identification of relevant exposure sources and pathways (Box 2). The term "problem formulation" refers to evaluating the population(s) and sources of exposure in a manner that allows determination of the potential for the population of concern to experience exposures from multiple sources for the chemical in question. Also, the data for the chemical in question must be representative of each source/medium of exposure and be relevant to the identified population(s). Evaluation includes determining whether the levels, multiple criteria or regulatory standards, or other circumstances make apportionment of the RfD or POD/UF reasonable. The initial problem formulation also determines the exposure parameters chosen, the intake assumptions chosen for each route, and any environmental justice or other social issues that aid in determining the population of concern. The term "data," as used here and discussed throughout this section, refers to ambient sampling data (whether from Federal, regional, State, or area-specific studies) and not internal human exposure measurements.

NMED Exhibit 84

4.2.2.2 Data Adequacy

In Box 3, it is necessary that adequate data exist for the relevant sources/pathways of exposure if one is to avoid using default procedures. The adequacy of data is a professional judgment for each individual chemical of concern, but EPA recommends that the minimum acceptable data for Box 3 are exposure distributions that can be used to determine, with an acceptable 95 percent confidence interval, the central tendency and high-end exposure levels for each source. In fact, distributional data may exist for some or most of the sources of exposure.

There are numerous factors to consider in order to determine whether a dataset is adequate. These include: (1) sample size (i.e., the number of data points); (2) whether the data set is a random sample representative of the target population (if not, estimates drawn from it may be biased no matter how large the sample); (3) the magnitude of the error that can be tolerated in the estimate (estimator precision); (4) the sample size needed to achieve a given precision for a given parameter (e.g., a larger sample is needed to precisely estimate an upper percentile than a mean or median value); (5) an acceptable analytical method detection limit; and (6) the functional form and variability of the underlying distribution, which determines the estimator precision (e.g., whether the distribution is normal or lognormal and whether the standard deviation is 1 or 10). Lack of information may prevent assessment of each of these factors; monitoring study reports often fail to include background information or sufficient summary statistics (and rarely the raw data) to completely characterize data adequacy. Thus, a case-by-case determination of data adequacy may be necessary.

That being stated, there are some guidelines, as presented below, that lead to a rough rule-of-thumb on what constitutes an "adequate" sample size for exposure assessment. Again, first and foremost, the representativeness of the data for the population evaluated and the analytical quality of the data must be acceptable. If so, the primary objective then becomes estimating an upper percentile (e.g., say the 90th) and a central tendency value of some exposure distribution based on a random sample from the distribution. Assuming that the distribution of exposures is unknown, a nonparametric estimate of the 90th percentile is required. The required estimate, based on a random sample of *n* observations from a target population, is obtained by ranking the data from smallest to largest and selecting the observation whose rank is 1 greater than the largest integer in the product of 0.9 times *n*. For example, in a data set of 25 points, the nonparametric estimate of the 90th percentile is the 23rd largest observation.

In addition to this point estimate, it is useful to have an upper confidence bound on the 90th percentile. To find the rank of the order statistic that gives an upper 95 percent confidence limit on the 90th percentile, the smallest value of *r* that satisfies the following formula is determined:

$$0.95 \approx \sum_{i=0}^{r-1} \binom{n}{i} 0.9^{i}\ 0.1^{n-i} \qquad \text{(Equation 4-2)}$$

NMED Exhibit 84

where:

r	=	the rank order of the observation
n	=	the number of observations
I	=	integer from 0 to r - 1

For relatively small data sets, the above formula will lead to selecting the largest observation as the upper confidence limit on the 90th percentile. However, the problem with using the maximum is that, in many environmental datasets, the largest observation is an outlier and would provide an unrealistic upper bound on the 90th percentile. It would, therefore, be preferable if the sample size *n* were large enough so that the formula yielded the second largest observation as the confidence limit (see for example Gibbons, 1971).

This motivates establishing the following criterion for setting an "adequate" sample size: pick the smallest *n* such that the nonparametric upper 95 percent confidence limit on the 90th percentile is the second largest value. Application of the above formula with *r* set to *n*-1 yields *n* = 45 for this minimum sample size.

For the upper 95 percent confidence limit to be a useful indicator of a high-end exposure, it must not be overly conservative (too large relative to the 90th percentile). It is, therefore, of interest to estimate the expected magnitude of the ratio of the upper 95 percent confidence limit to the 90th percentile. This quantity generally cannot be computed, since it is a function of the unknown distribution. However, to get a rough idea of its value, consider the particular case of a normal distribution. If the coefficient of variation (i.e., the standard deviation divided by the mean) is between 0.5 and 2.0, the expected value of the ratio in samples of 45 will be approximately 1.17 to 1.31; i.e., the upper 95 percent confidence limit will be only about 17 to 31 percent greater than the 90th percentile on the average.

It should be noted that the nonparametric estimate of the 95 percent upper confidence limit based on the second largest value can be obtained even if the data set has only two detects (it is assumed that the two detects are greater than the detection limit associated with all non-detects). This is an argument for using nonparametric rather than parametric estimation, since use of parametric methods would require more detected values. On the other hand, if non-detects were not a problem and the underlying distribution were known, a parametric estimate of the 90th percentile would generally be more precise.

As stated above, adequacy also depends on whether the samples are relevant to and representative of the population at risk. Data may, therefore, be adequate for some decisions and inadequate for others; this determination requires some professional judgment.

If the answer to Box 3 is no, based on the above determination of adequacy, then the decision tree moves to Box 4. As suggested by the separate boxes, the available data that will be reviewed as part of Box 4 do not meet the requirements necessary for Box 3. In Box 4, any limited data that are available (in addition to information about the chemical/physical properties, uses, and environmental fate and transformation, as well as any other information that would characterize the likelihood of exposure from various media for the chemical) are evaluated to

NMED Exhibit 84

make a qualitative determination of the relation of one exposure source to another. Although this information should always be reviewed at the outset, it is recommended that this information also be used to estimate the health-based water quality criteria. The estimate should be rather conservative (as indicated in the Decision Tree), given that it is either not based on actual monitoring data or is based on data that has been considered to be inadequate for a more accurate quantitative estimate. Therefore, greater uncertainties exist and accounting for variability is not really possible. Whether the available data are adequate and sufficiently representative will likely vary from chemical to chemical and may depend on the population of concern. If there are some data and/or other information to make a characterization of exposure, a determination can be made as to whether there are significant known or potential uses for the chemical/sources of exposure other than the source of concern (i.e., in this case, the drinking water and fish intakes relevant to developing an AWQC) that would allow one to anticipate/quantify those exposures (Box 6). If there are not, then it is recommended that 50 percent of the RfD or POD/UF can be safely apportioned to the source of concern (Box 7). While this leaves half of the RfD or POD/UF unapportioned, it is recommended as the maximum apportionment due to the lack of data needed to more accurately quantify actual or potential exposures. If the answer to the question in Box 6 is yes (there is multiple source information available for the exposures of concern), and some information is available on each source of exposure (Box 8A), apply the procedure in either Box 12 or Box 13 (depending on whether one or more criterion is relevant to the chemical), using a 50 percent ceiling (Box 8C)–again due to the lack of adequate data. If the answer to the question in Box 8A is no (there is no available information to characterize exposure), then the 20 percent default of the RfD or POD/UF is used (Box 8B).

If the answer to the question in Box 4 is no; that is, there are not sufficient data/information to characterize exposure, EPA intends to generally use the "default" assumption of 20 percent of the RfD or POD/UF (Box 5A) when deriving or revising the AWQC. It may be better to gather more data or information and re-review when this information becomes available (Box 5B). EPA has done this on occasion when resources permit the acquisition of additional data to enable better estimates of exposure instead of the default. If this is not possible, then the assumption of 20 percent of the RfD or POD/UF (Box 5A) should be used. Box 5A is likely to be used infrequently with the Exposure Decision Tree approach, given that the information described in Box 4 should be available in most cases. However, EPA intends to use 20 percent of the RfD (or POD/UF), which has also been used in past water program regulations, as the default value.

4.2.2.3 Regulatory Actions

If there are adequate data available to describe the central tendencies and high ends from each exposure source/pathway, then the levels of exposure relative to the RfD or POD/UF are compared (Box 9). If the levels of exposure for the chemical in question are not near (currently defined as greater than 80 percent), at, or in excess of the RfD or POD/UF, then a subsequent determination is made (Box 11) as to whether there is more than one health-based criterion or regulatory action relevant for the given chemical (i.e., more than one medium-specific criterion,

NMED Exhibit 84

standard or other guidance being planned, performed or in existence for the chemical). The subtraction method is considered acceptable when only one criterion (standard, etc.) is relevant for a particular chemical. In these cases, other sources of exposure can be considered "background" and can be subtracted from the RfD (or POD/UF). When more than one criterion is relevant to a particular chemical, apportioning the RfD (or POD/UF) via the percentage method is considered appropriate to ensure that the combination of health criteria, and thus the potential for resulting exposures, do not exceed the RfD (or POD/UF).

As indicated in Section 2, for EPA's national 304(a) criteria, the RSC intake estimates of non-water exposures (e.g., non-fish dietary exposures) will be based on arithmetic mean values when data are available. The assumed body weight used in calculating the national criteria will also be based on average values. The drinking water and fish intake values are 90th percentile estimates. EPA believes that these assumptions will be protective of a majority of the population and recommends them for State and Tribal use. However, States and authorized Tribes have the flexibility to choose alternative intake rate and exposure estimate assumptions to protect specific population groups that they have chosen.

4.2.2.4 Apportionment Decisions

If the answer to the question in Box 11 is no (there is not more than one relevant medium-specific criterion/regulatory action), then the recommended method for setting a health-based water quality criterion is to utilize a subtraction calculation (Box 12). Specifically, appropriate intake values for each exposure source other than the source of concern are subtracted out. EPA will rely on average values commonly used in the Agency for food ingestion and inhalation rates, combined with mean contaminant concentration values, for calculating RSC estimates to subtract. Alternatively, contaminant concentrations could be selected based on the variability associated with those concentrations for each source. This implies that a case-by-case determination of the variability and the resulting intake chosen would be made, as each chemical evaluated can be expected to have different variations in concentration associated with each source of intake. However, EPA anticipates that the available data for most contaminants will not allow this for determination (based on past experience). Guidance addressing this possibility is addressed in the Exposure Assessment TSD. EPA does not recommend that high-end intakes be subtracted for every exposure source, since the combination may not be representative of any actually exposed population or individual. The subtraction method would also include an 80 percent ceiling and a 20 percent floor.

If the answer to the question in Box 11 is yes (there is more than one medium-specific criterion/regulation relevant), then the recommended method for setting health-based water quality criteria is to apportion the RfD or POD/UF among those sources for which health-based criteria are being set (Box 13). This is done via a percentage approach (with a ceiling and floor). This simply refers to the percentage of overall exposure contributed by an individual exposure source. For example, if for a particular chemical, drinking water were to represent half of total exposure and diet were to represent the other half, then the drinking water contribution (or RSC) would be 50 percent. The health-based criteria would, in turn, be set at 50 percent of the RfD or POD/UF. This method also utilizes an appropriate combination of intake values for each

NMED Exhibit 84

exposure source based on values commonly used in the Agency for food ingestion and inhalation rates, combined with mean contaminant concentration values.

Finally, if the levels of exposure for the chemical in question are near (currently defined as greater than 80 percent), at, or in excess of the RfD or POD/UF (i.e., the answer in Box 9 is yes), then the estimates of exposures and related uncertainties, recommended apportionment (either box 12 or 13), toxicity-related information, control issues, and other information are to be presented to managers for a decision (Box 10). The high levels referred to in Box 9 may be due to one source contributing that high level (while other sources contribute relatively little) or due to more than one source contributing levels that, in combination, approach or exceed the RfD or POD/UF. Management input may be necessary due to the control issues (i.e., cost and feasibility concerns), especially when multiple criteria are at issue. In practice, risk managers are routinely a part of decisions regarding regulatory actions and will be involved with any recommended outcome of the Exposure Decision Tree or, for that matter, any alternative to the Exposure Decision Tree. However, because exposures approach or exceed the RfD or POD/UF and because the feasibility of controlling different sources of exposure are complicated issues, risk managers will especially need to be directly involved in final decisions in these circumstances.

It is emphasized here that the procedures in these circumstances are not different than the procedures when exposures are not at or above the RfD (or POD/UF). Therefore, in these cases, estimates should be performed as with Boxes 11, 12, and 13. The recommendation should be made based on health-based considerations only, just as when the chemical in question was not a Box 10 situation. If the chemical is relevant to one health criterion or regulatory action only, the other sources of exposure could be subtracted from the RfD or POD/UF to determine if there is any leftover amount for setting the criterion. If the chemical is a multiple media criteria issue, then an apportionment should be made, even though it is possible that all sources would need to be reduced. Regardless of the outcome of Box 9, all apportionments made (via the methods of Boxes 12 or 13) should include a presentation of the uncertainty in the estimate and in the RfD or POD/UF for a more complete characterization.

The process for a Box 10 situation (versus a situation that is not) differs in that the presentations for Boxes 12 and 13 are based on apportionments (following the review of available information and a determination of appropriate exposure parameters) that must address additional control issues and may result in more selective reductions. With Box 10, one or several criteria possibilities ("scenarios") could be presented for comparison along with implications of the effects of various control options. It is appropriate to present information in this manner to risk managers given the complexity of these additional control issues.

4.2.3 Additional Points of Clarification on the Exposure Decision Tree Approach for Setting AWQC

As with Box 9, if a determination is made in Box 8A (i.e., information is available to characterize exposure) that exposures are near, at, or above the RfD (or POD/UF) based on the available information, the apportionments made need to be presented to risk managers for decision. If information is lacking on some of the multiple exposure sources, then EPA would use a default of 20 percent of the RfD or POD/UF (Box 8B).

NMED Exhibit 84

Results of both Boxes 12 and 13 rely on the 80 percent ceiling and 20 percent floor. The 80 percent ceiling was implemented to ensure that the health-based goal will be low enough to provide adequate protection for individuals whose total exposure to a contaminant is, due to any of the exposure sources, higher than currently indicated by the available data. This also increases the margin of safety to account for possible unknown sources of exposure. The 20 percent floor has been traditionally rationalized to prevent a situation where small fractional exposures are being controlled. That is, below that point, it is more appropriate to reduce other sources of exposure, rather than promulgating standards for *de minimus* reductions in overall exposure.

If it can be demonstrated that other sources and routes of exposure are not anticipated for the pollutant in question (based on information about its known/anticipated uses and chemical/physical properties), then EPA would use the 80 percent ceiling. EPA qualifies this policy with the understanding that as its policy on cumulative risk assessment continues to develop, the 80 percent RSC may prove to be underprotective.

In the cases of pollutants for which substantial data sets describing exposures across all anticipated pathways of exposure exist, and probabilistic analyses have been conducted based on those data, consideration will be given to the results of those assessments as part of the Exposure Decision Tree approach for setting AWQC.

For many chemicals, the rate of absorption from ingestion can differ substantially from absorption by inhalation. There is also available information for some chemicals that demonstrates appreciable differences in gastrointestinal absorption depending on whether the chemical is ingested from water, soil, or food. For some contaminants, the absorption of the contaminant from food can differ appreciably for plant compared with animal food products. Regardless of the apportionment approach used, EPA recommends using existing data on differences in bioavailability between water, air, soils, and different foods when estimating total exposure for use in apportioning the RfD or POD/UF. The Agency has developed such exposure estimates for cadmium (USEPA, 1994). In the absence of data, EPA will assume equal rates of absorption from different routes and sources of exposure.

4.2.4 Quantification of Exposure

When selecting contaminant concentration values in environmental media and exposure intake values for the RSC analysis, it is important to realize that each value selected (including those recommended as default assumptions in the AWQC equation) may be associated with a distribution of values for that parameter. Determining how various subgroups fall within the distributions of overall exposure and how the combination of exposure variables defines what population is being protected is a complicated and, perhaps, unmanageable task, depending on the amount of information available on each exposure factor included. Many times, the default assumptions used in EPA risk assessments are derived from the evaluation of numerous studies and are considered to generally represent a particular population group or a national average. Therefore, describing with certainty the exact percentile of a particular population that is protected with a resulting criteria is often not possible.

NMED Exhibit 84

By and large, the AWQC are derived to protect the majority of the general population from chronic adverse health effects. However, as stated above in Section 4.1.1.1, States and authorized Tribes are encouraged to consider protecting population groups that they determine are at greater risk and, thus, would be better protected using alternative exposure assumptions. The ultimate choice of the contaminant concentrations used in the RSC estimate and the exposure intake rates requires the use of professional judgment. This is discussed in greater detail in the Exposure Assessment TSD.

4.2.5 Inclusion of Inhalation and Dermal Exposures

EPA intends to develop policy guidelines to apply to this Methodology for explicitly incorporating inhalation and dermal exposures. When estimating overall exposure to pollutants for AWQC development, EPA believes that the sources of inhalation and dermal exposures considered should include, on a case-by-case basis, both non-oral exposures from water and other inhalation and dermal sources (e.g., ambient or indoor air, soil). When the policy guidelines are completed, this Methodology will be refined to include that guidance.

A number of drinking water contaminants are volatile and thus diffuse from water into the air where they may be inhaled. In addition, drinking water is used for bathing and, thus, there is at least the possibility that some contaminants in water may be dermally absorbed. Volatilization may increase exposure via inhalation and decrease exposure via ingestion and dermal absorption. The net effect of volatilization and dermal absorption upon total exposure to volatile drinking water contaminants is unclear in some cases and varies from chemical to chemical. Dermal exposures are also important to consider for certain population groups, such as children and other groups with high soil contact.

With regard to additional non-water related exposures, it is clear that the type and magnitude of toxicity produced via inhalation, ingestion, and dermal contact may differ; that is, the route of exposure can affect absorption of a chemical and can otherwise modify its toxicity. For example, an inhaled chemical such as hydrogen fluoride may produce localized effects on the lung that are not observed (or only observed at much higher doses) when the chemical is administered orally. Also, the active form of a chemical (and principal toxicity) can be the parent compound and/or one or more metabolites. With this Methodology, EPA recommends that differences in absorption and toxicity by different routes of exposure be determined and accounted for in dose estimates and applied to the exposure assessment. EPA acknowledges that the issue of whether the doses received from inhalation and ingestion exposures are cumulative (i.e., toward the same threshold of toxicity) is complicated. Such a determination involves evaluating the chemical's physical characteristics, speciation, and reactivity. A chemical may also exhibit different metabolism by inhalation versus oral exposure and may not typically be metabolized by all tissues. In addition, a metabolite may be much more or much less toxic than the parent compound. Certainly with a systemic effect, if the chemical absorbed via different routes enters the bloodstream, then there is some likelihood that it will contact the same target organ. Attention also needs to be given to the fact that both the RfD and RfC are derived based on the administered level. Toxicologists generally believe that the effective concentration of the active form of a chemical(s) at the site(s) of action determines the toxicity. If specific differences between routes of exposure are not known, it may be reasonable to assume that the

NMED Exhibit 84

internal concentration at the site from any route contributes as much to the same effect as any other route. A default of assuming equal absorption has often been used. However, for many of the chemicals that the Agency has reviewed, there is a substantial amount of information already known to determine differences in rates of absorption. For example, absorption is, in part, a function of blood solubility (i.e., Henry's Constant) and better estimations than the default can be made.

The RSC analyses that accompany the 2000 Human Health Methodology accommodate inclusion of inhalation exposures. Even if different target organs are involved between different routes of exposure, a conservative policy may be appropriate to keep all exposures below a certain level. A possible alternative is to set allowable levels (via an equation) such that the total of ingestion exposures over the ingestion RfD added to the total of inhalation exposures over the inhalation RfC is not greater than 1 (Note: the RfD is typically presented in mg/kg-day and the RfC is in mg/m^3). Again, EPA intends to develop guidance for this Methodology to explicitly incorporate inhalation and dermal exposures, and will refine the Methodology when that guidance is completed.

4.3 EXPOSURE FACTORS USED IN THE AWQC COMPUTATION

This section presents values for the specific exposure factors that EPA will use in the derivation of AWQC. These include human body weight, drinking water consumption rates, and fish ingestion rates.

When choosing exposure factor values to include in the derivation of a criterion for a given pollutant, EPA recommends considering values that are relevant to population(s) that is (are) most susceptible to that pollutant. In addition, highly exposed populations should be considered when setting criteria. In general, exposure factor values specific to adults and relevant to lifetime exposures are the most appropriate values to consider when determining criteria to protect against effects from long-term exposure which, by and large, the human health criteria are derived to protect. However, infants and children may have higher rates of water and food consumption per unit body weight compared with adults and also may be more susceptible to some pollutants than adults (USEPA, 1997a). There may be instances where acute or subchronic developmental toxicity makes children the population group of concern. In addition, exposure of pregnant women to certain toxic chemicals may cause developmental effects in the fetus (USEPA, 1997b). Exposures resulting in developmental effects may be of concern for some contaminants and should be considered along with information applicable to long-term health effects when setting AWQC. (See Section 3.2 for further discussion of this issue.) Short-term exposure may include multiple intermittent or continuous exposures occurring over a week or so. Exposure factor values relevant for considering chronic toxicity, as well as exposure factor values relevant for short-term exposure developmental concerns, that could result in adverse health effects are discussed in the sections below. In appropriate situations, EPA may consider developing criteria for developmental health effects based on exposure factor values specific to children or to women of childbearing age. EPA encourages States and Tribes to do the same when health risks are associated with short-term exposures.

NMED Exhibit 84

EPA believes that the recommended exposure factor default intakes for adults in chronic exposure situations are adequately protective of the population over a lifetime. In providing additional exposure intake values for highly exposed subpopulations (e.g., sport anglers, subsistence fishers), EPA is providing flexibility for States and authorized Tribes to establish criteria specifically targeted to provide additional protection using adjusted values for exposure parameters for body weight, drinking water intake, and fish consumption. The exposure factor values provided for women of childbearing age and children would only be used in the circumstances indicated above.

Each of the following sections recommends exposure parameter values for use in developing AWQC. These are based on both science policy decisions that consider the best available data, as well as risk management judgments regarding the overall protection afforded by the choice in the derivation of AWQC. These will be used by EPA to derive new, or revise existing, 304(a) national criteria.

4.3.1 Human Body Weight Values for Dose Calculations

The source of data for default human body weights used in deriving the AWQC is the third *National Health and Nutrition Examination Survey* (NHANES III). NHANES III represents a very large interview and examination endeavor of the National Center for Health Statistics (NCHS) and included participation from the Centers for Disease Control (CDC). The NHANES III was conducted on a nationwide probability sample of over 30,000 persons from the civilian, non-institutionalized population of the United States. The survey began in October 1988 and was completed in October 1994 (WESTAT, 2000; McDowell, 2000). Body weight data were taken from the NHANES III Examination Data File. Sampling weights were applied to all persons examined in the Mobile Examination Centers (MECs) or at home, as was recommended by the NHANES data analysts (WESTAT, 2000).

The NHANES III survey has numerous strengths and very few weaknesses. Its primary strengths are the national representativeness, large sample size, and precise estimates due to this large sample size. Another strength is its high response rate; the examination rate was 73 percent overall, 89 percent for children under 1 year old, and approximately 85 percent for children 1 to 5 years old (McDowell, 2000). Interview response rates were even higher, but the body weight data come from the NHANES examinations; that is, all body weights were carefully measured by survey staff, rather than the use of self-reported body weights. The only significant potential weakness of the NHANES data is the fact that the data are now between 6 and 12 years old. Given that there were upward trends in body weight from NHANES II to NHANES III, and that NCHS has indicated the prevalence of overweight people increased in all age groups, the data could underestimate current body weights if that trend has continued (WESTAT, 2000).

The NHANES III collected standard body measurements of sample subjects, including height and weight, that were made at various times of the day and in different seasons of the year. This technique was used because one's weight may vary between winter and summer and may fluctuate with recency of food and water intake and other daily activities (McDowell, 2000).

NMED Exhibit 84

As with the other exposure assumptions, States and authorized Tribes are encouraged to use alternative body weight assumptions for population groups other than the general population and to use local or regional data over default values as more representative of their target population group(s).

4.3.1.1 Rate Protective of Human Health from Chronic Exposure

EPA recommends maintaining the default body weight of 70 kg for calculating AWQC as a representative average value for both male and female adults. As previously indicated, exposure factor values specific to adults are recommended to protect against effects from long-term exposure. The value of 70 kg is based on the following information. In the analysis of the NHANES III database, median and mean values for female adults 18-74 years old are 65.8 and 69.5 kg, respectively (WESTAT, 2000). For males in the same age range, the median and mean values are 79.9 and 82.1 kg, respectively. The mean body weight value for men and women ages 18 to 74 years old from this survey is 75.6 kg (WESTAT, 2000). This mean value is higher than the mean value for adults ages 20-64 years old of 70.5 kg from a study by the National Cancer Institute (NCI) which primarily measured drinking water intake (Ershow and Cantor, 1989). The NCI study is described in the subsection on Drinking Water Intake Rates that follows (Section 4.3.2). The value from the NHANES III database is also higher than the value given in the revised EPA *Exposure Factors Handbook* (USEPA, 1997b), which recommends 71.8 kg for adults, based on the older NHANES II data. The Handbook also acknowledges the commonly used 70 kg value and encourages risk assessors to use values which most accurately reflect the exposed population. However, the point is also made that the 70 kg value is used in the derivation of cancer slope factors and unit risks that appear in IRIS. Consistency is advocated between the dose-response relationship and exposure factors assumed. Therefore, if a value higher than 70 kg is used, the assessor needs to adjust the dose-response relationship as described in the Appendix to Chapter 1, Volume 1 of the Handbook (USEPA, 1997b).

4.3.1.2 Rates Protective of Developmental Human Health Effects

As noted above, pregnant women may represent a more appropriate population for which to assess risks from exposure to chemicals in ambient waters in some cases, because of the potential for developmental effects in fetuses. In these cases, body weights representative of women of childbearing age may be appropriate to adequately protect offspring from such health effects. To determine a mean body weight value appropriate to this population, separate body weight values for women in individual age groups within the range of 15 to 44 years old were analyzed from the NHANES III data (WESTAT, 2000). The resulting median and mean body weight values are 63.2 and 67.3 kg, respectively. Ershow and Cantor (1989) present body weight values specifically for pregnant women included in the survey; median and mean weights are 64.4 and 65.8 kilograms, respectively. Ershow and Cantor (1989), however, do not indicate the ages of these pregnant women. Based on this information for women of childbearing age and pregnant women, EPA recommends use of a body weight value of 67 kg in cases where pregnant women are the specific population of concern and the chemical of concern exhibits reproductive and/or developmental effects (i.e., the critical effect upon which the RfD or POD/UF is based). Using the 67 kg assumption would result in lower (more protective) criteria than criteria based on 70 kg.

NMED Exhibit 84

As discussed earlier, because infants and children generally have a higher rate of water and food consumption per unit body weight compared with adults, a higher intake rate per unit body weight may be needed when comparing estimated exposure doses with critical doses when RfDs are based on health effects in children. To calculate intake rates relevant to such effects, the body weight of children should be used. As with the default body weight for pregnant women, EPA is not recommending the development of additional AWQC (i.e., similar to drinking water health advisories) that focus on acute or short-term effects, since these are not seen routinely as having a meaningful role in the water quality criteria program. However, there may be circumstances where the consideration of exposures for these groups is warranted. Although the AWQC generally are based on chronic health effects data, they are intended to also be protective with respect to adverse effects that may reasonably be expected to occur as a result of elevated shorter-term exposures. EPA acknowledges this as a potential course of action and is, therefore, recommending these default values which EPA would consider in an appropriate circumstance and for States and authorized Tribes to utilize in such situations.

EPA is recommending an assumption of 30 kg as a default child's body weight to calculate AWQC to provide additional protection for children when the chemical of concern indicates health effects in children are of predominant concern (i.e., test results show children are more susceptible due to less developed immune systems, neurological systems, and/or lower body weights). The value is based on the mean body weight value of 29.9 kg for children ages 1 to14 years old, which combines body weight values for individual age groups within this larger group. The mean value is based on body weight information from NHANES III for individual-year age groups between one and 14 years old (WESTAT, 2000). A mean body weight of 28 kg is obtained using body weight values from Ershow and Cantor (1989) for five age groups within this range of 0-14 years and applying a weighting method for different ages by population percentages from the U.S. Bureau of the Census. The 30 kg assumption is also consistent with the age range for children used with the estimated fish intake rates. Unfortunately, fish intake rates for finer age group divisions are not possible due to the limited sampling base from the fish intake survey; there is limited confidence in calculated values (e.g., the mean) for such fine age groups. Given this limitation, the broad age category of body weight for children is suitable for use with the default fish intake assumption.

Given the hierarchy of preferences regarding the use of fish intake information (see Section 4.3.3), States may have more comprehensive data and prefer to target a more narrow, younger age group. If States choose to specifically evaluate toddlers, EPA recommends using 13 kg as a default body weight assumption for children ages 1 to 3 years old. The median and mean values of body weight for children 1 to 3 years old are 13.2 and 13.1 kg, respectively, based on an analysis of the NHANES III database (WESTAT, 2000). The NHANES III median and mean values for females between 1 and 3 years old are 13.0 and 12.9 kg, respectively, and are 13.4 and 13.4 kg for males, respectively. Median and mean body weight values from the earlier Ershow and Cantor (1989) study for children ages 1 to 3 years old were 13.6 and 14.1 kg, respectively. Finally, if infants are specifically evaluated, EPA recommends a default body weight of 7 kg based on the NHANES III analysis. Median and mean body weights for both male and female infants (combined) 2 months old were 6.3 and 6.3 kg, respectively, and for infants 3 months old were 7.0 and 6.9 kg, respectively. With the broader age category of males and females 2 to 6 months old, median and mean body weights were 7.4 and 7.4 kg, respectively. The NHANES

NMED Exhibit 84

analysis did not include infants under 2 months of age. Although EPA is not recommending body weight values for newborns, the NCHS National Vital Statistics Report indicates that, for 1997, the median birth weight ranged from 3 to 3.5 kg, according to WESTAT (2000).

Body weight values for individual ages within the larger range of 0-14 years are listed in the Exposure Assessment TSD for those States and authorized Tribes who wish to use body weight values for these individual groups. States and Tribes may wish to consider certain general developmental ages (e.g., infants, pre-adolescents, etc.), or certain specific developmental landmarks (e.g., neurological development in the first four years), depending on the chemical of concern. EPA encourages States and authorized Tribes to choose a body weight intake from the tables presented in the TSD, if they believe a particular age subgroup is more appropriate.

4.3.2 Drinking Water Intake Rates

The basis for the drinking water intake rates (also for the fish intake rates presented in Section 4.3.3) is the 1994-96 Continuing Survey of Food Intake by Individuals *(*CSFII) conducted by the U.S. Department of Agriculture (USDA, 1998). The CSFII survey collects dietary intake information from nationally representative samples of non-institutionalized persons residing in United States households. Households in these national surveys are sampled from the 50 states and the District of Columbia. Each survey collects daily consumption records for approximately 10,000 food codes across nine food groups. These food groups are (1) milk and milk products; (2) meat, poultry, and fish; (3) eggs; (4) dry beans, peas, legumes, nuts, and seeds; (5) grain products; (6) fruit; (7) vegetables; (8) fats, oils, and salad dressings; and (9) sweets, sugars, and beverages. The survey also asks each respondent how many fluid ounces of plain drinking water he or she drank during each of the survey days. In addition, the CSFII collects household information, including the source of plain drinking water, water used to prepare beverages, and water used to prepare foods. Data provide "up-to-date information on food intakes by Americans for use in policy formation, regulation, program planning and evaluation, education, and research." The survey is "the cornerstone of the National Nutritional Monitoring and Related Research Program, a set of related federal activities intended to provide regular information on the nutritional status of the United States population" (USDA, 1998).

The 1994-96 CSFII was conducted according to a stratified, multi-area probability sample organized using estimates of the 1990 United States population. Stratification accounted for geographic location, degree of urbanization, and socioeconomics. Each year of the survey consisted of one sample with oversampling for low-income households.

Survey participants provided two non-consecutive, 24-hour days of dietary data. Both days' dietary recall information was collected by an in-home interviewer. Interviewers provided participants with an instructional booklet and standard measuring cups and spoons to assist them in adequately describing the type and amount of food ingested. If the respondent referred to a cup or bowl in their own home, a 2-cup measuring cup was provided to aid in the calculation of the amount consumed. The sample person could fill their own bowl or cup with water to represent the amount eaten or drunk, and the interviewer could then measure the amount consumed by pouring it into the 2-cup measure. The Day 2 interview occurred three to 10 days

NMED Exhibit 84

after the Day 1 interview, but not on the same day of the week. The interviews allowed participants "three passes" through the daily intake record to maximize recall (USDA, 1998). Proxy interviews were conducted for children aged six and younger and sampled individuals unable to report due to mental or physical limitations. The average questionnaire administration time for Day 1 intake was 30 minutes, while Day 2 averaged 27 minutes.

Two days of dietary recall data were provided by 15,303 individuals across the three survey years. This constitutes an overall two-day response rate of 75.9 percent. Survey weights were corrected by the USDA for nonresponse.

All three 1994-96 CSFII surveys are multistage, stratified-cluster samples. Sample weights, which project the data from a sampled individual to the population, are based on the probability of an individual being sampled at each stage of the sampling design. The sample weights associated with each individual reporting two days of consumption data were adjusted to correct for nonresponse bias.

The 1994-96 CSFII surveys have advantages and limitations for estimating per capita water (or fish) consumption. The primary advantage of the CSFII surveys is that they were designed and conducted by the USDA to support unbiased estimation of food consumption across the population in the United States and the District of Columbia. Second, the survey is designed to record daily intakes of foods and nutrients and support estimation of food consumption.

One limitation of the 1994-96 CSFII surveys is that individual food consumption data were collected for only two days–a brief period which does not necessarily depict "usual intake." Usual dietary intake is defined as "the long-run average of daily intakes by an individual." Upper percentile estimates may differ for short-term and longer-term data because short-term food consumption data tend to be inherently more variable. It is important to note, however, that variability due to duration of the survey does not result in bias of estimates of overall mean consumption levels. Also, the multistage survey design does not support interval estimates for many of the subpopulations of interest because of sparse representation in the sample. Subpopulations with sparse representation include Native Americans on reservations and certain ethnic groups. While these individuals are participants in the survey, they are not present in sufficient numbers to support consumption estimates.

Despite these limitations, the CSFII is considered one of the best sources of current information on consumption of water and fish-containing foods. The objective of estimating per capita water and fish consumption by the United States population is compatible with the statistical design and scope of the CSFII survey.

4.3.2.1 Rate Protective of Human Health from Chronic Exposure

EPA recommends maintaining the default drinking water intake rate of 2 L/day to protect most consumers from contaminants in drinking water. EPA believes that the 2 L/day assumption is representative of a majority of the population over the course of a lifetime. EPA also notes that there is comparatively little variability in water intake within the population compared with

NMED Exhibit 84

fish intake (i.e., drinking water intake varies, by and large, by about a three-fold range, whereas fish intake can vary by 100-fold). EPA believes that the 2 L/day assumption continues to represent an appropriate risk management decision. The results of the 1994-96 CSFII analysis indicate that the arithmetic mean, 75th, and 90th percentile values for adults 20 years and older are 1.1, 1.5, and 2.2 L/day, respectively (USEPA, 2000a). The 2 L/day value represents the 86th percentile for adults. These values can also be compared to data from an older National Cancer Institute (NCI) study, which estimated intakes of tapwater in the United States based on the USDA's 1977-78 Nationwide Food Consumption Survey (NFCS). The arithmetic mean, 75th, and 90th percentile values for adults 20 - 64 years old were 1.4, 1.7, and 2.3 L/day, respectively (Ershow and Cantor, 1989). The 2 L/day value represents the 88th percentile for adults from the NCI study.

The 2 L/day assumption was used with the original 1980 AWQC National Guidelines and has also been used in EPA's drinking water program. EPA believes that the newer studies continue to support the use of 2 L/day as a reasonable and protective consumption rate that represents the intake of most water consumers in the general population. However, individuals who work or exercise in hot climates could have water consumption rates significantly above 2 L/day, and EPA believes that States and Tribes should consider regional or occupational variations in water consumption.

4.3.2.2 Rates Protective of Developmental Human Health Effects

Based on the 1994-96 CSFII study data, EPA also recommends 2 L/day for women of childbearing age. The analysis for women of childbearing age (ages 15-44) indicate mean, 75th, and 90th percentile values of 0.9, 1.3, and 2.0 L/day, respectively. These rates compare well with those based on an analysis of tapwater intake by pregnant and lactating women by Ershow et al. (1991), based on the older USDA data, for women ages 15-49. Arithmetic mean, 75th and 90th percentile values were 1.2, 1.5, and 2.2 L/day, respectively, for pregnant women. For lactating women, the arithmetic mean, 75th and 90th percentile values were 1.3, 1.7, and 1.9 L/day, respectively.

As noted above, because infants and children have a higher daily water intake per unit body weight compared with adults, a water consumption rate measured for children is recommended for use when RfDs are based on health effects in children. Use of this water consumption rate should result in adequate protection for infants and children when setting criteria based on health effects for this target population. EPA recommends a drinking water intake of 1 L/day to, again, represent a majority of the population of children that consume drinking water. The results of the 1994-96 CSFII analysis indicate that for children from 1 to 10 years of age, the arithmetic mean, 75th, and 90th percentile values are 0.4, 0.6, and 0.9 L/day, respectively (USEPA, 2000a). The 1 L/day value represents the 93rd percentile for this group. The arithmetic mean, 75th, and 90th percentile values for smaller children, ages 1 to 3 years, are 0.3, 0.5, and 0.7 L/day, respectively. The 1 L/day value represents the 97th percentile of the group ages 1 to 3 years old. For the category of infants under 1 year of age, the arithmetic mean, 75th, and 90th percentile values are 0.3, 0.7, and 0.9 L/day, respectively. These data can similarly be compared to those of the older National Cancer Institute (NCI) study. The arithmetic mean, 75th, and 90th percentile values for children 1 to 10 years old were 0.74, 0.96, and 1.3 L/day,

NMED Exhibit 84

respectively. The mean, 75th, and 90th percentile values for children 1 to 3 years old in the NCI study were 0.6, 0.8, and 1.2 L/day, respectively. Finally, the mean, 75th, and 90th percentile values for infants less than 6 months old were 0.3, 0.3, and 0.6 L/day, respectively (Ershow and Cantor, 1989).

4.3.2.3 Rates Based on Combining Drinking Water Intake and Body Weight

As an alternative to considering body weight and drinking water intake rates separately, EPA is providing rates based on intake per unit body weight data (in units of ml/kg) in the Exposure Assessment TSD, with additional discussion on their use. These rates are based on self-reported body weights from the CSFII survey respondents for the 1994-96 data. While EPA intends to derive or revise national default criteria on the separate intake values and body weights, in part due to the strong input received from its State stakeholders, the ml/kg-BW/day values are provided in the TSD for States or authorized Tribes that prefer their use. It should be noted that in their 1993 review, EPA's Science Advisory Board (SAB) felt that using drinking water intake rate assumptions on a per unit body weight basis would be more accurate, but did not believe this change would appreciably affect the criteria values (USEPA, 1993).

4.3.3 Fish Intake Rates

The basis for the fish intake rates is the 1994-96 CSFII conducted by the USDA, and described above in Section 4.3.2.

4.3.3.1 Rates Protective of Human Health from Chronic Exposure

EPA recommends a default fish intake rate of 17.5 grams/day to adequately protect the general population of fish consumers, based on the 1994 to 1996 data from the USDA's CSFII Survey. EPA will use this value when deriving or revising its national 304(a) criteria. This value represents the 90th percentile of the 1994-96 CSFII data. This value also represents the uncooked weight estimated from the CSFII data, and represents intake of freshwater and estuarine finfish and shellfish only. For deriving AWQC, EPA has also considered the States' and Tribes' needs to provide adequate protection from adverse health effects to highly exposed populations such as recreational and subsistence fishers, in addition to the general population. Based on available studies that characterize consumers of fish, recreational fishers and subsistence fishers are two distinct groups whose intake rates may be greater than the general population. It is, therefore, EPA's decision to discuss intakes for these two groups, in addition to the general population.

EPA recommends default fish intake rates for recreational and subsistence fishers of 17.5 grams/day and 142.4 grams/day, respectively. These rates are also based on uncooked weights for fresh/estuarine finfish and shellfish only. However, because the level of fish intake in highly exposed populations varies by geographical location, EPA suggests a four preference hierarchy for States and authorized Tribes to follow when deriving consumption rates that encourages use of the best local, State, or regional data available. A thorough discussion of the development of this policy method and relevant data sources is contained in the Exposure Assessment TSD. The hierarchy is also presented here because EPA strongly emphasizes that States and authorized

NMED Exhibit 84

Tribes should consider developing criteria to protect highly exposed population groups and use local or regional data over the default values as more representative of their target population group(s). The four preference hierarchy is: (1) use of local data; (2) use of data reflecting similar geography/population groups; (3) use of data from national surveys; and (4) use of EPA's default intake rates.

The recommended four preference hierarchy is intended for use in evaluating fish intake from fresh and estuarine species only. Therefore, to protect humans who additionally consume marine species of fish, the marine portion should be considered an *other source of exposure* when calculating an RSC for dietary intake. Refer to the Exposure Assessment TSD for further discussion. States and Tribes need to ensure that when evaluating overall exposure to a contaminant, marine fish intake is not double-counted with the other dietary intake estimate used. Coastal States and authorized Tribes that believe accounting for total fish consumption (i.e., fresh/estuarine and marine species) is more appropriate for protecting the population of concern may do so, provided that the marine intake component is not double-counted with the RSC estimate. Tables of fish consumption intakes based on the CSFII in the TSD provide rates for fresh/estuarine species, marine species, and total (combined) values to facilitate this option for States and Tribes. Throughout this section, the terms "fish intake" or "fish consumption" are used. These terms refer to the consumption of finfish and shellfish, and the CSFII survey includes both. States and Tribes should ensure that when selecting local or regionally-specific studies, both finfish and shellfish are included when the population exposed are consumers of both types.

EPA's first preference is that States and authorized Tribes use the results from fish intake surveys of local watersheds within the State or Tribal jurisdiction to establish fish intake rates that are representative of the defined populations being addressed for the particular waterbody. Again, EPA recommends that data indicative of fresh/estuarine species only be used which is, by and large, most appropriate for developing AWQC. EPA also recommends the use of uncooked weight intake values, which is discussed in greater detail with the fourth preference. States and authorized Tribes may use either high-end values (such as the 90^{th} or 95^{th} percentile values) or average values for an identified population that they plan to protect (e.g., subsistence fishers, sport fishers, or the general population). EPA generally recommends that arithmetic mean values should be the lowest value considered by States or Tribes when choosing intake rates for use in criteria derivation. When considering geometric mean (median) values from fish consumption studies, States and authorized Tribes need to ensure that the distribution is based on survey respondents who reported consuming fish because surveys based on both consumers and nonconsumers can often result in median values of zero. If a State or Tribe chooses values (whether the central tendency or high-end values) from studies that particularly target high-end consumers, these values should be compared to high-end fish intake rates for the general population to make sure that the high-end consumers within the general population would be protected by the chosen intake rates. EPA believes this is a reasonable procedure and is also consistent with the recent Great Lakes Water Quality Initiative (known as the "GLI") (USEPA, 1995). States and authorized Tribes may wish to conduct their own surveys of fish intake, and EPA guidance is available on methods to conduct such studies in *Guidance for Conducting Fish and Wildlife Consumption Surveys* (USEPA, 1998). Results from broader geographic regions in which the State or Tribe is located can also be used, but may not be as applicable as results from

NMED Exhibit 84

local watersheds. Since such studies would ultimately form the basis of a State or Tribe's AWQC, EPA would review any surveys of fish intake for consistency with the principles of EPA's guidance as part of the Agency's review of water quality standards under Section 303(c).

If surveys conducted in the geographic area of the State or Tribe are not available, EPA's second preference is that States and authorized Tribes consider results from existing fish intake surveys that reflect similar geography and population groups (e.g., from a neighboring State or Tribe or a similar watershed type), and follow the method described above regarding target values to derive a fish intake rate. Again, EPA recommends the use of uncooked weight intake values and the use of fresh/estuarine species data only. Results of existing local and regional surveys are discussed in greater detail in the TSD.

If applicable consumption rates are not available from local, State, or regional surveys, EPA's third preference is that States and authorized Tribes select intake rate assumptions for different population groups from national food consumption surveys. EPA has analyzed one such national survey, the 1994-96 CSFII. As described in Section 4.3.2, this survey, conducted annually by the USDA, collects food consumption information from a probability sample of the population of all 50 states. Respondents to the survey provide two days of dietary recall data. A detailed description of the combined 1994-96 CSFII survey, the statistical methodology, and the results and uncertainties of the EPA analyses are provided in a separate EPA report (USEPA, 2000b). The Exposure Assessment TSD for this Methodology presents selected results from this report including point and interval estimates of combined finfish and shellfish consumption for the mean, 50^{th} (median), 90^{th}, 95^{th}, and 99^{th} percentiles. The estimated fish consumption rates are by fish habitat (i.e., freshwater/estuarine, marine and all habitats) for the following population groups: (1) all individuals; (2) individuals age 18 and over; (3) women ages 15-44; and (4) children age 14 and under. Three kinds of estimated fish consumption rates are provided: (1) per capita rates (i.e., rates based on consumers and nonconsumers of fish from the survey period– refer to the TSD for further discussion); (2) consumers-only rates (i.e., rates based on respondents who reported consuming finfish or shellfish during the two-day reporting period); and (3) per capita consumption by body weight (i.e., per capita rates reported as milligrams of fish per kilogram of body weight per day).

EPA's fourth preference is that States and authorized Tribes use as fish intake assumptions the following default rates, based on the 1994-96 CSFII data, that EPA believes are representative of fish intake for different population groups: 17.5 grams/day for the general adult population and sport fishers, and 142.4 grams/day for subsistence fishers. These are risk management decisions that EPA has made after evaluating numerous fish intake surveys. These values represent the uncooked weight intake of freshwater/estuarine finfish and shellfish. As with the other preferences, EPA requests that States and authorized Tribes routinely consider whether there is a substantial population of sport fishers or subsistence fishers when developing site-specific estimates, rather than automatically basing them on the typical individual. Because the combined 1994-96 CSFII survey is national in scope, EPA will use the results from this survey to estimate fish intake for deriving national criteria. EPA has recognized the data gaps and uncertainties associated with the analysis of the 1994-96 CSFII survey in the process of making its default recommendations. The estimated mean of freshwater and estuarine fish ingestion for adults is 7.50 grams/day, and the median is 0 grams/day. The estimated 90^{th}

NMED Exhibit 84

percentile is 17.53 grams/day; the estimated 95th percentile is 49.59 grams/day; and the estimated 99th percentile is 142.41 grams/day. The median value of 0 grams/day may reflect the portion of individuals in the population who never eat fish as well as the limited reporting period (2 days) over which intake was measured. By applying as a default 17.5 grams/day for the general adult population, EPA intends to select an intake rate that is protective of a majority of the population (again, the 90th percentile of consumers and nonconsumers according to the 1994-96 CSFII survey data). Trophic level breakouts are: TL2 = 3.8 grams/day; TL3 = 8.0 grams/day; and TL4 = 5.7 grams/day. EPA further considers 17.5 grams/day to be indicative of the average consumption among sport fishers based on averages in the studies reviewed, which are presented in the Exposure Assessment TSD. Similarly, EPA believes that the assumption of 142.4 grams/day is within the range of average consumption estimates for subsistence fishers based on the studies reviewed. Experts at the 1992 National Workshop that initiated the effort to revise this Methodology acknowledged that the national survey high-end values are representative of average rates for highly exposed groups such as subsistence fishermen, specific ethnic groups, or other highly exposed people. EPA is aware that some local and regional studies indicate greater consumption among Native American, Pacific Asian American, and other subsistence consumers, and recommends the use of those studies in appropriate cases, as indicated by the first and second preferences. Again, States and authorized Tribes have the flexibility to choose intake rates higher than an average value for these population groups. If a State or authorized Tribe has not identified a separate well-defined population of high-end consumers and believes that the national data from the 1994-96 CSFII are representative, they may choose these recommended rates.

As indicated above, the default intake values are based on the uncooked weights of the fish analyzed. There has been some question regarding whether to use cooked or uncooked weights of fish intake for deriving the AWQC. Studies show that, typically, with a filet or steak of fish, the weight loss in cooking is about 20 percent; that is, the uncooked weight is approximately 20 percent higher (Jacobs et al., 1998). This obviously means that using uncooked weights results in a slightly higher intake rate and slightly more stringent AWQC. In researching consumption surveys for this proposal, EPA has found that some surveys have reported rates for cooked fish, others have reported uncooked rates, and many more are unclear as to whether cooked or uncooked rates are used. The basis of the CSFII survey was prepared or *as consumed* intakes; that is, the survey respondents estimated the weight of fish that they consumed. This was also true with the GLI (which was specifically based on studies describing consumption rates of cooked fish) and, by and large, cooked fish is what people consume. However, EPA's *Guidance For Assessing Chemical Contaminant Data For Use In Fish Advisories* recommends analysis and advisories based on uncooked fish (USEPA, 1997a). EPA considered the potential confusion over the fact that the uncooked weights are used in the fish advisory program. Further, the measures of a contaminant in fish tissue samples that are applicable to compliance monitoring and the permitting program are related to the uncooked weights. The choice of intakes is also complicated by factors such as the effect of the cooking process, the different parts of a fish where a chemical may accumulate, and the method of preparation.

After considering all of the above (in addition to public input received), EPA will derive its national default criteria based on the uncooked weight fish intakes. The Exposure

NMED Exhibit 84

Assessment TSD provides additional guidance on site-specific modifications. Specifically, an alternate approach is described for calculating AWQC with the *as consumed* weight–which is more directly associated with human exposure and risk–and then adjusting the value by the approximate 20 percent loss to an uncooked equivalent (thereby representing the same relative risk as the *as consumed* value). This approach results in a different AWQC value (than using the uncooked weights) and represents a more direct translation of the *as consumed* risk to the uncooked equivalent. However, EPA understands that it is more scientifically rigorous and may be too intensive of a process for States and Tribes to rely on. The option is presented in the TSD to offer States and authorized Tribes greater flexibility with their water quality standards program.

The default fish intake values also reflect specific designations of species classified in accordance with information regarding the life history of the species or based on landings information form the National Marine Fisheries Service. Most significantly, salmon has been reclassified from a freshwater/estuarine species to a marine species. As marine harvested salmon represents approximately 99 percent of salmon consumption in the 1994-96 CSFII Survey, removal reduces the overall fresh/estuarine fish consumption rate by 13 percent. Although they represent a very small percentage of freshwater/estuarine intake, land-locked and farm-raised salmon consumed by 1994-96 CSFII respondents are still included. The rationale for the default intake species designations is explained in the Exposure Assessment TSD. Once again, EPA emphasizes the flexibility for States and authorized Tribes to use alternative assumptions based on local or regional data to better represent their population groups of concern.

4.3.3.2 Rates Protective of Developmental Human Health Effects

Exposures resulting in health effects in children or developmental effects in fetuses may be of primary concern. As discussed at the beginning of this section on exposure factors used, in a situation where acute or sub-chronic toxicity and exposure are the basis of an RfD (or POD/UF), EPA will consider basing its national default criteria on children or women of childbearing age, depending on the target population at greatest risk. EPA recommends that States and authorized Tribes use exposure factors for children or women of childbearing age in these situations. As stated previously, EPA is not recommending the development of additional AWQC but is acknowledging that basing a criterion on these population groups is a potential course of action and is, therefore, recommending the following default intake rates for such situations.

EPA's preferences for States and authorized Tribes in selecting values for intake rates relevant for children is the same as that discussed above for establishing values for average daily consumption rates for chronic effects; i.e., in decreasing order of preference, results from fish intake surveys of local watersheds, results from existing fish intake surveys that reflect similar geography and population groups, the distribution of intake rates from nationally based surveys (e.g., the CSFII), or lastly, the EPA default rates. When an RfD is based on health effects in children, EPA recommends a default intake rate of 156.3 grams/day for assessing those contaminants that exhibit adverse effects. This represents the 90th percentile consumption rate for actual consumers of freshwater/estuarine finfish and shellfish for children ages 14 and under using the combined 1994 to 1996 results from the CSFII survey. The value was calculated based

NMED Exhibit 84

on data for only those children who ate fish during the 2-day survey period, and the intake was averaged over the number of days during which fish was actually consumed. EPA believes that by selecting the data for consumers only, the 90th percentile is a reasonable intake rate to approximate consumption of fresh/estuarine finfish and shellfish within a short period of time for use in assessments where adverse effects in children are of primary concern. As discussed previously, EPA will use a default body weight of 30 kg to address potential acute or subchronic effects from fish consumption by children. EPA is also providing these default intake values for States and authorized Tribes that choose to provide additional protection when developing criteria that they believe should be based on health effects in children. This is consistent with the rationale in the recent GLI (USEPA, 1995) and is an approach that EPA believes is reasonable. Distributional information on intake values relevant for assessing exposure when health effects to children are of concern is presented in the Exposure Assessment TSD.

There are also cases in which pregnant women may be the population of most concern, due to the possibility of developmental effects that may result from exposures of the mother to toxicants. In these cases, fish intake rates specific to females of childbearing age are most appropriate when assessing exposures to developmental toxicants. When an RfD is based on developmental toxicity, EPA proposes a default intake rate of 165.5 grams/day for assessing exposures for women of childbearing age from contaminants that cause developmental effects. This is equivalent to the 90th percentile consumption rate for actual consumers of freshwater/ estuarine finfish and shellfish for women ages 15 to 44 using the combined 1994 to1996 results from the CSFII survey. As with the rate for children, this value represents only those women who ate fish during the 2-day survey period. As discussed previously, EPA will use a default body weight of 67 kg for women of childbearing age.

4.3.3.3 Rates Based on Combining Fish Intake and Body Weight

As with the drinking water intake values, EPA is providing values for fish intake based on a per unit body weight basis (in units of mg/kg) in the Exposure Assessment TSD. These rates use the self-reported body weights of the 1994-96 CSFII survey. Again, while EPA intends to derive or revise national default criteria on the separate intake values and body weights, the mg/kg-BW/day values are provided in the TSD for States or authorized Tribes that prefer their use.

5. BIOACCUMULATION

5.1 INTRODUCTION

Aquatic organisms can accumulate certain chemicals in their bodies when exposed to these chemicals through water, their diet, and other sources. This process is called bioaccumulation. The magnitude of bioaccumulation by aquatic organisms varies widely depending on the chemical but can be extremely high for some highly persistent and hydrophobic chemicals. For such highly bioaccumulative chemicals, concentrations in aquatic organisms may pose unacceptable human health risks from fish and shellfish consumption even when concentrations in water are too low to cause unacceptable health risks from drinking water consumption alone. These chemicals may also biomagnify in aquatic food webs, a process whereby chemical concentrations increase in aquatic organisms of each successive trophic level due to increasing dietary exposures (e.g., increasing concentrations from algae, to zooplankton, to forage fish, to predatory fish).

In order to prevent harmful exposures to waterborne chemicals through the consumption of contaminated fish and shellfish, national 304(a) water quality criteria for the protection of human health must address the process of chemical bioaccumulation in aquatic organisms. For deriving national 304(a) criteria to protect human health, EPA accounts for potential bioaccumulation of chemicals in fish and shellfish through the use of national bioaccumulation factors (BAFs). A national BAF is a ratio (in L/kg) that relates the concentration of a chemical in water to its expected concentration in commonly consumed aquatic organisms in a specified trophic level. An illustration of how national BAFs are used in the derivation of 304(a) criteria for carcinogens using linear low-dose extrapolation is shown in the following equation:

$$AWQC = RSD \bullet \left(\frac{BW}{DI + \sum_{i=2}^{4} (FI_i \bullet BAF_i)} \right) \qquad \text{(Equation 5-1)}$$

where:

RSD	=	Risk specific dose (mg/kg-day)
BW	=	Human body weight (kg)
DI	=	Drinking water intake (L/day)
FI_i	=	Fish intake at trophic level I, where I=2, 3, and 4;
BAF_i	=	National bioaccumulation factor at trophic level I, where I=2, 3, and 4

The purpose of this chapter is to present EPA's recommended methodology for deriving national bioaccumulation factors for setting national 304(a) water quality criteria to protect human health. A detailed scientific basis of the recommended national BAF methodology is provided in the Bioaccumulation TSD. While the methodology detailed in this chapter is

NMED Exhibit 84

intended to be used by EPA for deriving national BAFs, EPA encourages States and authorized Tribes to derive BAFs that are specific to certain regions or waterbodies, where appropriate. Guidance to States and authorized Tribes for deriving site-specific BAFs is provided in the Biaccumulation TSD.

5.1.1 Important Bioaccumulation and Bioconcentration Concepts

Several attributes of the bioaccumulation process are important to understand when deriving national BAFs for use in setting national 304(a) criteria. First, the term "bioaccumulation" refers to the uptake and retention of a chemical by an aquatic organism from all surrounding media (e.g., water, food, sediment). The term "bioconcentration" refers to the uptake and retention of a chemical by an aquatic organism from water only. For some chemicals (particularly those that are highly persistent and hydrophobic), the magnitude of bioaccumulation by aquatic organisms can be substantially greater than the magnitude of bioconcentration. Thus, an assessment of bioconcentration alone would underestimate the extent of accumulation in aquatic biota for these chemicals. Accordingly, EPA's guidelines presented in this chapter emphasize the measurement of chemical bioaccumulation by aquatic organisms, whereas EPA's 1980 Methodology emphasized the measurement of bioconcentration.

Another noteworthy aspect of bioaccumulation process is the issue of steady-state conditions. Specifically, both bioaccumulation and bioconcentration can be viewed simply as the result of competing rates of chemical uptake and depuration (chemical loss) by an aquatic organism. The rates of chemical uptake and depuration can be affected by various factors including the properties of the chemical, the physiology of the organism in question, water quality and other environmental conditions, ecological characteristics of the waterbody (e.g., food web structure), and the concentration and loadings history of the chemical. When the rates of chemical uptake and depuration are equal, tissue concentrations remain constant over time and the distribution of the chemical between the organism and its source(s) is said to be at steady-state. For constant chemical exposures and other conditions, the steady-state concentration in the organism represents the highest accumulation potential of the chemical in that organism under those conditions. The time required for a chemical to achieve steady state has been shown to vary according to the properties of the chemical and other factors. For example, some highly hydrophobic chemicals can require long periods of time to reach steady state between environmental compartments (e.g., many months), while highly hydrophilic chemicals usually reach steady-state relatively quickly (e.g., hours to days).

Since national 304(a) criteria for the protection of human health are typically designed to protect humans from harmful lifetime or long-term exposures to waterborne contaminants, the assessment of bioaccumulation that equals or approximates steady-state accumulation is one of the principles underlying the derivation of national BAFs. For some chemicals that require relatively long periods of time to reach steady-state in tissues of aquatic organisms, changes in water column concentrations may occur on a much more rapid time scale compared to the corresponding changes in tissue concentrations. Thus, if the system departs substantially from steady-state conditions and water concentrations are not averaged over a sufficient time period, the ratio of the tissue concentration to a water concentration may have little resemblance to the steady-state ratio and have little predictive value of long-term bioaccumulation potential.

NMED Exhibit 84

Therefore, BAF measurements should be based on water column concentrations which are averaged over a sufficient period of time (e.g., a duration comparable to the time required for the chemical to reach steady-state). In addition, BAF measurements should be based on adequate spatial averaging of both tissue and water column concentrations for use in deriving 304(a) criteria for the protection of human health.

For this reason, a BAF is defined in this Methodology as representing the ratio (in L/kg-tissue) of a concentration of a chemical in tissue to its concentration in the surrounding water in situations where the organism and its food are exposed and the ratio does not change substantially over time (i.e., the ratio which reflects bioaccumulation at or near steady-state). A bioconcentration factor (BCF) is the ratio (in L/kg-tissue) of the concentration of a substance in tissue of an aquatic organism to its concentration in the ambient water, in situations where the organism is exposed through the water only and the ratio does not change substantially over time.

5.1.2 Goal of the National BAF

The goal of EPA's national BAF is to represent the long-term, average bioaccumulation potential of a chemical in edible tissues of aquatic organisms that are commonly consumed by humans throughout the United States. National BAFs are not intended to reflect fluctuations in bioaccumulation over short time periods (e.g., a few days) because 304(a) human health criteria are generally designed to protect humans from long-term exposures to waterborne chemicals. National BAFs are also intended to account for some major chemical, biological, and ecological attributes that can affect bioaccumulation in bodies of water across the United States. For example, separate procedures are provided for deriving national BAFs depending on the type of chemical (i.e., nonionic organic, ionic organic, inorganic and organometallic). In addition, EPA's national BAFs are derived separately for each trophic level to account for potential biomagnification of some chemicals in aquatic food webs and broad physiological differences between trophic levels that may influence bioaccumulation. Because lipid content of aquatic organisms and the amount of organic carbon in the water column have been shown to affect bioaccumulation of nonionic organic chemicals, EPA's national BAFs are adjusted to reflect the lipid content of commonly consumed fish and shellfish and the freely dissolved fraction of the chemical in ambient water for these chemicals.

5.1.3 Changes to the 1980 Methodology

Numerous scientific advances have occurred in the area of bioaccumulation since the publication of the 1980 Methodology for deriving AWQC for the protection of human health (USEPA, 1980). These advances have significantly increased our ability to assess and predict the bioaccumulation of chemicals in aquatic biota. As a result, EPA has revised the bioaccumulation portion of the 1980 Methodology to reflect the current state of the science and to improve accuracy in assessing bioaccumulation for setting 304(a) criteria for the protection of human health. The changes contained in the bioaccumulation portion of the 2000 Human Health Methodology are mostly designed to:

NMED Exhibit 84

- Improve the ability to incorporate chemical exposure from sediments and aquatic food webs in assessing bioaccumulation potential,

- Expand the ability to account for site-specific factors which affect bioaccumulation, and

- Incorporate new data and assessment tools into the bioaccumulation assessment process.

A summary of the key changes that have been incorporated into the bioaccumulation portion of the 2000 Human Health Methodology and appropriate comparisons to the1980 Methodology are provided below.

5.1.3.1 Overall Approach

The 1980 Methodology for deriving 304(a) criteria for the protection of human health emphasized the assessment of bioconcentration (uptake from water only) through the use of the BCF. Based on the 1980 Methodology, measured BCFs were usually determined from laboratory data unless field data demonstrated consistently higher or lower accumulation compared with laboratory data. In these cases, "field BCFs" (currently termed field-measured BAFs) were recommended for use. For lipophilic chemicals where lab or field-measured data were unavailable, EPA recommended predicting BCFs from the octanol-water partition coefficient and the following equation from Veith et al. (1979): "log BCF = (0.85 log K_{ow}) - 0.70".

The 2000 Human Health Methodology revisions contained in this chapter emphasize the measurement of bioaccumulation (uptake from water, sediment, and diet) through the use of the BAF. Consistent with the 1980 Methodology, measured data are preferred over predictive approaches for determining the BAF (i.e., field-measured BAFs are generally preferred over predicted BAFs). However, the 2000 Human Health Methodology contains additional methods for deriving a national BAF that were not available in 1980. The preference for using the BAF methods also differs depending on the type and properties of the chemical. For example, the BAF derivation procedure differs for each of three broadly defined chemical categories: (1) nonionic organic, (2) ionic organic, and (3) inorganic and organometallic chemicals. Furthermore, within the category of nonionic organic chemicals, different procedures are used to derive the BAF depending on a chemicals' hydrophobicity and extent of chemical metabolism that would be expected to occur in aquatic biota.

5.1.3.2 Lipid Normalization

In the 1980 Methodology, BCFs for lipophilic chemicals were normalized by the lipid fraction in the tissue of fish and shellfish used to determine the BCF. Lipid normalization enabled BCFs to be averaged across tissues and organisms. Once the average lipid-normalized BCF was determined, it was adjusted by the consumption-weighted lipid content of commonly consumed aquatic organisms in the United States to obtain an overall consumption-weighted BCF. A similar procedure has been retained in the 2000 Human Health Methodology, whereby BAFs for nonionic organic chemicals are lipid normalized and adjusted by the consumption-weighted lipid content of commonly consumed organisms to obtain a BAF for criteria

NMED Exhibit 84

calculations. However, the 2000 Human Health Methodology uses more up-to-date lipid data and consumption data for deriving the consumption-weighted BAFs.

5.1.3.3 Bioavailability

Bioconcentration factors derived according to the 1980 Methodology were based on the total concentration of the chemical in water, for both lipophilic and nonlipophilic chemicals. In the 2000 Human Health Methodology, BAFs for nonionic organic chemicals are derived using the most bioavailable fraction (i.e., the freely dissolved fraction) to account for the influence of particulate and dissolved organic carbon on a chemical's bioavailability. Such BAFs are then adjusted to reflect the expected bioavailability at the sites of interest (i.e., by adjusting for organic carbon concentrations at the sites of interest). Procedures for accounting for the effect of organic carbon on bioaccumulation were published previously by EPA under the Great Lakes Water Quality Initiative (GLWQI or GLI) rulemaking (USEPA, 1995a,b). Bioavailability is also considered in developing BAFs for the other chemical classes defined in the 2000 Human Health Methodology (e.g., ionic organics, inorganics/organometallics) but is done so on a chemical-by-chemical basis.

5.1.3.4 Trophic Level Considerations

In the 1980 Methodology, BCFs were determined and used for criteria derivation without explicit regard to the trophic level of the aquatic organism (e.g., benthic filter feeder, forage fish, predatory fish). Over the past two decades, much information has been assembled which demonstrates that an organism's trophic position in the aquatic food web can have an important effect on the magnitude of bioaccumulation of certain chemicals. In order to account for the variation in bioaccumulation that is due to trophic position of the organism, the 2000 Human Health Methodology recommends that BAFs be determined and applied on a trophic level-specific basis.

5.1.3.5 Site-Specific Adjustments

The 1980 Methodology contained little guidance for making adjustments to the national BCFs to reflect site- or region-specific conditions. The 2000 Human Health Methodology has greatly expanded the guidance to States and authorized Tribes for making adjustments to national BAFs to reflect local conditions. This guidance is contained in the Bioaccumulation TSD. In the Bioaccumulation TSD, guidance and data are provided for adjusting national BAFs to reflect the lipid content in locally consumed aquatic biota and the organic carbon content in the waterbodies of concern. This guidance also allows the use of appropriate bioaccumulation models for deriving site-specific BAFs. EPA also plans to publish detailed guidance on designing and conducting field bioaccumulation studies for measuring BAFs and biota-sediment accumulation factors (BSAFs). In general, EPA encourages States and authorized Tribes to make site-specific modifications to EPA's national BAFs provided such adjustments are scientifically defensible and adequately protect the designated use of the waterbody.

While the aforementioned revisions are new to EPA's Methodology for deriving national 304(a) criteria for the protection of human health, many of these refinements have been

NMED Exhibit 84

incorporated in prior Agency guidance and regulations. For example, the use of food chain multipliers to account for the biomagnification of nonionic organic chemicals in aquatic food webs when measured data are unavailable was introduced by EPA in three documents*: Technical Support Document for Water Quality-Based Toxics Control* (USEPA, 1991), a draft document entitled *Assessment and Control of Bioconcentratable Contaminants in Surface Waters* (USEPA, 1993), and in the *Great Lakes Water Quality Initiative* (GLI) (USEPA, 1995b). Similarly, procedures for predicting BAFs using BSAFsand incorporating the effect of organic carbon on bioavailability were used to derive water quality criteria under the GLI.

5.1.4 Organization of This Section

The methodology for deriving national BAFs for use in deriving National 304(a) Human Health AWQC is provided in the following sections. Important terms used throughout this chapter are defined in Section 5.2. Section 5.3 provides an overview of the BAF derivation guidelines. Detailed procedures for deriving national BAFs are provided in Section 5.4 for nonionic organic chemicals, in Section 5.5 for ionic organic chemicals, and in Section 5.6 for inorganics and organometallic chemicals. Literature cited is provided in Section 5.7.

5.2 DEFINITIONS

The following terms and definitions are used throughout this chapter.

Bioaccumulation. The net accumulation of a substance by an organism as a result of uptake from all environmental sources.

Bioconcentration. The net accumulation of a substance by an aquatic organism as a result of uptake directly from the ambient water, through gill membranes or other external body surfaces.

Bioaccumulation Factor (BAF). The ratio (in L/kg-tissue) of the concentration of a substance in tissue to its concentration in the ambient water, in situations where both the organism and its food are exposed and the ratio does not change substantially over time. The BAF is calculated as:

$$BAF = \frac{C_t}{C_w} \qquad \text{(Equation 5-2)}$$

where:

C_t = Concentration of the chemical in the specified wet tissue
C_w = Concentration of chemical in water

NMED Exhibit 84

Bioconcentration Factor (BCF). The ratio (in L/kg-tissue) of the concentration of a substance in tissue of an aquatic organism to its concentration in the ambient water, in situations where the organism is exposed through the water only and the ratio does not change substantially over time. The BCF is calculated as:

$$BCF = \frac{C_t}{C_w} \qquad \text{(Equation 5-3)}$$

where:

C_t = Concentration of the chemical in the specified wet tissue
C_w = Concentration of chemical in water

Baseline BAF (BAF_ℓ^{fd}). For nonionic organic chemicals (and certain ionic organic chemicals where similar lipid and organic carbon partitioning behavior applies), a BAF (in L/kg-lipid) that is based on the concentration of freely dissolved chemical in the ambient water and the lipid normalized concentration in tissue.

Baseline BCF (BCF_ℓ^{fd}). For nonionic organic chemicals (and certain ionic organic chemicals where similar lipid and organic carbon partitioning behavior applies), a BCF (in L/kg-lipid) that is based on the concentration of freely dissolved chemical in the ambient water and the lipid normalized concentration in tissue.

Biomagnification. The increase in tissue concentration of a chemical in organisms at successive trophic levels through a series of predator-prey associations, primarily through the mechanism of dietary accumulation.

Biomagnification Factor (BMF). The ratio (unitless) of the tissue concentration of a chemical in a predator at a particular trophic level to the tissue concentration in its prey at the next lower trophic level for a given waterbody and chemical exposure. For nonionic organic chemicals (and certain ionic organic chemicals where similar lipid and organic carbon partitioning behavior applies), a BMF can be calculated using lipid-normalized concentrations in the tissue of organisms at two successive trophic levels as:

$$BMF_{(TL,\ n)} = \frac{C_{\ell\ (TL,\ n)}}{C_{\ell\ (TL,\ n-1)}} \qquad \text{(Equation 5-4)}$$

where:

$C_{\ell\ (TL,\ n)}$ = Lipid-normalized concentration in appropriate tissue of predator organism at a given trophic level (TL "n")

NMED Exhibit 84

$C_{\ell\ (TL,\ n-1)}$ = Lipid-normalized concentration in appropriate tissue of prey organism at the next lower trophic level from the predator (TL "n-1")

For inorganic, organometallic, and certain ionic organic chemicals where lipid and organic carbon partitioning does not apply, a BMF can be calculated using chemical concentrations in the tissue of organisms at two successive trophic levels as:

$$BMF_{(TL,\ n)} = \frac{C_{t\ (TL,\ n)}}{C_{t\ (TL,\ n-1)}} \qquad \text{(Equation 5-5)}$$

where:

$C_{t\ (TL,\ n)}$ = Concentration in appropriate tissue of predator organism at trophic level "n" (may be either wet weight or dry weight concentration so long as both the predator and prey concentrations are expressed in the same manner)

$C_{t\ (TL,\ n-1)}$ = Concentration in appropriate tissue of prey organism at the next lower trophic level from the predator (may be either wet weight or dry weight concentration so long as both the predator and prey concentrations are expressed in the same manner)

Biota-Sediment Accumulation Factor (BSAF). For nonionic organic chemicals (and certain ionic organic chemicals where similar lipid and organic carbon partitioning behavior applies), the ratio of the lipid-normalized concentration of a substance in tissue of an aquatic organism to its organic carbon-normalized concentration in surface sediment (expressed as kg of sediment organic carbon per kg of lipid), in situations where the ratio does not change substantially over time, both the organism and its food are exposed, and the surface sediment is representative of average surface sediment in the vicinity of the organism. The BSAF is defined as:

$$BSAF = \frac{C_{\ell}}{C_{soc}} \qquad \text{(Equation 5-6)}$$

where:

C_{ℓ} = The lipid-normalized concentration of the chemical in tissues of the biota (µg/g lipid)

C_{soc} = The organic carbon-normalized concentration of the chemical in the surface sediment (µg/g sediment organic carbon)

Depuration. The loss of a substance from an organism as a result of any active or passive process.

NMED Exhibit 84

Food Chain Multiplier (FCM). For nonionic organic chemicals (and certain ionic organic chemicals where similar lipid and organic carbon partitioning behavior applies), the ratio of a baseline BAF_{ℓ}^{fd} for an organism of a particular trophic level to the baseline BCF_{ℓ}^{fd} (usually determined for organisms in trophic level one). For inorganic, organometallic, and certain ionic organic chemicals where lipid and organic carbon partitioning does not apply, a FCM is based on total (wet or dry weight) concentrations of the chemical in tissue.

Freely Dissolved Concentration. For nonionic organic chemicals, the concentration of the chemical that is dissolved in ambient water, excluding the portion sorbed onto particulate or dissolved organic carbon. The freely dissolved concentration is considered to represent the most bioavailable form of an organic chemical in water and, thus, is the form that best predicts bioaccumulation. The freely dissolved concentration can be determined as:

$$C_w^{fd} = (C_w^t) \cdot (f_{fd}) \qquad \text{(Equation 5-7)}$$

where:

C_w^{fd}	=	Freely dissolved concentration of the organic chemical in ambient water
C_w^t	=	Total concentration of the organic chemical in ambient water
f_{fd}	=	Fraction of the total chemical in ambient water that is freely dissolved

Hydrophilic. A term that refers to the extent to which a chemical is attracted to partitioning into the water phase. Hydrophilic organic chemicals have a greater tendency to partition into polar phases (e.g., water) compared to chemicals of hydrophobic chemicals.

Hydrophobic. A term that refers to the extent to which a chemical avoids partitioning into the water phase. Highly hydrophobic organic chemicals have a greater tendency to partition into nonpolar phases (e.g., lipid, organic carbon) compared with chemicals of lower hydrophobicity.

Lipid-normalized Concentration (C_{ℓ}). The total concentration of a contaminant in a tissue or whole organism divided by the lipid fraction in that tissue or whole organism. The lipid-normalized concentration can be calculated as:

$$C_{\ell} = \frac{C_t}{f_{\ell}} \qquad \text{(Equation 5-8)}$$

where:

C_t	=	Concentration of the chemical in the wet tissue (either whole organism or specified tissue)

NMED Exhibit 84

f_ℓ = Fraction lipid content in the organism or specified tissue

Octanol-water Partition Coefficient (K_{ow}). The ratio of the concentration of a substance in the n-octanol phase to its concentration in the aqueous phase in an equilibrated two-phase octanol-water system. For log K_{ow}, the log of the octanol-water partition coefficient is a base 10 logarithm.

Organic Carbon-normalized Concentration (C_{soc}). For sediments, the total concentration of a contaminant in sediment divided by the fraction of organic carbon in sediment. The organic carbon-normalized concentration can be calculated as:

$$C_{soc} = \frac{C_s}{f_{oc}} \qquad \text{(Equation 5-9)}$$

where:

C_s = Concentration of chemical in sediment
f_{oc} = Fraction organic carbon in sediment

Uptake. Acquisition by an organism of a substance from the environment as a result of any active or passive process.

5.3 FRAMEWORK FOR DETERMINING NATIONAL BIOACCUMULATION FACTORS

5.3.1 Four Different Methods

Bioaccumulation factors used to derive national BAFs can be measured or predicted using some or all of the following four methods, depending on the type of chemical and its properties. These methods are:

(1) a measured BAF obtained from a field study (i.e., a field-measured BAF);

(2) a BAF predicted from a field-measured BSAF;

(3) a BAF predicted from a laboratory-measured BCF (with or without adjustment by an FCM); and

(4) a BAF predicted from a chemical's octanol-water partition coefficient (K_{ow}), with or without adjustment using an FCM.

NMED Exhibit 84

A brief summary of each of the four methods is provided below. Additional details on the use of these four methods is provided in Section 5.4 (for nonionic organics), Section 5.5 (for ionic organics) and Section 5.6 (for inorganics and organometallics).

1. **Field-Measured BAF.** Use of a field-measured BAF, which is the most direct measure of bioaccumulation, is the only method that can be used to derive a national BAF for all types of chemicals (i.e., nonionic organic, ionic organic, and inorganic and organometallic chemicals). A field-measured BAF is determined from a field study using measured chemical concentrations in the aquatic organism and its surrounding water. Because field studies are conducted in natural aquatic ecosystems, a field-measured BAF reflects an organism's exposure to a chemical through all relevant exposure pathways (i.e., water, sediment, and diet). A field-measured BAF also reflects any metabolism of a chemical that might occur in the aquatic organism or its food web. Therefore, field-measured BAFs are appropriate for all chemicals, regardless of the extent of chemical metabolism in biota.

2. **Field-measured BSAF.** For nonionic organic chemicals (and certain ionic organic chemicals where similar lipid and organic carbon partitioning behavior applies), a BAF can also be predicted from BSAFs. A BSAF is similar to a field-measured BAF in that the concentration of a chemical in biota is measured in the field and reflects an organism's exposure to all relevant exposure routes. A BSAF also reflects any chemical metabolism that might occur in the aquatic organism or its food web. However, unlike a field-measured BAF which references the biota concentration to the water concentration, a BSAF references the biota concentration to the sediment concentration. Use of the BSAF procedure is restricted to organic chemicals which are classified as being moderately to highly hydrophobic.

3. **Lab-measured BCF.** A laboratory-measured BCF can also be used to estimate a BAF for organic and inorganic chemicals. However, unlike a field-measured BAF or a BAF predicted from a field-measured BSAF, a laboratory-measured BCF only reflects the accumulation of chemical through the water exposure route. Laboratory-measured BCFs may therefore under estimate BAFs for chemicals where accumulation from sediment or dietary sources is important. In these cases, laboratory-measured BCFs can be multiplied by a FCM to reflect accumulation from non-aqueous (i.e., food chain) pathways of exposure. Since a laboratory-measured BCF is determined using the measured concentration of a chemical in an aquatic organism and its surrounding water, a laboratory-measured BCF reflects any metabolism of the chemical that occurs in the organism, but not in the food web.

4. **K_{ow}.** A chemical's octanol-water partition coefficient, or K_{ow}, can also be used to predict a BAF for nonionic organic chemicals. This procedure is appropriate only for nonionic organic chemicals (and certain ionic organic chemicals where similar lipid and organic carbon partitioning behavior applies). The K_{ow} has been extensively correlated with the BCF for nonionic organic chemicals that are poorly metabolized by aquatic organisms. Therefore, where substantial metabolism is known to occur in biota, the K_{ow} is not used

NMED Exhibit 84

to predict the BAF. For nonionic organic chemicals where chemical exposure through the food web is important, use of the K_{ow} alone will under predict the BAF. In such cases, the K_{ow} is adjusted with a FCM similar to the BCF procedure above.

5.3.2 Overview of BAF Derivation Framework

Although up to four methods can be used to derive a BAF as described in the previous section, it is evident that these methods do not apply equally to all types of chemicals. In addition, experience demonstrates that the required data will usually not be available to derive a BAF value using all of the applicable methods. As a result, EPA has developed the following guidelines to direct users in selecting the most appropriate method(s) for deriving a national BAF.

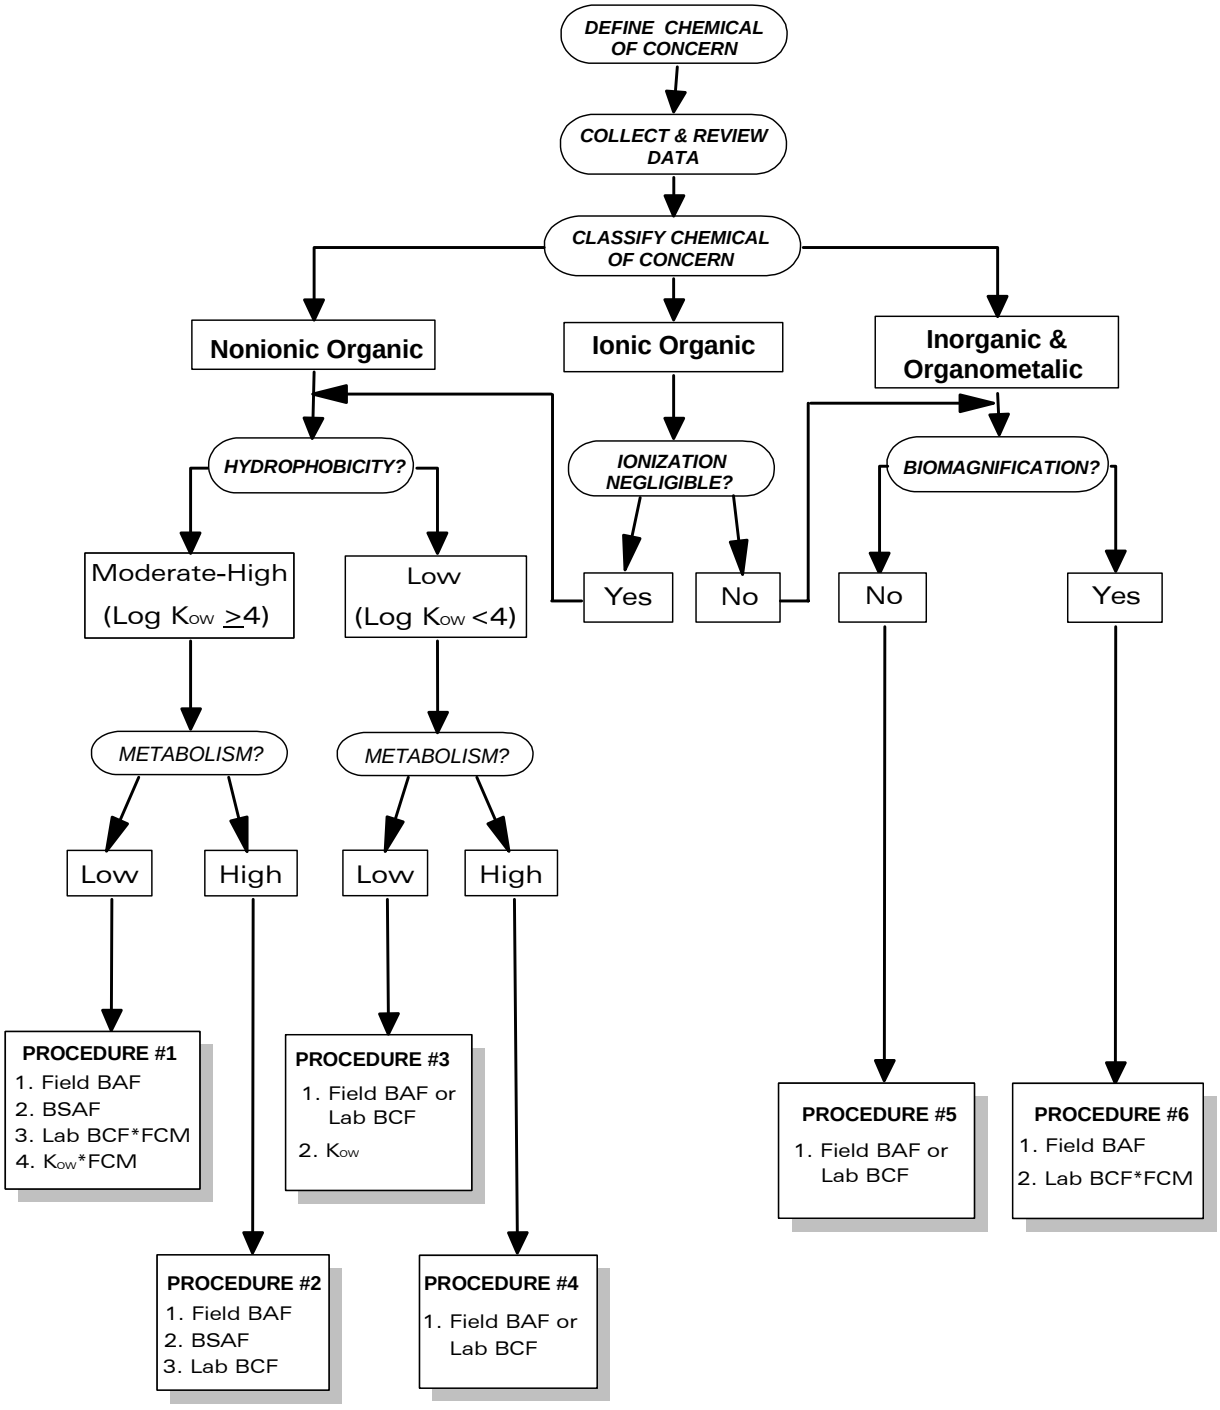

Figure 5-1 shows the overall framework of EPA's national BAF methodology. This framework illustrates the major steps and decisions that will ultimately lead to calculating a national BAF using one of six hierarchical procedures shown at the bottom of Figure 5-1. Each procedure contains a hierarchy of the BAF derivation methods discussed above, the composition of which depends on the chemical type and certain chemical properties (e.g., its degree of hydrophobicity and expected degree of metabolism and biomagnification). The number assigned to each BAF method within a procedure indicates its general order of preference for deriving a national BAF value. The goal of the framework and accompanying guidelines is to enable full use of available data and methods for deriving a national BAF value while appropriately restricting the use of certain methods to reflect their inherent limitations.

The first step in the framework is to define the chemical of concern. As described in Section 5.3.3, the chemical used to derive the national BAF should be consistent with the chemical used to derive the critical health assessment value. The second step is to collect and review all relevant data on bioconcentration and bioaccumulation of the chemical of concern (see Section 5.3.4). Once pertinent data are reviewed, the third step is to classify the chemical of concern into one of three broadly defined chemical categories: (1) nonionic organic chemicals, (2) ionic organic chemicals, and (3) and inorganic and organometallic chemicals. Guidance for classifying chemicals into these three categories is provided in Section 5.3.5.

After a chemical has been classified into one of the three categories, other information is used to select one of six hierarchical procedures to derive the national BAF. The specific procedures for deriving a BAF for each chemical group are discussed in Section 5.4 for nonionic organics, Section 5.5 for ionic organics, and Section 5.6 for inorganics and organometallics.

NMED Exhibit 84

Figure 5-1. Framework for Deriving a National BAF

NMED Exhibit 84

Detailed guidance concerning the first three steps of the derivation process (i.e, defining the chemical of concern, collecting and reviewing data, and classifying the chemical of concern) is provided in the following three sections.

5.3.3 Defining the Chemical of Concern

Defining the chemical of concern is the first step in deriving a national BAF. This step involves precisely defining the form(s) of the chemical upon which the national BAF value will be derived. Although this step is usually straightforward for single chemicals, complications can arise when the chemical of concern occurs as a mixture. The following guidelines should be followed for defining the chemical of concern.

1. Information for defining the chemical of concern should be obtained from the health and exposure assessment portions of the criteria derivation effort. The chemical(s) used to derive the national BAF should be consistent with the chemical(s) used to derive the reference dose (RfD), point of departure/uncertainty factor (POD/UF), or cancer potency factor.

2. In most cases, the RfD, POD/UF, or cancer potency factor will be based on a single chemical. In some cases, the RfD, POD/UF, or cancer potency factor will be based on a mixture of compounds, typically within the same chemical class (e.g., toxaphene, chlordane). In these situations, the national BAF should be derived in a manner that is consistent with the mixture used to express the health assessment.

    a. If sufficient data are available to reliably assess the bioaccumulation of each relevant compound contained in the mixture, then the national BAF(s) should be derived using the BAFs for the individual compounds of the mixture and appropriately weighted to reflect the mixture composition used to establish the RfD, POD/UF, or cancer potency factor. An example of this approach is shown in the derivation of BAFs for PCBs in the GLI Rulemaking (USEPA, 1997).

    b. If sufficient data are not available to reliably assess the bioaccumulation of individual compounds of the mixture, then the national BAF(s) should be derived using BAFs for the same or appropriately similar chemical mixture as that used to establish the RfD, POD/UF, or cancer potency value.

5.3.4 Collecting and Reviewing Data

The second step in deriving a national BAF is to collect and review all relevant bioaccumulation data for the chemical of concern. The following guidance should be followed for collecting and reviewing bioaccumulation data for deriving national BAFs.

1. All data on the occurrence and accumulation of the chemical of concern in aquatic animals and plants should be collected and reviewed for adequacy.

NMED Exhibit 84

2. A comprehensive literature search strategy should be used for gathering bioaccumulation-related data. An example of a comprehensive literature search strategy is provided in the Bioaccumulation TSD.

3. All data that are used should contain sufficient supporting information to indicate that acceptable measurement procedures were used and that the results are probably reliable. In some cases it may be appropriate to obtain additional written information from the investigator.

4. Questionable data, whether published or unpublished, should not be used. Guidance for assessing the acceptability of bioaccumulation and bioconcentration studies is found in Sections 5.4, 5.5, and 5.6.

5.3.5 Classifying the Chemical of Concern

The next step in deriving a national BAF consists of classifying the chemical of concern into one of three categories: nonionic organic, ionic organic, and inorganic and organometallic (Figure 5-1). This step helps to determine which of the four methods described in Section 5.3.1 are appropriate for deriving BAFs. The following guidance applies for classifying the chemical of concern.

1. **Nonionic Organic Chemicals.** For the purposes of the 2000 Human Health Methodology, nonionic organic chemicals are those organic compounds that do not ionize substantially in natural bodies of water. These chemicals are also referred to as neutral or nonpolar organics in the scientific literature. Due to their neutrality, nonionic organic chemicals tend to associate with other neutral (or near neutral) compartments in aquatic ecosystems (e.g., lipid, organic carbon). Examples of nonionic organic chemicals which have been widely studied in terms of their bioaccumulation include polychlorinated biphenyls (PCBs), polychlorinated dibenzo-p-dioxins and furans, many chlorinated pesticides, and polynuclear aromatic hydrocarbons (PAHs). Procedures for deriving a national BAF for nonionic organic chemicals are provided in Section 5.4.

2. **Ionic Organic Chemicals.** For the purposes of the 2000 Human Health Methodology, ionic organic chemicals are considered to include those chemicals that contain functional groups with exchangeable protons such as hydroxyl, carboxylic, and sulfonic groups and functional groups that readily accept protons such as amino and aromatic heterocyclic nitrogen (pyridine) groups. Ionic organic chemicals undergo ionization in water, the extent of which depends on pH and the pKa of the chemical. Because the ionized species of these chemicals behave differently from the neutral species, separate guidance is provided for deriving BAFs for ionic organic chemicals. Procedures for deriving national BAFs for ionic organic chemicals are provided in Section 5.5.

3. **Inorganic and Organometallic Chemicals.** The inorganic and organometallic category is considered to include inorganic minerals, other inorganic compounds and elements, metals (e.g., copper, cadmium, chromium, zinc), metalloids (selenium, arsenic) and

NMED Exhibit 84

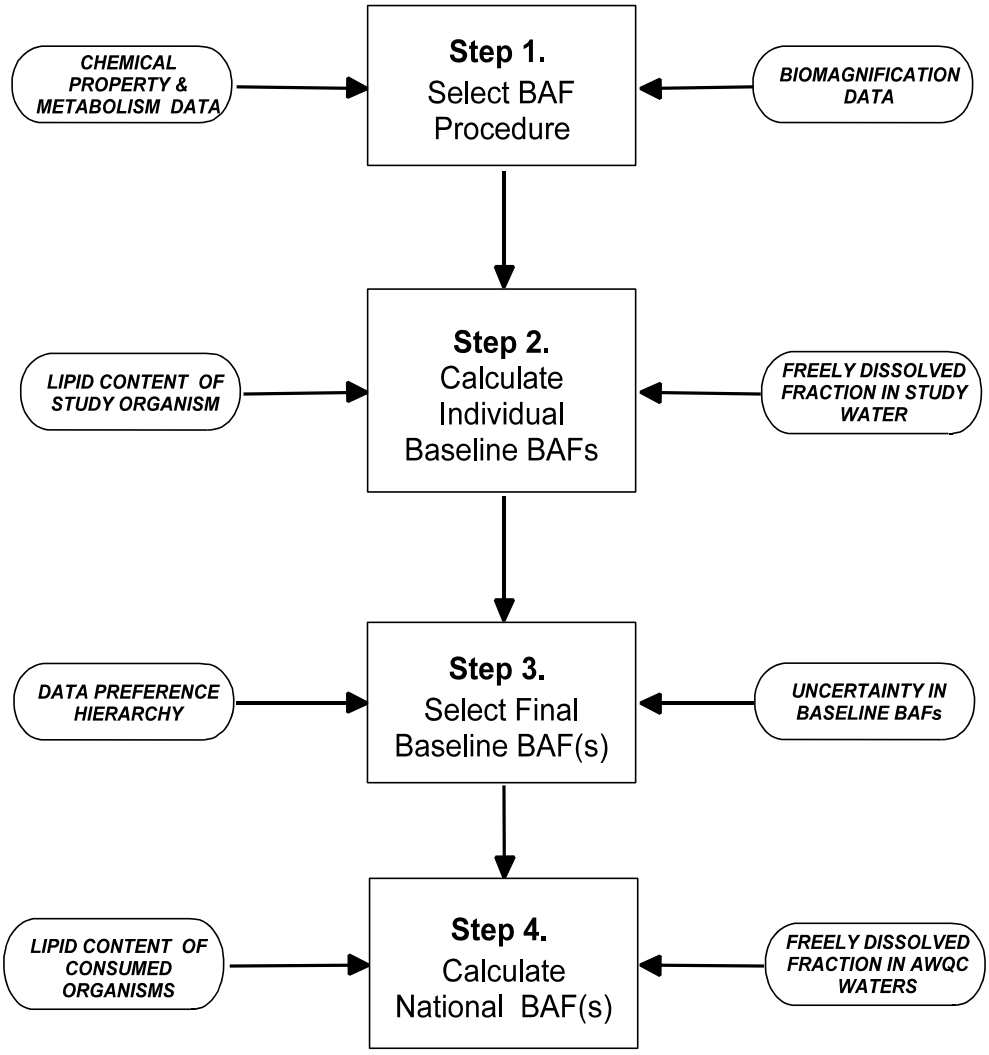
organometallic compounds (e.g., methylmercury, tributyltin, tetraalkyllead). Procedures for deriving BAFs for inorganic and organometallic chemicals are provided in Section 5.6.

5.4 NATIONAL BIOACCUMULATION FACTORS FOR NONIONIC ORGANIC CHEMICALS

5.4.1 Overview

This section contains the methodology for deriving national BAFs for nonionic organic chemicals as defined in Section 5.3.5. The four general steps of this methodology are:

1. Selecting the BAF derivation procedure,
2. Calculating individual baseline BAF_{ℓ}^{fd}s,
3. Selecting the final baseline BAF_{ℓ}^{fd}s, and
4. Calculating the national BAFs from the final baseline BAF_{ℓ}^{fd}s.



A schematic of this four-step process is shown in Figure 5-2.

Step 1 of the methodology (selecting the BAF derivation procedure) determines which of the four BAF procedures summarized in Figure 5-1 will be appropriate for deriving the national BAF. Step 2 involves calculating individual, species-specific BAF_{ℓ}^{fd}s using all of the methods available within the selected BAF derivation procedure. Calculating the individual baseline BAF_{ℓ}^{fd}s involves using data from the field site or laboratory where the original data were collected to account for site-specific factors which affect the bioavailability of the chemical to aquatic organisms (e.g., lipid content of study organisms and freely dissolved concentration in study water). Step 3 of the methodology consists of selecting the final baseline BAF_{ℓ}^{fd}s from the individual baseline BAF_{ℓ}^{fd}s by taking into account the uncertainty in the individual BAFs and the data preference hierarchy selected in Step 1. The final step is to calculate a BAF (or BAFs) that will be used in the derivation of 304(a) criteria (i.e., referred to as the national BAF). This step involves adjusting the final baseline BAF_{ℓ}^{fd}(s) to reflect certain factors that affect bioavailablity of the chemical to aquatic organisms in waters to which the national 304(a) criteria will apply (e.g., the freely dissolved fraction expected in U.S. waters and the lipid content of consumed aquatic organisms). Baseline BAF_{ℓ}^{fd}s are not used directly in the derivation of the 304(a) criteria because they do not reflect the conditions that affect bioavailability in U.S. waters.

Section 5.4.2 below provides detailed guidance for selecting the appropriate BAF derivation procedure (Step 1 of the process). Guidance on calculating individual baseline BAF_{ℓ}^{fd}s, selecting the final baseline BAF, and calculating the national BAF (Steps 2 through 4 of the process) is provided in separate sections under each of the four BAF derivation procedures.

NMED Exhibit 84

Figure 5-2. BAF Derivation for Nonionic Organic Chemicals

NMED Exhibit 84

5.4.2 Selecting the BAF Derivation Procedure

This section describes the decisions that should be made to select one of the four available hierarchical procedures for deriving a national BAF for nonionic organic chemicals (Procedures #1 through #4 of Figure 5-1). As shown in Figure 5-1, two decision points exist in selecting the BAF derivation procedure. The first decision point requires knowledge of the chemical's hydrophobicity (i.e., the K_{ow} of the chemical). Guidance for selecting the K_{ow} for a chemical is provided in the Bioaccumulation TSD. The K_{ow} provides an initial basis for assessing whether biomagnification may be a concern for nonionic organic chemicals. The second decision point is based on the rate of metabolism for the chemical in the target organism. Guidance for assessing whether a high or low rate of metabolism is likely for a chemical of concern is provided below in Section 5.4.2.3. With the appropriate information for these two decision points, the BAF derivation procedure should be selected using the following guidelines.

5.4.2.1 <u>Chemicals with Moderate to High Hydrophobicity</u>

1. For the purposes of the 2000 Human Health Methodology, nonionic organic chemicals with log K_{ow} values equal to or greater than 4.0 should be classified as moderately to highly hydrophobic. For moderately to highly hydrophobic nonionic organic chemicals, available data indicate that exposure through the diet and other non-aqueous routes can become important in determining chemical residues in aquatic organisms (e.g., Russell et al., 1999; Fisk et al., 1998; Oliver and Niimi, 1983; Oliver and Niimi, 1988; Niimi, 1985; Swackhammer and Hites, 1988). Dietary and other non-aqueous exposure can become extremely important for those nonionic organic chemicals that are poorly metabolized by aquatic biota (e.g., certain PCB congeners, chlorinated pesticides, and polychlorinated dibenzo-p-dioxins and furans).

2. **Procedure #1** should be used to derive national BAFs for moderately to highly hydrophobic nonionic organic chemicals in cases where:

   (a) the rate of chemical metabolism by target aquatic organisms is expected to be sufficiently low such that biomagnification is of concern, or

   (b) the rate of chemical metabolism by target aquatic organisms is not sufficiently known.

   Procedure #1 accounts for non-aqueous exposure and the potential for biomagnification in aquatic food webs through the use of field-measured values for bioaccumulation (i.e., field measured BAF or BSAF) and FCMs when appropriate field data are unavailable. Guidance on deriving national BAFs using Procedure #1 is found below in Section 5.4.3.

3. **Procedure #2** should be used to derive the national BAFs for moderately to highly hydrophobic nonionic organic chemicals in cases where:

   (a) the rate of chemical metabolism by target aquatic organisms is expected to be sufficiently high such that biomagnification is not of concern.

NMED Exhibit 84

Procedure #2 relaxes the requirement of using FCMs and eliminates the use of K_{ow}-based estimates of the BAF, two procedures that are most appropriate for poorly metabolized nonionic organic chemicals. Guidance on deriving national BAFs using Procedure #2 is found below in Section 5.4.4.

5.4.2.2 Chemicals with Low Hydrophobicity

1. For the purposes of these guidelines, nonionic organic chemicals with log K_{ow} values less than 4.0 should be classified as exhibiting low hydrophobicity. For nonionic organic chemicals that exhibit low hydrophobicity (i.e., log $K_{ow} < 4.0$), available information indicates that non-aqueous exposure to these chemicals is not likely to be important in determining chemical residues in aquatic organisms (e.g., Fisk et al., 1998; Gobas et al., 1993; Connolly and Pedersen, 1988; Thomann, 1989). For this group of chemicals, laboratory-measured BCFs and K_{ow}-predicted BCFs do not require adjustment with FCMs for determining the national BAF (Procedures #3 and #4), unless other appropriate data indicate differently.

   Other appropriate data include studies clearly indicating that non-aqueous exposure is important such that use of a BCF would substantially underestimate residues in aquatic organisms. In these cases, Procedure #1 should be used to derive the BAF for nonionic organic chemicals with log $K_{ow} < 4.0$. Furthermore, the data supporting the K_{ow} determination should be carefully reviewed for accuracy and appropriate interpretation, since the apparent discrepancy may be due to errors in determining K_{ow}.

2. **Procedure #3** should be used to derive national BAFs for nonionic organic chemicals of low hydrophobicity in cases where:

   (a) the rate of chemical metabolism by target aquatic organisms is expected to be negligible, such that tissue residues of the chemical of concern are not substantially reduced compared to an assumption of no metabolism, or

   (b) the rate of chemical metabolism by target aquatic organisms is not sufficiently known.

   Procedure #3 includes the use of K_{ow}-based estimates of the BCF to be used when lab or field data are absent. Guidance on deriving national BAFs using Procedure #3 is found below in Section 5.4.5.

3. **Procedure #4** should be used to derive national BAFs for nonionic organic chemicals of low hydrophobicity in cases where:

   (a) the rate of chemical metabolism by target aquatic organisms is expected to be sufficiently high, such that tissue residues of the chemical of concern are substantially reduced compared with an assumption of no metabolism.

NMED Exhibit 84

Procedure #4 eliminates the option of using K_{ow}-based estimates of the BAF because the K_{ow} may over-predict accumulation when a chemical is metabolized substantially by an aquatic organism. Guidance on deriving national BAFs using Procedure #4 is found below in Section 5.4.6.

5.4.2.3 Assessing Metabolism

Currently, assessing the degree to which a chemical is metabolized by aquatic organisms is confounded by a variety of factors. First, conclusive data on chemical metabolism in aquatic biota are largely lacking. Such data include whole organism studies where the metabolic rates and breakdown products are quantified in fish and other aquatic organisms relevant to human consumption. However, the majority of information on metabolism is derived from *in vitro* liver microsomal preparations in which primary and secondary metabolites may be identified and their rates of formation may or may not be quantified. Extrapolating results from *in vitro* studies to the whole organism involves considerable uncertainty. Second, there are no generally accepted procedures for reliably predicting chemical metabolism by aquatic organisms in the absence of measured data. Third, the rate at which a chemical is metabolized by aquatic organisms can be species and temperature dependent. For example, PAHs are known to be metabolized readily by vertebrate aquatic species (primarily fish), although at rates much less than those observed for mammals. However, the degree of metabolism in invertebrate species is generally much less than the degree in vertebrate species (James, 1989). One hypothesis for this difference is that the invertebrate species lack the detoxifying enzymes and pathways that are present in many vertebrate species.

Given the current limitations on assessing the degree of chemical metabolism by aquatic organisms, the assessment of metabolism should be made on a case-by-case basis using a weight-of-evidence approach. When assessing a chemical's likelihood to undergo substantial metabolism in a target aquatic organism, the following data should be carefully evaluated:

(1) *in vivo* chemical metabolism data,
(2) bioconcentration and bioaccumulation data,
(3) data on chemical occurrence in target aquatic biota, and
(4) *in vitro* chemical metabolism data.

1. ***In vivo* Data.** *In vivo* data on metabolism in aquatic organisms are from studies of chemical metabolism using whole organisms. These studies are usually conducted using large fish from which blood, bile, urine, and individual tissues can be collected for the identification and quantification of metabolites formed over time. *In vivo* studies are considered the most useful for evaluating a chemical's degree of metabolism in an organism because both oxidative (Phase I) and conjugative (Phase II) metabolism can be assessed in these studies. Mass-balance studies, in which parent compound elimination is quantified separately from biotransformation and elimination of metabolites, allow calculation of conversion rate of parent to metabolite as well as metabolite elimination. This information might be used to estimate loss due to metabolism separately from that due to elimination of the parent compound for adjustment of K_{ow}-predicted BAFs. However, due to the analytical and experimental challenges these studies pose, data of

NMED Exhibit 84

this type are limited. Less rigorous *in vivo* metabolism studies might include the use of metabolic blockers to demonstrate the influence of metabolism on parent compound kinetics. However, caution should be used in interpretation of absolute rates from these data due to the lack of specificity of mammalian derived blockers in aquatic species (Miranda et al., 1998).

2. **Bioconcentration or Bioaccumulation Data.** Data on chemical bioconcentration or bioaccumulation in aquatic organisms can be used indirectly for assessing metabolism. This assessment involves comparing acceptable lab-measured BCFs or field-measured BAFs (after converting to baseline values using procedures below) with the chemical's predicted value based on K_{ow}. The theoretical basis of bioconcentration and bioaccumulation for nonionic organic chemicals indicates that a chemical's baseline BCF should be similar to its K_{ow}-predicted value if metabolism is not occurring or is minimal (see the Bioaccumulation TSD). This theory also indicates that baseline BAFs should be similar to or higher than the K_{ow} for poorly metabolized organic chemicals, with highly hydrophobic chemicals often exhibiting higher baseline BAFs than K_{ow} values. Thus, if a chemical's baseline BCF or BAF is substantially lower than its K_{ow}, this may be an indication that the chemical is being metabolized by the aquatic organism of concern. Note, however, that this difference may also indicate problems in the experimental design or analytical chemistry, and that it may be difficult to discern the difference.

3. **Chemical Occurrence Data.** Although by no means definitive, data on the occurrence of chemicals in aquatic biota (i.e., residue studies) may offer another useful line of evidence for evaluating a chemical's likelihood to undergo substantial metabolism. Such studies are most useful if they have been conducted repeatedly over time and over wide geographical areas. Such studies might indicate a chemical is poorly metabolized if data show that the chemical is being biomagnified in the aquatic food web (i.e., higher lipid-normalized residues in successive trophic levels). Conversely, such studies might indicate a chemical is being metabolized substantially if residue data show a decline in residues with increasing trophic level. Again, other reasons for increases or decreases in concentrations with increasing trophic level might exist and should be carefully evaluated (e.g., incorrect food web assumptions, differences in exposure concentrations).

4. ***In vitro* Data.** *In vitro* metabolism data include data from studies where specific sub-cellular fractions (e.g., microsomal, cytosolic), cells, or tissues from an organism are tested outside the body (i.e., in test-tubes, cell- or tissue-culture). Compared with *in vivo* studies of chemical metabolism in aquatic organisms, *in vitro* studies are much more plentiful in the literature, with the majority of studies characterizing oxidative (Phase I) reactions de-coupled from conjugative (Phase II) metabolism. Cell, tissue, or organ level *in vitro* studies are less common but provide a more complete assessment of metabolism. While such studies are particularly useful for identifying the pathways, rates of formation, and metabolites formed, as well as the enzymes involved and differences in the temperature dependence of metabolism across aquatic species, they suffer from uncertainty when results are extrapolated to the whole organism. This uncertainty results from the fact that dosimetry (i.e., delivery of the toxicant to, and removal of metabolite

NMED Exhibit 84

from, the target tissue) cannot currently be adequately reproduced in the laboratory or easily modeled.

When assessing chemical metabolism using the above information, the following guidelines apply.

a. A finding of substantial metabolism should be supported by two or more lines of evidence identified using the data described above.

b. At least one of the lines of evidence should be supported by either *in vivo* metabolism data or acceptable bioconcentration or bioaccumulation data.

c. A finding of substantial metabolism in one organism should not be extrapolated to another organism or another group of organisms unless data indicate similar metabolic pathways exist (or are very likely to exist) in both organisms. *In vitro* data may be particularly useful in cross-species extrapolations.

d. Finally, in situations where sufficient data are not available to properly assess the likelihood of significant metabolism in aquatic biota of concern, the chemical should be assumed to undergo little or no metabolism. This assumptions reflects a policy decision by EPA to err on the side of public health protection when sufficient information on metabolism is lacking.

5.4.3 Deriving National BAFs Using Procedure #1

This section contains guidance for calculating national BAFs for nonionic organic chemicals using Procedure #1 shown in Figure 5-1. The types of nonionic organic chemicals for which Procedure #1 is most appropriate are those that are classified as moderately to highly hydrophobic and subject to low (or unknown) rates of metabolism by aquatic biota (see Section 5.4.2 above). Non-aqueous contaminant exposure and subsequent biomagnification in aquatic food webs are of concern for chemicals that are classified in this category. Some examples of nonionic organic chemicals for which Procedure #1 is considered appropriate include:

- tetra-, penta- & hexachlorobenzenes;
- PCBs;
- octachlorostyrene;
- hexachlorobutadiene;
- endrin, dieldrin, aldrin;
- mirex, photomirex;
- DDT, DDE, DDD; and
- heptachlor, chlordane, nonachlor.

Under Procedure #1, the following four methods may be used in deriving a national BAF:

- using a BAF from an acceptable field study (i.e., a field-measured BAF);
- predicting a BAF from an acceptable field-measured BSAF;

NMED Exhibit 84

- predicting a BAF from an acceptable laboratory-measured BCF and FCM; and
- predicting a BAF from an acceptable K_{ow} and FCM.

As shown in Figure 5-2, once the derivation procedure has been selected, the next steps in deriving a national BAF for a given trophic level include: calculating individual baseline BAF_{ℓ}^{fd}s (step 2), selecting the final baseline BAF_{ℓ}^{fd} (step 3), and calculating the national BAF from the final baseline BAF_{ℓ}^{fd} (step 4). Each of these three steps is discussed separately below.

5.4.3.1 Calculating Individual Baseline BAF_{ℓ}^{fd}s

Calculating an individual baseline BAF_{ℓ}^{fd} involves normalizing the field-measured BAF_T^t (or laboratory-measured BCF_T^t) which are based on total concentrations in tissue and water by the lipid content of the study organisms and the freely dissolved concentration in the study water. Both the lipid content in the organism and the freely dissolved concentration (as influenced by organic carbon in water) have been shown to be important factors that influence the bioaccumulation of nonionic organic chemicals (e.g., Mackay, 1982; Connolly and Pederson, 1988; Thomann, 1989, Suffet et al., 1994). Therefore, baseline BAF_{ℓ}^{fd}s (which are expressed on a freely dissolved and lipid-normalized basis) are considered more amenable to extrapolating between different species and bodies of water compared to BAFs expressed using the total concentration in the tissue and water. Because bioaccumulation can be strongly influenced by the trophic position of aquatic organisms (either due to biomagnification or physiological differences), extrapolation of baseline BAF_{ℓ}^{fd}s should not be performed between species of different trophic levels.

1. For each species for which acceptable data are available, calculate all possible baseline BAF_{ℓ}^{fd}s using each of the four methods shown above for Procedure #1.

2. Individual baseline BAF_{ℓ}^{fd}s should be calculated from field-measured BAF_T^ts, field-measured BSAFs, laboratory BCF_T^ts, and the K_{ow} according to the following procedures.

A. Baseline BAF_{ℓ}^{fd}s from Field-Measured BAFs

A baseline BAF_{ℓ}^{fd} should be calculated from each field-measured BAF_T^t using information on the lipid fraction in the tissue of concern for the study organism and the fraction of the total chemical that is freely dissolved in the study water.

1. **Baseline BAF_{ℓ}^{fd} Equation.** For each acceptable field-measured BAF_T^t, calculate a baseline BAF_{ℓ}^{fd} using the following equation:

$$\text{Baseline } BAF_{\ell}^{fd} = \left[\frac{\text{Measured } BAF_T^t}{f_{fd}} - 1 \right] \left(\frac{1}{f_{\ell}} \right) \qquad \text{(Equation 5-10)}$$

where:

NMED Exhibit 84

Baseline BAF_{ℓ}^{fd}	=	BAF expressed on a freely dissolved and lipid-normalized basis
Measured BAF_T^t	=	BAF based on total concentration in tissue and water
f_{ℓ}	=	Fraction of the tissue that is lipid
f_{fd}	=	Fraction of the total chemical that is freely dissolved in the ambient water

The technical basis of Equation 5-10 is provided in the Bioaccumulation TSD. Guidance for determining each component of Equation 5-10 is provided below.

2. **Determining the Measured BAF_T^t.** The field-measured BAF_T^t shown in Equation 5-10 should be calculated based on the total concentration of the chemical in the appropriate tissue of the aquatic organism and the total concentration of the chemical in ambient water at the site of sampling. The equation to derive a measured BAF_T^t is:

$$\text{Measured } BAF_T^t = \frac{C_t}{C_w} \qquad \text{(Equation 5-11)}$$

where:

C_t	=	Total concentration of the chemical in the specified wet tissue
C_w	=	Total concentration of chemical in water

The data used to calculate a field-measured BAF_T^t should be reviewed thoroughly to assess the quality of the data and the overall uncertainty in the BAF value. The following general criteria apply in determining the acceptability of field-measured BAFs that are being considered for deriving national BAFs using Procedure #1.

a. Aquatic organisms used to calculate a field-measured BAF_T^t should be representative of aquatic organisms that are commonly consumed in the United States. An aquatic organism that is not commonly consumed in the United States can be used to calculate an acceptable field-measured BAF_T^t provided that the organism is considered to be a reasonable surrogate for a commonly consumed organism. Information on the ecology, physiology, and biology of the organism should be reviewed when assessing whether an organism is a reasonable surrogate of a commonly consumed organism.

b. The trophic level of the study organism should be determined by taking into account its life stage, diet, size, and the food web structure at the study location. Information from the study site (or similar sites) is preferred when evaluating trophic status. If such information is lacking, general information for assessing trophic status of aquatic organisms can be found in USEPA (2000a,b,c).

NMED Exhibit 84

c. The percent lipid of the tissue used to determine the field-measured BAF_T^t should be either measured or reliably estimated to permit lipid-normalization of the chemical's tissue concentration.

d. The study from which the field-measured BAF_T^t is derived should contain sufficient supporting information from which to determine that tissue and water samples were collected and analyzed using appropriate, sensitive, accurate, and precise analytical methods.

e. The site of the field study should not be so unique that the BAF cannot be reasonably extrapolated to other locations where the BAF and resulting criteria will apply.

f. The water concentration(s) used to derive the BAF should reflect the average exposure of the aquatic organism that corresponds to the concentration measured in its tissue of concern. For nonionic organic chemicals, greater temporal and spatial averaging of chemical concentrations is required as the K_{ow} increases. In addition, as variability in water concentrations increase, greater temporal and spatial averaging is also generally required. Greater spatial averaging is also generally required for more mobile organisms.

g. The concentrations of particulate organic carbon and dissolved organic carbon in the study water should be measured or reliably estimated.

EPA is currently developing guidance for designing and conducting field studies for determining field-measured BAF_T^ts, including recommendations for minimum data requirements. A more detailed discussion of factors that should be considered when determining field-measured BAF_T^ts is provided in the Bioaccumulation TSD.

3. **Determining the Fraction Freely Dissolved (f_{fd}).** As illustrated by Equation 5-10, the fraction of the nonionic organic chemical that is freely dissolved in the study water is required for calculating a baseline BAF_ℓ^{fd} from a field-measured BAF_T^t. The freely dissolved fraction is the portion of the nonionic organic chemical that is not bound to particulate organic carbon or dissolved organic carbon. Together, the concentration of a nonionic organic chemical that is freely dissolved, bound to dissolved organic carbon, and bound to particulate organic carbon constitute its total concentration in water. As discussed further in the Bioaccumulation TSD, the freely dissolved fraction of a chemical is considered to be the best expression of the bioavailable form of nonionic organic chemicals to aquatic organisms (e.g., Suffet et al., 1994; USEPA, 1995b). Because the fraction of a nonionic organic chemical that is freely dissolved may vary among different bodies of water as a result of differences in dissolved and particulate organic carbon in the water, the bioavailability of the total chemical concentration in water is expected to vary from one body of water to another. Therefore, BAFs which are based on the freely dissolved concentration in water (rather than the total concentration in water) are considered to be more reliable for extrapolating and aggregating BAFs among different bodies of water. Currently, availability of BAFs based on measured freely dissolved

NMED Exhibit 84

concentrations is very limited, partly because of difficulties in analytically measuring the freely dissolved concentration. Thus, if a BAF based on the total water concentration is reported in a given study, the fraction of the chemical that is freely dissolved should be predicted using information on the organic carbon content in the study water.

a. **Equation for Determining the Freely Dissolved Fraction.** If reliable measured data are unavailable to directly determine the freely dissolved fraction of the chemical in water, the freely dissolved fraction should be estimated using the following equation.

$$f_{fd} = \frac{1}{[1 + (POC \cdot K_{ow}) + (DOC \cdot 0.08 \cdot K_{ow})]} \qquad \text{(Equation 5-12)}$$

where:

POC	=	concentration of particulate organic carbon (kg/L)
DOC	=	concentration of dissolved organic carbon (kg/L)
K_{ow}	=	n-octanol water partition coefficient for the chemical

In Equation 5-12, K_{ow} is being used to estimate the partition coefficient to POC (i.e., K_{POC} in L/kg) and $0.08 \cdot K_{ow}$ is being used to estimate the partition coefficient to DOC (i.e., the K_{DOC} in L/kg). A discussion of the technical basis, assumptions, and uncertainty associated with the derivation and application of Equation 5-12 is provided in the Bioaccumulation TSD.

b. **POC and DOC Values.** When converting from the total concentration of a chemical to a freely dissolved concentration using Equation 5-12 above, the POC and DOC concentrations should be obtained from the original study from which the field-measured BAF is determined. If POC and DOC concentrations are not reported in the BAF study, reliable estimates of POC and DOC might be obtained from other studies of the same site used in the BAF study or closely related site(s) within the same water body. When using POC/DOC data from other studies of the same water body, care should be taken to ensure that environmental and hydrological conditions that might affect POC or DOC concentrations (i.e., runoff events, proximity to ground water or surface water inputs, sampling season) are reasonably similar to those in the BAF study. Additional information related to selecting POC and DOC values is provided in the Bioaccumulation TSD.

In some cases, BAFs are reported using the concentration of the chemical in filtered or centrifuged water. When converting these BAFs to a freely dissolved basis, the concentration of POC should be set equal to zero when using Equation 5-12. Particulates are removed from water samples by filtering or centrifuging the sample.

NMED Exhibit 84

c. **Selecting K_{ow} Values.** A variety of techniques are available to measure or predict K_{ow} values. The reliability of these techniques depends to a large extent on the K_{ow} of the chemical. Because K_{ow} is an important input parameter for calculating the freely dissolved concentration of nonionic organic chemicals and for deriving BAFs using the other three methods of Procedure #1, care should be taken in selecting the most reliable K_{ow} value. The value of K_{ow} for use in estimating the freely dissolved fraction and other procedures used to derive national BAFs should be selected based on the guidance presented in the Bioaccumulation TSD.

4. **Determining the Fraction Lipid (f_ℓ).** Calculating a baseline BAF_ℓ^{fd} for a nonionic organic chemical using Equation 5-10 also requires that the total chemical concentration measured in the tissue used to determine the field-measured BAF_T^t be normalized by the lipid fraction (f_ℓ) in that same tissue. Lipid normalization of tissue concentrations reflects the assumption that BAFs (and BCFs) for nonionic organic chemicals are directly proportional to the percent lipid in the tissue upon which they are based. This assumption means that an organism with a two percent lipid content would be expected to accumulate twice the amount of a chemical at steady state compared with an organism with one percent lipid content, all else being equal. The assumption that aquatic organisms accumulate nonionic organic chemicals in proportion to their lipid content has been extensively evaluated in the literature (Mackay, 1982; Connell, 1988; Barron, 1990) and is generally accepted. Because the lipid content in aquatic organisms can vary both within and across species, BAFs that are expressed using the lipid-normalized concentration (rather than the total concentration in tissue) are considered to be the most reliable for aggregating multiple BAF values for a given species. Additional discussion of technical basis, assumptions, and uncertainties involved in lipid normalization is provided in the Bioaccumulation TSD.

a. The lipid fraction f_ℓ, is routinely reported in bioaccumulation studies involving nonionic organic chemicals. If the lipid fraction is not reported in the BAF study, it can be calculated using the following equation if the appropriate data are reported:

$$f_\ell = \frac{M_\ell}{M_t} \qquad \text{(Equation 5-13)}$$

where:

M_ℓ = Mass of lipid in specified tissue
M_t = Mass of specified tissue (wet weight)

b. Because lipid content can vary within an aquatic organism (and among tissues within that organism) due to several factors including the age and sex of the organism, changes in dietary composition, season of sampling and reproductive status, the lipid fraction used to calculate a baseline BAF_ℓ^{fd} should be measured in

NMED Exhibit 84

the same tissue and organisms used to determine the field-measured BAF_T^t, unless comparability is demonstrated across organisms.

c. Experience has shown that different solvent systems used to extract lipids for analytical measurement can result in different quantities of lipids being extracted and measured in aquatic organisms (e.g., Randall et al.,1991, 1998). As a result, lipid measurements determined using different solvent systems might lead to apparent differences in lipid-normalized concentrations and lipid-normalized BAFs. The extent to which different solvent systems might affect lipid extractions (and lipid-normalized concentrations) is thought to vary depending on the solvent, chemical of concern, and lipid composition of the tissue being extracted. Guidance on measurement of lipid content, including the choice of solvent system and how different solvent systems may affect lipid content, is provided in the Bioaccumulation TSD.

B. Baseline BAF_ℓ^{fd} Derived from BSAFs

The second method of determining a baseline BAF_ℓ^{fd} for the chemical of concern in Procedure #1 involves the use of BSAFs. Although BSAFs may be used for measuring and predicting bioaccumulation directly from concentrations of chemicals in surface sediment, they may also be used to estimate BAFs (USEPA, 1995b; Cook and Burkhard, 1998). Since BSAFs are based on field data and incorporate effects of chemical bioavailability, food web structure, metabolism, biomagnification, growth, and other factors, BAFs estimated from BSAFs will incorporate the net effect of all these factors. The BSAF approach is particularly beneficial for developing water quality criteria for chemicals which are detectable in fish tissues and sediments, but are difficult to detect or measure precisely in the water column.

As shown by Equation 5-14 below, predicting baseline BAF_ℓ^{fd}s using BSAFs requires that certain types of data be used for the chemicals of interest (for which BAFs are to be determined) and reference chemicals (for which BAFs are measured) from a common sediment-water-organism data set. Differences between BSAFs for different organic chemicals are good measures of the relative bioaccumulation potentials of the chemicals. When calculated from a common organism-sediment sample set, chemical-specific differences in BSAFs reflect the net effect of biomagnification, metabolism, food chain, bioenergetics, and bioavailability factors on the degree of each chemical's equilibrium/disequilibrium between sediment and biota. At equilibrium, BSAFs are expected to be approximately 1.0. However, deviations from 1.0 (reflecting disequilibrium) are common due to: conditions where water is not at equilibrium with surface sediment; differences in organic carbon content of water and sediment; kinetic limitations for chemical transfer between sediments and water associated with specific biota; biomagnification; or biological processes such as growth or biotransformation. BSAFs are most useful (i.e., most predictable from one site to another) when measured under steady-state (or near steady-state) conditions. The use of non-steady-state BSAFs, such as found with new chemical loadings or rapid increases in loadings, increases uncertainty in this method for the relative degree of disequilibrium between the reference chemicals and the chemicals of interest. In general, the fact that concentrations of hydrophobic chemicals in sediment are less sensitive than concentrations in water to fluctuations in chemical loading and distribution makes the BSAF

NMED Exhibit 84

method robust for estimating BAFs. Results from validation of the BAF procedure in Lake Ontario, the Fox River and Green Bay, Wisconsin, and the Hudson River, New York, demonstrate good agreement between observed and BSAF-predicted BAFs in the vast majority of comparisons made. Detailed results of the validation studies for the BSAF procedure are provided in the Bioaccumulation TSD.

Baseline BAF_{ℓ}^{fd}s should be calculated using acceptable BSAFs for chemicals of interest and appropriate sediment-to-water fugacity (disequilibrium) ratios $(\prod_{socw})_r/(K_{ow})_r$ for reference chemicals under the following guidelines.

1. **Baseline BAF_{ℓ}^{fd} Equation.** For each species with an acceptable field measured $(BSAF)_I$, a baseline BAF_{ℓ}^{fd} for the chemical of interest may be calculated using the following equation with an appropriate value of $(\prod_{socw})_r/(K_{ow})_r$:

$$(Baseline\ BAF_{\ell}^{fd})_i = (BSAF)_i \frac{(D_{i/r})\ (\prod_{socw})_r\ (K_{ow})_i}{(K_{ow})_r} \qquad \text{(Equation 5-14)}$$

where:

$(\text{Baseline } BAF_{\ell}^{fd})_I$	=	BAF expressed on a freely dissolved and lipid-normalized basis for chemical of interest "I"
$(BSAF)_I$	=	Biota-sediment accumulation factor for chemical of interest "I"
$(\prod_{socw})_r$	=	sediment organic carbon to water freely dissolved concentration ratio of reference chemical "r"
$(K_{ow})_I$	=	octanol-water partition coefficient for chemical of interest "I"
$(K_{ow})_r$	=	octanol-water partition coefficient for the reference chemical "r"
$D_{i/r}$	=	ratio between $\prod_{socw}/K_{ow}$ for chemicals "I" and "r" (normally chosen so that $D_{i/r} = 1$)

The technical basis, assumptions, and uncertainties associated with Equation 5-14 are provided in the Bioaccumulation TSD. Guidance for determining each component of Equation 5-14 is provided below.

2. **Determining Field-Measured BSAFs.** BSAFs should be determined by relating lipid-normalized concentrations of chemicals in an organism (C_{ℓ}) to organic carbon-normalized concentrations of the chemicals in surface sediment samples (C_{soc}) using the following equation:

$$BSAF = \frac{C_{\ell}}{C_{soc}} \qquad \text{(Equation 5-15)}$$

NMED Exhibit 84

a. **Lipid-Normalized Concentration.** The lipid-normalized concentration of a chemical in an organism should be determined by:

$$C_{\ell} = \frac{C_t}{f_{\ell}} \qquad \text{(Equation 5-16)}$$

where:

C_t = Concentration of the chemical in the wet tissue (either whole organism or specified tissue) (µg/g)
f_{ℓ} = Fraction lipid content in the tissue

b. **Organic Carbon-Normalized Concentration.** The organic carbon-normalized concentration of a chemical in sediment should be determined by:

$$C_{soc} = \frac{C_s}{f_{oc}} \qquad \text{(Equation 5-17)}$$

where:

C_s = Concentration of chemical in sediment (µg/g sediment)
f_{oc} = Fraction organic carbon in sediment

The organic carbon-normalized concentrations of the chemicals in surface sediment samples should be associated with the average exposure environment of the organism.

3. **Sediment-to-Water Partition Coefficient** $(\prod_{socw})_r$. Sediment-to-water partition coefficients for reference chemicals should be determined by:

$$(\prod_{socw})_r = \frac{(C_{soc})_r}{(C_w^{fd})_r} \qquad \text{(Equation 5-18)}$$

where:

$(C_{soc})_r$ = Concentration of a reference chemical in sediment normalized to sediment organic carbon
$(C_w^{fd})_r$ = Concentration of the reference chemical freely dissolved in water

4. **Selecting Reference Chemicals.** Reference chemicals with $(\prod_{socw}) / (K_{ow})$ similar to that of the chemical of interest are preferred for this method. Theoretically, knowledge of the

NMED Exhibit 84

difference between sediment-to-water fugacity ratios for two chemicals, "I" and "r" ($D_{i/r}$), could be used when reliable reference chemicals that meet the fugacity equivalence condition are not available. Similarity of $(\prod_{socw}) / (K_{ow})$ for two chemicals can be indicated on the basis of similar physical-chemical behavior in water (persistence, volatilization), similar mass loading histories, and similar concentration profiles in sediment cores.

Validation studies have demonstrated that choosing reference chemicals with well quantified concentrations in water is important because the uncertainty associated with measurement of barely detected chemicals is large (see the Bioaccumulation TSD). Similarity between K_{ow} values of the reference and target chemicals is generally desirable, although recent validation studies indicate that the accuracy of the method is not substantially decreased through use of reference chemicals with large differences in K_{ow}, as long as the chemicals are structurally similar and have similar persistence behavior in water and sediments.

5. The following data, procedural, and quality assurance requirements should be met for predicting baseline BAF_{ℓ}^{fd}s using field-measured BSAFs:

   a. Data on the reference chemicals and chemicals of interest should come from a common organism-water-sediment data set at a particular site.

   b. The chemicals of interest and reference chemicals should have similar physicochemical properties and persistence in water and sediment.

   c. The loadings history of the reference chemicals and chemicals of interest should be similar such that their expected sediment-water disequilibrium ratios $(\prod_{socw}/K_{ow})$ would not be expected to be substantially different (i.e., $D_{i/r} \sim 1$).

   d. The use of multiple reference chemicals is generally preferred for determining the value of $(\prod_{socw})_r$ so long as the concentrations are well quantified and the aforementioned conditions for selecting reference chemicals are met. In some cases, use of a single reference chemical may be necessary because of limited data.

   e. Samples of surface sediments (0-1 cm is ideal) should be from locations in which sediment is regularly deposited and is representative of average surface sediment in the vicinity of the organism.

   f. The K_{ow} value for the target and reference chemicals should be selected as described in the Bioaccumulation TSD.

   g. All other data quality and procedural guidelines described earlier for determining field-measured BAFs in Section 5.4.3.1(A) should be met.

NMED Exhibit 84

Further details on the requirements for predicting BAFs from BSAF measurements, including the data, assumptions, and limitations of this approach are provided in the Bioaccumulation TSD.

C. Baseline BAF_{ℓ}^{fd} from a Laboratory-Measured BCF_T^t and FCM

The third method in Procedure #1 consists of using a laboratory-measured BCF_T^t (i.e., a BCF based on total concentrations in tissue and water) and FCMs to predict a baseline BAF_{ℓ}^{fd} for the chemical of concern. The BCF_T^t is used in conjunction with an FCM because non-aqueous routes of exposure and subsequent biomagnification is of concern for the types of chemicals applicable to Procedure #1. A laboratory-measured BCF inherently accounts for the effects of chemical metabolism that occurs in the organism used to calculate the BCF, but does not account for metabolism which may occur in other organisms of the aquatic food web.

1. **Baseline BAF_{ℓ}^{fd} Equation.** For each acceptable laboratory-measured BCF_T^t, calculate a baseline BAF_{ℓ}^{fd} using the following equation:

$$\text{Baseline } BAF_{\ell}^{fd} = (FCM) \cdot \left[\frac{\text{Measured } BCF_T^t}{f_{fd}} - 1 \right] \cdot \left(\frac{1}{f_{\ell}} \right) \qquad \text{(Equation 5-19)}$$

where:

Baseline BAF_{ℓ}^{fd}	=	BAF expressed on a freely dissolved and lipid-normalized basis
Measured BCF_T^t	=	BCF based on total concentration in tissue and water
f_{ℓ}	=	Fraction of the tissue that is lipid
f_{fd}	=	Fraction of the total chemical in the test water that is freely dissolved
FCM	=	The food chain multiplier either obtained from Table 5-1 by linear interpolation for the appropriate trophic level, or from appropriate field data

The technical basis for Equation 5-19 is provided in the Bioaccumulation TSD. Guidance for determining each component of Equation 5-19 is provided below.

2. **Determining the Measured BCF_T^t.** The laboratory-measured BCF_T^t shown in Equation 5-19 should be calculated using information on the total concentration of the chemical in the tissue of the organism and the total concentration of the chemical in the laboratory test water. The equation to derive a measured BCF_T^t is:

$$\text{Measured } BCF_T^t = \frac{C_t}{C_w} \qquad \text{(Equation 5-20)}$$

NMED Exhibit 84

where:

C_t = Total concentration of the chemical in the specified wet tissue
C_w = Total concentration of chemical in the laboratory test water

The data used to calculate a laboratory-measured BCF_T^t should be reviewed thoroughly to assess the quality of the data and the overall uncertainty in the BCF value. The following general criteria apply in determining the acceptability of laboratory-measured BCF_T^t.

a. The test organism should not be diseased, unhealthy, or adversely affected by the concentration of the chemical because these attributes may alter accumulation of chemicals compared with healthy organisms.

b. The total concentration of the chemical in the water should be measured and should be relatively constant during the exposure period.

c. The organisms should be exposed to the chemical using a flow-through or renewal procedure.

d. The percent lipid of the tissue used to normalize the BCF_T^t should be either measured or reliably estimated to permit lipid normalization of chemical concentrations.

e. The concentrations of particulate organic carbon and dissolved organic carbon in the study water should be measured or reliably estimated.

f. Aquatic organisms used to calculate a laboratory-measured BCF_T^t should be representative of those aquatic organisms that are commonly consumed in the United States. An aquatic organism which is not commonly consumed in the United States can be used to calculate an acceptable laboratory-measured BCF_T^t provided that the organism is considered to be a reasonable surrogate for a commonly consumed organism. Information on the ecology, physiology, and biology of the organism should be reviewed when assessing whether an organism is a reasonable surrogate of a commonly consumed organism.

g. BCFs may be based on measurement of radioactivity from radiolabeled parent compounds only when the BCF is intended to include metabolites, when there is confidence that there is no interference due to metabolites of the parent compounds, or when studies are conducted to determine the extent of metabolism, thus allowing for a proper correction.

h. The calculation of the BCF_T^t should appropriately address growth dilution, which can be particularly important in affecting BCF_T^t determinations for poorly depurated chemicals.

NMED Exhibit 84

I. Other aspects of the methodology used should be similar to those described by the American Society of Testing and Materials (ASTM, 1999) and USEPA *Ecological Effects Test Guidelines* (USEPA, 1996).

j. In addition, the magnitude of the K_{ow} and the availability of corroborating BCF data should be considered. For example, if the steady-state method is used for the BCF_T^t determination, exposure periods longer than 28 days will generally be required for highly hydrophobic chemicals to reach steady state between the water and the organism.

k. If a baseline BCF_ℓ^{fd} derived from a laboratory-measured BCF_T^t consistently increases or decreases as the chemical concentration increases in the test solutions for the test organisms, the BCF_T^t should be selected from the test concentration(s) that would most closely correspond to the 304(a) criterion. Note: a BCF_T^t should not be calculated from a control treatment.

3. **Selecting Food Chain Multipliers.** An FCM reflects a chemical's tendency to biomagnify in the aquatic food web. Values of FCMs greater than 1.0 are indicative of biomagnification and typically apply to organic chemicals with log K_{ow} values between 4.0 and 9.0. For a given chemical, FCMs tend to be greater at higher trophic levels, although FCMs for trophic level three can be higher than those for trophic level four.

Food chain multipliers used to derive baseline BAF_ℓ^{fd}s using Procedure #1 can be selected from model-derived or field-derived estimates.

a. **Model-Derived FCMs.** For nonionic organic chemicals appropriate for Procedure #1, EPA has calculated FCMs for various K_{ow} values and trophic levels using the bioaccumulation model of Gobas (1993). The FCMs shown in Table 5-1 were calculated using the Gobas model as the ratio of the baseline BAF_ℓ^{fd}s for trophic levels 2, 3, and 4 to the baseline BCF_ℓ^{fd}.

EPA recommends using the biomagnification model by Gobas (1993) to derive FCMs for nonionic organic chemicals for several reasons. First, the Gobas model includes both benthic and pelagic food chains, thereby incorporating exposure of organisms to chemicals from both the sediment and the water column. Second, the input data needed to run the model can be readily defined. Third, the predicted BAFs using the model are in agreement with field-measured BAFs for chemicals, even those with very high log K_{ow}s. Finally, the model predicts chemical residues in benthic organisms using equilibrium partitioning theory, which is consistent with EPA's equilibrium partitioning sediment guidelines (USEPA, 2000d).

The Gobas model requires input of specific data on the structure of the food chain and the water quality characteristics of the water body of interest. For calculating national BAFs, a mixed pelagic/benthic food web structure consisting of four trophic levels is assumed. Trophic level 1 is phytoplankton, trophic level 2 is

NMED Exhibit 84

zooplankton, trophic level 3 is forage fish (e.g., sculpin and smelt), and trophic level 4 are predatory fish (e.g., salmonids). Additional assumptions are made regarding the composition of the aquatic species' diets (e.g., salmonids consume 10 percent sculpin, 50 percent alewives, and 40 percent smelt), the physical parameters of the aquatic species (e.g., lipid values), and the water quality characteristics (e.g., water temperature, sediment organic carbon).

A mixed pelagic/benthic food web structure has been assumed for the purpose of calculating FCMs because it is considered to be most representative of the types of food webs that occur in aquatic ecosystems. FCMs derived using the mixed pelagic/benthic structure are also about mid-range in magnitude between a 100% pelagic and 100% benthic driven food web (see the Bioaccumulation TSD). The validity of FCMs derived using the mixed pelagic/benthic food web structure has

NMED Exhibit 84

Table 5-1
Food-Chain Multipliers for Trophic Levels 2, 3 and 4
(Mixed Pelagic and Benthic Food Web Structure and $\prod_{socw} / K_{OW} = 23$)

been evaluated in several different ecosystems including Lake Ontario, the tidally influenced Bayou D'Inde in Louisiana, the Fox River and Green Bay, Wisconsin, and the Hudson River in New York. Additional details of the validation of EPA's national default FCMs and the assumptions, uncertainties, and input parameters for the model are provided in the Bioaccumulation TSD.

NMED Exhibit 84

Although EPA uses the FCMs in Table 5-1 to derive its national 304(a) criteria, EPA recognizes that food webs of other waterbodies might differ from the assumptions used to calculate national BAFs. In these situations, States and authorized Tribes may wish to use alternate food web structures for calculating FCMs for use in setting State or Tribal water quality criteria. Additional guidance on the use of alternate food web structures for calculating State, Tribal, or site-specific criteria is provided in the Bioaccumulation TSD.

b. **Field-Derived FCMs.** In addition to model-derived estimates of FCMs, field data may also be used to derive FCMs. Currently, the use of field-derived FCMs is the only method recommended for estimating FCMs for inorganic and organometalic chemicals because appropriate model-derived estimates are not yet available (see Section 5.6). In contrast to the model-based FCMs described previously, field-derived FCMs account for any metabolism of the chemical of concern by the aquatic organisms used to calculate the FCM.

Field-derived FCMs should be calculated using lipid-normalized concentrations of the nonionic organic chemical in appropriate predator and prey species using the following equations.

$$FCM_{TL2} = BMF_{TL2} \quad \text{(Equation 5-21)}$$

$$FCM_{TL3} = (BMF_{TL3})\,(BMF_{TL2}) \quad \text{(Equation 5-22)}$$

$$FCM_{TL4} = (BMF_{TL4})\,(BMF_{TL3})\,(BMF_{TL2}) \quad \text{(Equation 5-23)}$$

where:

FCM = Food chain multiplier for designated trophic level (TL2, TL3, or TL4)
BMF = Biomagnification factor for designated trophic level (TL2, TL3, or TL4)

The basic difference between FCMs and BMFs is that FCMs relate back to trophic level one (or trophic level two as assumed by the Gobas (1993) model), whereas BMFs always relate back to the next lowest trophic level. For nonionic organic chemicals, BMFs can be calculated from tissue residue concentrations determined in biota at a site according to the following equations.

$$BMF_{TL2} = (C_{\ell, TL2}) / (C_{\ell, TL1}) \quad \text{(Equation 5-24)}$$

$$BMF_{TL3} = (C_{\ell, TL3}) / (C_{\ell, TL2}) \quad \text{(Equation 5-25)}$$

$$BMF_{TL4} = (C_{\ell, TL4}) / (C_{\ell, TL3}) \quad \text{(Equation 5-26)}$$

where:

NMED Exhibit 84

C_ℓ = Lipid-normalized concentration of chemical in tissue of appropriate biota that occupy the specified trophic level (TL2, TL3, or TL4)

In addition to the acceptability guidelines pertaining to field-measured BAFs, the following procedural and quality assurance requirements apply to field-measured FCMs.

(1) Information should be available to identify the appropriate trophic levels for the aquatic organisms and appropriate predator-prey relationships for the site from which FCMs are being determined. General information on determining trophic levels of aquatic organisms can be found in USEPA 2000a,b,c.

(2) The aquatic organisms sampled from each trophic level should reflect the most important exposure pathways leading to human exposure via consumption of aquatic organisms. For higher trophic levels (e.g., 3 and 4), aquatic species should also reflect those that are commonly consumed by humans.

(3) The studies from which the FCMs are derived should contain sufficient supporting information from which to determine that tissue samples were collected and analyzed using appropriate, sensitive, accurate, and precise methods.

(4) The percent lipid should be either measured or reliably estimated for the tissue used to determine the FCM.

(5) The tissue concentrations should reflect average exposure over the approximate time required to achieve steady-state in the target species.

D. Baseline BAF_ℓ^{fd} from a K_{ow} and FCM

The fourth method in Procedure #1 consists of using a K_{ow} and an appropriate FCM for estimating the baseline BAF_ℓ^{fd}. In this method, the K_{ow} is assumed to be equal to the baseline BCF_ℓ^{fd}. Numerous investigations have demonstrated a linear relationship between the logarithm of the BCF and the logarithm of the octanol-water partition coefficient (K_{ow}) for organic chemicals for fish and other aquatic organisms. Isnard and Lambert (1988) list various regression equations that illustrate this linear relationship. When the regression equations are constructed using lipid-normalized BCFs, the slopes and intercepts are not significantly different from one and zero, respectively (e.g., de Wolf, et al., 1992). The underlying assumption for the linear relationship between the BCF and K_{ow} is that the bioconcentration process can be viewed as the partitioning of a chemical between the lipid of the aquatic organisms and water and that the K_{ow} is a useful surrogate for this partitioning process (Mackay, 1982). To account for biomagnification, Procedure #1 requires the K_{ow} value be used in conjunction with an appropriate FCM.

NMED Exhibit 84

1. **Baseline BAF_{ℓ}^{fd} Equation.** For each acceptable K_{ow} value and FCM for the chemical of concern, calculate a baseline BAF_{ℓ}^{fd} using the following equation.

$$\text{Baseline } BAF_{\ell}^{fd} = (FCM) \cdot (K_{ow}) \qquad \text{(Equation 5-27)}$$

where:

Baseline BAF_{ℓ}^{fd}	=	BAF expressed on a freely dissolved and lipid-normalized basis for a given trophic level
FCM	=	The food chain multiplier for the appropriate trophic level obtained from Table 5-1 by linear interpolation or from appropriate field data (used with Procedure #1 only)
K_{ow}	=	Octanol-water partition coefficient

The BCF-K_{ow} relationship has been developed primarily for nonionic organic chemicals that are not readily metabolized by aquatic organisms and thus is most appropriate for poorly-metabolized nonionic organic chemicals (i.e., Procedures #1 and #3 as depicted in Figure 5-1). For poorly-metabolized nonionic organic chemicals with large log K_{ow}s (i.e., > 6), reported log BCFs are often not equal to log K_{ow}. EPA believes that this nonlinearity is primarily due to not accounting for several factors which affect the BCF determination. These factors include not basing BCFs on the freely dissolved concentration in water, not accounting for growth dilution, not assessing BCFs at steady-state, inaccuracies in measurements of uptake and elimination rate constants, and complications from the use of solvent carriers in the exposure. Application of Equation 5-27 for predicting BAFs has been conducted in several different ecosystems including Lake Ontario, the tidally influenced Bayou D'Inde in Louisiana, the Fox River and Green Bay, Wisconsin, and the Hudson River in New York. Additional detail on the validation, technical basis, assumptions, and uncertainty associated with Equation 5-27 and is provided in the Bioaccumulation TSD.

2. **FCMs and K_{ow}s**. Food chain multipliers and K_{ow} values should be selected as described previously in Procedure #1.

5.4.3.2 Selecting Final Baseline BAF_{ℓ}^{fd}s

After calculating individual baseline BAF_{ℓ}^{fd}s using as many of the methods in Procedure #1 as possible, the next step is to determine a final baseline BAF_{ℓ}^{fd} for each trophic level from the individual baseline BAF_{ℓ}^{fd}s (see Figures 5-1 and 5-2). The final baseline BAF_{ℓ}^{fd} will be used in the last step to determine the national BAF for each trophic level. The final baseline BAF_{ℓ}^{fd} for each trophic level should be determined from the individual baseline BAF_{ℓ}^{fd}s by considering the data preference hierarchy defined by Procedure #1 and uncertainty in the data. The data preference hierarchy for Procedure #1 is (in order of preference):

1. a baseline BAF_{ℓ}^{fd} from an acceptable field-measured BAF (method 1)

NMED Exhibit 84

2. a baseline BAF_{ℓ}^{fd} predicted from an acceptable field-measured BSAF (method 2),
3. a baseline BAF_{ℓ}^{fd} predicted from an acceptable BCF and FCM (method 3), or
4. a baseline BAF_{ℓ}^{fd} predicted from an acceptable K_{ow} and FCM (method 4).

This data preference hierarchy reflects EPA's preference for BAFs based on field-measurements of bioaccumulation (methods 1 and 2) over those based on laboratory-measurements and/or predictions of bioaccumulation (methods 3 and 4). However, this data preference hierarchy should not be considered inflexible. Rather, it should be used as a guide for selecting the final baseline BAF_{ℓ}^{fd}s when the uncertainty is similar among two or more baseline BAF_{ℓ}^{fd}s derived using different methods. The following steps and guidelines should be followed for selecting the final baseline BAF_{ℓ}^{fd}s using Procedure #1.

1. **Calculate Species-Mean Baseline BAF_{ℓ}^{fd}s.** For each BAF method where more than one acceptable baseline BAF_{ℓ}^{fd} is available for a given species, calculate a species-mean baseline BAF_{ℓ}^{fd} as the geometric mean of all available individual baseline BAF_{ℓ}^{fd}s. When calculating a species-mean baseline BAF_{ℓ}^{fd}, individual baseline BAF_{ℓ}^{fd}s should be reviewed carefully to assess the uncertainty in the BAF values. For highly hydrophobic chemicals applicable to Procedure #1, particular attention should be paid to whether sufficient spatial and temporal averaging of water and tissue concentrations was likely achieved in the BAF, BSAF, or BCF study. Highly uncertain baseline BAF_{ℓ}^{fd}s should not be used. Large differences in individual baseline BAF_{ℓ}^{fd}s for a given species (e.g., greater than a factor of 10) should be investigated further. In such cases, some or all of the baseline BAF_{ℓ}^{fd}s for a given species might not be used. Additional discussion on evaluating acceptability of BAF values is provided in the Bioaccumulation TSD.

2. **Calculate Trophic-Level-Mean Baseline BAF_{ℓ}^{fd}s.** For each BAF method where more than one acceptable species-mean baseline BAF_{ℓ}^{fd} is available within a given trophic level, calculate a trophic-level-mean baseline BAF_{ℓ}^{fd} as the geometric mean of acceptable species-mean baseline BAF_{ℓ}^{fd}s in that trophic level. Trophic-level-mean baseline BAF_{ℓ}^{fd}s should be calculated for trophic levels two, three, and four because available data on U.S. consumers of fish and shellfish indicate significant consumption of organisms in these trophic levels.

3. **Select a Final Baseline BAF_{ℓ}^{fd} for Each Trophic Level.** For each trophic level, select the final baseline BAF_{ℓ}^{fd} using best professional judgment by considering: (1) the data preference hierarchy shown previously, (2) the relative uncertainty in the trophic-level-mean baseline BAF_{ℓ}^{fd}s derived using different methods, and (3) the weight of evidence among the four methods.

    a. In general, when more than one trophic-level-mean baseline BAF_{ℓ}^{fd} is available for a given trophic level, the final trophic-level-mean baseline BAF_{ℓ}^{fd} should be selected from the most preferred BAF method defined by the data preference hierarchy for Procedure #1.

    b. If uncertainty in a trophic-level-mean baseline BAF based on a higher tier (more preferred) method is judged to be substantially greater than a trophic-level-mean

NMED Exhibit 84

baseline BAF from a lower tier method, and the weight of evidence among the various methods suggests that a BAF value from lower tier method is likely to be more accurate, then the final baseline BAF_{ℓ}^{fd} should be selected using a trophic level-mean baseline BAF_{ℓ}^{fd} from a lower tier method.

c. When considering the weight of evidence among the various BAF methods, greater confidence in the final baseline BAF_{ℓ}^{fd} is generally assigned when BAFs from a greater number of methods are in agreement for a given trophic level. However, lack of agreement among methods does not necessarily indicate less confidence if such disagreements can be adequately explained. For example, if the chemical of concern is metabolized by aquatic organisms represented by a BAF value, one would expect disagreement between a field-measured BAF (the highest priority data) and a predicted BAF using a K_{ow} and model-derived FCM. Thus, field-measured BAFs should generally be given the greatest weight among methods because they reflect direct measures of bioaccumulation and incorporate any metabolism which might occur in the organism and its food web.

d. The above steps should be performed for each trophic level until a final baseline BAF_{ℓ}^{fd} is selected for trophic levels two, three, and four.

5.4.3.3 Calculating National BAFs

The last step in deriving a national BAF for each trophic level is to convert the final baseline BAF_{ℓ}^{fd} determined in the previous step to a BAF that reflects conditions to which the national 304(a) criteria will apply (Figure 5-2). Since a baseline BAF_{ℓ}^{fd} is by definition normalized by lipid content and expressed on a freely dissolved basis, it needs to be adjusted to reflect the lipid fraction of aquatic organisms commonly consumed in the U.S. and the freely dissolved fraction expected in U.S. bodies of water. Converting a final baseline BAF_{ℓ}^{fd} to a national BAF requires information on: (1) the percent lipid of the aquatic organisms commonly consumed by humans, and (2) the freely dissolved fraction of the chemical of concern that would be expected in the ambient waters of interest. For each trophic level, a national BAF should be determined from a final baseline BAF_{ℓ}^{fd} according to the following guidelines.

1. **National BAF Equation.** For each trophic level, calculate a national BAF using the following equation.

$$\text{National BAF}_{(TL\ n)} = [(\text{Final Baseline BAF}_{\ell}^{fd})_{TL\ n} \cdot (f_{\ell})_{TL\ n} + 1] \cdot (f_{fd}) \qquad \text{(Equation 5-28)}$$

where:

Final Baseline BAF_{ℓ}^{fd} = Final trophic-level-mean baseline BAF expressed on a freely dissolved and lipid-normalized basis for trophic level "n"

NMED Exhibit 84

$f_{\ell(TL\ n)}$	=	Lipid fraction of aquatic species consumed at trophic level "n"
f_{fd}	=	Fraction of the total chemical in water that is freely dissolved

The technical basis of Equation 5-28 is provided in the Bioaccumulation TSD. Guidance for determining each component of Equation 5-28 is provided below.

2. **Determining the Final Baseline BAF_{ℓ}^{fd}.** The final trophic-level-mean baseline BAF_{ℓ}^{fd}s used in this equation are those which have been determined using the guidance presented in Section 5.4.3.2 for selecting the final baseline BAF_{ℓ}^{fd}s.

3. **Lipid Content of Commonly Consumed Aquatic Species.** As illustrated by Equation 5-28, the percent lipid of the aquatic species consumed by humans is needed to accurately characterize the potential exposure to a chemical from ingestion of aquatic organisms.

   a. **National Default Lipid Values.** For the purposes of calculating a national 304(a) criterion, the following national default values for lipid fraction should be used: 1.9% (for trophic level two organisms), 2.6% (for trophic level three organisms), and 3.0% (for trophic level four organisms).

      These national default values for lipid content reflect national per capita average patterns of fish consumption in the United States. Specifically, they were calculated using the consumption-weighted mean lipid content of commonly consumed fish and shellfish as identified by the USDA Continuing Survey of Food Intake by Individuals (CSFII) for 1994 through 1996. This same national survey data was used to derive national default values of fish consumption. To maintain consistency with the fish consumption assumptions, only freshwater and estuarine organisms were included in the derivation of the national default lipid values. Additional details on the technical basis, assumptions, and uncertainty in the national default values of lipid fraction are provided in the Bioaccumulation TSD.

      Although national default lipid values are used by EPA to set national 304(a) criteria, EPA encourages States and authorized Tribes to use local or regional data on lipid content of consumed aquatic species when adopting criteria into their water quality standards because local or regional consumption patterns (and lipid content) can differ from national consumption patterns. Additional guidance on developing site-specific values of lipid content, including a database of lipid content for many commonly consumed aquatic organisms, is found in the Bioaccumulation TSD.

4. **Freely Dissolved Fraction.** The third piece of information required for deriving a national BAF is the freely dissolved fraction of the chemical of concern that is expected

NMED Exhibit 84

in waters of the United States. As noted previously, expressing BAFs on the freely dissolved concentration in water allows a common basis for averaging BAFs from several studies. However, for use in criteria development, these BAFs should be converted back to values based on the total concentration in the water to be consistent with monitored water column and effluent concentrations, which are typically based on total concentrations of chemicals in the water. This should be done by multiplying the freely dissolved baseline BAF_{ℓ}^{fd} by the fraction of the freely dissolved chemical expected in water bodies of the United States where criteria are to be applied, as shown in Equation 5-29.

$$f_{fd} = \frac{1}{[1 + (POC \cdot K_{ow}) + (DOC \cdot 0.08 \cdot K_{ow})]} \qquad \text{(Equation 5-29)}$$

where:

POC	=	national default value for the particulate organic carbon concentration (kg/L)
DOC	=	national default value for the dissolved organic carbon concentration (kg/L)
K_{ow}	=	n-octanol water partition coefficient for the chemical

Equation 5-29 is identical to Equation 5-12, which was used to determine the freely dissolved fraction for deriving baseline BAF_{ℓ}^{fd}s from field-measured BAFs. However, the POC and DOC concentrations used in Equation 5-29 reflect those values that are expected in U.S. bodies of water, not the POC and DOC values in the study water used to derive the BAF. Guidance for determining each component of Equation 5-29 follows.

a. **National Default Values of POC and DOC.** For estimating the freely dissolved fraction of the chemical of concern that is expected in U.S. water bodies, national default values of 0.5 mg/L (5×10^{-7} kg/L) for POC and 2.9 mg/L (2.9×10^{-6} kg/L) for DOC should be used. These values are 50th percentile values (medians) based on an analysis of over 110,000 DOC values and 85,000 POC values contained in EPA's STORET database from 1980 through 1999. These default values reflect a combination of values for streams, lakes and estuaries across the United States. Additional details on the technical basis, assumptions, and uncertainty in the derivation and application of the national default values of POC and DOC are provided in the Bioaccumulation TSD.

   Although national default values of POC and DOC concentrations are used by EPA to set national 304(a) criteria as described by this document, EPA encourages States and authorized Tribes to use local or regional data on POC and DOC when adopting criteria into their water quality standards. EPA encourages States and Tribes to consider local or regional data on POC and DOC because local or regional conditions may result in differences in POC or DOC

NMED Exhibit 84

concentrations compared with the values used as national defaults. Additional guidance on developing local or regional values of POC and DOC, including a database of POC and DOC values segregated by waterbody type, is found in the Bioaccumulation TSD.

b. **K_{ow} Value.** The value selected for the K_{ow} of the chemical of concern should be the same value used in earlier calculations (e.g., for calculating baseline BAF_{ℓ}^{fd}s and FCMs). Guidance for selecting the K_{ow} value is found in the Bioaccumulation TSD.

5.4.4 Deriving National BAFs Using Procedure #2

This section provides guidance for calculating national BAFs for nonionic organic chemicals using Procedure #2 shown in Figure 5-1. The types of nonionic organic chemicals for which Procedure #2 is most appropriate are those that are classified as moderately to highly hydrophobic and subject to high rates of metabolism by aquatic biota (see Section 5.4.2 above). Non-aqueous contaminant exposure and subsequent biomagnification in aquatic food webs are not generally of concern for chemicals that are classified in this category. As a result, FCMs are not used in this procedure. In addition, K_{ow} -based predictions of bioconcentration are not used in this procedure since the K_{ow} /BCF relationship is primarily based on poorly metabolized chemicals. Some nonionic organic chemicals for which Procedure #2 is probably appropriate include certain PAHs which are believed to be metabolized substantially by fish (e.g., benzo[a]pyrene, phenanthrene, fluoranthene, pyrene, benzo[a]anthracene and chrysene/triphenylene; USEPA, 1980; Burkhard and Lukasewycz, 2000).

According to Procedure #2, the following three methods can be used in deriving a national BAF:

- using a BAF from an acceptable field study (i.e., a field-measured BAF) (method 1),
- predicting a BAF from an acceptable BSAF (method 2), and
- predicting a BAF from an acceptable BCF (method 3).

Each of these three methods relies on measured data for assessing bioaccumulation and therefore, includes the effects of chemical metabolism by the study organism in the BAF estimate. The field-measured BAF and BSAF methods also incorporate any metabolism which occurs in the aquatic food web.

As shown in Figure 5-2, the next steps in deriving a national BAF after selecting the derivation procedure are: (1) calculating individual baseline BAF_{ℓ}^{fd}s, (2) selecting the final baseline BAF_{ℓ}^{fd}s, and (3) calculating the national BAFs. Each of these three steps is discussed separately below.

5.4.4.1 Calculating Individual Baseline BAF_{ℓ}^{fd}s

As described previously in Procedure #1, calculating individual baseline BAF_{ℓ}^{fd}s involves normalizing the measured BAF_{T}^{t} or BCF_{T}^{t} (which are based on the total chemical in water and

NMED Exhibit 84

tissue) by the lipid content of the study organisms and the freely dissolved fraction of the chemical in the study water. Converting measured BAF_T^t (or BCF_T^t) values to baseline BAF_ℓ^{fd} (or BCF_ℓ^{fd}) values is designed to account for variation in measured BAF_T^ts that is caused by differences in lipid content of study organisms and differences in the freely dissolved fraction of chemical in study waters. Therefore, baseline BAF_ℓ^{fd}s are considered more amenable for extrapolating and averaging BAFs across different species and different study waters compared with total BAF_T^ts.

1. For each species where acceptable data are available, calculate all possible baseline BAF_ℓ^{fd}s using each of the three methods shown above for Procedure #2.

2. Individual baseline BAF_ℓ^{fd}s should be calculated from field-measured BAF_T^ts, field-measured BSAFs, and laboratory BCF_T^ts according to the following procedures.

A. Baseline BAF_ℓ^{fd} from Field-Measured BAFs

1. Except where noted below, a baseline BAF_ℓ^{fd} should be calculated from a field-measured BAF_T^t using the guidance and equations outlined in Section 5.4.3.1(A) for determining baseline BAF_ℓ^{fd}s from field-measured BAFs in Procedure #1.

2. Because nonionic organic chemicals applicable to Procedure #2 have relatively high rates of metabolism in aquatic organisms, they will tend to reach steady state more quickly than nonionic organic chemicals with similar K_{ow} values but which undergo little or no metabolism. Therefore, less temporal averaging of chemical concentrations would generally be required for determining field-measured BAF_T^ts with highly metabolizable chemicals compared with chemicals that are poorly metabolized by aquatic biota.

NMED Exhibit 84

B. Baseline BAF_{ℓ}^{fd} Derived from Field-measured BSAFs

1. A baseline BAF_{ℓ}^{fd} should be calculated from a field-measured BSAF using the guidance and equations outlined in Section 5.4.3.1(B) for determining baseline BAF_{ℓ}^{fd}s from field-measured BSAFs in Procedure #1.

C. Baseline BAF_{ℓ}^{fd} from a Laboratory-Measured BCF

1. Except where noted below, a baseline BAF_{ℓ}^{fd} should be calculated from a laboratory-measured BCF_{T}^{t} using the guidance and equations outlined in Section 5.4.3.1(c) for determining baseline BAF_{ℓ}^{fd}s from a laboratory-measured BCF and FCM in Procedure #1.

2. Because biomagnification is not an overriding concern for nonionic organic chemicals applicable to Procedure #2, food chain multipliers are not used in the derivation of a baseline BAF_{ℓ}^{fd} from a laboratory-measured BCF_{T}^{t} .

5.4.4.2 Selecting Final Baseline BAF_{ℓ}^{fd}s

After calculating individual, baseline BAF_{ℓ}^{fd}s using as many of the methods in Procedure #2 as possible, the next step is to determine a final baseline BAF_{ℓ}^{fd} for each trophic level from the individual baseline BAF_{ℓ}^{fd}s. The final baseline BAF_{ℓ}^{fd} will be used in the last step to determine the national BAF for each trophic level. A final baseline BAF_{ℓ}^{fd} for each trophic level should be determined from the individual baseline BAF_{ℓ}^{fd}s by considering the data preference hierarchy defined by Procedure #2 and uncertainty in the data. The data preference hierarchy for Procedure #2 is (in order of preference):

1. a baseline BAF_{ℓ}^{fd} from an acceptable field-measured BAF (method 1),
2. a baseline BAF_{ℓ}^{fd} from an acceptable field-measured BSAF (method 2), or
3. a baseline BAF_{ℓ}^{fd} from an acceptable laboratory-measured BCF (method 3).

This data preference hierarchy reflects EPA's preference for BAFs based on field-measurements of bioaccumulation (methods 1 and 2) over those based on laboratory-measurements (method 3). However, as explained in Procedure #1, this data preference hierarchy should not be considered inflexible. Rather, it should be used as a guide for selecting the final baseline BAF_{ℓ}^{fd}s when the underlying uncertainty is similar among two or more baseline BAF_{ℓ}^{fd}s derived using different methods. Although biomagnification is not generally a concern for chemicals subject to Procedure #2, trophic level differences in bioaccumulation might be substantial to the extent that the rate of chemical metabolism by organisms in different trophic levels differs. For example, certain PAHs have been shown to be metabolized to a much greater extent by some fish compared with some invertebrate species (James, 1989). Therefore, final baseline BAF_{ℓ}^{fd}s for chemicals applicable to Procedure #2 should be determined on a trophic-level-specific basis according to the following guidelines.

1. The final baseline BAF_{ℓ}^{fd}s in Procedure #2 should be selected according to the same steps described in Procedure #1 but with the substitution of the data preference hierarchy described above for Procedure #2. Specifically, the species-mean baseline BAF_{ℓ}^{fd}s,

NMED Exhibit 84

trophic-level-mean baseline BAF_{ℓ}^{fd}s, and the final baseline BAF_{ℓ}^{fd}s should be determined according to the guidelines presented in Procedure #1 (Section 5.4.3.2, Steps 1, 2, and 3).

5.4.4.3 Calculating the National BAFs

As described in Procedure #1, the last step in deriving national BAFs for nonionic organic chemicals is to convert the final baseline BAF_{ℓ}^{fd}s determined in the previous step to BAFs which reflect conditions to which the national 304(a) criteria will apply (Figure 5-2).

1. For trophic levels two, three, and four, national BAFs should be calculated from the final baseline BAF_{ℓ}^{fd}s using the same equation and procedures described previously in Procedure #1 (see Section 5.4.3.3 entitled "Calculating the National BAFs").

5.4.5 Deriving National BAFs Using Procedure #3

This section provides guidance for calculating national BAFs for nonionic organic chemicals using Procedure #3 shown in Figure 5-1. The types of nonionic organic chemicals for which Procedure #3 is most appropriate are those that are classified as low in hydrophobicity (i.e., log K_{ow} values less than 4.0) and subject to low (or unknown) rates of metabolism by aquatic biota (see Section 5.4.2 above). Non-aqueous contaminant exposure and subsequent biomagnification in aquatic food webs are not generally of concern for chemicals that are classified in this category (Fisk et al., 1998; Gobas et al., 1993; Connolly and Pedersen, 1988; Thomann, 1989). As a result, FCMs are not used in this procedure.

According to Procedure #3, the following three methods can be used in deriving a national BAF:

- using a BAF from an acceptable field study (i.e., a field-measured BAF),
- predicting a BAF from an acceptable laboratory-measured BCF, and
- predicting a BAF from an acceptable K_{ow}.

After selecting the derivation procedure, the next steps in deriving a national BAF at a given trophic level for nonionic organic chemicals are: (1) calculating individual baseline BAF_{ℓ}^{fd}s, (2) selecting the final baseline BAF_{ℓ}^{fd}, and (3) calculating the national BAF (Figure 5-2). Each of these three steps is discussed separately below.

5.4.5.1 Calculating Individual Baseline BAF_{ℓ}^{fd}s

Calculating individual baseline BAF_{ℓ}^{fd}s involves normalizing each measured BAF_{T}^{t} or BCF_{T}^{t} (which are based on the total chemical in water and tissue) by the lipid content of the study organism and the freely dissolved fraction of the chemical in the study water. For additional discussion of the technical basis for calculating baseline BAF_{ℓ}^{fd}s, see Section 5.4.3.1 in Procedure #1.

NMED Exhibit 84

1. For each species where acceptable data are available, calculate all possible baseline BAF_{ℓ}^{fd}s using each of the three methods shown above for Procedure #3.

2. An individual baseline BAF_{ℓ}^{fd} should be calculated from field-measured BAF_{T}^{t}s, laboratory-measured BCF_{T}^{t}s, and K_{ow} values according to the following procedures.

A. Baseline BAF_{ℓ}^{fd} from Field-Measured BAFs

1. Except where noted below, a baseline BAF_{ℓ}^{fd} should be calculated from a field-measured BAF_{T}^{t} using the guidance and equations outlined in Section 5.4.3.1(A) in Procedure #1.

2. **Freely Dissolved Fraction**. Due to their low hydrophobicity (i.e., log $K_{ow} < 4.0$), nonionic organic chemicals applicable to Procedure #3 are expected to remain almost entirely in the freely dissolved form in natural waters with dissolved and particulate organic carbon concentrations typical of most field BAF studies. Therefore, the freely dissolved fraction should be assumed to be equal to 1.0, unless the concentrations of DOC and POC are very high in the field BAF study. For studies with very high DOC or POC concentrations, (e.g., about 100 mg/L or higher for DOC or 10 mg/L or higher for POC), the freely dissolved fraction may be substantially lower than 1.0 and therefore should be calculated using Equation 5-12.

3. **Temporal Averaging of Concentrations.** Also due to their low hydrophobicity, nonionic organic chemicals appropriate to Procedure #3 will also tend to reach steady state quickly compared with those chemicals to which Procedure #1 applies. Therefore, the extent of temporal averaging of tissue and water concentrations is typically much less than that required for highly hydrophobic chemicals to which Procedure #1 is applied. In addition, field studies used to calculate BAFs for these chemicals should have sampled water and tissue at similar points in time because tissue concentrations respond more rapidly to changes in water concentrations. EPA will be providing additional guidance on appropriate BAF study designs for nonionic organic chemicals (including those appropriate to Procedure #3) in its forthcoming guidance document on conducting field BAF and BSAF studies.

B. Baseline BAF_{ℓ}^{fd} from a Laboratory-Measured BCF

1. Except where noted below, a baseline BAF_{ℓ}^{fd} should be calculated from a laboratory-measured BCF_{T}^{t} using the guidance and equations outlined in Section 5.4.3.1(c) of Procedure #1.

2. **Food Chain Multipliers.** Because biomagnification is not an overriding concern for the minimally hydrophobic chemicals applicable to Procedure #3, FCMs are not used in the derivation of a baseline BAF_{ℓ}^{fd} from a laboratory-measured BCF_{T}^{t}.

3. **Freely Dissolved Fraction**. Due to their low hydrophobicity (i.e., log $K_{ow} < 4.0$), nonionic organic chemicals to which Procedure #3 is applied are expected to remain

NMED Exhibit 84

almost entirely in the freely dissolved form in waters containing dissolved and particulate organic carbon concentrations typical of laboratory BCF studies. Therefore, the freely dissolved fraction should usually be assumed equal to 1.0. The freely dissolved fraction will be substantially less than 1.0 only in situations where unusually high concentrations of DOC and POC are present in the laboratory BCF study (e.g., above about 100 mg/L for DOC or about 10 mg/L for POC). In this situation, the freely dissolved fraction should be calculated according to Equation 5-12.

C. Baseline BAF_{ℓ}^{fd} from a K_{ow}

1. Except where noted below, a baseline BAF_{ℓ}^{fd} should be calculated from an acceptable K_{ow} using the guidance and equations outlined in Section 5.4.3.1(D) in Procedure #1.

2. Because biomagnification is not an overriding concern for nonionic organic chemicals with low hydrophobicity (i.e., log K_{ow} < 4.0), food chain multipliers are not used in Procedure #3 for deriving the baseline BAF_{ℓ}^{fd} from a K_{ow}.

5.4.5.2 Selecting Final Baseline BAF_{ℓ}^{fd}s

After calculating individual baseline BAF_{ℓ}^{fd}s using as many of the methods in Procedure #3 as possible, the next step is to determine a final baseline BAF_{ℓ}^{fd} for each trophic level from the individual baseline BAF_{ℓ}^{fd}s (Figure 5-2). The final baseline BAF_{ℓ}^{fd} will be used in the last step to determine the national BAF for each trophic level. The final baseline BAF_{ℓ}^{fd} for each trophic level should be determined from the individual baseline BAF_{ℓ}^{fd}s by considering the data preference hierarchy defined by Procedure #3 and uncertainty in the data. The data preference hierarchy for Procedure #3 is (in order of preference):

1. a baseline BAF_{ℓ}^{fd} from an acceptable field-measured BAF or laboratory-measured BCF, or
2. a baseline BAF_{ℓ}^{fd} predicted from an acceptable K_{ow} value.

This data preference hierarchy reflects EPA's preference for BAFs that are based on measured data (field-measured BAFs and laboratory-measured BCFs) over BAFs based on predictive methods (K_{ow}). This data preference hierarchy should be used as a guide for selecting the final baseline BAF_{ℓ}^{fd}s when the uncertainty is similar among two or more baseline BAF_{ℓ}^{fd}s derived using different methods. Since bioaccumulation via dietary uptake and subsequent biomagnification generally are not of concern for chemicals subject to Procedure #3, field-measured BAFs and laboratory-measured BCFs are considered equally in determining the national BAF.

Final baseline BAF_{ℓ}^{fd}s should be selected for each trophic level using the following steps and guidelines.

1. **Calculate Species-Mean Baseline BAF_{ℓ}^{fd}s.** For each BAF method (i.e., field-measured BAF, BAF from a lab-measured BCF, or BAF from a K_{ow}) where more than one

NMED Exhibit 84

acceptable baseline BAF_{ℓ}^{fd} is available for a given species, calculate a species-mean baseline BAF_{ℓ}^{fd} according to the guidance described previously in Procedure #1.

2. **Calculate Trophic-Level-Mean Baseline BAF_{ℓ}^{fd}s.** For each BAF method where more than one acceptable species-mean baseline BAF_{ℓ}^{fd} is available within a given trophic level, calculate the trophic-level-mean baseline BAF_{ℓ}^{fd} as the geometric mean of acceptable species-mean baseline BAF_{ℓ}^{fd}s in that trophic level.

3. **Select a Final Baseline BAF_{ℓ}^{fd} for Each Trophic Level.** For each trophic level, select the final baseline BAF_{ℓ}^{fd} using best professional judgment by considering: (1) the data preference hierarchy, (2) the relative uncertainties among trophic-level-mean baseline BAF_{ℓ}^{fd}s derived using different methods, and (3) the weight of evidence among the three methods.

   a. In general, when more than one trophic-level-mean baseline BAF_{ℓ}^{fd} is available within a given trophic level, the final baseline BAF_{ℓ}^{fd} should be selected from the most preferred BAF method defined by the data preference hierarchy for Procedure #3. Within the first data preference tier, field-measured BAFs and laboratory-measured BCFs are considered equally desirable for deriving a final trophic-level-mean baseline BAF_{ℓ}^{fd} using Procedure #3. If a trophic-level-mean baseline BAF_{ℓ}^{fd} is available from both a field-measured BAF and a laboratory-measured BCF, the final baseline BAF_{ℓ}^{fd} should be selected using the trophic-level-mean baseline BAF_{ℓ}^{fd} or BCF_{ℓ}^{fd} with the least overall uncertainty.

   b. If uncertainty in a trophic-level-mean baseline BAF_{ℓ}^{fd} based on a higher tier (more preferred) method is judged to be substantially greater than a trophic-level-mean baseline BAF_{ℓ}^{fd} from a lower tier method, then the final baseline BAF_{ℓ}^{fd} should be selected using a trophic-level-mean baseline BAF_{ℓ}^{fd} from a lower tier method.

   c. The above steps should be performed for each trophic level until a final baseline BAF_{ℓ}^{fd} is selected for trophic level two, three, and four.

5.4.5.3 Calculating the National BAFs

As described in Procedure #1, the last step in deriving a national BAF for a given trophic level for nonionic organic chemicals is to convert the final baseline BAF_{ℓ}^{fd} determined in the previous step to a BAF that reflect conditions to which the national 304(a) criterion will apply (Figure 5-2). Each national BAF should be determined from a final baseline BAF_{ℓ}^{fd} according to the following guidelines.

1. **National BAF Equation.** Except where noted below, national BAFs for trophic levels two, three, and four should be calculated from the final, trophic-level-mean baseline BAF_{ℓ}^{fd}s using Equation 5-28 and associated guidance described in Procedure #1 (see Section 5.4.3.3).

NMED Exhibit 84

2. **Freely Dissolved Fraction**. Due to their low hydrophobicity (i.e., log K_{ow} < 4.0), a freely dissolved fraction of 1.0 should be assumed for calculating national BAFs for nonionic organic chemicals using Procedure #3. A freely dissolved fraction of 1.0 should be assumed because at a log K_{ow} of less than 4.0, nonionic organic chemicals are expected to remain over 99 percent in the freely dissolved form at POC and DOC concentrations corresponding to national default values for U.S. bodies of water (i.e., 0.5 mg/L and 2.9 mg/L, respectively).

5.4.6 Deriving National BAFs Using Procedure #4

This section provides guidance for calculating national BAFs for nonionic organic chemicals using Procedure #4 shown in Figure 5-1. The types of nonionic organic chemicals for which Procedure #4 is most appropriate are those that are classified as having low hydrophobicity and subject to high rates of metabolism by aquatic biota (see Section 5.4.2 above). Non-aqueous contaminant exposure and subsequent biomagnification in aquatic food webs are not generally of concern for chemicals that are classified in this category. As a result, FCMs are not used in this procedure. In addition, K_{ow} -based predictions of bioconcentration are not used in this procedure since the K_{ow} /BCF relationship is primarily based on poorly metabolized chemicals. One example of a nonionic organic chemical for which Procedure #4 appears appropriate is butyl benzyl phthalate in fish. Using radiolabeling techniques with confirmation by chromatographic analysis, Carr et al. (1997) present evidence that indicates butyl benzyl phthalate is extensively metabolized in sunfish. Carr et al. (1997) also report measured BCFs (and subsequently lipid-normalized BCFs) which are substantially below predicted BCFs based on log $K_{ow.}$ In a study of chlorinated anilines (which would be essentially un-ionized at ambient pH), de Wolf et al. (1992) reported measured BCFs substantially lower than those predicted based on K_{ow}. The authors suggested that biotransformation (metabolism) involving the amine (NH_2) was responsible for the lower measured BCFs.

According to Procedure #4, the following two methods can be used in deriving a national BAF:

- using a BAF from an acceptable field study (i.e., a field-measured BAF), and
- predicting a BAF from an acceptable BCF.

After selecting the derivation procedure, the next steps in deriving a national BAF for a given trophic level for nonionic organic chemicals are: (1) calculating individual baseline BAF_{ℓ}^{fd}s, (2) selecting the final baseline BAF_{ℓ}^{fd}, and (3) calculating the national BAF (Figure 5-2). Each of these three steps is discussed separately below.

5.4.6.1 Calculating Individual Baseline BAF_{ℓ}^{fd}s

Calculating individual baseline BAF_{ℓ}^{fd}s involves normalizing the measured BAF_T^t or BCF_T^t (which are based on the total chemical in water and tissue) by the lipid content of the study organism and the freely dissolved fraction of the chemical in the study water. For additional discussion of the technical basis for calculating baseline BAF_{ℓ}^{fd}s, see Section 5.4.3.1 in Procedure #1.

NMED Exhibit 84

1. For each species where acceptable data are available, calculate all possible baseline BAF_{ℓ}^{fd}s using each of the two methods shown above for Procedure #4.

2. Individual baseline BAF_{ℓ}^{fd}s should be calculated from field-measured BAF_{T}^{t}s and laboratory-measured BCF_{T}^{t}s according to the following procedures.

A. Baseline BAF_{ℓ}^{fd} from Field-Measured BAFs

1. A baseline BAF_{ℓ}^{fd} should be calculated from a field-measured BAF_{T}^{t} using the guidance and equations outlined in Section 5.4.3.1(A) in Procedure #1.

2. **Freely Dissolved Fraction**. Due to their low hydrophobicity (i.e., log K_{ow} < 4.0), nonionic organic chemicals applicable to Procedure #4 are expected to remain almost entirely in the freely dissolved form in natural waters with dissolved and particulate organic carbon concentrations typical of most field BAF studies. Therefore, the freely dissolved fraction should be assumed equal to 1.0 unless the concentrations of DOC and POC are very high in the field BAF study. For studies with very high DOC or POC concentrations, (e.g., about 100 mg/L or higher for DOC or 10 mg/L or higher for POC), the freely dissolved fraction may be substantially lower than 1.0 and therefore should be calculated using Equation 5-12.

3. **Temporal Averaging of Concentrations.** Also due to their low hydrophobicity, nonionic organic chemicals appropriate to Procedure #4 will also tend to reach steady-state quickly compared with those chemicals to which Procedure #1 applies. Therefore, the extent of temporal averaging of tissue and water concentrations is typically much less than that required for highly hydrophobic chemicals to which Procedure #1 is applied. In addition, field studies used to calculate BAFs for these chemicals should have sampled water and tissue at similar points in time because tissue concentrations should respond rapidly to changes in water concentrations. EPA will be providing additional guidance on appropriate BAF study designs for nonionic organic chemicals (including those appropriate to Procedure #4) in its forthcoming guidance document on conducting field BAF and BSAF studies.

B. Baseline BAF_{ℓ}^{fd} from a Laboratory-Measured BCF

1. Except where noted below, a baseline BAF_{ℓ}^{fd} should be calculated from a laboratory-measured BCF_{T}^{t} using the guidance and equations outlined in Section 5.4.3.1(c) of Procedure #1.

2. **Food Chain Multipliers.** Because biomagnification is not an important concern for the minimally hydrophobic chemicals applicable to Procedure #4, FCMs are not used in the derivation of a baseline BAF_{ℓ}^{fd} from a laboratory-measured BCF_{T}^{t}.

3. **Freely Dissolved Fraction**. Due to their low hydrophobicity (i.e., log K_{ow} < 4.0), nonionic organic chemicals to which Procedure #4 is applied are expected to remain

NMED Exhibit 84

almost entirely in the freely dissolved form in waters containing dissolved and particulate organic carbon concentrations typical of laboratory BCF studies. Therefore, the freely dissolved fraction should usually be assumed to be equal to 1.0. The freely dissolved fraction will be substantially less than 1.0 only in situations where unusually high concentrations of DOC and POC are present in the lab BCF study (e.g., above about 100 mg/L for DOC or about 10 mg/L for POC). In this situation, the freely dissolved fraction should be calculated according to Equation 5-12.

5.4.6.2 Selecting Final Baseline BAF_{ℓ}^{fd}s

After calculating individual baseline BAF_{ℓ}^{fd}s using as many of the methods in Procedure #4 as possible, the next step is to determine a final baseline BAF_{ℓ}^{fd} for a given trophic level from the individual baseline BAF_{ℓ}^{fd}s (Figure 5-2). The final baseline BAF_{ℓ}^{fd} will be used in the last step to determine the national BAF for each trophic level. A final baseline BAF_{ℓ}^{fd} should be determined for each trophic level from the individual baseline BAF_{ℓ}^{fd}s by considering the data preference hierarchy defined by Procedure #4 and uncertainty in the data. The data preference hierarchy for Procedure #4 is:

1. a baseline BAF_{ℓ}^{fd} from an acceptable field-measured BAF or predicted from an acceptable laboratory-measured BCF.

Since bioaccumulation via dietary uptake and subsequent biomagnification generally are not of concern for chemicals subject to Procedure #4, field-measured BAFs and laboratory-measured BCFs are considered equally in determining the national BAF.

Final baseline BAF_{ℓ}^{fd}s should be selected for each trophic level using the following steps and guidelines.

1. **Calculate Species-Mean Baseline BAF_{ℓ}^{fd}s.** For each BAF method (i.e., field-measured BAF or a BAF from a lab-measured BCF) where more than one acceptable baseline BAF_{ℓ}^{fd} is available for a given species, calculate a species-mean baseline BAF_{ℓ}^{fd} according to the guidance described previously in Procedure #1.

2. **Calculate Trophic-Level-Mean Baseline BAF_{ℓ}^{fd}s.** For each BAF method where more than one acceptable species-mean baseline BAF_{ℓ}^{fd} is available within a given trophic level, calculate the trophic-level-mean baseline BAF_{ℓ}^{fd} as the geometric mean of acceptable species-mean baseline BAF_{ℓ}^{fd}s for that trophic level.

3. **Select a Final Baseline BAF_{ℓ}^{fd} for Each Trophic Level.** For each trophic level, select the final baseline BAF_{ℓ}^{fd} using best professional judgment by considering: (1) the data preference hierarchy, and (2) the relative uncertainties among trophic-level-mean BAFs derived using different methods.

    a. As discussed above, field-measured BAFs and laboratory-measured BCFs are considered equally desirable for deriving a final trophic-level-mean baseline

NMED Exhibit 84

BAF_{ℓ}^{fd} using Procedure #4. If a trophic-level-mean baseline BAF_{ℓ}^{fd} is available from both a field-measured BAF and a laboratory-measured BCF, the final baseline BAF_{ℓ}^{fd} should be selected using the trophic-level-mean baseline BAF_{ℓ}^{fd} or BCF_{ℓ}^{fd} with the least overall uncertainty.

b. The above steps should be performed for each trophic level until a final baseline BAF_{ℓ}^{fd} is selected for trophic levels two, three, and four.

5.4.6.3 Calculating National BAFs

As described in Procedure #1, the last step in deriving a national BAF for a given trophic level for nonionic organic chemicals is to convert the final baseline BAF_{ℓ}^{fd} determined in the previous step to a BAF that reflects conditions to which the national 304(a) criterion will apply (Figure 5-2). Each national BAF should be determined from a final baseline BAF_{ℓ}^{fd} according to the following guidelines.

1. **National BAF Equation.** Except where noted below, national BAFs for trophic-levels two, three, and four should be calculated from the final, trophic-level-mean baseline BAF_{ℓ}^{fd}s using the same equation and procedures described previously in Procedure #1 (see Section 5.4.3.3 in Procedure #1).

2. **Freely Dissolved Fraction**. Due to their low hydrophobicity (i.e., log $K_{ow} < 4.0$), a freely dissolved fraction of 1.0 should be assumed for calculating national BAFs for nonionic organic chemicals using Procedure #4. A freely dissolved fraction of 1.0 should be assumed because at a log K_{ow} value of less than 4.0, nonionic organic chemicals are expected to remain over 99 percent in the freely dissolved form at POC and DOC concentrations corresponding to national default values for U.S. bodies of water (i.e., 0.5 mg/L and 2.9 mg/L, respectively).

5.5 NATIONAL BIOACCUMULATION FACTORS FOR IONIC ORGANIC CHEMICALS

This section contains guidelines for deriving national BAFs for ionic organic chemicals (i.e., organic chemicals which undergo significant ionization in water). As defined in Section 5.3.5, ionic organic chemicals contain functional groups which can either readily donate protons (e.g., organic acids with hydroxyl, carboxylic, and sulfonic groups) or readily accept protons (e.g., organic bases with amino and aromatic heterocyclic nitrogen groups). Some examples of ionic organic compounds include:

- chlorinated phenols (e.g., 2,4,6-trichlorophenol, pentachlorophenol),
- chlorinated phenoxyalkanoic acids (e.g., 2,4-dichlorophenoxyacetic acid [2,4-D]),
- nitrophenols (e.g., 2-nitrophenol, 2,4,6-trinitrophenol),
- cresols (e.g., 2,4-dinitro-*o*-cresol [DNOC]),
- pyridines (e.g., 2,4-dimethypyidine),
- aliphatic and aromatic amines (e.g., trimethylamine, aniline), and

NMED Exhibit 84

- linear alkylbenzenesulfonate (LAS) surfactants.

Ionic organic chemicals are considered separately for deriving national BAFs because the anionic or cationic species of these chemicals behave much differently in the aquatic environment compared with their neutral (un-ionized) counterparts. The neutral species of ionic organic chemicals are thought to behave in a similar manner as nonionic organic compounds (e.g., partitioning to lipids and organic carbon as a function of hydrophobicity). However, the ionized (cationic, anionic) species exhibit a considerably more complex behavior involving multiple environmental partitioning mechanisms (e.g., ion exchange, electrostatic, and hydrophobic interactions) and a dependency on pH and other factors including ionic strength and ionic composition (Jafvert et al., 1990; Jafvert 1990; Schwarzenbach, et al., 1993). As a consequence, methods to predict the environmental partitioning of organic cations and anions are less developed and validated compared with methods for nonionic organic chemicals (Spacie, 1994; Suffet et al., 1994).

Given the current limitations in the state of the science for predicting the partitioning and bioaccumulation of the ionized species of ionic organic chemicals, procedures for deriving national BAFs for these chemicals differ depending on the extent to which the fraction of the total chemical is likely to be represented by the ionized (cationic, anionic) species in U.S. surface waters. When a significant fraction of the total chemical concentration is expected to be present as the ionized species in water, procedures for deriving the national BAF rely on empirical (measured) methods (i.e., Procedures #5 and 6 in Section 5.6). When an insignificant fraction of the total chemical is expected to be present as the ionized species (i.e., the chemical exists essentially in the neutral form), procedures for deriving the national BAF will follow those established for nonionic organic chemicals (e.g., Procedures #1 through #4 in Section 5.4). The following guidelines apply for assessing the occurrence of cationic and anionic forms at typical environmental pH ranges.

1. For the ionic organic chemical of concern, the dissociation constant, pK_a, should be compared to the range of pH values expected in fresh and estuarine waters of the U.S. At pH equal to the pK_a, 50% of the organic acid or base is expected to be present in the ionized species. The pH values for U.S. fresh and estuarine waters typically range between 6 and 9, although somewhat higher and lower values can occur in some bodies of water (e.g., acidic bogs and lakes, highly alkaline and eutrophic systems, etc.).

2. For organic acids, the chemical will exist almost entirely in its un-ionized form when pH is about 2 or more units below the pK_a. For organic bases, the chemical will exist almost entirely in its un-ionized form when pH is about 2 or more units above the pK_a. In these cases, the aqueous behavior of the chemical would be expected to be similar to nonionic organic chemicals. Therefore, national BAF should usually be derived using Procedures #1 through #4 in Section 5.4.

3. When pH is greater than the pK_a minus 2 for organic acids (or less than the pKa plus 2 for organic bases), the fraction of the total chemical that is expected to exist in its ionized form can become significant (i.e., $\geq$1% in the ionized). In these cases, the national BAF should usually be derived using Procedures #5 and #6 in Section 5.6.

NMED Exhibit 84

4. In general, most organic acids (e.g., pentachlorophenol and silvex), exist primarily in the ionized form in ambient waters because their pK_a's (4.75 and 3.07, respectively) are much smaller than the pH of the ambient waters. Conversely, most organic bases, (e.g., aniline) exist mostly in the un-ionized form in ambient waters because their pK_a's (4.63 for aniline) are much smaller than the pH of the ambient waters.

5. The above guidelines are intended to be a general guide for deriving national BAFs for ionic organic chemicals, not an inflexible rule. Modifications to these guidelines should be considered on a case-by-case basis, particularly when such modifications are strongly supported by measured bioaccumulation or bioconcentration data. For example, initial models have been developed for predicting the solid and organic-phase partitioning of certain organic acids (e.g., Jafvert 1990, Jafvert et al., 1990). As these or other models become more fully developed and appropriately validated in the future, they should be considered in the development of national BAFs. In addition, since pH is a controlling factor for dissociation and subsequent partitioning of ionic organic chemicals, consideration should be given to expressing BAFs or BCFs as a function of pH (or other factors) where sufficient data exist to reliably establish such relationships.

NMED Exhibit 84

5.6 NATIONAL BIOACCUMULATION FACTORS FOR INORGANIC AND ORGANOMETALLIC CHEMICALS

This section contains guidelines for deriving national BAFs for inorganic and organometallic chemicals as defined in Section 5.3.5. The derivation of BAFs for inorganic and organometallic chemicals differs in several ways from procedures for nonionic organic chemicals. First, lipid normalization of chemical concentrations in tissues does not generally apply for inorganic and organometallic chemicals. Thus, BAFs and BCFs cannot be extrapolated from one tissue to another based on lipid-normalized concentrations as is done for nonionic organic chemicals. Second, the bioavailability of inorganics and organometallics in water tends to be chemical-specific and thus, the techniques for expressing concentrations of nonionic organic chemicals based on the freely dissolved form do not generally apply. Third, at the present time there are no generic bioaccumulation models that can be used to predict BAFs for inorganic and organometallic chemicals as a whole, unlike the existence of K_{ow}-based models for nonionic organic chemicals. While some chemical-specific bioaccumulation models have been developed for inorganic and organometallic chemicals (e.g., Mercury Cycling Model by Hudson et. al, 1994), those models currently tend to require site-specific data for input to the model and are restricted to site-specific applications. As the models become more fully developed and validated in the future, they should be considered on a case-by-case basis in conjunction with the following procedures for deriving national BAFs.

5.6.1 Selecting the BAF Derivation Procedure

As shown in Figure 5-1, national BAFs can be derived using two procedures for inorganic and organometallic chemicals (Procedures #5 and #6). The choice of the BAF derivation procedure depends on whether or not the chemical undergoes biomagnification in aquatic food webs.

1. For many inorganic and organometallic chemicals, biomagnification does not occur and the BCF will be equal to the BAF. For these types of chemicals, Procedure #5 should be used to derive the national BAF. Procedure #5 considers BAFs and BCFs to be of equal value in determining the national BAF and does not require the use of FCMs with BCF measurements. Guidance for deriving BAFs using Procedure #5 is provided in Section 5.6.3.

2. For some inorganic and organometallic chemicals (e.g., methylmercury), biomagnification does occur and Procedure #6 should be used to determine the national BAF. Procedure #6 gives general preference to the use of field-measured BAFs over laboratory-measured BCFs and requires FCMs to be used with BCF measurements for predicting BAFs. Guidance for deriving BAFs using Procedure #6 is provided in Section 5.6.4.

3. Determining whether or not biomagnification occurs for inorganic and organometallic chemicals requires chemical-specific data on measured concentrations of the chemical in aquatic organisms and their prey. Concentrations in aquatic organisms that increase substantially at successive trophic levels of a food web suggest that biomagnification is

NMED Exhibit 84

occurring. Concentrations in aquatic organisms that remain about the same or decrease at successive trophic levels of a food web suggest that biomagnification is not occurring. When comparing tissue concentrations for assessing biomagnification, care should be taken to ensure that the aquatic organisms chosen actually represent functional predator-prey relationships and that all major prey species are considered in the comparisons.

5.6.2 Bioavailability

The chemical-specific nature of inorganic and organometallic bioavailability is likely due in part to chemical-specific differences in several factors which affect bioavailability and bioaccumulation. These factors include differences in the mechanisms for chemical uptake by aquatic organisms (e.g., passive diffusion, facilitated transport, active transport), differences in sorption affinities to biotic and abiotic ligands, and differences in chemical speciation in water. Some inorganic and organometallic chemicals exist in multiple forms and valence states in aquatic ecosystems that can differ in their bioavailability to aquatic organisms and undergo conversions between forms. For example, selenium can exist in various forms in aquatic ecosystems, including inorganic selenite($^{+4}$) and selenate($^{+6}$) oxyanions, elemental selenium (^{0}) under reducing conditions (primarily in sediments), and organoselenium compounds of selenide ($^{-2}$). Dominant forms of mercury in natural, oxic waters include inorganic ($^{+2}$) mercury compounds and methylmercury; the latter is generally considered to be substantially more bioavailable than inorganic mercury compounds to higher trophic level organisms. Although a generic analogue to the "freely dissolved" conversion for nonionic organic chemicals does not presently exist for inorganic and organometallic chemicals as a whole, the occurrence and bioavailability of different forms of these chemicals should be carefully considered when deriving national BAFs.

1. If data indicate that: (1) a particular form (or multiple forms) of the chemical of concern largely governs its bioavailability to target aquatic organisms, and (2) BAFs are more reliable when derived using the bioavailable form(s) compared with using other form(s) of the chemical of concern, then BAFs and BCFs should be based on the appropriate bioavailable form(s).

2. Because different forms of many inorganic and organometallic chemicals may interconvert once released to the aquatic environment, regulatory and mass balance considerations typically require an accounting of the total concentration in water. In these cases, sufficient data should be available to enable conversion between total concentrations and the other (presumably more bioavailable) forms in water.

5.6.3 Deriving BAFs Using Procedure #5

This section contains guidance for calculating national BAFs for inorganic and organometallic chemicals using Procedure #5 as shown in Figure 5-1. The types of inorganic and organometallic chemicals for which Procedure #5 is appropriate are those that are not likely to biomagnify in aquatic food webs (see Section 5.1 above). In Procedure #5, two methods are available to derive the national BAF for a given trophic level:

NMED Exhibit 84

- using a BAF from an acceptable field study (i.e., field-measured BAF), or
- predicting a BAF from an acceptable laboratory-measured BCF.

Individual BAFs should be determined from field-measured BAFs or laboratory-measured BCFs according to the following guidelines.

5.6.3.1 Determining Field-Measured BAFs

1. Except where noted below, field-measured BAFs should be determined using the guidance provided in Section 5.4.3.1(A) of Procedure #1.

2. As described previously, conversion of field-measured BAFs to baseline BAF_{ℓ}^{fd}s based on lipid-normalized and freely-dissolved concentrations does not apply for inorganic and organometallic chemicals. Therefore, the guidance and equations provided in Procedure #1 which pertain to converting field-measured BAFs to baseline BAF_{ℓ}^{fd}s and subsequently to national BAFs do not generally apply to inorganic chemicals. As discussed in Section 5.6.2 above, an analogous procedure in concept might be required for converting total BAFs to BAFs based on the most bioavailable form(s) for some inorganic and organometallic chemicals of concern. Such procedures should be applied on a chemical-specific basis.

3. BAFs should be expressed on a wet-weight basis; BAFs reported on a dry-weight basis can be used only if they are converted to a wet-weight basis using a conversion factor that is measured or reliably estimated for the tissue used in the determination of the BAF.

4. BAFs should be based on concentrations in the edible tissue(s) of the biota unless it is demonstrated that whole-body BAFs are similar to edible tissue BAFs. For some finfish and shellfish species, whole body is considered to be the edible tissue.

5. The concentrations of an inorganic or organometallic chemical in a bioaccumulation study should be greater than normal background levels and greater than levels required for normal nutrition of the test species if the chemical is a micronutrient, but below levels that adversely affect the species. Bioaccumulation of an inorganic or organometallic chemical that is essential to the nutrition of aquatic organisms might be overestimated if concentrations are at or below normal background levels due to selective accumulation by the organisms to meet their nutritional requirements.

NMED Exhibit 84

5.6.3.2 Determining Laboratory-Measured BCFs

1. Except where noted below, BAFs should be predicted from laboratory-measured BCFs using the guidance provided in Section 5.4.3.1(c) of Procedure #1.

2. As described previously, conversion of laboratory-measured BCFs to baseline BCF_{ℓ}^{fd}s based on lipid-normalized and freely dissolved concentrations does not apply for inorganic and organometallic chemicals. Therefore, the guidance and equations provided in Procedure #1 which pertain to converting laboratory-measured BCFs to baseline BCF_{ℓ}^{fd}s and subsequently to national BCFs do not generally apply to inorganic and organometallic chemicals. As discussed in Section 5.6.2 above, an analogous procedure in concept might be required for converting total BCFs to BCFs based on the most bioavailable form(s) of some inorganic and organometallic chemicals of concern. Such procedures should be applied on a chemical-specific basis. In addition, the use of FCMs with BCFs does not apply to chemicals applicable to Procedure #5.

3. BCFs should be expressed on a wet-weight basis; BCFs reported on a dry-weight basis can be used only if they are converted to a wet-weight basis using a conversion factor that is measured or reliably estimated for the tissue used in the determination of the BCF.

4. BCFs should be based on concentrations in the edible tissue(s) of the biota unless it is demonstrated that whole-body BCFs are similar to edible tissue BCFs. For some finfish and shellfish species, whole body is considered to be the edible tissue.

5. The concentrations of an inorganic or organometallic chemical in a bioconcentration test should be greater than normal background levels and greater than levels required for normal nutrition of the test species if the chemical is a micronutrient, but below levels that adversely affect the species. Bioaccumulation of an inorganic or organometallic chemical that is essential to the nutrition of aquatic organisms might be overestimated if concentrations are at or below normal background levels due to selective accumulation by the organisms to meet their nutritional requirements.

5.6.3.3 Determining the National BAFs

After calculating individual BAFs using as many of the methods in Procedure #5 as possible, the next step is to determine national BAFs for each trophic level from the individual BAFs. The national BAFs will be used to determine the national 304(a) criteria. The national BAFs should be determined from the individual BAFs by considering the data preference hierarchy defined for Procedure #5 and uncertainty in the data. The data preference hierarchy for Procedure #5 is:

1. a BAF from an acceptable field-measured BAF or predicted from an acceptable laboratory-measured BCF.

Since bioaccumulation via dietary uptake and subsequent biomagnification are not of concern for chemicals subject to Procedure #5, field-measured BAFs and laboratory-measured

NMED Exhibit 84

BCFs are considered equally in determining the national BAFs. The national BAFs should be selected for each trophic level using the following steps and guidelines.

1. **Calculate Species-Mean BAFs.** For each BAF method where more than one acceptable field-measured BAF (or a BAF predicted from a BCF) is available for a given species, calculate the species-mean BAF as the geometric mean of all acceptable individual measured or BCF-predicted BAFs. When calculating species-mean BAFs, individual measured or BCF-predicted BAFs should be reviewed carefully to assess uncertainties in the BAF values. Highly uncertain BAFs should not be used. Large differences in individual BAFs for a given species (e.g., greater than a factor of 10) should be investigated further and in such cases, some or all of the BAFs for a given species might not be used. Additional discussion on evaluating the acceptability of BAF and BCF values is provided in the Bioaccumulation TSD.

2. **Calculate Trophic-Level-Mean BAFs.** For each BAF method where more than one acceptable species-mean BAF is available within a given trophic level, calculate the trophic-level-mean BAF as the geometric mean of acceptable species-mean BAFs in that trophic level. Trophic-level-mean BAFs should be calculated for trophic levels two, three and four because available data on U.S. consumers of fish and shellfish indicate significant consumption of organisms in these trophic levels.

3. **Select a Final National BAF for Each Trophic Level.** For each trophic level, select the final national BAF using best professional judgment by considering: (1) the data preference hierarchy in Procedure #5, and (2) the relative uncertainties among trophic level-mean BAFs derived using different methods.

    a. As discussed above, field-measured BAFs and laboratory-measured BCFs are considered equally desirable for deriving a final national BAF using Procedure #5. If a trophic-level-mean BAF is available from both a field-measured BAF and a laboratory-measured BCF, the final national BAF should be selected using the trophic-level-mean BAF with the least overall uncertainty.

    b. The above steps should be performed for each trophic level until a national BAF is selected for trophic levels two, three, and four.

5.6.4 Deriving BAFs Using Procedure #6

This section contains guidance for calculating national BAFs for inorganic and organometallic chemicals using Procedure #6 as shown in Figure 5-1. The types of inorganic and organometallic chemicals for which Procedure #6 is appropriate are those that are considered likely to biomagnify in aquatic food webs (see Section 5.6.1 above). Methylmercury is an example of an organometallic chemical to which Procedure #6 applies. In Procedure #6, two methods are available to derive the national BAF:

- using a BAF from an acceptable field study (i.e., field-measured BAF), or

NMED Exhibit 84

- predicting a BAF from an acceptable laboratory-measured BCF and a FCM.

Individual BAFs should be determined from field-measured BAFs or laboratory-measured BCFs and FCMs according to the following guidelines.

5.6.4.1 Determining Field-Measured BAFs

1. Field-measured BAFs should be determined using the guidance provided in Section 5.6.3.1 of Procedure #5.

5.6.4.2 Determining Laboratory-Measured BCFs

1. Except where noted below, BAFs should be predicted from laboratory-measured BCFs using the guidance provided in Section 5.6.3.2 of Procedure #5.

2. Because biomagnification is of concern for chemicals applicable to Procedure #6, BAFs should be predicted from laboratory-measured BCF using FCMs. Currently, there are no generic models from which to predict FCMs for inorganic or organometallic chemicals. Therefore, FCMs should be determined using field data as described in the section entitled: "Field-Derived FCMs" in Section 5.4.3.1(c) of Procedure #1. Unlike nonionic organic chemicals, field-derived FCMs for inorganic and organometallic chemicals are not based on lipid-normalized concentrations in tissues. For calculating FCMs for inorganic and organometallic chemicals, concentrations in tissues should be based on the consistent use of either wet-weight or dry-weight concentrations in edible tissues. FCMs should be derived for trophic levels two, three, and four.

5.6.4.3 Determining the National BAF

After calculating individual BAFs using as many of the methods in Procedure #6 as possible, the next step is to determine national BAFs for each trophic level from the individual BAFs. The national BAFs will be used to determine the national 304(a) criteria. The national BAFs should be determined from the individual BAFs by considering the data preference hierarchy defined for Procedure #6 and uncertainty in the data. The data preference hierarchy for Procedure #6 is (in order of preference):

1. a BAF from an acceptable field-measured BAF, or
2. a predicted BAF from an acceptable laboratory-measured BCF and FCM.

This data preference hierarchy reflects EPA's preference for field-measured BAFs over BAFs predicted from a laboratory-measured BCF and FCM, because field-measured BAFs are direct measures of bioaccumulation and biomagnification in aquatic food webs. BAFs predicted from laboratory-measured BCFs and FCMs indirectly account for biomagnification through the use of the FCM. For each trophic level, the national BAFs should be determined using the following steps and guidelines.

NMED Exhibit 84

1. **Calculate Species-Mean BAFs.** For each BAF method where more than one acceptable field-measured BAF or BAF predicted using a BCF and FCM is available, calculate a species-mean BAF according to the guidance described previously in Procedure #5.

2. **Calculate Trophic Level-Mean BAFs.** For each BAF method where more than one acceptable species-mean BAF is available within a given trophic level, calculate the trophic level-mean BAF according to guidance described previously in Procedure #5.

3. **Select a Final National BAF for Each Trophic Level.** For each trophic level, select the final national BAF using best professional judgment by considering: (1) the data preference hierarchy in Procedure #6, and (2) the relative uncertainties among trophic level-mean BAFs derived using different methods.

    a. When a trophic-level mean BAF is available using both methods for a given trophic level (i.e., a field-measured BAF and a BAF predicted from a BCF and FCM), the national BAF should usually be selected using the field-measured BAF which is the preferred BAF method in the data preference hierarchy in Procedure #6.

    b. If uncertainty in the trophic-level mean BAF derived using field-measured BAFs is considered to be substantially greater than a trophic-level mean BAF derived using a BCF and FCM, the national BAF for that trophic level should be selected from the second tier (BCF · FCM) method.

    c. The above steps should be performed for each trophic level until a national BAF is selected for trophic levels two, three, and four.

Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

This document is available the public to through the National Technical Information Service (NTIS), 5285 Port Royal Road, Springfield, VA 22161.

Special Note

This December 2010 electronic version of the 1985 Guidelines serves to meet the requirements of Section 508 of the Rehabilitation Act. While converting the 1985 Guidelines to a 508-compliant version, EPA updated the taxonomic nomenclature in the tables of Appendix 1 to reflect changes that occurred since the table were originally produced in 1985. The numbers included for Phylum, Class and Family represent those currently in use from the Integrated Taxonomic Information System, or ITIS, and reflect what is referred to in ITIS as Taxonomic Serial Numbers. ITIS replaced the National Oceanographic Data Center (NODC) taxonomic coding system which was used to create the original taxonomic tables included in the 1985 Guidelines document (NODC, Third Addition - see Introduction). For more information on the NODC taxonomic codes, see http://www.nodc.noaa.gov/General/CDR-detdesc/taxonomic-v8.html.

The code numbers included in the reference column of the tables have not been updated from the 1985 version. These code numbers are associated with the old NODC taxonomic referencing system and are simply replicated here for historical purposes. Footnotes may or may not still apply.

EPA is working on a more comprehensive update to the 1985 Guidelines, including new taxonomic tables which better reflect the large number of aquatic animal species known to be propagating in U.S. waters.

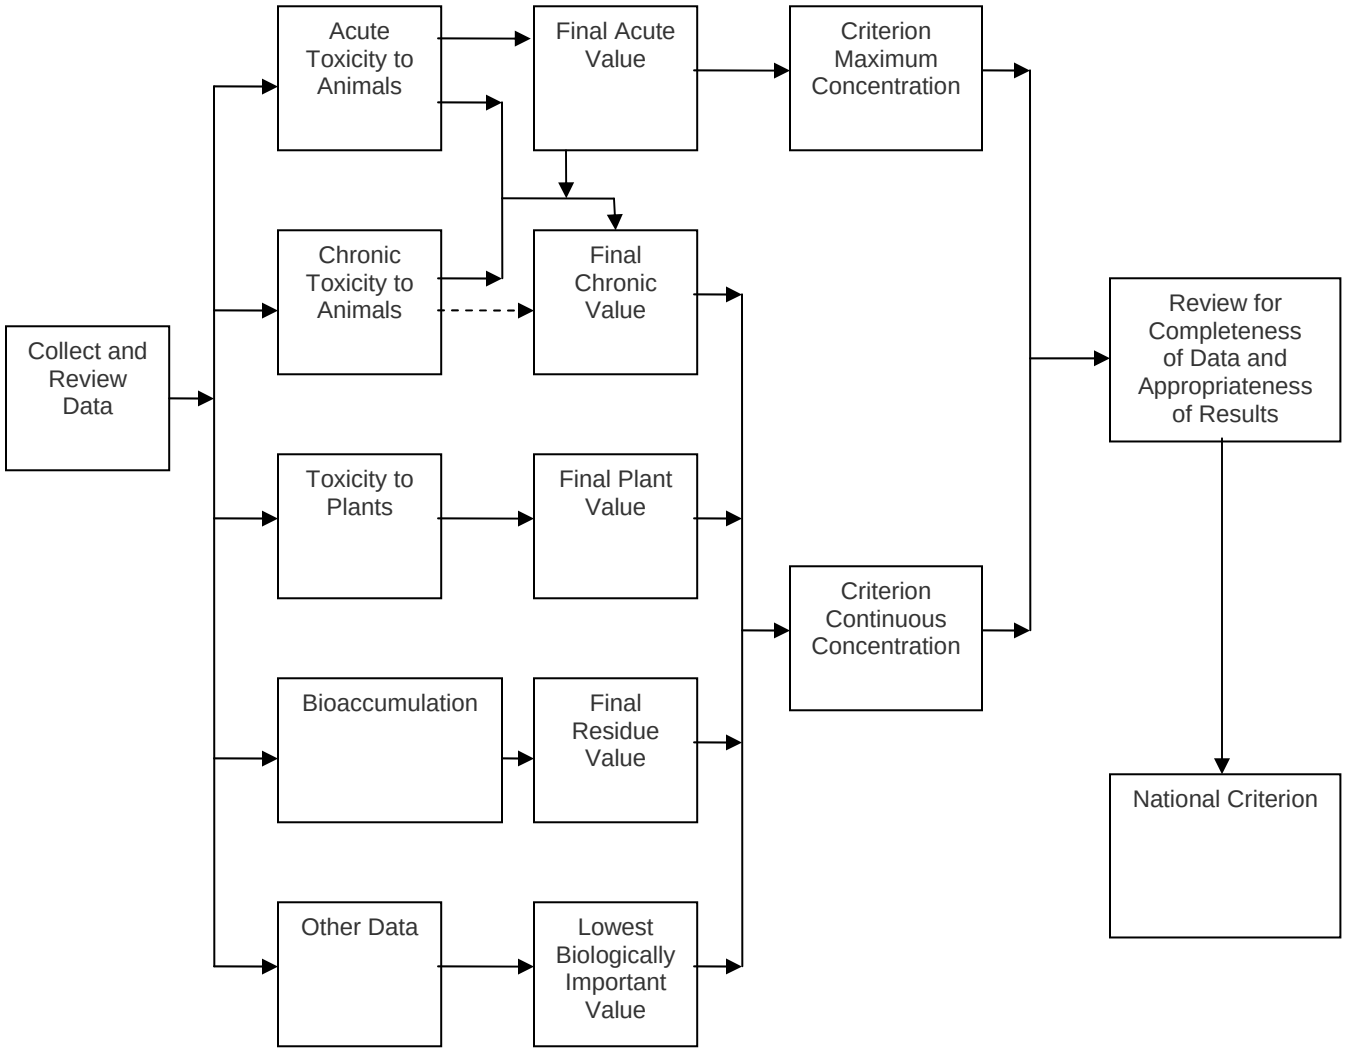
Executive Summary

Derivation of numerical national water quality criteria for the protection of aquatic organism and their uses is a complex process (Figure 1) that uses information from many areas of aquatic toxicology. After a decision is made that a national criterion is needed for a particular material, all available information concerning toxicity to, and bioaccumulation by, aquatic organisms is collected, reviewed for acceptability, and sorted. If enough acceptable data on acute toxicity to aquatic animals are available, they are used to estimate the highest one-hour average concentration that should not result in unacceptable effects on aquatic organisms and their uses. If justified, this concentration is made a function of a water quality characteristic such as pH, salinity, or hardness. Similarly, data on the chronic toxicity of the material to aquatic animals are used to estimate the highest four-daily average concentration that should not cause unacceptable toxicity during a long-term exposure. If appropriate, this concentration is also related to a water quality characteristic.



Data on toxicity to aquatic plants are examined to determine whether plants are likely to be unacceptably affected by concentrations that should not cause unacceptable effects on animals. Data on bioaccumulation by aquatic organisms are used to determine if residues might subject edible species to restrictions by the U.S. Food and Drug Administration or if such residues might harm some wildlife consumers of aquatic life. All other available data are examined for adverse effects that might be biologically important.

If a thorough review of the pertinent information indicates that enough acceptable data are available, numerical national water quality criteria are derived for fresh water or salt water or both to protect aquatic organisms and their uses from unacceptable effects due to exposures to high concentrations for short periods of time, lower concentrations for longer periods of time, and combinations of the two.

NMED Exhibit 85

Figure 1

Derivation of Numerical National Water Quality Crtieria for the Protection of Aquatic Organisms and Their Uses

Introduction

Of the several possible forms of criteria, the numerical form is the most common, but the narrative (e.g., pollutants must not be present in harmful concentrations) and operational (e.g., concentrations of pollutants must not exceed one-tenth of the 96-hr LC50) forms can be used if numerical criteria are not possible or desirable. If it were feasible, a freshwater (or saltwater) numerical aquatic life national criterion* for a material should be determined by conducting field tests on a wide variety of unpolluted bodies of fresh (or salt) water. It would be necessary to add various amounts of the material to each body of water in order to determine the highest concentration that would not cause any unacceptable long-term or short-term effect on the aquatic organisms or their uses. The lowest of these highest concentrations would become the freshwater (or saltwater) national aquatic life water quality criterion for that material, unless one or more of the lowest concentrations were judged to be outliers. Because it is not feasible to determine national criteria by conducting such field tests, these Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses (hereafter referred to as the National Guidelines) describe an objective, internally consistent, appropriate, and feasible way of deriving national criteria, which are intended to provide the same level of protection as the infeasible field testing approach described above.

Because aquatic ecosystems can tolerate some stress and occasional adverse effects, protection of all species at all times and places is not deemed necessary. If acceptable data are available for a large number of appropriate taxa from an appropriate variety of taxonomic and functional groups, a reasonable level of protection will probably be provided if all except a small fraction of the taxa are protected, unless a commercially or recreationally important species is very sensitive. The small fraction is set at 0.05 because other fractions resulted in criteria that seemed too high or too low in comparison with the sets of data from which they were calculated. Use of 0.05 to calculate a Final Acute Value does not imply that this percentage of adversely affected taxa should be used to decide in a field situation whether a criterion is too high or too low or just right.

Determining the validity of a criterion derived for a particular body of water, possibly by modification of a national criterion to reflect local conditions [1, 2, 3], should be based on an operation definition of "protection of aquatic organisms and their uses" that takes into account the practicalities of field monitoring programs and the concerns of the public. Monitoring programs should contain sampling points at enough times and places that all unacceptable changes, whether caused directly or indirectly, will be detected. The programs should adequately monitor the kinds of species of concern to the public, i.e., fish in fresh water and fish and macroinvertebrates in salt water. If the kinds of species of concern cannot be adequately monitored at a reasonable cost, appropriate surrogate species should be monitored. The kinds of species most likely to be good surrogates are those that either (a) are a major food of the desired kinds of species or (b) utilize the same food as the desired species or (c) both. Even if a major adverse effect on appropriate surrogate species does not directly result in an unacceptable effect on the kinds of species of concern to the public, it indicates a high probability that such an effect will occur.

* The term "national criteria" is used herein because it is more descriptive than the synonymous term "section 304(a) criteria", which is used in the Water Quality Standards Regulation [1].

NMED Exhibit 85

To be acceptable to the public and useful in field situations, protection of aquatic organisms and their uses should be defined as prevention of unacceptable long-term short-term effects on (1) commercially, recreationally, and other important species and (2) (a) fish and benthic invertebrate assemblages in rivers and streams, and (b) fish, benthic invertebrate, and zooplankton assemblages in lakes, reservoirs, estuaries, and oceans. Monitoring programs intended to be able to detect unacceptable effects should be tailored to the body of water of concern so that necessary samples are obtained at enough times and places to provide adequate data on the populations of the important species, as well as data directly related to the reasons for their being considered important. For example, for substances that are residue limited, species that are consumed should be monitored for contaminants to ensure that wildlife predators are protected, FDA action levels are not exceeded, and flavor is not impaired. Monitoring programs should also provide data on the number of taxa and number of individuals in the above-named assemblages that can be sampled at reasonable cost. The amount of decrease in the number of taxa or number of individuals in an assemblage that should be considered unacceptable should take into account appropriate features of the body of water and its aquatic community. Because most monitoring programs can only detect decreases of more than 20 percent, any statistically significant decrease should usually be considered unacceptable. The insensitivity of most monitoring programs greatly limits their usefulness for studying the validity of criteria because unacceptable changes can occur and not be detected. Therefore, although limited field studies can sometimes demonstrate that criteria are underprotective, only high quality field studies can reliably demonstrate that criteria are not underprotective.

If the purpose of water quality criteria were to protect only commercially and recreationally important species, criteria specifically derived to protect such species and their uses from the direct adverse effects of a material would probably, in most situations, also protect those species from indirect adverse effects due to effects of the material on other species in the ecosystem. For example, in most situations either the food chain would be more resistant than the important species and their uses or the important species and their food chains would be adaptable enough to overcome effects of the material on portions of the food chains.

These National Guidelines have been developed on the theory that effects which occur on a species in appropriate laboratory tests will generally occur on the same species in comparable field situations. All North American bodies of water and resident aquatic species and their uses are meant to be taken into account, except for a few that may be too atypical, such as the Great Salt Lake, brine shrimp, and the siscowet subspecies of lake trout, which occurs in Lake Superior and contains up to 67% fat in the fillets [4]. Derivation of criteria specifically for the Great Salt Lake or Lake Superior might have to take brine shrimp and siscowet, respectively, into account.

Numerical aquatic life criteria derived using these National Guidelines are expressed as two numbers, rather than the traditional one number, so that the criteria more accurately reflect toxicological and practical realities. If properly derived and used, the combination of a maximum concentration and a continuous concentration should provide an appropriate degree of protection of aquatic organisms and their uses from acute and chronic toxicity to animals, toxicity to plants, and bioaccumulation by aquatic organisms, without being as restrictive as a one-number criterion would have to be in order to provide the same degree of protection.

Criteria produced by these Guidelines are intended to be useful for developing water quality standards, mixing zone standards, effluent limitations, etc. The development of such standards

NMED Exhibit 85

and limitations, however, might have to take into account such additional factors as social, legal, economic, and hydrological considerations, the environmental and analytical chemistry of the material, the extrapolation from laboratory data to field situations, and relationships between species for which data are available and species in the body of water of concern. As an intermediate step in the development of standards, it might be desirable to derive site-specific criteria by modification of national criteria to reflect such local conditions as water quality, temperature, or ecologically important species [1, 2, 3]. In addition, with appropriate modifications these National Guidelines can be used to derive criteria for any specific geographical area, body of water (such as the Great Salt Lake), or group of similar bodies of water, if adequate information is available concerning the effects of the material of concern on appropriate species and their uses.

Criteria should attempt to provide a reasonable and adequate amount of protection with only a small possibility of considerable overprotection or underprotection. It is not enough that a national criterion be the best estimate that can be obtained using available data; it is equally important that a criterion be derived only if adequate appropriate data are available to provide reasonable confidence that it is a good estimate. Therefore, these National Guidelines specify certain data that should be available if a numerical criterion is to be derived. If all the required data are not available, usually a criterion should not be derived. On the other hand, the availability of all required data does not ensure that a criterion can be derived.

A common belief is that national criteria are based on "worst case" assumptions and that local considerations will raise, but not lower, criteria. For example, it will usually be assumed that if the concentration of a material in a body of water is lower than the national criterion, no unacceptable effects will occur and no site-specific criterion needs to be derived. If, however, the concentration of a material in a body of water is higher than the national criterion, it will usually be assumed that a site-specific criterion should be derived. In order to prevent the assumption of the "worst case" nature of national criteria from resulting in the underprotection of too many bodies of water, national criteria must be intended to protect all or almost all bodies of water. Thus, if bodies of water and the aquatic communities in them do differ substantially in their sensitivities to a material, national criteria should be at least somewhat overprotective for a majority of the bodies of water. To do otherwise would either (a) require derivation of site-specific criteria even if the site-specific concentration were substantially below the national criterion or (b) cause the "worst case" assumption to result in the underprotection of numerous bodies of water. On the other hand, national criteria are probably underprotective of some bodies of water.

The two factors that will probably cause the most difference between national and site-specific criteria are the species that will be exposed and the characteristics of the water. In order to ensure that national criteria are appropriately protective, the required data for national criteria include some species that are sensitive to many materials and national criteria are specifically based on tests conducted in water relatively low in particulate matter and organic matter. Thus, the two factors that will usually be considered in the derivation of site-specific criteria from national criteria are used to help ensure that national criteria are appropriately protective.

On the other hand, some local conditions might require that site-specific criteria be lower than national criteria. Some untested locally important species might be very sensitive to the material of concern, and local water quality might not reduce the toxicity of the material. In addition,

NMED Exhibit 85

aquatic organisms in field situations might be stressed by diseases, parasites, predators, other pollutants, contaminated or insufficient food, and fluctuating and extreme conditions of flow, water quality, and temperature. Further, some materials might degrade to more toxic materials, or some important community functions or species interactions might be adversely affected by concentrations lower than those that affect individual species.

Criteria must be used in a manner that is consistent with the way in which they were derived if the intended level of protection is to be provided in the real world. Although derivation of water quality criteria for aquatic life is constrained by the ways toxicity and bioconcentration tests are usually conducted, there are still many different ways that criteria can be derived, expressed, and used. The means used to derive and state criteria should relate, in the best possible way, the kinds of data that are available concerning toxicity and bioconcentration and the ways criteria can be used to protect aquatic organisms and their uses.

The major problem is to determine the best way that the statement of a criterion can bridge the gap between the nearly constant concentrations used in most toxicity and bioconcentration tests and the fluctuating concentrations that usually exist in the real world. A statement of a criterion as a number that is not to be exceeded any time or place is not acceptable because few, if any, people who use criteria would take it literally and few, if any, toxicologists would defend a literal interpretation. Rather than try to reinterpret a criterion that is neither useful nor valid, it is better to develop a more appropriate way of stating criteria.

Although some materials might not exhibit thresholds, many materials probably do. For any threshold material, continuous exposure to any combination of concentrations below the threshold will not cause an unacceptable effect (as defined on pages 1 and 2) on aquatic organisms and their uses, except that the concentration of a required trace nutrient might be too low. However, it is important to note that this is a threshold of unacceptable effect, not a threshold of adverse effect. Some adverse effect, possibly even a small reduction in the survival, growth, or reproduction of a commercially or recreationally important species, will probably occur at, and possibly even below, the threshold. The Criterion Continuous Concentration (CCC) is intended to be a good estimate of this threshold of unacceptable effect. If maintained continuously, any concentration above the CCC is expected to cause an unacceptable effect. On the other hand, the concentration of a pollutant in a body of water can be above the CCC without causing an unacceptable effect if (a) the magnitudes and durations of the excursions above the CCC are appropriately limited and (b) there are compensating periods of time during which the concentration is below the CCC. The higher the concentration is above the CCC, the shorter the period of time it can be tolerated. But it is unimportant whether there is any upper limit on concentrations that can be tolerated instantaneously or even for one minute because concentrations outside mixing zones rarely change substantially in such short periods of time.

An elegant, general approach to the problem of defining conditions (a) and (b) would be to integrate the concentration over time, taking into account uptake and depuration rates, transport within the organism to a critical site, etc. Because such an approach is not currently feasible, an approximate approach is to require that the average concentration not exceed the CCC. The average concentration should probably be calculated as the arithmetic average rather than the geometric mean [5]. If a suitable averaging period is selected, the magnitudes and durations of concentrations above the CCC will be appropriately limited, and suitable compensating periods below the CCC will be required.

NMED Exhibit 85

In the elegant approach mentioned above, the uptake and depuration rates would determine the effective averaging period, but these rates are likely to vary from species to species for any particular material. Thus the elegant approach might not provide a definitive answer to the problem of selecting an appropriate averaging period. An alternative is to consider that the purpose of the averaging period is to allow the concentration to be above the CCC only if the allowed fluctuating concentrations do not cause more adverse effect than would be caused by a continuous exposure to the CCC. For example, if the CCC caused a 10% reduction in growth of rainbow trout, or a 13% reduction in survival of oysters, or a 7% reduction in reproduction of smallmouth bass, it is the purpose of the averaging period to allow concentrations above the CCC only if the total exposure will not cause any more adverse effect than continuous exposure to the CCC would cause.

Even though only a few tests have compared the effects of a constant concentration with the effects of the same average concentration resulting from a fluctuating concentration, nearly all the available comparisons have shown that substantial fluctuations result in increased adverse effects [5, 6]. Thus if the averaging period is not to allow increased adverse effects, it must not allow substantial fluctuations. Life-cycle tests with species such as mysids and daphnids and early life-stage tests with warmwater fishes usually last for 20 to 30 days. An averaging period that is equal to the length of the test will obviously allow the worst possible fluctuations and would very likely allow increased adverse effects.

An averaging period of four days seems appropriate for use with the CCC for two reasons. First, it is substantially shorter than the 20 to 30 days that is obviously unacceptable. Second, for some species it appears that the results of chronic tests are due to the existence of a sensitive life stage at some time during the test [7], rather than being caused by either long-term stress or long-term accumulation of the test material in the organism. The existence of a sensitive life stage is probably the cause of acute-chronic ratios that are not much greater than 1, and is also possible when the ratio is substantially greater than 1. In addition, some experimentally determined acute-chronic ratios are somewhat less than 1, possibly because prior exposure during the chronic test increased the resistance of the sensitive life stage [8]. A four-day averaging period will probably prevent increased adverse effects on sensitive life stages by limiting the durations and magnitudes of exceedences* of the CCC.

The considerations applied to interpretation of the CCC also apply to the CMC. For the CMC the averaging period should again be substantially less than the lengths of the tests it is based on, i.e., substantially less than

48 to 96 hours. One hour is probably an appropriate averaging period because high concentrations of some materials can cause death in one to three hours. Even when organisms do not die within the first hour or so, it is not known how many might have died due to delayed effects of this short of an exposure. Thus it is not appropriate to allow concentrations above the CMC to exist for as long as one hour.

The durations of the averaging periods in national criteria have been made short enough to restrict allowable fluctuations in the concentration of the pollutant in the receiving water and to restrict the length of time that the concentration in the receiving water can be continuously above

* Although "exceedence" has not been found in any dictionary, it is used here because it is not appropriate to use "violation" in conjunction with criteria, no other word seems appropriate, and all appropriate phrases are awkward.

NMED Exhibit 85

a criterion concentrations. The statement of a criterion could specify that the four-day average should never exceed the CCC and that the one-hour average should never exceed the CMC. However, one of the most important uses of criteria is for designing waste treatment facilities. Such facilities are designed based on probabilities and it is not possible to design for a zero probability. Thus, one of the important design parameters is the probability that the four-day average or the one-hour-average will be exceeded, or, in other words, the frequency with which exceedences will be allowed.

The frequency of allowed exceedences should be based on the ability of aquatic ecosystems to recover from the exceedences, which will depend in part on the magnitudes and durations of the exceedences. It is important to realize that high concentrations caused by spills and similar major events are not what is meant by an "exceedence", because spills and other accidents are not part of the design of the normal operation of waste treatment facilities. Rather, exceedences are extreme values in the distribution of ambient concentrations and this distribution is the result of the usual variations in the flows of both the effluent and the receiving water and the usual variations in the concentrations of the material of concern in both the effluent and in the upstream receiving water. Because exceedences are the result of usual variation, most of the exceedences will be small and exceedences as large as a factor of two will be rare. In addition, because these exceedences are due to random variation, they will not be evenly spaced. In fact, because many receiving waters have both one-year and multi-year cycles and many treatment facilities have daily, weekly, and yearly cycles, exceedences will often be grouped, rather than being evenly spaced or randomly distributed. If the flow of the receiving water is usually much greater than the flow of the effluent, normal variation and the flow cycles will result in the ambient concentration usually being below the CCC, occasionally being near the CCC, and rarely being above the CCC. In addition, exceedences that do occur will be grouped. On the other hand, if the flow of the effluent is much greater than the flow of the receiving water, the concentration might be close to the CCC much of the time and rarely above the CCC, with exceedences being randomly distributed.

The abilities of ecosystems to recover differ greatly, and depend on the pollutant, the magnitude and duration of the exceedence, and the physical and biological features of the ecosystem. Documented studies of recoveries are few, but some systems recover from small stresses in six weeks whereas other systems take more than ten years to recover from severe stress [3]. Although most exceedences are expected to be very small, larger exceedences will occur occasionally. Most aquatic ecosystems can probably recover from most exceedences in about three years. Therefore, it does not seem reasonable to purposely design for stress above that caused by the CCC to occur more than once every three years on the average, just as it does not seem reasonable to require that these kinds of stresses only occur once every five or ten years on the average.

If the body of water is not subject to anthropogenic stress other than the exceedences of concern and if exceedences as large as a factor of two are rare, it seems reasonable that most bodies of water could tolerate exceedences once every three years on the average. In situations in which exceedences are grouped, several exceedences might occur in one or two years, but then there will be, for example, 10 to 20 years during which no exceedences will occur and the concentration will be substantially below the CCC most of the time. In situations in which the concentration is often close to the CCC and exceedences are randomly distributed, some adverse effect will occur regularly, and small additional, unacceptable effects will occur about every

NMED Exhibit 85

third year. The relative long-term ecological consequences of evenly spaced and grouped exceedences are unknown, but because most exceedences will probably be small, the long-term consequences should be about equal over long periods of time.

The above considerations lead to a statement of a criterion in the frequency-intensity-duration format that is often used to describe rain and snow fall and stream flow, e.g., how often, on the average, does more than ten inches of rain fall in a week? The numerical values chosen for frequency (or average recurrence interval), intensity (i.e., concentration), and duration (of averaging period) are those appropriate for national criteria. Whenever adequately justified, a national criterion may be replaced by a site-specific criterion [1], which may include not only site-specific criterion concentrations [2], but also site-specific durations of averaging periods and site-specific frequencies of allowed exceedences [3].

The concentrations, durations, and frequencies specified in criteria are based on biological, ecological, and toxicological data, and are designed to protect aquatic organisms and their uses from unacceptable effects. Use of criteria for designing waste treatment facilities requires selections of an appropriate wasteload allocation model. Dynamic models are preferred for the application of water quality criteria, but a steady-state model might have to be used instead of a dynamic model in some situations. Regardless of the model that is used, the durations of the averaging periods and the frequencies of allowed exceedences must be applied correctly if the intended level of protection is to be provided. For example, in the criterion statement frequency refers to the average frequency, over a long period of time, of rare events (i.e., exceedences). However, in some disciplines, frequency is often thought of in terms of the average frequency, over a long period of time, of the years is which rare events occur, without any consideration of how many rare events occur within each of those eventful years. The distinction between the frequency of events and the frequency of years in important for all those situations in which the rare events, e.g., exceedences, tend to occur in groups within the eventful years. The two ways of calculating frequency produce the same results in situations in which each rare event occurs in a different year because then the frequency of events is the same as the frequency of eventful years.

Because fresh water and salt water have basically different chemical compositions and because freshwater and saltwater (i.e., estuarine and true marine) species rarely inhabit the same water simultaneously, these National Guidelines provide for the derivation of separate criteria for these two kinds of water. For some materials sufficient data might not be available to allow derivation of criteria for one or both kinds of water. Even though absolute toxicities might be different in fresh and salt waters, such relative data as acute-chronic ratios and bioconcentration factors often appear to be similar in the two waters. When data are available to indicate that these ratios and factors are probably similar, they are used interchangeably.

The material for which a criterion is desired is usually defined in terms of a particular chemical compound or ion, or a group of closely related compounds or ions, but it might possibly be defined in terms of an effluent. These National Guidelines might also be useful for deriving criteria for temperature, dissolved oxygen, suspended solids, pH, etc., if the kinds of data on which the Guidelines are based are available.

Because they are meant to be applied only after a decision has been made that a national water quality criterion for aquatic organisms is needed for a material, these National Guidelines do not

NMED Exhibit 85

address the rationale for making that decision. If the potential for adverse effects on aquatic organisms and their uses is part of the basis for deciding whether an aquatic life criterion is needed for a material, these Guidelines will probably be helpful in the collection and interpretation of relevant data. Such properties as volatility might affect the fate of a material in the aquatic environment and might be important when determining whether a criterion is needed for a material; for example, aquatic life criteria might not be needed for materials that are highly volatile or highly degradable in water. Although such properties can affect how much of the material will get from the point of discharge through any allowed mixing zone to some portion of the ambient water and can also affect the size of the zone of influence in the ambient water, such properties do not affect how much of the material aquatic organisms can tolerate in the zone of influence.

This version of the National Guidelines provides clarifications, additional details, and technical and editorial changes from the previous version [9]. These modifications are the result of comments on the previous version and subsequent drafts [10], experience gained during the U.S. EPA's use of previous versions and drafts, and advances in aquatic toxicology and related fields. Future versions will incorporate new concepts and data as their usefulness is demonstrated. The major technical changes incorporated into this version of the National Guidelines are:

1. The requirement for acute data for freshwater animals has been changed to include more tests with invertebrate species. The taxonomic, functional, and probably the toxicological, diversities among invertebrate species are greater than those among vertebrate species and this should be reflected in the required data.

2. When available, 96-hr EC50s based on the percentage of fish immobilized plus the percentage of fish killed are used instead of 96-hr LC50s for fish; comparable EC50s are used instead of LC50s for other species. Such appropriately defined EC50s better reflect the total severe acute adverse impact of the test material on the test species than do LC50s or narrowly defined EC50s. Acute EC50s that are based on effects that are not severe, such as reduction in shell deposition and reduction in growth, are not used in calculating the Final Acute Value.

3. The Final Acute Value is now defined in terms of Genus Mean Acute Values rather than Species Mean Acute Values. A Genus Mean Acute Value is the geometric mean of all the Species Mean Acute Values available for species in the genus. On the average, species within a genus are toxicologically much more similar than species in different genera, and so the use of Genus Mean Acute Values will prevent data sets from being biased by an overabundance of species in one or a few genera.

4. The Final Acute Value is now calculated using a method [11] that is not subject to the bias and anomalous behavior that the previous method was. The new method is also less influenced by one very low value because it always gives equal weight to the four values that provide the most information about the cumulative probability of 0.05. Although the four values receive the most weight, the other values do have a substantial effect on the Final Acute Value (see examples in Appendix 2).

5. The requirements for using the results of tests with aquatic plants have been made more stringent.

NMED Exhibit 85

6. Instead of being equal to the Final Acute Value, the Criterion Maximum Concentration is now equal to one-half the Final Acute Value. The Criterion Maximum Concentration is intended to protect 95 percent of a group of diverse genera, unless a commercially or recreationally important species is very sensitive. However, a concentration that would severely harm 50 percent of the fifth percentile or 50 percent of a sensitive important species cannot be considered to be protective of that percentile or that species. Dividing the Final Acute Value by 2 is intended to result in a concentration that will not severely adversely affect too many of the organisms.

7. The lower of the two numbers in the criterion is now called the Criterion Continuous Concentration, rather than the Criterion Average Concentration, to more accurately reflect the nature of the toxicological data on which it is based.

8. The statement of a criterion has been changed (a) to include durations of averaging periods and frequencies of allowed exceedences that are based on what aquatic organisms and their uses can tolerate, and (b) to identify a specific situation in which site-specific criteria [1, 2, 3] are probably desirable.

In addition, Appendix 1 was added to aid in determining whether a species should be considered resident in North America and its taxonomic classification. Appendix 2 explains the calculation of the Final Acute Value.

The amount of guidance in these National Guidelines has been increased, but much of the guidance is necessarily qualitative rather than quantitative; much judgment will usually be required to derive a water quality criterion for aquatic organisms and their uses. In addition, although this version of the National Guidelines attempts to cover all major questions that have arisen during use of previous versions and drafts, it undoubtedly does not cover all situations that might occur in the future. All necessary decisions should be based on a thorough knowledge of aquatic toxicology and an understanding of these Guidelines and should be consistent with the spirit of these Guidelines, i.e., to make best use of the available data to derive the most appropriate criteria. These National Guidelines should be modified whenever sound scientific evidence indicates that a national criterion produced using these Guidelines would probably be substantially overprotective or underprotective of the aquatic organisms and their uses on a national basis. Derivation of numerical national water quality criteria for aquatic organisms and their uses is a complex process and requires knowledge in many areas of aquatic toxicology; any deviation from these Guidelines should be carefully considered to ensure that it is consistent with other parts of these Guidelines.

I. Definition of Material of Concern

A. Each separate chemical that does not ionize substantially in most natural bodies of water should usually be considered a separate material, except possibly for structurally similar organic compounds that only exist in large quantities as commercial mixtures of various compounds and apparently have similar biological, chemical, physical, and toxicological properties.

B. For chemicals that do ionize substantially in most natural bodies of water (e.g., some phenols and organic acids, some salts of phenols and organic acids, and most

NMED Exhibit 85

inorganic salts and coordination complexes of metals), all forms that would be in chemical equilibrium should usually be considered one material. Each different oxidation state of a metal and each different nonionizable covalently bonded organometallic compound should usually be considered a separate material.

C. The definition of the material should include an operational analytical component. Identification of a material simply, for example, as "sodium" obviously implies "total sodium", but leaves room for doubt. If "total" is meant, it should be explicitly stated. Even "total" has different operational definitions, some of which do not necessarily measure "all that is there" in all samples. Thus, it is also necessary to reference or describe the analytical method that is intended. The operational analytical component should take into account the analytical and environmental chemistry of the material, the desirability of using the same analytical method on samples from laboratory tests, ambient water, and aqueous effluents, and various practical considerations, such as labor and equipment requirements and whether the method would require measurement in the field or would allow measurement after samples are transported to a laboratory.

   The primary requirements of the operational analytical component are that it be appropriate for use on samples of receiving water, that it be compatible with the available toxicity and bioaccumulation data without making extrapolations that are too hypothetical, and that it rarely result in underprotection or overprotection of aquatic organisms and their uses. Because an ideal analytical measurement will rarely be available, a compromise measurement will usually have to be used. This compromise measurement must fit with the general approach that if an ambient concentration is lower than the national criterion, unacceptable effects will probably not occur, i.e., the compromise measurement must not err on the side of underprotection when measurements are made on a surface water. Because the chemical and physical properties of an effluent are usually quite different from those of the receiving water, an analytical method that is acceptable for analyzing an effluent might not be appropriate for analyzing a receiving water, and vice versa. If the ambient concentration *calculated* from a measured concentration in an effluent is higher than the national criterion, an additional option is to *measure* the concentration after dilution of the effluent with receiving water to determine if the measured concentration is lowered by such phenomena as complexation or sorption. A further option, of course, is to derive a site-specific criterion [1, 2, 3]. Thus, the criterion should be based on an appropriate analytical measurement, but the criterion is not rendered useless if an ideal measurement either is not available or is not feasible.

   NOTE: The analytical chemistry of the material might have to be taken into account when defining the material or when judging the acceptability of some toxicity tests, but a criterion should not be based on the sensitivity of an analytical method. When aquatic organisms are more sensitive than routine analytical methods, the proper solution is to develop better analytical methods, not to underprotect aquatic life.

NMED Exhibit 85

II. Collection of Data

A. Collect all available data on the material concerning (a) toxicity to, and bioaccumulation by, aquatic animals and plants, (b) FDA action levels [12], and (c) chronic feeding studies and long-term field studies with wildlife species that regularly consume aquatic organisms.

B. All data that are used should be available in typed, dated, and signed hard copy (publication, manuscript, letter, memorandum, etc.) with enough supporting information to indicate that acceptable test procedures were used and that the results are probably reliable. In some cases it may be appropriate to obtain additional written information from the investigator, if possible. Information that is confidential or privileged or otherwise not available for distribution should not be used.

C. Questionable data, whether published or unpublished, should not be used. For example, data should usually be rejected if they are from tests that did not contain a control treatment, tests in which too many organisms in the control treatment died or showed signs of stress or disease, and tests in which distilled or deionized water was used as the dilution water without addition of appropriate salts.

D. Data on technical grade materials may be used if appropriate, but data on formulated mixtures and emulsifiable concentrates of the material of concern should not be used.

E. For some highly volatile, hydrolyzable, or degradable materials it is probably appropriate to use only results of flow-through tests in which the concentrations of test material in the test solutions were measured often enough using acceptable analytical methods.

F. Data should be rejected if they were obtained using:

    1. Brine shrimp, because they usually only occur naturally in water with salinity greater than 35 g/kg.

    2. Species that do not have reproducing wild populations in North America (see Appendix 1).

    3. Organisms that were previously exposed to substantial concentrations of the test material or other contaminants.

G. Questionable data, data on formulated mixtures and emulsifiable concentrates, and data obtained with non-resident species in North America or previously exposed organisms may be used to provide auxiliary information but should not be used in the derivation of criteria.

III. Required data

A. Certain data should be available to help ensure that each of the four major kinds of possible adverse effects receives adequate consideration. Results of acute and chronic toxicity tests with representative species of aquatic animals are necessary so that data available for tested species can be considered a useful indication of the sensitivities of

NMED Exhibit 85

appropriate untested species. Fewer data concerning toxicity to aquatic plants are required because procedures for conducting tests with plants and interpreting the results of such tests are not as well developed. Data concerning bioaccumulation by aquatic organisms are only required if relevant data are available concerning the significance of residues in aquatic organisms.

B. To derive a criterion for freshwater aquatic organisms and their uses, the following should be available:

1. Results of acceptable acute tests (see Section IV) with at least one species of freshwater animal in at least eight different families such that all of the following are included:

    a. the family Salmonidae in the class Osteichthyes

    b. a second family in the class Osteichthyes, preferably a commercially or recreationally important warmwater species (e.g., bluegill, channel catfish, etc.)

    c. a third family in the phylum Chordata (may be in the class Osteichthyes or may be an amphibian, etc.)

    d. a planktonic crustacean (e.g., cladoceran, copepod, etc.)

    e. a benthic crustacean (e.g., ostracod, isopod, amphipod, crayfish, etc.)

    f. an insect (e.g., mayfly, dragonfly, damselfly, stonefly, caddisfly, mosquito, midge, etc.)

    g. a family in a phylum other than Arthropoda or Chordata (e.g., Rotifera, Annelida, Mollusca, etc.)

    h. a family in any order of insect or any phylum not already represented.

2. Acute-chronic ratios (see Section VI) with species of aquatic animals in at least three different families provided that one of the three species:

    - at least one is a fish
    - at least one is an invertebrate
    - at least one is an acutely sensitive freshwater species (the other two may be saltwater species).

3. Results of at least one acceptable test with a freshwater alga or vascular plant (see Section VIII). If plants are among the aquatic organisms that are most sensitive to the material, results of a test with a plant in another phylum (division) should also be available.

NMED Exhibit 85

4. At least one acceptable bioconcentration factor determined with an appropriate freshwater species, if a maximum permissible tissue concentration is available (see Section IX).

C. To derive a criterion for saltwater aquatic organisms and their uses, the following should be available:

1. Results of acceptable acute tests (see Section IV) with at least one species of saltwater animal in at least eight different families such that all of the following are included:

    a. two families in the phylum Chordata

    b. a family in a phylum other than Arthropoda or Chordata

    c. either the Mysidae or Penaeidae family

    d. three other families not in the phylum Chordata (may include Mysidae or Penaeidae, whichever was not used above)

    e. any other family.

2. Acute-chronic ratios (see Section VI) with species of aquatic animals in at least three different families provided that of the three species:

    - at least one is a fish
    - at least one is an invertebrate
    - at least one is an acutely sensitive saltwater species (the other two may be freshwater species).

3. Results of at least one acceptable test with a saltwater alga or vascular plant (see Section VIII). If plants are among the aquatic organisms most sensitive to the material, results of a test with a plant in another phylum (division) should also be available.

4. At least one acceptable bioconcentration factor determined with an appropriate saltwater species, if a maximum permissible tissue concentration is available (see Section IX).

D. If all the required data are available, a numerical criterion can usually be derived, except in special cases. For example, derivation of a criterion might not be possible if the available acute-chronic ratios vary by more than a factor of ten with no apparent pattern. Also, if a criterion is to be related to a water quality characteristic (see Sections V and VII), more data will be necessary.

Similarly, if all required data are not available, a numerical criterion should not be derived except in special cases. For example, even if not enough acute and chronic data are available, it might be possible to derive a criterion if the available data

NMED Exhibit 85

clearly indicate that the Final Residue Value should be much lower than either the Final Chronic Value or Final Plant Value.

E. Confidence in a criterion usually increases as the amount of available pertinent data increases. Thus, additional data are usually desirable.

IV. Final Acute Value

A. Appropriate measures of the acute (short-term) toxicity of the material to a variety of species of aquatic animals are used to calculate the Final Acute Value. The Final Acute Value is an estimate of the concentration of the material corresponding to a cumulative probability of 0.05 in the acute toxicity values for the genera with which acceptable acute tests have been conducted on the material. However, in some cases, if the Species Mean Acute Value of a commercially or recreationally important species is lower than the calculated Final Acute Value, then that Species Mean Acute Value replaces the calculated Final Acute Value in order to provide protection for that important species.

B. Acute toxicity tests should have been conducted using acceptable procedures [13].

C. Except for test with saltwater annelids and mysids, results of acute tests during which the test organisms were fed should not be used, unless data indicate that the food did not affect the toxicity of the test material.

D. Results of acute tests conducted in unusual dilution water, e.g., dilution water in which total organic carbon or particulate matter exceeded 5 mg/L, should not be used, unless a relationship is developed between acute toxicity and organic carbon or particulate matter or unless data show that organic carbon, particulate matter, etc., do not affect toxicity.

E. Acute values should be based on endpoints which reflect the total severe acute adverse impact of the test material on the organisms used in the test. Therefore, only the following kinds of data on acute toxicity to aquatic animals should be used:

1. Tests with daphnids and other cladocerans should be started with organisms less than 24 hours old and tests with midges should be started with second- or third-instar larvae. The result should be the 48-hr EC50 based on percentage of organisms immobilized plus percentage of organisms killed. If such an EC50 is not available from a test, the 48-hr LC50 should be used in place of the desired 48-hr EC50. An EC50 or LC50 of longer than 48 hr can be used as long as the animals were not fed and the control animals were acceptable at the end of the test.

2. The result of a test with embryos and larvae of barnacles, bivalve molluscs (clams, mussels, oysters, and scallops), sea urchins, lobsters, crabs, shrimp, and abalones, should be the 96-hr EC50 based on the percentage of organisms with incompletely developed shells plus the percentage of organisms killed. If such an EC50 is not available from a test, the lower of the 96-hr EC50 based on the percentage of organisms with incompletely developed shells and the 96-hr LC50

NMED Exhibit 85

should be used in place of the desired 96-hr EC50. If the duration of the test was between 48 and 96 hr, the EC50 or LC50 at the end of the test should be used.

3. The acute values from tests with all other freshwater and saltwater animal species and older life stages of barnacles, bivalve molluscs, sea urchins, lobsters, crabs, shrimps, and abalones should be the 96-hr EC50 based on the percentage of organisms exhibiting loss of equilibrium plus the percentage of organisms immobilized plus the percentage of organisms killed. If such an EC50 is not available from a test, the 96-hr LC50 should be used in place of the desired 96-hr EC50.

4. Tests with single-celled organisms are not considered acute tests, even if the duration was 96 hours or less.

5. If the tests were conducted properly, acute values reported as "greater than" values and those which are above the solubility of the test material should be used, because rejection of such acute values would unnecessarily lower the Final Acute Value by eliminating acute values for resistant species.

F. If the acute toxicity of the material to aquatic animals apparently has been shown to be related to a water quality characteristic such as hardness or particulate matter for freshwater animals or salinity or particulate matter for saltwater animals, a Final Acute Equation should be derived based on that water quality characteristic. Go to Section V.

G. If the available data indicate that one or more life stages are at least a factor of two more resistant than one or more other life stages of the same species, the data for the more resistant life stages should not be used in the calculation of the Species Mean Acute Value because a species can only be considered protected from acute toxicity if all life stages are protected.

H. The agreement of the data within and between species should be considered. Acute values that appear to be questionable in comparison with other acute and chronic data for the same species and for other species in the same genus probably should not be used in calculation of a Species Mean Acute Value. For example, if the acute values available for a species or genus differ by more than a factor of 10, some or all of the values probably should not be used in calculations.

I. For each species for which at least one acute value is available, the Species Mean Acute Value (SMAV) should be calculated as the geometric mean of the results of all flow-through tests in which the concentrations of test material were measured. For a species for which no such result is available, the SMAV should be calculated as the geometric mean of all available acute values, i.e., results of flow-through tests in which the concentrations were not measured and results of static and renewal tests based on initial concentrations (nominal concentrations are acceptable for most test materials if measured concentrations are not available) of test material.

NOTE: Data reported by original investigators should not be rounded off. Results of all intermediate calculations should be rounded [14] to four significant digits.

NMED Exhibit 85

NOTE: The geometric mean of N numbers is the Nth root of the product of the N numbers. Alternatively, the geometric mean can be calculated by adding the logarithms of the N numbers, dividing the sum by N, and taking the antilog of the quotient. The geometric mean of two numbers is the square root of the product of the two numbers, and the geometric mean of one number is that number. Either natural (base e) or common (base 10) logarithms can be used to calculate geometric means as long as they are used consistently within each set of data, i.e., the antilog used must match the logarithm used.

NOTE: Geometric means, rather than arithmetic means, are used here because the distributions of sensitivities of individual organisms in toxicity tests on most materials and the distributions of sensitivities of species within a genus are more likely to be lognormal than normal. Similarly, geometric means are used for acute-chronic ratios and bioconcentration factors because quotients are likely to be closer to lognormal than normal distributions. In addition, division of the geometric mean of a set of numerators by the geometric mean of the set of corresponding denominators will result in the geometric mean of the set of corresponding quotients.

J. For each genus for which one or more SMAVs are available, the Genus Mean Acute Value (GMAV) should be calculated as the geometric mean of the SMAVs available for the genus.

K. Order the GMAVs from high to low.

L. Assign ranks, R, to the GMAVs from "1" for the lowest to "N" for the highest. If two or more GMAVs are identical, arbitrarily assign them successive ranks.

M. Calculate the cumulative probability, P, for each GMAV as R/(N+1).

N. Select the four GMAVs which have cumulative probabilities closest to 0.05 (if there are less than 59 GMAVs, these will always be the four lowest GMAVs).

O. Using the selected GMAVs and Ps, calculate

$$S^2 = \frac{\sum((\ln GMAV)^2) - ((\sum \ln GMAV))^2 / 4}{\sum (F) - ((\sum(\sqrt{P}))^2 / 4)}$$

$$L = (\sum (\ln GMAV) - S(\sum(\sqrt{P}))) / 4$$

$$A = S(\sqrt{0.05}) + L$$

$$FAV = e^A$$

(See [11] for development of the calculation procedure and Appendix 2 for an example calculations and computer program.)

NOTE: Natural logarithms (logarithms to base e, denoted as ln) are used herein merely because they are easier to use on some hand calculators and computers than common (base 10) logarithms. Consistent use of either will produce the same result.

NMED Exhibit 85

P. If for a commercially or recreationally important species the geometric mean of the acute values from ~~the~~ flow-through tests in which the concentrations of test material were measured is lower than the calculated Final Acute Value, then that geometric mean should be used as the Final Acute Value instead of the calculated Final Acute Value.

Q. Go to Section VI.

V. Final Acute Equation

A. When enough data are available to show that acute toxicity to two or more species is similarly related to a water quality characteristic, the relationship should be taken into account as described in Sections B-G below or using analysis of covariance [15, 16]. The two methods are equivalent and produce identical results. The manual method described below provides an understanding of this application of covariance analysis, but computerized versions of covariance analysis are much more convenient for analyzing large data sets. If two or more factors affect toxicity, multiple regression analysis should be used.

B. For each species for which comparable acute toxicity values are available at two or more different values of the water quality characteristic, perform a least squares regression of the acute toxicity values on the corresponding values of the water quality characteristic to obtain the slope and its 95% confidence limits for each species.

NOTE: Because the best documented relationship is that between hardness and acute toxicity of metals in fresh water and a log-log relationship fits these data, geometric means and natural logarithms of both toxicity and water quality are used in the rest of this section. For relationships based on other water quality characteristics, such as pH, temperature, or salinity, no transformation or a different transformation might fit the data better, and appropriate changes will be necessary throughout this section.

C. Decide whether the data for each species is useful, taking into account the range and number of the tested values of the water quality characteristic and the degree of agreement within and between species. For example, a slope based on six data points might be of limited value if it is based only on data for a very narrow range of values of the water quality characteristic. A slope based on only two data points, however, might be useful if it is consistent with other information and if the two points cover a broad enough range of the water quality characteristic. In addition, acute values that appear to be questionable in comparison with other acute and chronic data available for the same species and for other species in the same genus probably should not be used. For example, if after adjustment for the water quality characteristic, the acute values available for a species or genus differ by more than a factor of 10, rejection of some or all of the values is probably appropriate. If useful slopes are not available for at least one fish and one invertebrate or if the available slopes are too dissimilar or if too few data are available to adequately define the relationship between acute toxicity and the water quality characteristic, return to Section IV.G., using the results of tests

NMED Exhibit 85

conducted under conditions and in waters similar to those commonly used for toxicity tests with the species.

D. Individually for each species calculate the geometric mean of the available acute values and then divide each of the acute values for a species by the mean for the species. This normalizes the acute values so that the geometric mean of the normalized values for each species individually and for any combination of species is 1.0.

E. Similarly normalize the values of the water quality characteristic for each species individually.

F. Individually for each species perform a least squares regression of the normalized acute toxicity values on the corresponding normalized values of the water quality characteristic. The resulting slopes and 95% confidence limits will be identical to those obtained in Section B above. Now, however, if the data are actually plotted, the line of best fit for each individual species will go through the point 1,1 in the center of the graph.

G. Treat all the normalized data as if they were all for the same species and perform a least squares regression of all the normalized acute values on the corresponding normalized values of the water quality characteristic to obtain the pooled acute slope, V, and its 95% confidence limits. If all the normalized data are actually plotted, the line of best fit will go through the point 1,1 in the center of the graph.

H. For each species calculate the geometric mean, W, of the acute toxicity values and the geometric mean, X, of the values of the water quality characteristic. (These were calculated in steps D and E above.)

I. For each species calculate the logarithm, Y, of the SMAV at a selected value, Z, of the water quality characteristic using the equation:

$$Y = \ln W - V(\ln X - \ln Z).$$

J. For each species calculate the SMAV at Z using the equation: $SMAV = e^{Y}$.

NOTE: Alternatively, the SMAVs at Z can be obtained by skipping step H above, using the equations in steps I and J to adjust each acute value individually to Z, and then calculating the geometric mean of the adjusted values for each species individually. This alternative procedure allows an examination of the range of the adjusted acute values for each species.

K. Obtain the Final Acute Value at Z by using the procedure described in Section IV.J-O.

L. If the SMAV at Z of a commercially or recreationally important species is lower than the calculated Final Acute Value at Z, then that SMAV should be used as the Final Acute Value at Z instead of the calculated Final Acute Value.

M. The Final Acute Equation is written as: Final Acute Value = $e^{(V[\ln(\text{water quality characteristic})] + \ln A - V[\ln Z])}$, where V = pooled acute slope and A = Final Acute Value at Z. Because

NMED Exhibit 85

V, A, and Z are known, the Final Acute Value can be calculated for any selected value of the water quality characteristic.

VI. Final Chronic Value

A. Depending on the data that are available concerning chronic toxicity to aquatic animals, the Final Chronic Value might be calculated in the same manner as the Final Acute Value or by dividing the Final Acute Value by the Final Acute-Chronic Ratio. In some cases it may not be possible to calculate a Final Chronic Value.

NOTE: As the name implies, the acute-chronic ration (ARC) is a way of relating acute and chronic toxicities. The acute-chronic ratio is basically the inverse of the application factor, but this new name is better because it is more descriptive and should help prevent confusion between "application factors" and "safety factors". Acute-chronic ratios and application factors are ways of relating the acute and chronic toxicities of a material to aquatic organisms. Safety factors are used to provide an extra margin of safety beyond the known or estimated sensitivities of aquatic organisms. Another advantage of the acute-chronic ratio is that it will usually be greater than one; this should avoid the confusion as to whether a large application factor is one that is close to unity or one that has a denominator that is much greater than the numerator.

B. Chronic values should be based on results of flow-through (except renewal is acceptable for daphnids) chronic tests in which the concentrations of test material in the test solutions were properly measured at appropriate times during the test.

C. Results of chronic tests in which survival, growth, or reproduction in the control treatment was unacceptably low should not be used. The limits of acceptability will depend on the species.

D. Results of chronic tests conducted in unusual dilution water, e.g., dilution water in which total organic carbon or particulate matter exceeded 5 mg/L, should not be used, unless a relationship is developed between chronic toxicity and organic carbon or particulate matter or unless data show that organic carbon, particulate matter, etc., do not affect toxicity.

E. Chronic values should be based on endpoints and lengths of exposure appropriate to the species. Therefore, only results of the following kinds of chronic toxicity tests should be used:

1. Life-cycle toxicity tests consisting of exposures of each of two or more groups of individuals of a species to a different concentration of the test material throughout a life cycle. To ensure that all life stages and life processes are exposed, tests with fish should begin with embryos or newly hatched young less than 48 hours old, continue through maturation and reproduction, and should end not less than 24 days (90 days for salmonids) after the hatching of the next generation. Tests with daphnids should begin with young less than 24 hours old and last for not less than 21 days. Tests with mysids should begin with young less than 24 hours old and continue until 7 days past the median time of first brood release in the

controls. For fish, data should be obtained and analyzed on survival and growth of adults and young, maturation of males and females, eggs spawned per female, embryo viability (salmonids only), and hatchability. For daphnids, data should be obtained and analyzed on survival and young per female. For mysids, data should be obtained and analyzed on survival, growth, and young per female.

2. Partial life-cycle toxicity tests consisting of exposures of each of two or more groups of individuals of a species of fish to a different concentration of the test material through most portions of a life cycle. Partial life-cycle tests are allowed with fish species that require more than a year to reach sexual maturity, so that all major life stages can be exposed to the test material in less than 15 months. Exposure to the test material should begin with immature juveniles at least 2 months prior to active gonad development, continue through maturation and reproduction, and end not less than 24 days (90 days for salmonids) after the hatching of the next generation. Data should be obtained and analyzed on survival and growth of adults and young, maturation of males and females, eggs spawned per female, embryo viability (salmonids only), and hatchability.

3. Early life-stage toxicity tests consisting of 28- to 32-day (60 days post hatch for salmonids) exposures of the early life stages of a species of fish from shortly after fertilization through embryonic, larval, and early juvenile development. Data should be obtained and analyzed on survival and growth.

   NOTE: Results of an early life-stage test are used as predictions of results of life-cycle and partial life-cycle tests with the same species. Therefore, when results of a life-cycle or partial life-cycle test are available, results of an early life-stage test with the same species should not be used. Also, results of early life-stage tests in which the incidence of mortalities or abnormalities increased substantially near the end of the test should not be used because results of such tests are possibly not good predictions of the results of comparable life-cycle or partial life-cycle tests.

F. A chronic value may be obtained by calculating the geometric mean of the lower and upper chronic limits from a chronic test or by analyzing chronic data using regression analysis. A lower chronic limit is the highest tested concentration (a) in an acceptable chronic test, (b) which did not cause an unacceptable amount of adverse effect on any of the specified biological measurements, and (c) below which no tested concentration caused an unacceptable effect. An upper chronic limit is the lowest tested concentration (a) in an acceptable chronic test, (b) which did cause an unacceptable amount of adverse effect on one or more of the specified biological measurements, and (c) above which all tested concentrations also caused such an effect.

   NOTE: Because various authors have used a variety of terms and definitions to interpret and report results of chronic tests, reported results should be reviewed carefully. The amount of effect that is considered unacceptable is often based on a statistical hypothesis test, but might also be defined in terms of a specified percent reduction from the controls. A small percent reduction (e.g., 3%) might be

NMED Exhibit 85

considered acceptable even if it is statistically significantly different from the control, whereas a large percent reduction (e.g., 30%) might be considered unacceptable even if it is not statistically significant.

G. If the chronic toxicity of the material to aquatic animals apparently has been shown to be related to a water quality characteristic such as hardness or particulate matter for freshwater animals or salinity or particulate matter for saltwater animals, a Final Chronic Equation should be derived based on that water quality characteristic. Go to Section VII.

H. If chronic values are available for species in eight families as described in Sections III.B.1 or III.C.1, a Species Mean Chronic Value (SMCV) should be calculated for each species for which at least one chronic value is available by calculating the geometric mean of all chronic values available for the species, and appropriate Genus Mean Chronic Values should be calculated. The Final Chronic Value should then be obtained using the procedure described in Section IV.J-O. Then go to Section VI.M.

I. For each chronic value for which at least one corresponding appropriate acute value is available, calculate an acute-chronic ratio, using for the numerator the geometric mean of the results of all acceptable flow-through (except static is acceptable for daphnids) acute tests in the same dilution water and in which the concentrations were measured. For fish, the acute test(s) should have been conducted with juveniles. The acute test(s) should have been part of the same study as the chronic test. If acute tests were not conducted as part of the same study, acute tests conducted in the same laboratory and dilution water, but in a different study, may be used. If no such acute tests are available, results of acute tests conducted in the same dilution water in a different laboratory may be used. If no such acute tests are available, an acute-chronic ratio should not be calculated.

J. For each species, calculate the species mean acute-chronic ratio as the geometric mean of all acute-chronic ratios available for that species.

K. For some materials the acute-chronic ratio seems to be the same for all species, but for other materials the ratio seems to increase or decrease as the Species Mean Acute Value (SMAV) increases. Thus the Final Acute-Chronic Ratio can be obtained in four ways, depending on the data available:

    1. If the species mean acute-chronic ratio~~s~~ seems to increase or decrease as the SMAV increases, the Final Acute-Chronic Ratio should be calculated as the geometric mean of the acute-chronic ratios for species whose SMAVs are close to the Final Acute Value.

    2. If no major trend is apparent and the acute-chronic ratios for a number of species are within a factor of ten, the Final Acute-Chronic Ratio should be calculated as the geometric mean of all the species mean acute-chronic ratios available for both freshwater and saltwater species.

    3. For acute tests conducted on metals and possibly other substances with embryos and larvae of barnacles, bivalve molluscs, sea urchins, lobsters,

NMED Exhibit 85

crabs, shrimp, and abalones (see Section IV.E.2), it is probably appropriate to assume that the acute-chronic ratio is 2. Chronic tests are very difficult to conduct with most such species, but it is likely that the sensitivities of embryos and larvae would determine the results of life-cycle tests. Thus, if the lowest available SMAVs were determined with embryos and larvae of such species, the Final Acute-Chronic Ratio should probably be assumed to be 2, so that the Final Chronic Value is equal to the Criterion Maximum Concentration (see Section XI.B).

4. If the most appropriate species mean acute-chronic ratios are less than 2.0, and especially if they are less than 1.0, acclimation has probably occurred during the chronic test. Because continuous exposure and acclimation cannot be assured to provide adequate protection in field situations, the Final Acute-Chronic Ratio should be assumed to be 2, so that the Final Chronic Value is equal to the Criterion Maximum Concentration (see Section XI.B).

If the available species mean acute-chronic ratios do not fit one of these cases, a Final Acute-Chronic Ratio probably cannot be obtained, and a Final Chronic Value probably cannot be calculated.

L. Calculate the Final Chronic Value by dividing the Final Acute Value by the Final Acute-Chronic Ratio. If there was a Final Acute Equation rather than a Final Acute Value, see also Section VII.A.

M. If the Species Mean Chronic Value of a commercially or recreationally important species is lower than the calculated Final Chronic Value, then that Species Mean Chronic Value should be used as the Final Chronic Value instead of the calculated Final Chronic Value.

N. Go to Section VIII.

VII. Final Chronic Equation

A. A Final Chronic Equation can be derived in two ways. The procedure described here in Section A will result in the chronic slope being the same as the acute slope. The procedure described in Sections B-N will usually result in the chronic slope being different from the actual slope.

1. If acute-chronic ratios are available for enough species at enough values of the water quality characteristic to indicate that the acute-chronic ratio is probably the same for all species and is probably independent of the water quality characteristic, calculate the Final Acute-Chronic Ratio as the geometric mean of the available species mean acute-chronic ratios.

2. Calculate the Final Chronic Value at the selected value Z of the water quality characteristic by dividing the Final Acute Value at Z (see Section V.M.) by the Final Acute-Chronic Ratio.

NMED Exhibit 85

3. Use V = pooled acute slope (see section V.M.) as L = pooled chronic slope.

4. Go to Section VII.M.

B. When enough data are available to show that chronic toxicity to at least one species is related to a water quality characteristic, the relationship should be taken into account as described in Sections B-G below or using analysis of covariance [15, 16]. The two methods are equivalent and produce identical results. The manual method described below provides an understanding of this application of covariance analysis, but computerized versions of covariance analysis are much more convenient for analyzing large data sets. If two more factors affect toxicity, multiple regression analysis should be used.

C. For each species for which comparable chronic toxicity values are available at two or more different values of the water quality characteristic, perform a least squares regression of the chronic toxicity values on the corresponding values of the water quality characteristic to obtain the slope and its 95% confidence limits for each species.

NOTE: Because the best documented relationship is that between hardness and acute toxicity of metals in fresh water and a log-log relationship fits these data, geometric means and natural logarithms of both toxicity and water quality are used in the rest of this section. For relationships based on other water quality characteristics, such as pH, temperature, or salinity, no transformation or a different transformation might fit the data better, and appropriate changes will be necessary throughout this section. It is probably preferable, but not necessary, to use the same transformation that was used with the acute values in Section V.

D. Decide whether the data for each species is useful, taking into account the range and number of the tested values of the water quality characteristic and the degree of agreement within and between species. For example, a slope based on six data points might be of limited value if it is based only on data for a very narrow range of values of the water quality characteristic. A slope based on only two data points, however, might be useful if it is consistent with other information and if the two points cover a broad enough range of the water quality characteristic. In addition, chronic values that appear to be questionable in comparison with other acute and chronic data available for the same species and for other species in the same genus probably should not be used. For example, if after adjustment for the water quality characteristic, the chronic values available for a species or genus differ by more than a factor of 10, rejection of some or all of the values is probably appropriate. If a useful chronic slope is not available for at least one species or if the available slopes are too dissimilar or if too few data are available to adequately define the relationship between chronic toxicity and the water quality characteristic, it might be appropriate to assume that the chronic slope is the same as the acute slope, which is equivalent to assuming that the acute-chronic ratio is independent of the water quality characteristic. Alternatively, return to Section VI.H, using the results of tests

NMED Exhibit 85

conducted under conditions and in waters similar to those commonly used for toxicity tests with the species.

E. Individually for each species calculate the geometric mean of the available chronic values and then divide each chronic value for a species by the mean for the species. This normalizes the chronic values so that the geometric mean of the normalized values for each species individually and for any combination of species is 1.0.

F. Similarly normalize the values of the water quality characteristic for each species individually.

G. Individually for each species perform a least squares regression of the normalized chronic toxicity values on the corresponding normalized values of the water quality characteristic. The resulting slopes and the 95% confidence limits will be identical to those obtained in Section B above. Now, however, if the data are actually plotted, the line of best fit for each individual species will go through the point 1,1 in the center of the graph.

H. Treat all the normalized data as if they were all for the same species and perform a least squares regression of all the normalized chronic values on the corresponding normalized values of the water quality characteristic to obtain the pooled chronic slope, L, and its 95% confidence limits. If all the normalized data are actually plotted, the line of best fit will go through the point 1,1 in the center of the graph.

I. For each species calculate the geometric mean, M, of the toxicity values and the geometric mean, P, of the values of the water quality characteristic. (These were calculated in steps E and F above.)

J. For each species calculated the logarithm, Q, of the Species Mean Chronic Value at a selected value, Z, of the water quality characteristic using the equation: $Q = \ln M - L(\ln P - \ln Z)$.

NOTE: Although it is not necessary, it will usually be best to use the same value of the water quality characteristic here as was used in Section V.I.

K. For each species calculate a Species Mean Chronic Value at Z using the equation: $SMCV = e^{Q}$.

NOTE: Alternatively, the Species Mean Chronic Values at Z can be obtained by skipping step J above, using the equations in steps J and K to adjust each acute value individually to Z and then calculating the geometric means of the adjusted values for each species individually. This alternative procedure allows an examination of the range of the adjusted chronic values for each species.

L. Obtain the Final Chronic Value at Z by using the procedure described in Section IV.J-O.

M. If the Species Mean Chronic Value at Z of a commercially or recreationally important species is lower than the calculated Final Chronic Value at Z, then that Species Mean

NMED Exhibit 85

N. The Final Chronic Equation is written as: Final Chronic Value = $e^{(L[\ln(\text{water quality characteristic})] + \ln S - L[\ln Z])}$, where L = pooled chronic slope and S = Final Chronic Value at Z. Because L, S and Z are known, the Final Chronic Value can be calculated for any selected value of the water quality characteristic.

VIII. Final Plant Value

A. Appropriate measures of the toxicity of the material to aquatic plants are used to compare the relative sensitivities of aquatic plants and animals. Although procedures for conducting and interpreting the results of toxicity tests with plants are not well developed, results of tests with plants usually indicate that criteria which adequately protect aquatic animals and their uses will probably also protect aquatic plants and their uses.

B. A plant value is the result of a 96-hr test conducted with an alga or a chronic test conducted with an aquatic vascular plant.

NOTE: A test of the toxicity of a metal to a plant usually should not be used if the medium contained an excessive amount of a complexing agent, such as EDTA, that might affect the toxicity of the metal. Concentrations of EDTA above about 200 µg/L should probably be considered excessive.

C. The Final Plant Value should be obtained by selecting the lowest result from a test with an important aquatic plant species in which the concentrations of test material were measured and the endpoint was biologically important.

IX. Final Residue Value

A. The Final Residue Value is intended to (a) prevent concentrations in commercially or recreationally important aquatic species from affecting marketability because of exceedance of applicable FDA action levels and (b) protect wildlife, including fishes and birds, that consume aquatic organisms from demonstrated unacceptable effects. The Final Residue Value is the lowest of the residue values that are obtained by dividing maximum permissible tissue concentrations by appropriate bioconcentration or bioaccumulation factors. A maximum permissible tissue concentration is either (a) an FDA action level [12] for fish oil or for the edible portion of fish or shellfish, or (b) a maximum acceptable dietary intake based on observations on survival, growth, or reproduction in a chronic wildlife feeding study or a long-term wildlife field study. If no maximum permissible tissue concentration is available, go to Section X because no Final Residue Value can be derived.

B. Bioconcentration factors (BCFs) and bioaccumulation factors (BAFs) are quotients of the concentration of a material in one or more tissues of an aquatic organism divided by the average concentration in the solution in which the organism had been living. A BCF is intended to account only for net uptake directly from water, and thus almost

NMED Exhibit 85

has to be measured in a laboratory test. Some uptake during the bioconcentration test might not be directly from water if the food sorbs some of the test material before it is eaten by the test organisms. A BAF is intended to account for the net uptake from both food and water in a real-world situation. A BAF almost has to be measured in a field situation in which predators accumulate the material directly from water and by consuming prey that itself could have accumulated the material from both food and water. The BCF and BAF are probably similar for a material with a low BCF, but the BAF is probably higher than the BCF for materials with high BCFs. Although BCFs are not too difficult to determine, very few BAFs have been measured acceptably because it is necessary to make enough measurements of the concentration of the material in water to show that it was reasonably constant for a long enough period of time over the range of territory inhabited by the organisms. Because so few acceptable BAFs are available, only BCFs will be discussed further. However, if an acceptable BAF is available for a material, it should be used instead of any available BCFs.

C. If a maximum permissible tissue concentration is available for a substance (e.g., parent material, parent material plus metabolites, etc.), the tissue concentration used in the calculation of the BCF should be for the same substance. Otherwise, the tissue concentration used in the calculation of the BCF should be that of the material and its metabolites which are structurally similar and are not much more soluble in water than the parent material.

D.

1. A BCF should be used only if the test was flow-through, the BCF was calculated based on measured concentrations of the test material in tissue and in the test solution, and the exposure continued at least until either apparent steady-state or 28 days was reached. Steady-state is reached when the BCF does not change significantly over a period of time, such as two days or 16 percent of the length of the exposure, whichever is longer. The BCF used from a test should be the highest of (a) the apparent steady-state BCF, if apparent steady-state was reached, (b) the highest BCF obtained, if apparent steady-state was not reached, and (c) the projected steady-state BCF, if calculated.

2. Whenever a BCF is determined for a lipophilic material, the percent lipids should also be determined in the tissue(s) for which the BCF was calculated.

3. A BCF obtained from an exposure that adversely affected the test organisms may be used only if it is similar to a BCF obtained with unaffected organisms of the same species at lower concentrations that did not cause adverse effects.

4. Because maximum permissible tissue concentrations are almost never based on dry weights, a BCF calculated using dry tissue weights must be converted to a wet tissue weight basis. If no conversion factor is reported with the BCF, multiply the dry weight BCF by 0.1 for plankton and by 0.2 for individual species of fishes and invertebrates [17].

NMED Exhibit 85

5. If more than one acceptable BCF is available for a species, the geometric mean of the available values should be used, except that if the BCFs are from different lengths of exposure and the BCF increases with length of exposure, the BCF for the longest exposure should be used.

E. If enough pertinent data exist, several residue values can be calculated by dividing maximum permissible tissue concentrations by appropriate BCFs:

1. For each available maximum acceptable dietary intake derived from a chronic feeding study or a long-term field study with wildlife, including birds and aquatic organisms, the appropriate BCF is based on the whole body of aquatic species which constitute or represent a major portion of the diet of the tested wildlife species.

2. For an FDA action level for fish or shellfish, the appropriate BCF is the highest geometric mean species BCF for the edible portion (muscle for decapods, muscle with or without skin for fishes, adductor muscle for scallops, and total soft tissue for other bivalve molluscs) of a consumed species. The highest species BCF is used because FDA action levels are applied on a species-by-species basis.

F. For lipophilic materials, it might be possible to calculate additional residue values. Because the steady-state BCF for a lipophilic material seems to be proportional to percent lipids from one tissue to another and from one species to another [18, 19, 20], extrapolations can be made from tested tissues or species to untested tissues or species on the basis of percent lipids.

1. For each BCF for which the percent lipids is known for the same tissue for which the BCF was measured, normalize the BCF to a one percent lipid basis by dividing the BCF by the percent lipids. This adjustment to a one percent lipid basis is intended to make all the measured BCFs for a material comparable regardless of the species or tissue with which the BCF was measured.

2. Calculate the geometric mean normalized BCF. Data for both saltwater and freshwater species should be used to determine the mean normalized BCF, unless the data show that the normalized BCFs are probably not similar.

3. Calculate all possible residue values by dividing the available maximum permissible tissue concentrations by the mean normalized BCF and by the percent lipids values appropriate to the maximum permissible tissue concentrations, i.e.,

$$\text{Residue Value} = \frac{(\text{maximum permissible tissue concentration})}{(\text{mean normalized BCF})\,(\text{appropriate percent lipids})}$$

a. For an FDA action level for fish oil, the appropriate percent lipids value is 100.

NMED Exhibit 85

b. For an FDA action level for fish, the appropriate percent lipids value is 11 for freshwater criteria and 10 for saltwater criteria because FDA action levels are applied on a species-by-species basis to commonly consumed species. The highest lipid contents in the edible portions of important consumed species are about 11 percent for both the freshwater chinook salmon and lake trout and about 10 percent for the saltwater Atlantic herring [21].

c. For a maximum acceptable dietary intake derived from a chronic feeding study or a long-term field study with wildlife, the appropriate percent lipids is that of an aquatic species or group of aquatic species which constitute a major portion of the diet of the wildlife species.

G. The Final Residue Value is obtained by selecting the lowest of the available residue values.

NOTE: In some cases the Final Residue Value will not be low enough. For example, a residue value calculated from an FDA action level will probably result in an average concentration in the edible portion of a fatty species that is at the action level. Some individual organisms, and possibly some species, will have residue concentrations higher than the mean value but no mechanism has been devised to provide appropriate additional protection. Also, some chronic feeding studies and long-term field studies with wildlife identify concentrations that cause adverse effects but do not identify concentrations which do not cause adverse effects; again no mechanism has been devised to provide appropriate additional protection. These are some of the species and uses that are not protected at all times in all places.

X. Other Data

Pertinent information that could not be used in earlier sections might be available concerning adverse effects on aquatic organisms and their uses. The most important of these are data on cumulative and delayed toxicity, flavor impairment, reduction in survival, growth, or reproduction, or any other adverse effect that has been shown to be biologically important. Especially important are data for species for which no other data are available. Data from behavioral, biochemical, physiological, microcosm, and field studies might also be available. Data might be available from tests conducted in unusual dilution water (see IV.D and VI.D), from chronic tests in which the concentrations were not measured (see VI.B), from tests with previously exposed organisms (see II.F), and from tests on formulated mixtures or emulsifiable concentrates (see II.D). Such data might affect a criterion if the data were obtained with an important species, the test concentrations were measured, and the endpoint was biologically important.

XI. Criterion

A. A criterion consists of two concentrations: the Criterion Maximum Concentration and the Criterion Continuous Concentration.

NMED Exhibit 85

B. The Criterion Maximum Concentration (CMC) is equal to one-half the Final Acute Value.

C. The Criterion Continuous Concentration (CCC) is equal to the lowest of the Final Chronic Value, the Final Plant Value, and the Final Residue Value, unless other data (see Section X) show that a lower value should be used. If toxicity is related to a water quality characteristic, the CCC is obtained from the Final Chronic Equation, the Final Plant Value, and the Final Residue Value by selecting the one, or the combination, that results in the lowest concentrations in the usual range of the water quality characteristic, unless other data (see Section X) show that a lower value should be used.

D. Round [14] both the CMC and the CCC to two significant digits.

E. The criterion is stated as:

The procedures described in the "Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses" indicate that, except possibly where a locally important species is very sensitive, (1) aquatic organisms and their uses should not be affected unacceptably if the four-day average concentration of (2) does not exceed (3) µg/L more than once every three years on the average and if the one-hour average concentration does not exceed (4) µg/L more than once every three years on the average.

where (1) = insert "freshwater" or "saltwater"

(2) = insert name of material

(3) = insert the Criterion Continuous Concentration

(4) = insert the Criterion Maximum Concentration.

XII. Final Review

A. The derivation of the criterion should be carefully reviewed by rechecking each step of the Guidelines. Items that should be especially checked are:

1. If unpublished data are used, are they well documented?
2. Are all required data available?
3. Is the range of acute values for any species greater than a factor of 10?
4. Is the range of Species Mean Acute Values for any genus greater than a factor of 10?
5. Is there more than a factor of ten difference between the four lowest Genus Mean Acute Values?
6. Are any of the four lowest Genus Mean Acute Values questionable?

NMED Exhibit 85

7. Is the Final Acute Value reasonable in comparison with the Species Mean Acute Values and Genus Mean Acute Values?

8. For any commercially or recreationally important species, is the geometric mean of the acute values from flow-through tests in which the concentrations of test material were measured lower than the Final Acute Value?

9. Are any of the chronic values questionable?

10. Are chronic values available for acutely sensitive species?

11. Is the range of acute-chronic ratios greater than a factor of 10?

12. Is the Final Chronic Value reasonable in comparison with the available acute and chronic data?

13. Is the measured or predicted chronic value for any commercially or recreationally important species below the Final Chronic Value?

14. Are any of the other data important?

15. Do any data look like they might be outliers?

16. Are there any deviations from the Guidelines? Are they acceptable?

B. On the basis of all available pertinent laboratory and field information, determine if the criterion is consistent with sound scientific evidence. If it is not, another criterion, either higher or lower, should be derived using appropriate modifications of these Guidelines.

Appendix 1. Resident North American Species of Aquatic Animals Used in Toxicity and Bioconcentation Tests

Introduction

These lists identify species of aquatic animals which have reproducing wild populations in North America and have been used in toxicity or bioconcentration tests. "North America" includes only the 48 contiguous states, Canada, and Alaska; Hawaii and Puerto Rico are not included. Saltwater (i.e., estuarine and true marine) species are considered resident in North America if they inhabit or regularly enter shore waters on or above the continental shelf to a depth of 200 meters. Species do not have to be native to be resident. Unlisted species should be considered resident North American species if they can be similarly confirmed or if the test organisms were obtained from a wild population in North America.

The sequence for fishes is taken from A List of Common and Scientific Names of Fishes from the United States and Canada. For other species, the sequence of phyla, classes, and families is taken from the NODC Taxonomic Code, Third Edition, National Oceanographic Data Center, NOAA, Washington, DC 20235, July, 1981, and the numbers given are from that source to facilitate verification. Within a family, genera are in alphabetical order, as are species in a genus.

The references given are those used to confirm that the species is a resident North American species. (The NODC Taxonomic Code contains foreign as well as North American species.) If no such reference could be found, the species was judged to be nonresident. No reference is given for organisms not identified to species; these are considered resident only if obtained from wild North American populations. A few nonresident species are listed in brackets and noted as "nonresident" because they were mistakenly identified as resident in the past or to save other investigators from doing literature searches on the same species.

Special Note

This December 2010 electronic version of the 1985 Guidelines serves to meet the requirements of Section 508 of the Rehabilitation Act. While converting the 1985 Guidelines to a 508-compliant version, EPA updated the taxonomic nomenclature to reflect changes that occurred since the tables were originally produced in 1985. The numbers included for Phylum, Class and Family represent those currently in use from the Integrated Taxonomic Information System, or ITIS, and reflect what is referred to in ITIS as Taxonomic Serial Numbers. ITIS replaced the National Oceanographic Data Center (NODC) taxonomic coding system which was used to create the original taxonomic tables included in the 1985 Guidelines document (NODC, Third Addition - see Introduction). For more information on the NODC taxonomic codes, see http://www.nodc.noaa.gov/General/CDR-detdesc/taxonomic-v8.html.

The code numbers included in the reference column of the tables have not been updated from the 1985 version. These code numbers are associated with the old NODC taxonomic referencing system and are simply replicated here for historical purposes. Footnotes may or may not still apply.

EPA is working on a more comprehensive update to the 1985 Guidelines, including new taxonomic tables which better reflect the large number of aquatic animal species known to be propagating in U.S. waters.

NMED Exhibit 85

Freshwater Species Table

Synonyms appear after the official Scientific Name and are marked with an asterisk (*).
Non-resident species are noted in the Reference column and are marked with a dagger (†)

Footnotes for Freshwater Species

[1] Apparently this is an outdated name (D19, 20). Organisms identified as such should only be used if they were obtained from North America.

[2] Apparently this is an outdated name (D19, 20). Organisms identified as such should only be used if they were obtained from North America.

[3] If from North America, it is resident and should be called *D. similis* (C). If not from North America, it should be considered nonresident.

[4] If from North America, it is resident and may be any one of a number of species such as *D. laevie*, *D. dubia*, or *D. galeate mendoca* (C). If not from North America, it should be considered nonresident.

[5] If from North America, it is resident and may be any one of a number of species such as *D. ambigua*, *D. longiremis*, or *D. rosea* (C). If not from North America, it should be considered nonresident.

[6] This species might be established in portions of the southern United States.

[7] The taxonomy of this species and this and similar genera has not been clarified, but this species should be considered resident.

Footnotes for Saltwater Species

[1] Organisms not identified to species are considered resident only if obtained from wild populations in North America.

[2] This species should not be used because it might be too atypical.

[3] This species might be established in portions of the southern United States.

NMED Exhibit 85

Appendix 2. Example Calculation of Final Acute Value, Computer Program, and Printouts

A. Example Calculation

N = total number of MAVs in data set = 8

Rank	MAV	ln(MAV)	$\ln(MAV)^2$	P = R / (N+1)	$\sqrt{P}$
4	6.4	1.8563	3.4458	0.44444	0.66667
3	6.2	1.8245	3.3290	0.33333	0.57735
2	4.8	1.5686	2.4606	0.22222	0.47140
1	0.4	-0.9163	0.8396	0.11111	0.33333
Sum		4.3331	10.0750	1.11110	2.04875

$$S^2 = \frac{10.0750 - (4.3331)^2 / 4}{1.11110 - (2.04875)^2 / 4} = 87.134$$

$S = 9.3346$

$L = [\ 4.3331 - (9.3346)(2.04875)] / 4 = -3.6978$

$A = (9.3346)\ (\sqrt{0.05}\ ) - 3.6978 = -1.6105$

$FAV = e^{-1.6105} = 0.1998$

B. Example Computer Program in BASIC Language for Calculating the FAV

```
10    REM This program calculates the FAV when there are less than
20    REM 59 MAVs in the data set
30    X = 0
40    X2 = 0
50    Y = 0
60    Y2 = 0
70    PRINT "How many MAVs are in the data set?"
80    INPUT N
90    PRINT "What are the four lowest MAVs?"
100   FOR R = 1 TO 4
110         INPUT V
```

```
120         X = X + LOG(V)
130         X2 = X2 + (LOG(V)) * (LOG(V))
140         P = R / (N + 1)
150         Y2 = Y2 + P
160         Y = Y + SQR((X2 – X * X / 4))
170   NEXT R
180   S = SQR((X2 – X * X / 4) / (Y2 – Y * Y / 4))
190   L = (X – S * Y) / 4
200   A = S * SQR(0.05) + L
210   F = EXP(A)
220   PRINT "FAV = " F
230   END
```

This document has been reviewed by the Criteria and Standards Division, Office of Water Regulations and Standards, U.S. Environmental Protection Agency, and approved for publication.

Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

This document is available to the public through the National Technical Information Service (NTIS), 5285 Port Royal Road, Springfield, VA 22161.
NTIS Number: PB 87 153581

NMED Exhibit 86

FOREWORD

Section 304(a)(1) of the Clean Water Act of 1977 (P.L. 95-217) requires the Administrator of the Environmental Protection Agency to publish water quality criteria that accurately reflect the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare that might be expected from the presence of pollutants in any body of water, including ground water. This document is a revision of proposed criteria based upon consideration of comments received from other Federal agencies, State agencies, special interest groups, and individual scientists. Criteria contained in this document replace any previously published EPA aquatic life criteria for the same pollutant(s).

The term "water quality criteria" is used in two sections of the Clean Water Act, section 304(a)(1) and section 303(c)(2). The term has a different program impact in each section. In section 304, the term represents a non-regulatory, scientific assessment of ecological effects. Criteria presented in this document are such scientific assessments. If water quality criteria associated with specific stream uses are adopted by a State as water quality standards under section 303, they become enforceable maximum acceptable pollutant concentrations in ambient waters within that State. Water quality criteria adopted in State water quality standards could have the same numerical values as criteria developed under section 304. However, in many situations States might want to adjust water quality criteria developed under section 304 to reflect local environmental conditions and human exposure patterns before incorporation into water quality standards. It is not until their adoption as part of State water quality standards that criteria become regulatory.

Guidelines to assist States in the modification of criteria presented in this document, in the development of water quality standards, and in other water-related programs of this Agency, have been developed by EPA.

William A. Whittington
Director
Office of Water Regulations and Standards

NMED Exhibit 86

Introduction*

Zinc is the fourth most widely used metal in the world (Cammarota 1980), and its major uses are for galvanizing steel, for producing alloys, and as an ingredient in rubber and paints. Because zinc(II) substitutes to some extent for magnesium in the silicate minerals of igneous rocks, weathering of bedrock gives rise to zinc in surface water. Zinc always has the oxidation state of +2 in aqueous solution. Zinc(II) is amphoteric, dissolving in acids to form hydrated Zn(II) cations and in strong bases to form zincate anions, usually $Zn(OH)_4^{-2}$. Complexes of zinc with the common ligands of surface waters are soluble in neutral and acidic solutions, so that zinc is readily transported in most natural waters and is one of the most mobile of the heavy metals. Concentrations of zinc in uncontaminated fresh water are typically in the range of 0.5 to 10 µg/L (Trefry and Presley 1979), whereas concentrations in clean sea water range from 0.002 to 0.1 µg/L and increase with depth (Salomons and Forstner 1984; Wallace et al. 1983).

Zinc occurs in many forms in natural waters and aquatic sediments. At pH = 6.0 in fresh water, the dominant forms of dissolved zinc are the free ion (98%) and zinc sulfate (2%), whereas at pH = 9.0, the dominant forms are the mono-hydroxide ion (78%), zinc carbonate (16%), and the free ion (6%) (Turner et al. 1981). In sea water at pH = 8.1, the dominant species of soluble zinc are zinc hydroxide (62%), the free ion (17%), the mono-chloride ion (6.4%), and zinc carbonate (5.8%)

---

* An understanding of the "Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses" (Stephan et al. 1985), hereafter referred to as the Guidelines, and the response to public comment (U.S. EPA 1985a) is necessary in order to understand the following text, tables, and calculations.

NMED Exhibit 86

(Zirino and Yamamoto 1972). At pH = 7.0, the percentage of dissolved zinc present in sea water as the free ion increases to 50%. In the presence of dissolved organic materials, particularly humic substances, the major fraction of dissolved zinc is in the form of zinc-organic complexes (Lu and Chen 1977).

Zinc can be present in sediments in several forms, including precipitated $Zn(OH)_2$, precipitates with ferric and manganic oxyhydroxides, insoluble organic complexes, insoluble sulfides, and residual forms (Patrick et al. 1977). As sediments change from a reduced to an oxidized state, more zinc is mobilized and released in a soluble form (Lu and Chen 1977). The bioavailability of different forms of zinc in sediment varies substantially and is poorly understood (Luoma and Bryan 1979). Baccini (1985), Krantzberg and Stokes (1985), and Salomons (1985) reported that benthic organisms influenced the partitioning of zinc between sediment and the water column.

Most of the zinc introduced into the aquatic environment is partitioned into sediment by sorption onto hydrous iron and manganese oxides, clay minerals, and organic materials (Lu and Chen 1977; Luoma and Bryan 1981; Parker et al. 1982; Warren 1981). Precipitation of the sulfide is an important control on the mobility of zinc in reducing environments, and precipitation of the hydroxide, carbonate, and basic sulfate salts can occur when zinc is present in high concentrations. Formation of complexes with organic and inorganic ligands can increase the solubility of zinc and might increase or decrease the tendency for zinc to be sorbed (Salomons and Forstner 1984).

The tendency of zinc to be sorbed is affected not only by the form of the zinc and the nature and concentration of the sorbent but also by pH

NMED Exhibit 86

and salinity. In a study of heavy metal sorption by two oxides and two soils, zinc was completely removed from solution when pH exceeded 7, but little or no zinc was sorbed when pH was below 6. Addition of inorganic complexing ligands enhanced sorption (Huang et al. 1977). Helz et al. (1975) and Solomons (1980) found less sorption of zinc to particulate matter and sediment as salinity increased. This phenomenon was exhibited by many other metals as well and apparently is due to displacement of the sorbed zinc ions by alkali and alkaline earth cations, which are abundant in brackish and saline waters. An increase in pH can increase sorption of zinc even if salinity increases (Millward and Moore 1982; Solomons 1980). Watanabe et al. (1985) reported that sorption of zinc was also dependent on the organic carbon content of river sediments.

Zinc is an essential micronutrient for all living organisms (Leland and Kuwabara 1985). Because zinc is essential, aquatic organisms have evolved efficient mechanisms for accumulation of zinc from water and food. The concentration of zinc in tissues of aquatic organisms is far in excess of that required for various metabolic functions (Wolfe 1970). Much of the excess zinc is bound to macromolecules or is present as insoluble metal inclusions in tissues (Simkiss et al. 1982). Inducible low molecular weight metal-binding proteins, metallothioneins, are thought to function, in part, in the intracellular sequestration and regulation of the essential metals zinc and copper (Kojima and Kogi 1978; Roesijadi 1981).

Above some theoretical maximum beneficial concentration of zinc in water, there exists a range of zinc concentrations that is readily tolerated through each organism's capacity to regulate the uptake, internal distribution, and excretion of zinc (Weiner and Giesy 1979). This range undoubtedly varies among individuals, species, and larger phylogenetic groups. In

NMED Exhibit 86

addition, this tolerated range probably varies with the range of zinc concentrations to which various populations have been historically exposed and acclimated. Thus, biological variability in tolerance of zinc is probably the result of phylogenetic differences and historic exposure patterns, both short-term and geologic in scale.

Paramount to the question of the toxicity of zinc are the physical and chemical forms of zinc, the toxicity of each form, and the degree of interconversion among the various forms. Presumably, all forms of zinc that can be sorbed or bound by biological tissues are potentially toxic. Most likely, zinc will not be sorbed or bound unless it is dissolved, but some dissolution of zinc can reasonably be expected to occur in the alimentary canal following ingestion of particulates containing undissolved zinc. Thus, the toxicity of undissolved zinc to a particular species probably depends on feeding habits. Therefore, plants and most fish are probably relatively unaffected by suspended zinc, but many invertebrates and some fishes might be adversely affected by ingestion of sufficient quantities of particulates containing zinc.

The toxicity of zinc, as well as other heavy metals, is apparently influenced by a number of chemical factors including calcium, magnesium, hardness, pH, and ionic strength. These factors appear to affect the toxicity of zinc either by influencing the availability of zinc or by inhibiting the sorption or binding of available zinc by biological tissues. In fresh water zinc appears to be less toxic at high hardness for a variety of reasons, such as:

1) The ions contributing to hardness, primarily calcium and magnesium, are divalent and compete with zinc, which is also divalent, for sites of uptake and binding in biological tissues.

NMED Exhibit 86

2) Harder waters have higher ionic strengths due to the greater quantity of charged ions (primarily mono- and divalent cations and anions) in solution, and these ions electrostatically inhibit the ability of other ions, such as zinc, to approach the sorption or binding sites of the organisms. Thus zinc ions have lower activity in harder waters.

3) Generally, harder waters have higher alkalinities and higher pHs, resulting in the formation of insoluble, and possible soluble, zinc carbonate and hydroxide compounds that are not sorbed by many species.

Thus, hardness appears to be the single best water quality characteristic to reflect the variation in zinc toxicity induced by differences in general water chemistry.

Because of the variety of forms of zinc (Callahan et al. 1979; Hem 1972; Salomons and Forstner 1984) and lack of definitive information about their relative toxicities, no available analytical measurement is known to be ideal for expressing aquatic life criteria for zinc. Previous aquatic life criteria for zinc (U.S. EPA 1980) were expressed in terms of total recoverable zinc (U.S. EPA 1983a), but this measurement is probably too rigorous in some situations. Acid-soluble zinc (operationally defined as the zinc that passes through a 0.45 μm membrane filter after the sample is acidified to pH = 1.5 to 2.0 with nitric acid) is probably the best measurement at the present for the following reasons:

1. This measurement is compatible with nearly all available data concerning toxicity of zinc to, and bioaccumulation of zinc by, aquatic organisms. No test results were rejected just because it was likely that they would have been substantially different if they had been reported in terms of acid-soluble zinc. For example, results reported in terms of dissolved

NMED Exhibit 86

zinc would not have been used if the concentration of precipitated zinc had been substantial.

2. On samples of ambient water, measurement of acid-soluble zinc will probably measure all forms of zinc that are toxic to aquatic life or can be readily converted to toxic forms under natural conditions. In addition, this measurement probably will not measure several forms, such as zinc that is occluded in minerals, clays, and sand or is strongly sorbed to particulate matter, that are not toxic and are not likely to become toxic under natural conditions. Although this measurement (and many others) will measure soluble complexed forms of zinc, such as the EDTA complex of zinc, that probably have low toxicities to aquatic life, concentrations of these forms probably are negligible in most ambient water.
3. Although water quality criteria apply to ambient water, the measurement used to express criteria is likely to be used to measure zinc in aqueous effluents. Measurement of acid-soluble zinc probably will be applicable to effluents because it will measure precipitates, such as carbonate and hydroxide precipitates of zinc, that might exist in an effluent and dissolve when the effluent is diluted with receiving water. If desired, dilution of effluent with receiving water before measurement of acid-soluble zinc might be used to determine whether the receiving water can decrease the concentration of acid-soluble zinc because of sorption.
4. The acid-soluble measurement is probably useful for most metals, thus minimizing the number of samples and procedures that are necessary.
5. The acid-soluble measurement does not require filtration at the time of collection, as does the dissolved measurement.

NMED Exhibit 86

6. The only treatment required at the time of collection is preservation by acidification to pH = 1.5 to 2.0, similar to that required for the total recoverable measurement.
7. Durations of 10 minutes to 24 hours between acidification and filtration of most samples of ambient water probably will not affect the result substantially.
8. The carbonate system has a much higher buffer capacity from pH = 1.5 to 2.0 than it does from pH = 4 to 9 (Weber and Stumm 1963).
9. Differences in pH within the range of 1.5 to 2.0 probably will not affect the result substantially.
10. The acid-soluble measurement does not require a digestion step, as does the total recoverable measurement.
11. After acidification and filtration of the sample to isolate the acid-soluble zinc, the analysis can be performed using either atomic absorption spectrophotometric or ICP-atomic emission spectrometric analysis (U.S. EPA 1983a), as with the total recoverable measurement.

Thus, expressing aquatic life criteria for zinc in terms of the acid-soluble measurement has both toxicological and practical advantages. On the other hand, because no measurement is known to be ideal for expressing aquatic life criteria for zinc or for measuring zinc in ambient water or aqueous effluents, measurement of both acid-soluble zinc and total recoverable zinc in ambient water or effluent or both might be useful. For example, there might be cause for concern if total recoverable zinc is much above an applicable limit, even though acid-soluble zinc is below the limit.

NMED Exhibit 86

Unless otherwise noted, all concentrations reported herein from toxicity and bioconcentration tests are expected to be essentially equivalent to acid-soluble zinc concentrations. All concentrations are expressed as zinc, not as the chemical tested. The criteria presented herein supersede previous aquatic life water quality criteria for zinc (U.S. EPA 1976,1980) because these new criteria were derived using improved procedures and additional information. Whenever adequately justified, a national criterion may be replaced by a site-specific criterion (U.S. EPA 1983b), which may include not only site-specific criterion concentrations (U.S. EPA 1983c), but also site-specific durations of averaging periods and site-specific frequencies of allowed excursions (U.S. EPA 1985b). The latest comprehensive literature search for information for this document was conducted in July, 1986; some more recent information might have been included.

Acute Toxicity to Aquatic Animals

Available data, which are usable according to the Guidelines, on the acute toxicity of zinc to aquatic animals are presented in Table 1. Acute values for freshwater invertebrates ranged from 32 to 40,930 µg/L (Table 1), and those for fishes ranged from 66 to 40,900 µg/L, except for two values that appeared high for the guppy. The two ranges are very similar and very wide, probably due at least in part to hardness-related factors.

Although many factors might affect the results of tests of the toxicity of zinc to aquatic organisms (Sprague 1985), water quality criteria can quantitatively take into account only factors for which enough data are available to show that the factor similarly affects the

NMED Exhibit 86

results of tests with a variety of species. Hardness is often thought of as having a major effect on the toxicity of zinc in fresh water, although the observed effect is probably due to one or more of a number of usually interrelated ions, such as hydroxide, carbonate, calcium, and magnesium. Hardness (expressed as mg $CaCO_3$/L) is used here as a surrogate for the ions that affect the results of toxicity tests on zinc. An analysis of covariance (Dixon and Brown 1979; Neter and Wasserman 1974) was performed using the natural logarithm of the acute value as the dependent variable, species as the treatment or grouping variable, and the natural logarithm of hardness as the covariate or independent variable. This analysis of covariance model was fit to the data in Table 1 for the eight species for which acute values are available over a range of hardness such that the highest hardness is at least three times the lowest and the highest is also at least 100 mg/L higher than the lowest. The eight slopes are between 0.56 and 1.65 (see end of Table 1) and most are close to the slope of 1.0 that is expected on the basis that zinc, calcium, magnesium, and carbonate all have a charge of two. An F-test showed that, under the assumption of equality of slopes, the probability of obtaining eight slopes as dissimilar as these is $P = 0.77$. This was interpreted as indicating that it is reasonable to assume that the slopes for these eight species are the same.

Where possible, the pooled slope of 0.8473 was used to adjust the freshwater acute values in Table 1 to hardness = 50 mg/L. Species Mean Acute Values were calculated as geometric means of the adjusted acute values. Five of the seven most resistant species (Table 3) were tested in a series of experiments reported by Rehwoldt et al. (1971,1972,1973) using Hudson River water, and high acute values were obtained in two

NMED Exhibit 86

other tests whose results were placed in Table 6 because the organisms were not identified to genus. It is not known whether the river water reduced the toxicity of zinc or if the species were inherently resistant. Rehwoldt et al. (1971,1972) also reported LC50s of 6,700 and 6,800 µg/L for the striped bass, Morone saxatilis. These were considerably higher than the LC50s reported by Hughes (1970,1973) and Palawski et al. (1985) for the same species, although the values reported by Hughes were not used due to inadequate acclimation of the test organisms.

Genus Mean Acute Values (GMAVs) at hardness = 50 mg/L (Table 3) were then calculated as geometric means of the available freshwater Species Mean Acute Values. The GMAV for Morone was based only on the SMAV for the striped bass because of the probability that the LC50s reported by Rehwoldt et al. (1971,1972) were two high for both species in this genus. Of the 35 genera for which acute values are available, the most sensitive genus, Ceriodaphnia, is about 950 times more sensitive than the most resistant genus, Argia. Acute values are available for more than one species in each of seven genera and the range of Species Mean Acute Values within each genus is less than a factor of 3.7. The freshwater Final Acute Value for zinc at hardness = 50 mg/L was calculated to be 130.1 µg/L using the procedure described in the Guidelines and the Genus Mean Acute Values in Table 3. This value is above the Species Mean Acute Value for a cladoceran and for the striped bass, but the results for the striped bass were not obtained in a flow-through test in which the concentrations of test material were measured. Thus, the freshwater Criterion Maximum Concentration (in µg/L) = $e^{(0.8473[\ln(\text{hardness})]+0.8604)}$

Acute tests considered useful in the derivation of a saltwater criterion for zinc have been conducted with 26 species of invertebrates

NMED Exhibit 86

and 7 species of fish (Table 1). The range of Species Mean Acute Values for saltwater invertebrates extends from 195 µg/L for embryos of the quahog clam, Mercenaria mercenaria, (Calabrese and Nelson 1974) to 320,400 µg/L for adults of the clam Macoma balthica (Bryant et al. 1985). The range of Species Mean Acute Values for fish is narrower, extending from 191.4 µg/L for larvae of the cabezon, Scorpaenichthys marmoratus, (Dinnel et al. 1983) to 38,000 µg/L for juvenile spot, Leiostomus xanthurus (Hansen 1983). As a general rule, early life stages of saltwater invertebrates and fish are more sensitive to zinc than juveniles and adults.

Both temperature and salinity affect the results of acute tests on zinc. The effect of temperature has been studied with four bivalve molluscs and one amphipod, whereas the effect of salinity has been studied with a worm, clam, amphipod, two isopods, and a fish (Table 1). In general, the LC50 increases as salinity increases (presumably because complexation by chloride increases) and as temperature decreases. However, the LC50 for a species also seems to decrease as salinity and temperature deviate from the optimum for the species.

Of the 28 genera for which saltwater Genus Mean Acute Values are available (Table 3), the most sensitive genus, Scorpaenichthys is about 1,700 times more sensitive than the most resistant, Macoma. Clams are both sensitive and resistant to zinc. Acute values are available for more than one species in each of five genera and the range of Species Mean Acute Values within each genus is less than a factor of 5.2. The saltwater Final Acute Value for zinc was calculated to be 190.2 µg/L, which is slightly lower than the acute value for the most sensitive species.

NMED Exhibit 86

Chronic Toxicity to Aquatic Animals

Although most of the chronic toxicity tests conducted on zinc with freshwater species were in soft water ranging in hardness from 25 to 52 mg/L, Chapman et al. (Manuscript) studied the chronic toxicity of zinc to *Daphnia magna* at hardnesses of 52, 104, and 211 mg/L (Table 2). They found that the chronic toxicity of zinc decreased when hardness increased from 52 to 104 mg/L. When hardness was further increased to 211 mg/L, the toxicity of zinc did not change. No other data are available concerning the relationship between hardness and the chronic toxicity of zinc.

The chronic values for the two species of freshwater invertebrates ranged from 46.73 to >5,243 µg/L, whereas those for six species of fish ranged from 36.41 to 854.7 µg/L.

A life-cycle toxicity test has been conducted with the saltwater mysid, *Mysidopsis bahia* (Lussier et al. 1985). Survival, days to first brood, and young/female reproductive day were all affected at 231 µg/L, but no effects were detected at 120 µg/L.

Acute-chronic ratios are available for six freshwater and one saltwater species. The freshwater Species Mean Acute-Chronic Ratios range from 0.7027 to 41.20, whereas the saltwater ratio is 2.997 (Table 3). Because the Final Acute-Chronic Ratio is meant to apply to sensitive species, which often have lower acute-chronic ratios than resistant species, it was calculated as the geometric mean of the ratios for the freshwater *Daphnia magna*, chinook salmon, and rainbow trout and the saltwater mysid. The resulting value of 2.208 is lower than all the other Species Mean Acute-Chronic Ratios (Table 3). Division of the freshwater and saltwater Final Acute Values by 2.208 results in freshwater and saltwater Final Chronic Values of 58.92 µg/L (at hardness = 50 mg/L) and 86.14 µg/L,

NMED Exhibit 86

respectively. In spite of the data on the effect of hardness on the chronic toxicity of zinc to Daphnia magna, the freshwater chronic slope is assumed to be the same as the acute slope, resulting in a freshwater Final Chronic Value = $e^{(0.8473[\ln(\text{hardness})]+0.7614)}$.

Toxicity to Aquatic Plants

Toxicity tests on zinc have been conducted with 20 species of freshwater plants, which were affected by zinc concentrations ranging from 30 to >200,000 µg/L (Table 4). Although tests have been conducted with several vascular plants, both the highest and lowest values were obtained with algae.

Few data are available concerning the effect of hardness on toxicity to plants. One study with the diatom, Navicula seminulum, (Academy of Natural Sciences 1960) tested zinc toxicity at two hardnesses. At hardness = 58.46 mg/L, zinc was more toxic, on the average, than in tests at hardness = 174 mg/L. However, there was overlap in EC50s between the hardnesses tested. The toxicity of zinc to algae might be related to the concentration of phosphate or nitrate (Kuwabara 1985; Rao and Subramanian 1982).

The toxicity of zinc to saltwater plants has been tested with 18 species of phytoplankton and 8 species of macroalgae (Tables 4 and 6). The diatom, Schroederella schroederi, was the most sensitive phytoplankter, with a 48-hour EC50 of 19.01 µg/L. Other species affected at concentrations less than the Final Chronic Value are Cricosphaera carterae, Isochrysis gabana, Thalassiosira rotula, Glenodinium halli, and Gymnodinium splendens. Macroalgae were affected at concentrations $\geq$100 µg/L. Therefore, although data on most saltwater plants indicate that they will be protected by a

NMED Exhibit 86

saltwater criterion derived from data on animals, some phytoplankters might be affected under certain environmental conditions.

Bioaccumulation

Six freshwater species were exposed to zinc and had tissue concentrations measured after sufficient time to achieve steady-state (Table 5). Bioconcentration factors (BCF) ranged from 51 for the Atlantic salmon (Farmer et al. 1979) to 1,130 for a mayfly (Nehring 1976). A mean BCF of 100 was obtained in three tests with a clam (Graney et al. 1983), and the BCF of 106 for a stonefly was much lower than that for the mayfly. Both the flagfish and the guppy had BCFs between 400 and 500. Atchinson et al. (1977), McIntosh and Bishop (1976), and Murphy et al. (1978a,b) measured the concentrations of zinc in several species of fish obtained from a pond contaminated with zinc. Direct accumulation from water did not appear to be a major route of uptake of zinc by two species of fish in a lake (Klaverkamp et al. 1983). Cushing and Rose (1970), Cushing and Watson (1971), and Cushing et al. (1975) studied the uptake of zinc by periphyton and fish in microcosms. Van der Werff (1984) found that humic and fulvic acids reduced the uptake of zinc by an alga.

Bioaccumulation data for zinc are available for six species of saltwater algae and seven species of saltwater animals (Table 5). Steady-state BCFs derived from laboratory exposures of saltwater algae for periods of 0.5 to 140 days ranged from 75.5 for the brown macroalga, Laminaria digitata (Haritonidis et al. 1983) to 10,768 for another brown macroalga, Fucus serratus (Young 1975). BCFs based on data derived from field collections of macroalgae ranged from 1,027 to 2,029 for a third brown macroalga, Fucus vesiculosus (Foster 1976; Foster and Bale 1975).

NMED Exhibit 86

BCFs derived from laboratory exposures of saltwater animals for periods of 14 to 126 days range from 3.692 in the whole body of the shrimp, Pandalus montagui (Ray et al. 1980) to 23,820 in the total soft tissue of the eastern oyster, Crassostrea virginica (Shuster and Pringle 1968).

For the mummichog, Fundulus heteroclitus, the BCF for both whole body and scales decreased with increasing concentration in water between 210 and 7,880 µg/L (Sauer and Watabe 1984). At all concentrations, the scales had a higher BCF than the whole body. Sequestration of zinc in scales, which is accompanied by a decrease in scale calcification (Sauer and Watabe 1984), might be a mechanism of zinc storage or detoxification in fish. O'Grady (1981) showed that sea trout, Salmo trutta, mobilized zinc stored in its scales during the upstream spawning migration.

For both algae and animals, there is a definite trend toward an inverse relationship between concentration in water and BCF. This is best exemplified by the data in Table 5 for the brown macroalga, Laminaria digitata (Bryan 1969) and the mummichog, Fundulus heteroclitus (Sauer and Watabe 1984). Seip (1979) developed a mathematical model for the accumulation of zinc and other metals by the brown macroalga, Ascophyllum nodosum. The concentration of zinc in the alga was found to be an approximately linear function of the mean concentration of zinc in water up to about 100 µg/L. Because the slope of the curve was less than 1, BCFs tended to decrease with increasing concentration in water.

No U.S. FDA action level or other maximum acceptable concentration in tissue is available for zinc, and, therefore, no Final Residue Value can be calculated.

NMED Exhibit 86

Other Data

A wide variety of other data is presented in Table 6. In a test on zinc phosphate, growth of a freshwater green alga was inhibited during a 14-day exposure to 64 µg/L (Garton 1972). Growth of Scenedesmus quadricauda was inhibited during exposure to 1,200 µg/L in river water (Bringmann and Kuhn 1959a,b). The primary productivity of plankton was reduced when exposed to 15 µg/L for 14 days (Marshall et al. 1983).

Several studies have been conducted on the effect of temperature on the acute toxicity of zinc (Braginskiy and Shcherban 1978; Cairns et al. 1975a, 1978; Pickering and Henderson 1966; See et al. 1974; Smith and Heath 1979). Except for the rainbow trout and golden shiners, the species were more sensitive to zinc at higher temperatures. Snails were more sensitive to thermal shock after exposure to zinc (Cairns et al. 1976).

Concentrations of dissolved oxygen down to 3.5 mg/L did not affect the toxicity of zinc to the bluegill, but lower concentrations did (Pickering 1968). Anderson (1973) and Anderson and Weber (1975) found that the acute sensitivity of the guppy to zinc depended on the weight of the fish. Sabodash (1974) studied the effects of zinc and calcium on survival and growth of larval grass carp.

Most insects were more resistant to zinc than the other freshwater species tested. Mayflies, damselflies, stoneflies, and caddisflies had LC50s ranging from 1,330 to 58,100 µg/L (Table 6). One midge (Chironomous sp.) had a 96-hr LC50 of 18,200 µg/L (Rehwoldt et al. 1973), whereas another (Tanytarsus dissimilis) had a 10-day LC50 of 36.8 µg/L (Anderson et al. 1980). The T. dissimilis value is very low compared to other values obtained with insects.

Although most LC50s for rainbow trout ranged from 2,000 to 5,000 µg/L, Garton (1972) obtained an LC50 of 90 µg/L in a test on zinc phosphate.

NMED Exhibit 86

A 7-day EC50 of 10 µg/L was obtained with embryos and larva of the narrow-mouthed toad (Birge 1978; Birge et al. 1979).

Cairns et al. (1975b) and Khangarot (1982) examined the effect of feeding on the results of acute tests on zinc, whereas McLeay and Munro (1979) and Sparks et al. (1972b) studied the effects of photoperiod and shelters, respectively. Brafield and Mattiessen (1976), Hughes (1975), Hughes and Tort (1985), and Thompson et al. (1983) studied the effect of zinc on respiration of fishes. Allen et al. (1980) and Muramota (1978) found that various chelating agents reduced the acute toxicity of zinc. Several studies examined the use of fishes as biomonitoring organisms for zinc (Cairns and Waller 1971; Cairns et al. 1973a; Sparks et al. 1972; Waller and Cairns 1972).

Many studies have examined zinc as a dietary requirement for freshwater plants (e.g., Vaughn et al. 1982) and fish (e.g., Barash et al. 1982; Bell et al. 1984; Dabrowski et al. 1981; Gatlina and Wilson 1983,1984; Jeng and Sun 1981; Ketola 1979; Knox et al. 1982,1984; Ogino and Yang 1978,1979; Richardson et al. 1985; Rodgers 1982; Satoh et al. 1983a,b,c; Takeda and Shimma 1977).

Armitage (1980), Armitage and Blackburn (1985), Austin and Munteanu (1984), Carlson et al. (1986), Eichenberger (1981), Eichenberger et al. (1981), Foster (1982a), Harding et al. (1981), Hughes (1985), Lang and Lang-Dobler (1979), Maas (1978), Meyer (1978), Rice (1977), Roline and Boehmke (1981), Ruthven and Cairns (1973), Say and Whitton (1983), Say et al. (1977), Sheehan and Knight (1985), Shehata and Whitton (1981), Solbe (1973), Swain and White (1985), Swift (1985), Wehr and Whitton (1983b,c), Wentsel and McIntosh (1977), Williams and Mount (1965), Yan

NMED Exhibit 86

et al. (1985), Yasuno et al. (1985), and Zanella (1982) investigated relationships between the abundance and diversity of freshwater species and the concentration of zinc in water and sediment.

The detoxification of zinc was studied by Kito et al. (1982), Klaverkamp et al. (1985), Ley et al. (1983), Marofante (1962), Pierson (1985a,b), Roch and McCarter (1984a,b), and Takeda and Shimizu (1982).

Low concentrations of zinc stimulate the rate of growth of saltwater microalgae. Concentrations equal to or less than 100 µg/L stimulated growth of Nitzchia longissima during exposures lasting one to five days (Subramanian et al. 1980). Similarly, growth of Skeletonema costatum was both stimulated by zinc concentrations equal to or lower than 200 µg/L during one to five days of exposure (Subramanian et al. 1980) and reduced by 20% during exposure for 10 to 14 days to 100 µg/L zinc (Braek et al. 1976). Wikfors and Ukeles (1982) reported a 6.7% increase in the growth of Phaeodactylum tricornutum during exposure for 12 days to 4,800 µg/L. Therefore the difference between beneficial and detrimental concentrations of zinc to phytoplankton might be small and dependent on the species and exposure.

Stromgren (1979) studied the effect of zinc on growth of five species of saltwater macroalgae. Growth was reduced at 1,400, but not 100, µg/l for Ascophyllum nodosum, Fucus serratus, Fucus spiralis, and Pelvetia canaliculata, and at 7,000, but not 3,500, µg/L for Fucus vesiculosus. Bryan (1969) reported reduced growth of Laminaria digitata during exposure for 24 days to concentrations as low as 100 µg/L. A concentration of 250 µg/L reduced growth of sporophytes of Laminaria hyperboria, whereas 5,000 µg/L induced abnormal maturation of gametophytes of the same species (Hopkins and Kain 1971). Zinc concentrations as low as 8.8 µg/L altered lipid metabolism in Fucus serratus (Smith and Harwood 1984).

NMED Exhibit 86

Two ciliate protozoans exhibited markedly different sensitivities to zinc. Growth of Cristigera sp. was reduced by exposure for four to five hours to concentrations as low as 50.63 µg/L (Gray 1974; Gray and Ventilla 1973), but a concentration of 10,000 µg/L only reduced the growth of Euplotes vannus by 10% (Persoone and Uyttersprot 1975).

Bryan and Hummerstone (1973) compared the sensitivity of the polychaete, Nereis diversicolor, from sediments heavily contaminated with zinc and other metals to that of the same species from clean sediments at three salinities (Tables 1 and 6). At all three salinities, worms from the contaminated sediments were less than a factor of two more resistant to zinc than those from clean sediments. Worms from the contaminated sediments also had somewhat lower BCFs than worms from clean sediments when exposed to zinc in the laboratory for 34 days. These results suggest that acclimation or genetic adaptation of the worms to contaminated sediments provided only a minor ability to regulate zinc more efficiently than worms from uncontaminated sediments.

The polychaetes, Ophryotiocha diadema and Ctenodrilus serratus, were exposed to zinc in partial life-cycle tests that began with adults and examined effects on survival and reproduction (Reish and Carr 1978). Population size was reduced 500 µg/L in both static tests but effects of zinc were not detected at 100 µg/L.

A variety of responses were observed in mud snails, Nassarius obsoletus, during exposure for 72 hr to progressively higher concentrations of zinc (MacInnes and Thurberg 1973). At 2,000 µg/L, there was a depression of oxygen consumption. Locomotor behavior was inhibited at 10,000 µg/L, and death ensued at 50,000 µg/L. Similarly, shell deposition by adults of the blue mussel, Mytilus edulis, was inhibited by 50% following exposure

NMED Exhibit 86

for two to six days to ≥60 µg/L (Manley et al. 1984; Stromgren 1982). The EC50 based on reduced byssal thread production was 1,800 µg/L, whereas the 7-day LC50 was 5,000 µg/L (Martin et al. 1975). The 72-hr EC50 for development of mussel embryos to the veliger stage was between 96 and 314 µg/L (Dinnel et al. 1983).

Different life stages and developmental processes of gametes, embryos, and larvae of Pacific oysters have different sensitivities to zinc. The ability of oyster sperm to fertilize eggs was depressed by 50% after exposure for 60 min to 443.6 µg/L (Dinnel et al. 1983). The 48-hr LC50 for embryos was 241.5 µg/L (Brereton et al. 1973). Larvae developed abnormally and grew more slowly than controls at zinc concentrations between 125 and 500 µg/L (Brereton et al. 1973), whereas EC50s for growth of 6-day-old and 16-day old larvae exposed for four days were 80 and 95 µg/L, respectively (Watling 1982). The 96-hr LC50 for 6-day and 16-day larvae was in excess of 100 µg/L, whereas that for 19-day larvae was between 30 and 35 µg/L (Watling 1982). Significant delay of, and reduction in, successful settlement was observed after 5 days in 125 µg/L (Boyden et al. 1975) and after 20 days in 10 to 20 µg/L (Watling 1983). Juvenile oyster spat had a 23-day LC50 of 75 µg/L (Watling 1983).

Exposure to 176 µg/L for 72 hr caused a 50% reduction in the rate of calcium uptake by larvae of the clam, Mulinia lateralis, whereas a concentration of 200 µg/L caused 53% mortality among the clam larvae in the same time period (Ho and Suboff 1982). The 8 to 10-day LC50 was 195.4 µg/L for larvae of the quahog clam, Mercenaria mercenaria and growth of survivors was estimated to be reduced by 38.4% (Calabrese et al. 1977).

At concentrations as low as 250 µg/L, zinc caused significant delays in molting and development rate of larvae of the grass shrimp, Palaemonetes

NMED Exhibit 86

pugio, particularly under stressful temperature-salinity regimes (McKenney 1979; McKenney and Neff 1979,1981). Concentrations of 25 to 50 µg/L were without effect on the development rate of larvae of the mud crab, Rhithropanopeus harrisii (Benijts-Claus and Benijts 1975). However, in the presence of lead at 25 to 50 µg/L, these concentrations of zinc produced a significant delay in the rate of larval development of mud crabs. Rate of limb regeneration by adults of the fiddler crab, Uca pugilator, was inhibited at zinc concentrations of 1,000 (Weis 1980). This inhibitory effect was amplified at low salinities.

Motility of the sperm of the sea urchins, Arbacia punctulata and Strongylocentrotus purpuratus, was stimulated by brief exposure to zinc concentrations at or below 1,634 and 654.8 µg/L, respectively (Timourian and Watchmaker 1977; Young and Nelson 1974). At concentrations of 3,269 and 6,538 µg/L, respectively, sperm motility was inhibited. Reduction of the ability of echinoderm sperm to fertilize eggs appeared to be more sensitive than sperm motility to the toxic effects of zinc (Dinnel et al. 1983). EC50s after one hour of exposure of sperm ranged from 28 to 382.8 µg/L. In tests with the sand dollar, Dendraster excentricus, and two sea urchins, Strongylocentrotus droebachiensis and S. purpuratus, development to the pluteus stage was less sensitive than fertilization. Waterman (1937) found that 810 µg/L inhibited gastrulation and that 2,314 µg/L was lethal to embryos of Arbacia punctulata.

Somasundarum et al. (1984a,b,c,d;1985) identified several developmental anomalies and histopathological lesions in developing embryos and larvae of Atlantic herring, Clupea harengus, that were exposed to 50 to 12,000 µg/L. Zinc concentrations below 6,000 µg/L did not affect embryo volume. Below 2,000 µg/L, zinc accelerated embryonic development, but

NMED Exhibit 86

6,000 µg/L inhibited development. At zinc concentrations as low as 50 µg/L, there was a significant increase in the incidence of jaw and branchial abnormalities. Concentrations above 500 µg/L increased the incidence of vertebral abnormalities. Significant decreases in the size of the otic capsules and eyes were observed at zinc concentrations higher than 2,000 and 6,000 µg/L, respectively. Ultrastructural changes in brain cells and somatic musculature were observed in herring larvae that were allowed to develop for 14 days in sea water containing 50 to 12,000 µg/L.

In contrast to the toxic effects noted above, Weis et al. (1981) found that exposure to 10,000 µg/L ameliorated teratogenic effects on Fundulus heteroclitus exposed to methyl mercury. Also, zinc concentrations of 1,000 µg/L or greater enhanced regeneration of the tail fin and ameliorated effects of methyl mercury on fin regeneration in adult mummichogs (Weis and Weis 1980).

Exposure of adult mummichogs to 2,200 µg/L resulted in increased activity of the hepatic enzyme aminolevulinic acid dehydrase (Jackim 1973), whereas exposure to 60,000 µg/L caused 30% mortality and histopathological lesions in the oral epithelium of survivors (Eisler and Gardner 1973). Calcification of the scales of juvenile mummichogs was inhibited at 760 to 7,100 µg/L (Sauer and Watabe 1984).

Crustaceans and fish are able to accumulate zinc from both water and food. For adult green crabs, Carcinus maenas, the BCF for zinc from water was 130 and the bioaccumulation factor (BAF) for zinc from water and food was 210 (Renfro et al. 1975), but the BAF was not significantly higher. However the BAF was statistically higher than the BCF with adult mosquito fish, Gambusia affinis, and juvenile spot, Leiostomus xanthurus (Willis and Sunda 1984). At 120 days, the BAF and BCF for uptake of zinc from

NMED Exhibit 86

water alone and water plus food by mosquito fish were 45 and 8, respectively. The BAF and BCF for spot after a 28-day exposure were 28 and 3, respectively. These results suggest that these fish obtain five to nine times more zinc from food than from water. It must be recognized, however, that the relative magnitude of the contribution from both sources to the concentration of zinc in saltwater animals will depend on the relative concentrations of zinc in the water and food. Eisler (1967) and Eisler and Gardner (1973) have shown that BCFs for adult mummichogs, Fundulus heteroclitus, are inversely related to the concentration of zinc in the water.

Unused Data

Some data on the effects of zinc on aquatic organisms were not used because the studies were conducted with species that are not resident in North America (e.g., Abbasi and Soni 1986; Ahsanullah and Arnott 1978; Baudoin and Scoppa 1974; Bengtsson 1974a,b,c,d,e; Carter and Nicholas 1978; Chapman and Dunlop 1981; Dunlop and Chapman 1981; Greenwood and Fielder 1983; Harrison 1969; Howell 1985; Jones and Wacker 1979; Jones et al. 1984; Karbe et al. 1975; Khangarot 1981,1984; Khangarot et al. 1982, 1985; Kumar and Pant 1984; Lomte and Jackhar 1982; Lyon et al. 1983; Martin et al. 1977; Mathur et al. 1981; McFeters et al. 1983; Mecham and Holliman 1975; Millington and Walker 1983; Milner 1982; Murti and Shukla 1984; Natarajan 1982; Nazarenko 1970; Pentreath 1973; Sartory and Lloyd 1976; Sastry and Subhadra 1984; Saxena and Parashari 1983; Seiffer and Schoof 1967; Shaffi 1979; Shehata and Whitton 1981; Shukla et al. 1983; Solbe and Flook 1975; Speranza et al. 1977; Srivastava et al. 1985; Stary and Krantzer 1982; Subhadra and Sastry 1985; Thorp and Lake 1974; Verma et al. 1984; Wagh et al. 1985; White and Rainbow 1982; Willis 1983)

NMED Exhibit 86

or because the test specices was not obtained in North America and was not identified well enough to determine whether it is resident in North America (e.g., Greichus et al. 1978; Jennett et al. 1981; Pommery et al. 1985; Tishinova 1977). Results (e.g., Bagshaw et al. 1986; Brown and Ahsanullah 1971) of tests conducted with brine shrimp, Artemia sp., were not used because these species are from a unique saltwater environment.

Babich and Stotzky (1985), Biddinger and Gloss (1984), Cairns (1957), Campbell and Stokes (1985), Connolly (1985), Doudoroff and Katz (1953), Duxbury (1985), Eisler (1981), Hartman (1980), Kaiser (1980), LeBlanc (1984), Lim (1972), Lloyd (1965), Macek and Sleight (1977), Mancini (1983), McKim (1977), Pagenkopf (1976), Patrick et al. (1968), Phillips and Russo (1978), Polikarpov (1966), Rai et al. (1981b), Riordan (1976), Skidmore (1964), Skidmore and Firth (1983), Slooff et al. (1986), Sprague et al. (1964), Strufe (1964), Taylor et al. (1982), Thomson and MacPhee (1985), Vernon (1954), Vymazal (1985), Weatherley et al. (1980), and Whitton (1970) only contain data that have been published elsewhere.

Results were not used if either the test procedures, test material, or dilution water was not adequately described (e.g., Back 1983; Bates et al. 1981; Baudin 1983a,b; Berg and Brazzell 1975; Biegert and Valkovic 1980; Birge and Just 1973,1975; Bradley and Sprague 1983; Brauwers 1982; Brkovic-Popovic and Popovic 1977a,b; Brown 1968; Carpenter 1927; Coburn and Friedman 1976; Danil'chenko 1977; Darnall et al. 1986; Dilling and Healy 1927; Fleming and Richards 1982; Hutchinson and Sprague 1985; Ishizaka et al. 1966; Joraensostrorasks and McLaughlin 1974; Knittel 1980; Labat et al. 1977; Miller et al. 1985; Muramoto 1980; Pavicic 1980; Petry 1983; Rao and Saxena 1981; Sabodash 1974; See et al. 1974,1975;

NMED Exhibit 86

Sicko-Goad and Lazinsky 1981; Tokunago and Kishikawa 1982; Vinot and Larpent 1984).

Data were not used if zinc was a component of an effluent (e.g., Bailey and Liu 1980; Cherry et al. 1979; Finlayson and Ashuchian 1979; Frazier 1976; Grushko et al. 1980; Guthrie et al. 1977; Jay and Muncy 1979; Lewis 1986; Lu et al. 1975; Nagy-Toth and Barna 1983; Nehring and Goettl 1974; Neufeld and Wallach 1984; Newman et al. 1985; O'Conner 1976; Oladimeji and Wade 1984; Ozlmek 1985; Phillips and Gregory 1980; Rana and Kumar 1975; Roesijadi et al. 1984; Saunders and Sprague 1967; Sprecht et al. 1984; Wang 1982; Whitton et al. 1981; Wong and Tam 1984a,b; Wood 1975), mixture (e.g., Baker and Boldigo 1984; Besser 1985; Biesinger et al. 1974; Birge et al. 1978; Borgmann 1980; Brown et al. 1969; Cairns and Scheier 1968; Cearley 1971; Chang et al. 1981; Christensen et al. 1985; Cowgill et al. 1986; Danil'chenko and Stroganov 1975; Davies 1985; Davies and Woodling 1980; Doudoroff 1956; Doudoroff et al. 1966; Eaton 1973; Eisler 1977b; Finlayson and Verrue 1980; Giesy et al. 1980; Hedtke and Puglisi 1980; Henry and Atchison 1979a,b; Hutchinson and Czyrska 1972; Hutchinson and Sprague 1983; Lubinski and Sparks 1981; Markarian et al. 1980; Marking and Bills 1985; McLeese and Ray 1984; Muller and Payer 1980; Muska 1977; Patrick and Loutit 1976,1978; Pope 1981; Roch and McCarter 1984c,1986; Roch et al. 1985,1986; Rodgers and Beamish 1983; Sprague 1965; Stromegren 1980; Vymazal 1984; Wong et al. 1982a,b,1984b), or a sediment (e.g., Arruda et al. 1983; Broberg 1984; Bryan et al. 1983; Dean 1974; Krantzberg 1983; Laskowski-Hoke and Prater 1984; Lewis and McIntosh 1984, 1986; Luoma and Jenne 1977; Malueg 1984; McMurtry 1984; Munawar et al. 1985; Oakden et al. 1984; Ray et al. 1981; Seelye et al. 1982; Wentsel et al. 1977; Wong and Kwan 1981; Wong and Tam 1984; Wong et al. 1984a).

NMED Exhibit 86

Data were not used if the organisms were exposed to zinc by injection or gavage or in food (e.g., Barash et al. 1982; Baudin 1985; Bell et al. 1984; Cancalon 1982; Cowgill et al. 1985; Dallinger and Wieser 1984; Dixon and Compher 1977; Gatlin and Wilson 1983,1984; Hibiya and Oguri 1961; Jeng and Sun 1981; Knox et al. 1984; Lyon et al. 1984; Mansouri-Aliabadi and Sharp 1985; Marafonte 1976; Ogino and Yang 1978,1979; Patrick and Loutit 1978; Richardson et al. 1985; Saiki and Mori 1955; Satoh et al. 1983a,b; Smith-Sonneborn et al. 1983; Suzuki and Ebihara 1984; Suzuki and Kawamura 1984; Suzuki et al. 1983,1984; Takeda and Shimma 1977; Vaughan et al. 1982; Windom et al. 1982; Young 1975).

Adragna and Privitera (1978,1979), Akberali and Earnshaw (1982), Anderson et al. (1978), Babich et al. (1985,1986a,b), Brown (1976), Burton and Peterson (1979), Cenini and Turner (1983), Crespo (1984), Crist et al. (1981), Doyle et al. (1981), Everaarts et al. (1979), Fleming et al. (1982), George (1983), Hiller and Perlmutter (1971), Hiltibran (1971), Kodama et al. (1982a), Nemosok et al. (1984), Rachlin and Perlmutter (1969), Sirover and Loeb (1976), and Watson and Beamish (1981) only exposed enzymes, excised or homogenized tissue, or cell cultures.

Results of some laboratory tests were not used because the tests were conducted in distilled or deionized water without addition of appropriate salts (e.g., Afflect 1952; Carter and Cameron 1973; Eddy and Fraser 1982; Matthiessen and Brafield 1973; McDonald et al. 1980; Porter and Hakanson 1976; Stary and Kratzer 1982; Stary et al. 1983; Taylor 1978; Vijayamadhavan and Iwai 1975; Wang 1959) or were conducted in chlorinated or "tap" water (e.g., Goodman 1951; Grande 1966; Haider and Wunder 1983; Hughes and Adeney 1977; Jones 1935,1938,1939; Matthiessen and Brafield 1977; Rahel

NMED Exhibit 86

1981; Shcherban 1977; Skidmore 1970; Skidmore and Tovell 1972). Dilution water was at too low a pH in tests by Michnowicz and Weaks (1984), whereas temperature fluctuated too much in the test reported by Mills (1976b).

Allan et al. (1980), Bates et al. (1983), Buikema et al. (1974a,b, 1977), Cairns and Dickson (1970), Fayed and Abd-El-Shafy (1985), Kuwabara (1985), Mills (1976a,b), Petersen (1982), Rainbow et al. (1980), Ruthven and Cairns (1973), Say and Whitton (1977), Sullivan et al. (1973), and Zitko et al. (1973) used dilution water that contained too high a concentration of chelating agent or other organic matter. Mukhopadhyay and Konar (1984) used a phosphate buffer, which might have detoxified zinc, although their LC50s for two invertebrate species were quite low after adjustment for hardness.

Benson and Birge (1985), Berglind and Dave (1984), and Birge et al. (1983) cultured or acclimated organisms in one water and conducted tests in another. Hughes (1970,1973) did not acclimate organisms for a long enough time. Tests conducted with too few test organisms (e.g., Applegate et al. 1957; Gardner 1975; McLeese 1976; Sprague 1964a; Tishinova 1977) were not used. High control mortalities occurred in tests reported by Cairns and Scheier (1964) and Havas and Hutchinson (1982). The water quality varied too much during tests conducted by Cairns et al. (1981), Nehring and Goettl (1974), and Thompson et al. (1980). Toxicity tests conducted without controls were not used (e.g., Graham et al. 1986). The 96-hr values reported by Buikema et al. (1974a,b) were subject to error because of possible reproductive interactions (Buikema et al. 1977). The test organisms were possibly stressed by disease or parasites during tests reported by Boyce and Yamada (1977), Guth et al. (1977), and Sakanari et al. (1984). Hublou et al. (1954) conducted tests on zinc leached from galvanized trays. Anudu (1983), Bradley et al. (1985a,b),

NMED Exhibit 86

Cairns (1972), Cairns et al. (1973a,b), DeFilippis and Pallaghy (1976), Duncan and Klaverkamp (1980), Foster (1982b), LeBlanc (1982), and Wang (1986b) conducted studies of acclimation to zinc or used organisms that had been exposed or were resistant to zinc.

Biochemical and histological studies were not used (e.g., Anderson and Sparks 1978; Canalon 1982; Cenini and Turner 1979; Eddy and Talbot 1985; Kearns and Atchison 1979; Kodama et al. 1982a,b; Nemcsok et al. 1984; Rachlin et al. 1985; Sailer et al. 1980; Schmitt et al. 1984; Taban et al. 1982; Thomas et al. 1985; Vijayamadhauan and Iwai 1975; Watson and Beamish 1980; Watson and McKoewn 1976; Yamamoto et al. 1977).

Results of chronic tests were not used if the concentration of test material was not measured (e.g., Winner and Gauss 1986) or if the test solutions were only renewed once a week (e.g., Crandall and Goodnight 1962,1963). Data on toxicity or accumulation or both from microcosm or model ecosystem studies were not used if the concentration of zinc in water decreased with time (e.g., Bachman 1963; Davis and Negilski 1972).

Results of laboratory bioconcentration tests were not used if the test was not flow-through or renewal (e.g., Dean 1974; Evtushenko et al. 1984; Fayed et al. 1983; Hughes and Flos 1978; Joyner 1961; Joyner and Eisler 1961; Lyngby et al. 1982; Skipnes et al. 1975; Sklar 1980; Slater 1961; Young 1977) or if the concentration of zinc in the test solution was not adequately measured (e.g., Mellinger 1972; Munda 1979,1984; Phillips 1976,1977). Hardy and Raber (1985) did not measure the concentration of zinc in tissues.

Van Hoof and Van San (1981) found high concentrations of zinc in their control fish. Harvey (1974) studied depuration, but not uptake, of zinc by a freshwater clam, and Ferguson and Bubela (1974) studied uptake by homogenized algal suspensions. The concentration of zinc fluctuated too much in the tests reported by Kormondy (1965) and O'Grady and Obdullah (1985).

NMED Exhibit 86

Reports of the concentrations of zinc in wild aquatic organisms (e.g., Abdullah et al. 1976; Abo-Rady 1979,1983; Adams et al. 1980,1981; Amemiya and Nakayama 1984; Anderson 1977; Anderson et al. 1978; Arnac and Lassus 1985; Badsha and Goldspink 1982; Bailey and Stokes 1985; Barber and Trefry 1981; Bohn and Fallis 1978; Bosserman 1985; Bradley and Morris 1986; Brezina and Arnold 1977; Brooks et al. 1976; Brown 1977; Brown and Chlow 1977; Burrows and Whitton 1983; Burton and Peterson 1979; Bussey et al. 1976; Caines et al. 1985; Chapman 1985; Chassard and Balvay 1978; Coughtrey and Martin 1977; Cover and Wilhm 1982; Cowx 1982; Dallinger and Kautzky 1985; EIFAC 1977; Elder and Mattraw 1984; Elliott et al. 1981; Elwood et al. 1976; Estabrook et al. 1985; Felat and Melzer 1978; Fletcher and King 1978; Fletcher et al. 1975; Franzin and McFarlane 1980; Frazier 1975; Friant and Koerner 1981; Friant and Sherman 1980; Gale et al. 1973a,b; Giesy and Weiner 1977; Greichus et al. 1978; Guillizzoni 1980; Hakanson 1984; Harding and Whitton 1978; Heit and Klusek 1985; Holm 1980; Howard and Brown 1983; Huggett et al. 1973; Jeng and Lo 1974; Johannessan et al. 1983; Jones et al. 1985; Kleinert et al. 1974; Kole et al. 1978; Korda et al. 1977; Lee et al. 1984; Lewis 1980; Lobel and Wright 1983; Lord et al. 1977; Lowe et al. 1985; Lucas and Edgington 1970; Lundholm and Andersson 1985; Maas 1978; McFarlane and Franzin 1978; McHardy and George 1985; Moreau et al. 1983; Morrison et al. 1985; Nabrzyski 1975; Nabrzyski and Gajewski 1978; Namminga and Wilhm 1977; Ney and Martin 1985; Ney et al. 1982; Norris and Lake 1984; O'Grady 1981; Paul and Pillai 1983; Pennington et al. 1982; Percy and Borland 1985; Peverly 1985; Rabe et al. 1977; Ranta et al. 1978; Ray and White 1979; Rehwoldt et al. 1976; Romberg and Refro 1973; Salanki et al. 1982; Saltes and Bailey 1984; Seagle and Ehlmann 1974; Shearer 1984; Shimma et al. 1984;

NMED Exhibit 86

Shuman et al. 1977; Simpson 1979; Stary et al. 1982; Stokes et al. 1985; Strufe 1964; Teherani et al. 1979; Tessier et al. 1984; Tisa and Strange 1981; Tsui and McCart 1981; Uthe and Bligh 1971; Van Coillie and Rousseau 1974; Van Loon and Beamish 1977; Villarreal-Trevino et al. 1986; Vinikour et al. 1980; Wachs 1982; Walker et al. 1975; Wehr and Whitton 1983a,b; Wehr et al. 1983; Whitton et al. 1981,1982; Wiener and Giesy 1979; Winger and Andreasen 1985; Wissmar et al. 1982; Young and Blevins 1981, Zadory 1984) were not used to calculate bioaccumulation factors because either the number of measurements of the concentration in water was too small or the range of the measured concentrations in water was too large.

Summary

Acute toxicity values are available for 43 species of freshwater animals and data for eight species indicate that acute toxicity decreases as hardness increases. When adjusted to a hardness of 50 mg/L, sensitivities range from 50.70 µg/L for Ceriodaphnia reticulata to 88,960 µg/L for a damselfly. Additional data indicate that toxicity increases as temperature increases. Chronic toxicity data are available for nine freshwater species. Chronic values for two invertebrates ranged from 46.73 µg/L for Daphnia magna to >5,243 µg/L for the caddisfly, Clistoronia magnifica. Chronic values for seven fish species ranged from 36.41 µg/L for the flagfish, Jordanella floridae, to 854.7 µg/L for the brook trout, Salvelinus fontinalis. Acute-chronic ratios ranged from 0.2614 to 41.20, but the ratios for the sensitive species were all less than 7.3.

The sensitivity range of freshwater plants to zinc is greater than that for animals. Growth of the alga, Selenastrum capricornutum, was inhibited by 30 µg/L. On the other hand, with several other species of

NMED Exhibit 86

green algae, 4-day EC50s exceeded 200,000 µg/L. Zinc was found to bioaccumulate in freshwater animal tissues from 51 to 1,130 times the concentration present in the water.

Acceptable acute toxicity values for zinc are available for 33 species of saltwater animals including 26 invertebrates and 7 fish. LC50s range from 191.5 µg/L for cabezon, Scorpaenichthys marmoratus to 320,400 µg/L for adults of another clam, Macoma balthica. Early life stages of saltwater invertebrates and fishes are generally more sensitive to zinc than juveniles and adults. Temperature has variable and inconsistent effects on the sensitivity of saltwater invetebrates to zinc. The sensitivity of saltwater animals to zinc decreases with increasing salinity, but the magnitude of the effect is species-specific.

A life-cycle test with the mysid, Mysidopsia bahia, found unacceptable effects at 120 µg/L, but not at 231 µg/L, and the acute-chronic ratio was 2.997. Seven species of saltwater plants were affected at concentrations ranging from 19 to 10,100 µg/L. Bioaccumulation data for zinc are available for seven species of saltwater algae and five species of saltwater animals. Steady-state zinc bioconcentration factors for the twelve species range from 3.692 to 23,820.

National Criteria

The procedures described in the "Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses" indicate that, except possibly where a locally important species is very sensitive, freshwater aquatic organisms and their uses should not be affected unacceptably if the four-day average concentration (in µg/L) of zinc does not exceed the numerical value given by

NMED Exhibit 86

$e^{(0.8473[\ln(\text{hardness})]+0.7614)}$ more than once every three years on the average and if the one-hour average concentration (in µg/L) does not exceed the numerical value given by $e^{(0.8473[\ln(\text{hardness})]+0.8604)}$ more than once every three years on the average. For example, at hardnesses of 50, 100, and 200 mg/L as $CaCO_3$ the four-day average concentrations of zinc are 59, 110, and 190 µg/L, respectively, and the one-hour average concentrations are 65, 120, and 210 µg/L. If the striped bass is as sensitive as some data indicate, it will not be protected by this criterion.

The procedures described in the "Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses" indicate that, except possibly where a locally important species is very sensitive, saltwater aquatic organisms and their uses should not be affected unacceptably if the four-day average concentration of zinc does not exceed 86 µg/L more than once every three years on the average and if the one-hour average concentration does not exceed 95 µg/L more than once every three years on the average.

"Acid-soluble" is probably the best measurement at present for expressing criteria for metals and the criteria for zinc were developed on this basis. However, at this time, no EPA approved method for such a measurement is available to implement criteria for metals through the regulatory programs of the Agency and the States. The Agency is considering development and approval of a method for a measurement such as "acid-soluble." Until one is approved, however, EPA recommends applying criteria for metals using the total recoverable method. This has two impacts: (1) certain species of some metals cannot be measured because the total recoverable method cannot distinguish between individual oxidation

NMED Exhibit 86

states, and (2) in some cases these criteria might be overly protective when based on the total recoverable method.

Three years is the Agency's best scientific judgment of the average amount of time aquatic ecosystems should be provided between excursions (U.S. EPA 1985b). The resiliencies of ecosystems and their abilities to recover differ greatly, however, and site-specific allowed excursion frequencies may be established if adequate justification is provided.

Use of criteria for developing water quality-based permit limits and for designing waste treatment facilities requires selection of an appropriate wasteload allocation model. Dynamic models are preferred for the application of these criteria (U.S. EPA 1985b). Limited data or other considerations might make their use impractical, in which case one must rely on a steady-state model (U.S. EPA 1986).

* S = static; R = renewal; F = flow-through; M = measured; U = measured.

** Results are expressed as zinc, not as the chemical.

*** Freshwater LC50s and EC50s were adjusted to hardness = 50 mg/L using the pooled slope of 0.8195 (see text). When the hardness is given as a range, the geometric mean of the limits of the range was used as the hardness.

**** Freshwater Species Mean Acute Values were calculated at hardness = 50 mg/L.

***** Calculated by probit analysis of the authors' data.

† In river water or stream water.

†† Average of values calculated using two different methods.

††† Value not used in calculation of slope or Species Mean Acute Value because this was a "greater than" value and a number of other values are available for this species.

†††† Value not used in calculation of slope or Species Mean Acute Value because value appeared to be high in comparison with other values available for this species.

††††† Not used in calculation of Genus Mean Acute Value (see text).

†* Value not used in calculation of Species Mean Acute Value because data are available for a more sensitive life stage.

NMED Exhibit 86

Table 1. (Continued)

Results of Covariance Analysis of Freshwater Acute Toxicity versus Hardness

Species	n	Slope	Standard Deviation	95% Confidence Limits	Degrees of Freedom
Physa heterostropha	12	0.9296	0.2590	0.3521, 1.5071	10
Daphnia magna	7	1.2549	0.4026	0.2206, 2.2892	5
Rainbow trout	25	0.8755	0.1152	0.6370, 1.1140	23
Brook trout	6	0.8179	0.1243	0.4731, 1.1627	4
Fathead minnow	36	0.8310	0.2217	0.3802, 1.2818	34
Guppy	5	1.6441	0.4432	0.2323, 3.0559	3
Striped bass	2	0.6500	-*	-* , -*	0
Bluegill	16	0.5603	0.1461	0.2467, 0.8739	14
All of above	109	0.8473**	0.0866	0.6754, 1.0192	100

* Standard deviation and confidence limits cannot be calculated because degrees of freedom = 0.

** P = 0.77 for equality of slopes.

NMED Exhibit 86

* Ranked from most resistant to most sensitive based on Genus Mean Acute Value. Inclusion of "greater than" values does not necessarily imply a true ranking, but does allow use of all genera for which useful data are available so that the Final Acute Value is not unnecesarily lowered.

** Freshwater Genus Mean Acute Values are at hardness = 50 mg/L.

*** From Table 1; freshwater values are at hardness = 50 mg/L.

**** From Table 2.

† Geometric mean of range given in Table 2.

†† Geometric mean of three values in Table 2.

NMED Exhibit 86

Table 3. (Continued)

Fresh water

Final Acute Value = 130.1 µg/L (at hardness = 50 mg/L)

Criterion Maximum Concentration = (130.1 µg/L) / 2 = 65.05 µg/L (at hardness = 50 mg/L)

Pooled Slope = 0.8473 (see Table 1)

ln(Criterion Maximum Intercept) = ln(65.05) - [slope x ln(50)]

= 4.175 - (0.8473 x 3.9120) = 0.8604

Criterion Maximum Concentration = $e^{(0.8473[\ln(\text{hardness})]+0.8604)}$

Final Acute-Chronic Ratio = 2.208 (see text)

Final Chronic Value = (130.1 µg/L) / 2.208 = 58.92 µg/L (at hardness = 50 mg/L)

Assumed Chronic Slope = 0.8473 (see text)

ln(Final Chronic Intercept) = ln(58.92) - [slope x ln(50)]

= 4.076 - (0.8473 x 3.9120) = 0.7614

Final Chronic Value = $e^{(0.8473[\ln(\text{hardness})]+0.7614)}$

Salt water

Final Acute Value = 190.2 µg/L

Criterion Maximum Concentration = (190.2 µg/L) / 2 = 95.10 µg/L

Final Acute-Chronic Ratio = 2.208 (see text)

Final Chronic Value = (190.2 µg/L) / 2.208 = 86.14 µg/L

NMED Exhibit 86

Mummichog (adult), Fundulus heteroclitus	Zinc chloride	20	96 hr	BCF = 18.83***,†	60,000	Eisler and Gardner 1973
Mummichog (adult), Fundulus heteroclitus	Zinc chloride	20	96 hr	30% mortality; histopathological lesions in oral epithelium	60,000	Eisler and Gardner 1973

NMED Exhibit 86

Table 6. (Continued)

Species	Chemical	Salinity (g/kg)	Duration	Effect	Concentration (µg/L)*	Reference
Mummichog (adult), Fundulus heteroclitus	Zinc chloride	-	14 days	Increased activity of liver enzyme	2,200	Jackim 1973
Mummichog (adult), Fundulus heteroclitus	Zinc chloride	10-30	14 days	Enhanced regeneration of tail fin and ameliorated effects of methyl mercury	>1,000	Weis and Weis 1980
Mummichog (embryo), Fundulus heteroclitus	Zinc chloride	30	96 hr	Ameliorated teratogenic effects of methyl mercury	10,000	Weis et al. 1981
Mummichog (juvenile), Fundulus heteroclitus	Zinc chloride	25	70 days	Inhibited scale calcification	760-7,100	Sauer and Watabe 1984
Mummichog (juvenile), Fundulus heteroclitus	Zinc chloride	30	56 days	BCF = 33.91-240.0 (scales)	210-7,880	Sauer and Watabe 1984
Mosquitofish (adult), Gambusia affinis	††††	30	120 days	BCF = 8† (uptake from water alone)	650	Willis and Sunda 1984
Mosquitofish (adult), Gambusia affinis	††††	30	120 days	BAF = 45† (uptake from food and water)	650	Willis and Sunda 1984
Spot (juvenile), Leiostomus xanthurus	††††	30	28 days	BCF = 3† (uptake from water alone)	650	Willis and Sunda 1984
Spot (juvenile), Leiostomus xanthurus	††††	30	28 days	BAF = 28† (uptake from food and water)	650	Willis and Sunda 1984

* Concentration of zinc, not the chemical.

** Field study.

*** Converted from dry weight to wet weight basis.

**** Static test; concentrations not measured.

† Derived from authors' data or graph.

†† Geometric mean of data from four stations, but concentrations in water varied widely.

††† Animals obtained from sediment heavily contaminated with zinc.

†††† Nitrilotriacetic acid (NTA) was used to buffer the concentration of zinc ions.

WATER QUALITY STANDARDS FOR INTERSTATE AND INTRASTATE STREAMS IN NEW MEXICO

(Supersedes WQCC 88-1 filed March 24, 1988)

PART 1

1-100. PURPOSE AND AUTHORITY.

A. The purpose of these standards is to designate the uses for which the surface waters of the State of New Mexico shall be protected and to prescribe the water quality standards necessary to sustain the designated uses.

B. These standards are consistent with Section 101(a)(2) of the federal Clean Water Act, as amended, (33 U.S.C. 1251 et seq.) which declares that "it is the national goal that wherever attainable, an interim goal of water quality which provides for the protection and propagation of fish, shellfish, and wildlife and provides for recreation in and on the water be achieved by July 1, 1983...." Agricultural, municipal, domestic and industrial water supply are other essential uses of New Mexico's water; however, water contaminants resulting from these activities will not be permitted to lower the quality of streams below that which is required for recreation and maintenance of a fishery, where practicable.

C. These standards are adopted by the Water Quality Control Commission under the authority of Paragraph C, Section 74-6-4 of the New Mexico Water Quality Act (NMSA 1978).

D. Part 3 of the Water Quality Control Commission Regulations includes standards to protect ground water and regulations controlling discharges onto or below the surface of the ground.

E. These water quality standards do not grant to the Commission or any other entity the power to take away or modify property rights in water.

F. Adopted August 22, 1973; revised September 29, 1975, January 13, 1976, February 8, 1977, March 14, 1978, May 23, 1979, July 8, 1980, April 22, 1981, May 11, 1982, June 8, 1982, November 20, 1984, January 8, 1985, August 18, 1987, March 8, 1988, May 22, 1991, and October 8, 1991.

NMED Exhibit 87

1-101. ANTIDEGRADATION POLICY AND IMPLEMENTATION PLAN.

A. Antidegradation Policy: Degradation of waters the quality of which is better than the stream standards established by the New Mexico Water Quality Control Commission is not reasonable degradation and is subject to abatement under the authority granted the Commission by the New Mexico Water Quality Act, as amended, unless it is justifiable as a result of necessary economic and social development. Existing instream water uses and water quality necessary to sustain existing uses shall be maintained and protected in all surface waters of the State. No degradation shall be allowed in high quality waters of designated national and state monuments, parks and wildlife refuges including waters designated by the U.S. Congress under the Wild and Scenic Rivers Act, if such degradation would impair any of the qualities which caused designation of these waters, parks and wildlife refuges. To protect the existing quality of water, the Commission under that Act will require the highest and best degree of effluent treatment practicable. In those cases where potential water quality impairment associated with a thermal discharge is involved, this antidegradation policy shall be consistent with Section 316 of the federal Clean Water Act. In implementing this section, the Commission through the appropriate regional offices of the United States Environmental Protection Agency will keep the Administrator advised and provided with such information concerning the waters of New Mexico as he will need to discharge his responsibilities under the federal Clean Water Act.

B. Implementation Plan: The New Mexico Environment Department, acting under authority delegated by the Commission, implements the water quality standards, including the antidegradation policy, by establishing and maintaining controls on the discharge of pollutants to surface waters. This stepwise process involves several interrelated programs and is summarized in the following paragraphs. The Department:

1. obtains information pertinent to the impact of the effluent on the receiving water and advises the prospective discharger of requirements for obtaining a permit to discharge;

2. reviews the adequacy of the existing data base and, if needed, obtains additional data by conducting an intensive survey of the receiving water;

3. assesses the probable impact of the effluent on the receiving water relative to its attainable or designated uses and numeric and narrative standards;

4. requires the highest and best degree of wastewater treatment practicable and commensurate with protecting and maintaining the designated uses and existing water quality of receiving waters, or attainable uses and existing water quality of unclassified lakes and perennial streams and perennial reaches of interrupted streams;

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

1991 OCT 11 PM 1:52

5. develops water quality based effluent limitations and comments on technology based effluent limitations, as appropriate, for inclusion in any federal permit issued to a discharger pursuant to Section 402 of the Clean Water Act;

6. requires that these effluent limitations be included in any such permit as a condition for state certification pursuant to Section 401 of the federal Clean Water Act;

7. coordinates its water pollution control activities with other constituent agencies of the Commission, and with local, state and federal agencies, as appropriate;

8. develops and pursues inspection and enforcement programs to ensure that dischargers comply with state regulations, and complements EPA's enforcement of federal permits;

9. ensures that the provisions for public participation required by the New Mexico Water Quality Act and the federal Clean Water Act are followed;

10. provides continuing technical training for wastewater treatment facility operators through the utility operators training and certification programs;

11. provides funds to assist the construction of publicly owned wastewater treatment facilities through the wastewater construction program authorized by Section 601 of the federal Clean Water Act, and through funds appropriated by the New Mexico Legislature;

12. conducts water quality surveillance of the waters of the State to assess the effectiveness of water pollution controls and to determine whether water quality standards are being attained;

13. encourages, in conjunction with other state agencies, voluntary implementation of the best management practices set forth in the "State of New Mexico Water Quality Management Plan;" and

14. evaluates effectiveness of best management practices selected to prevent or abate non-point sources of water pollutants.

1-102. GENERAL STANDARDS.

General standards are established to sustain and protect uses which are existing or attainable by flows resulting from point source discharges or the earth's natural hydrologic cycle. These general standards apply at all times, except as otherwise specified in Sections 1-102.F, 1-102.K, 1-105.B, 1-105.E, 3-101 or Part 2, to all surface waters of the State. Watercourses shall be free of any water contaminant in such quantity and of such duration as may with reasonable probability injure human health, animal or plant life or property, or to unreasonably interfere with the public welfare or the use of property. The occurrence

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

1991 OCT 11 PM 1:52

of a water contaminant or a deficiency of dissolved oxygen attributable to natural causes or the reasonable operation and maintenance of irrigation and flood control facilities is not subject to these general standards. The foregoing provision does not include major reconstruction of storage dams or diversion dams except for emergency actions necessary to protect health and safety of the public, or discharges from municipal separate storm sewers.

A. Stream Bottom Deposits: The stream shall be free of water contaminants from other than natural causes that will settle and adversely inhibit the growth of normal flora and fauna or significantly alter the physical or chemical properties of the bottom. Siltation resulting from the reasonable operation and maintenance of irrigation and flood control facilities is not subject to these standards.

B. Floating Solids, Oil and Grease: Receiving water shall be free of objectionable oils, scum, grease and other floating materials resulting from other than natural causes.

C. Color: Color-producing materials resulting from other than natural causes shall not create an aesthetically undesirable condition nor should color impair the use of the water by desirable aquatic life presently common in New Mexico waters.

D. Odor and Taste of Fish: Water contaminants from other than natural causes shall be limited to concentrations that will not impart unpalatable flavor to fish, or result in offensive odor arising from the stream or otherwise interfere with the reasonable use of the water.

E. Plant Nutrients: Plant nutrients from other than natural causes shall not be present in concentrations which will produce undesirable aquatic life or result in a dominance of nuisance species in receiving waters.

F. Hazardous Substances: Toxic substances such as, but not limited to, pesticides, herbicides, heavy metals, and organics, shall not be present in receiving waters in concentrations which will change the ecological conditions of receiving waters to an extent detrimental to man or other organisms of direct or indirect commercial, recreational, or aesthetic value. Toxicities of substances in receiving waters will be determined by appropriate bioassay techniques, or other acceptable means, for the particular form of aquatic life which is to be preserved with the concentrations of toxic substances not to exceed 5% of the LC-50 (see 3-100.T) provided that: toxic substances which, through uptake in the aquatic food chain and/or storage in plant and animal tissues, can be magnified to levels which are toxic to man or other organisms, shall not be present in concentrations which result in this biological magnification or exceed 1% of the LC-50. Chlorine residual shall not be considered a hazardous substance when discharged to non-perennial streams, provided that such discharge does not reach a perennial stream or perennial reaches of an interrupted stream except in response to direct precipitation or runoff.

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

1991 OCT 11 PM 1:52

G. Radioactivity: The radioactivity of surface waters shall be maintained at the lowest practical level and shall in no case exceed the standards set forth in Part 4 of New Mexico Environmental Improvement Board Radiation Protection Regulations, filed March 10, 1989.

H. Pathogens: The stream shall be virtually free of pathogens. In particular, waters used for irrigation of table crops such as lettuce shall be virtually free of Salmonella and Shigella species.

I. Temperature: Maximum temperatures for each stream reach have been specified in Part 2 of these standards. However, the introduction of heat by other than natural causes shall not increase the temperature, as measured from above the point of introduction, by more than 2.7 C (5 F) in a stream, or more than 1.7 C (3 F) in a lake or reservoir. In no case will the introduction of heat be permitted when the maximum temperature specified for the reach (generally 20 C (68 F) for coldwater fisheries and 32.2 C (90 F) for warmwater fisheries) would thereby be exceeded. These temperature standards shall not apply to impoundments constructed offstream for the purpose of heat disposal. High water temperatures caused by unusually high ambient air temperatures or the reasonable operation of irrigation and aquacultural facilities are not violations of these standards.

J. Turbidity: Turbidity attributable to other than natural causes shall not reduce light transmission to the point that desirable aquatic life presently common in New Mexico waters is inhibited or that will cause substantial visible contrast with the natural appearance of the water. Turbidity attributable to natural causes or the reasonable operation of irrigation and flood control facilities is not subject to these standards.

K. Salinity: Where existing information is sufficient numerical standards for total dissolved solids (or conductivity), chlorides and sulfates, have been adopted in Part 2 of these standards.

1. For the tributaries of the Colorado River System, the State of New Mexico will cooperate with the Colorado River Basin States and the federal government to support and implement the salinity policy and program outlined in the report "1990 Review, Water Quality Standards for Salinity, Colorado River System."

2. Numeric criteria for salinity are established at three points in the Colorado River Basin as follows: below Hoover Dam, 723 mg/l; below Parker Dam, 747 mg/l; and at Imperial Dam, 879 mg/l.

3. As a part of the program, objectives for New Mexico shall include the elimination of discharges of water containing solids in solution as a result of the use of water to control or convey fly ash from coal-fired electric generators, wherever practicable.

4. In determining compliance with the numeric criteria hereby adopted, salinity (TDS) is determined by the "calculation method" (sum of

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER
1991 OCT 11 PM 1:52

constituents) as described in the latest edition of "Techniques of Water-Resources Investigations of the United States Geological Survey, Methods for Collection and Analysis of Water Samples for Dissolved Minerals and Gases."

L. Dissolved Gases: Surface waters shall be free of nitrogen and other dissolved gases at levels above 110% saturation when this supersaturation is attributable to municipal, industrial or other discharges.

1-103. SAMPLING AND ANALYSIS.

A. All methods of sample collection, preservation and analysis used in determining water quality and maintenance of these standards shall be in accordance with currently approved procedures given in the latest edition of:

1. "Standard Methods for the Examination of Water and Wastewater," American Public Health Association; or

2. "Methods for Chemical Analysis of Water and Wastes" and other publications of the Analytical Quality Control Laboratory, EPA; or

3. "Guidelines Establishing Test Procedures for the Analysis of Pollutants Under the Clean Water Act," 40 CFR Part 136; or

4. "National Handbook of Recommended Methods for Water-Data Acquisition," U.S. Geological Survey."

B. Bacteriological Surveys:

1. The monthly logarithmic mean shall be used in assessing attainment of standards when a minimum of five samples is collected in a 30-day period.

C. Sampling Procedures:

1. Streams: Stream monitoring stations below waste discharges shall be located a sufficient distance downstream to ensure adequate vertical and lateral mixing.

2. Lakes: Sampling stations in lakes shall be located at least 250 feet from a waste discharge.

3. Lakes: Except for the restriction specified in Section 103.C.2, lake sampling stations shall be located at any site where the attainment of a water quality standard is to be assessed. Water quality measurements taken at intervals in the entire water column at a sampling station shall be averaged for the epilimnion, or in the absence of an epilimnion, for the upper 1/3 of the water column of the lake to determine attainment of standards, except that attainment of standards for toxic

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER
1991 OCT 11 PM 1:52

substances shall be assessed during periods of complete vertical mixing, e.g., during spring or fall turnover, or by taking depth-integrated composite samples of the water column.

D. Acute toxicity of effluent to aquatic life shall be determined using the procedures specified in U.S. Environmental Protection Agency "Methods for Measuring the Acute Toxicity of Effluents to Freshwater and Marine Organisms" (3rd Ed., 1985, EPA 600/4-85/013), or latest edition thereof, which is incorporated herein by reference. Acute toxicities of substances shall be determined using at least two species tested in whole effluent and a series of effluent dilutions. Acute toxicity due to discharges shall not occur within the wastewater mixing zone in any stream with an existing or designated fishery use.

E. Chronic toxicity of effluent or ambient surface water to aquatic life shall be determined using the procedures specified in U.S. Environmental Protection Agency "Short-term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to Freshwater Organisms" (2nd Ed., 1989, EPA 600/4-89/001), or latest edition thereof, which is incorporated herein by reference. Chronic toxicities of substances shall be determined using at least two species tested in ambient surface water or whole effluent and a series of effluent dilutions. Chronic toxicity due to discharges shall not occur at the critical low flow in any stream with an exiting or designated fishery use more that once every three years.

1-104. REVIEW OF STANDARDS, NEED FOR ADDITIONAL STUDIES.

A. Section 303(c)(1) of the federal Clean Water Act requires that public hearings be held at least once every three years for the purpose of reviewing and proposing necessary revisions of these water quality standards.

B. It is recognized that, in some cases, numeric standards have been adopted which reflect stream use designations rather than existing stream conditions. Narrative standards are required for many constituents because accurate data on background levels are lacking. More intensive water quality monitoring may identify stream reaches where existing quality is considerably better than the established standards. When justified by sufficient data and need, the stream standards will be modified to reflect true stream conditions.

C. It is also recognized that contributions of water contaminants by diffuse non-point sources of water pollution may make attainment of certain standards difficult. Revision of these standards may be required as new information is obtained on non-point sources and other problems unique to semi-arid regions.

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

1991 OCT 11 PM 1:52

1-105. APPLICABILITY OF WATER QUALITY STANDARDS.

A. The numeric standards for salinity set out in Part 2 shall apply at the downstream point of the reach in question.

B. Critical Low Flow: The numeric standards set under Section 1-102.F, Part 2 and Section 3-101 may not be attainable when streamflow is less than the critical low flow of the stream in question. The critical low flow of a stream at a particular site shall be the minimum average four consecutive day flow which occurs with a frequency of once in three years (4Q3). Critical low-flow numeric values may be determined on an annual, a seasonal or a monthly basis, as appropriate, after due consideration of site-specific conditions.

C. Guaranteed Minimum Flow: On a case-by-case basis and upon consultation with the Interstate Stream Commission, the Water Quality Control Commission may allow the use of a contractually guaranteed minimum streamflow in lieu of a critical low flow determined under Section 1-105.B. Should drought, litigation or any other reason interrupt or interfere with minimum flows under a guaranteed minimum flow contract for a period of at least thirty consecutive days, such permission may, at the sole discretion of the WQCC, then be revoked. Any minimum flow specified under such revoked permission shall be superseded by a critical low flow determined under Section 1-105.B. A public notice of the request for a guaranteed minimum flow shall be published by the Environment Department at least 30 days prior to scheduled action by the Commission. These water quality standards do not grant to the Commission or any other entity the power to create, take away or modify property rights in water.

D. Mixing Zones: A limited mixing zone, contiguous to a point source wastewater discharge, may be allowed in any stream receiving such a discharge. Mixing zones serve as regions of initial dilution which allow the application of a dilution factor in calculations of effluent limitations. Effluent limitations shall be developed which will protect the most sensitive designated or attainable aquatic use of the receiving water.

E. Limitations: Wastewater mixing zones, in which the numeric standards set under Section 1-102.F., Part 2 or Section 3-101 may be exceeded, shall be subject to the following limitations:

1. Mixing zones are not allowed for discharges to publicly owned lakes or reservoirs; these effluents shall meet all applicable standards set under Section 1-102.F, Part 2 and Section 3-101 at the point of discharge.

2. The shape and volume of a particular mixing zone will depend on site-specific conditions such as, but not limited to, wastewater flow, receiving water critical low flow, outfall design, channel characteristics and climatic conditions, and shall be determined on a case-by-case basis.

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

1991 OCT 11 PM 1:52

3. All applicable water quality standards set under Section 1-102.F, Part 2 and Section 3-101 shall be attained at the boundaries of mixing zones. A continuous zone of passage through or around the mixing zone shall be maintained in which the water quality meets all applicable standards and allows the migration of aquatic life presently common in New Mexico waters with no effect on their populations.

4. Mixing zones shall be free of substances in concentrations which are acutely toxic to aquatic organisms passing through the zone of mixing. Compliance with this provision shall be determined by performance of the biomonitoring procedures set out in Section 1-103.D, or by demonstration of compliance with acute standards set out in Section 3-101.J and applicable un-ionized ammonia and total chlorine residual standards set out in Sections 3-101.A, 3-101.C, 3-101.E, 3-101.F and 3-101.H.

1-106. COMPLIANCE WITH WATER QUALITY STANDARDS.

A. Compliance with acute water quality standards shall be determined from the analytical results of a single grab sample. Acute standards shall not be exceeded.

B. Compliance with chronic water quality standards shall be determined from the arithmetic mean of the analytical results of a minimum of four samples collected on each of four consecutive days. Chronic standards shall not be exceeded more than once every three years.

C. Compliance with water quality standards for un-ionized ammonia shall be determined by performing the biomonitoring procedures set out in Section 1-103.E, or by attainment of applicable ammonia standards set out in Sections 3-101.A, 3-101.C, 3-101.E, 3-101.F and 3-101.H.

D. Compliance Schedules: It shall be the policy of the Commission to allow on a case-by-case basis the inclusion of a schedule of compliance in a National Pollutant Discharge Elimination System (NPDES) permit issued to an existing facility. Such schedule of compliance will be for the purpose of providing a permittee with adequate time to make treatment facility modifications necessary to comply with water quality based permit limitations determined to be necessary to implement new or revised water quality standards. Compliance schedules may be included in NPDES permits at the time of permit renewal or modification and shall be written to require compliance at the earliest practicable time. Compliance schedules shall also specify milestone dates so as to measure progress towards final project completion (e.g., design completion, construction start, construction completion, date of compliance).

PART 2

STREAM USE DESIGNATIONS AND STANDARDS

2-100. RIO GRANDE BASIN.

2-101. The main stem of the Rio Grande from the International Boundary and Water Commission sampling station above American Dam upstream to one mile below Percha Dam.[1]

A. Designated Uses: irrigation, limited warmwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall not exceed 34 C (93.2 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

3. At mean monthly flows above 350 cfs, the monthly average concentration for: TDS shall be less than 2,000 mg/l, sulfate shall be less than 500 mg/l, and chlorides shall be less than 400 mg/l.

2-102. The main stem of the Rio Grande from one mile below Percha Dam upstream to the headwaters of Caballo Reservoir including Caballo Reservoir.[1]

A. Designated Uses: irrigation, livestock and wildlife watering, primary contact recreation, and warmwater fishery.

B. Standards:

1. At any sampling site: dissolved oxygen shall be greater than 5.0 mg/l except for brief periods (6 hours or less) of not less than 4.0 mg/l, pH shall be within the range of 6.0 to 9.0, temperature shall be less than 32.2 C (90 F), and turbidity shall be less than 50 NTU.

---

[1]Sustained flow in the Rio Grande below Caballo Reservoir is dependent on release from Caballo Reservoir during the irrigation season; at other times of the year, there may be little or no flow.

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

1991 MAY 29 AM 10:24

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-103. The main stem of the Rio Grande from the headwaters of Caballo Lake upstream to Elephant Butte Dam[1] and perennial reaches of tributaries to the Rio Grande in Sierra and Socorro counties.

A. Designated Uses: fish culture, irrigation, livestock and wildlife watering, marginal coldwater fishery, secondary contact recreation, and warmwater fishery.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 25 C (77 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

2-104. Elephant Butte Reservoir.

A. Designated Uses: irrigation storage, livestock and wildlife watering, primary contact recreation, and warmwater fishery.

B. Standards:

1. At any sampling site: dissolved oxygen shall be greater than 5.0 mg/l except for brief periods (6 hours or less) of not less than 4.0 mg/l, pH shall be within the range of 6.6 to 9.0, temperature shall be less than 32.2 C (90 F), and turbidity shall be less than 50 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

---

[1]Flow in this reach of the Rio Grande main stem is dependent upon release from Elephant Butte Dam.

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-105. The main stem of the Rio Grande from the headwaters of Elephant Butte Reservoir upstream to Alameda Bridge (Corrales Bridge), including any flow below the perennial reaches of the Rio Puerco and Jemez River which enters the main stem of the Rio Grande.

A. Designated Uses: irrigation, limited warmwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 4.0 mg/l, pH shall be within the range of 6.0 to 9.0, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

3. At mean monthly flows above 100 cfs, the monthly average concentration for: TDS shall be less than 1,500 mg/l, sulfate shall be less than 500 mg/l, and chloride shall be less than 250 mg/l.

2-105.1 The main stem of the Rio Grande from Alameda Bridge (Corrales Bridge) upstream to the Angostura Diversion Works.

A. Designated Uses: irrigation, limited warmwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.0 to 9.0, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

3. At mean monthly flows above 100 cfs, the monthly average concentration for: TDS shall be less than 1,500 mg/l, sulfate shall be less than 500 mg/l, and chloride shall be less than 250 mg/l.

2-105.5 The Jemez River from its confluence with the Rio Guadalupe upstream to State Highway 4 near the town of Jemez Springs and perennial reaches of Vallecito Creek.

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

A. Designated Uses: coldwater fishery, primary contact recreation, irrigation, and livestock and wildlife watering.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, temperature shall be less than 25 C (77 F), total chlorine residual shall be less than 0.002 mg/l, pH shall be within the range of 6.6 to 8.8, and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-106. The Jemez River and all its tributaries above State Highway 4 near the town of Jemez Springs and the Guadalupe River and all its tributaries.

A. Designated Uses: domestic water supply, fish culture, high quality coldwater fishery, irrigation, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l; conductivity shall be less than 400 umhos; dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; total inorganic nitrogen (as N) shall be less than 1.0 mg/l; pH shall be within the range of 6.6 to 8.8; temperature shall be less than 20 C (68 F); total chlorine residual shall be less than 0.002 mg/l; total organic carbon shall be less than 7 mg/l; total phosphorus (as P) shall be less than 0.1 mg/l; and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-107. Perennial reaches of Bluewater Creek, Rio Moquino, Seboyeta Creek, Rio Paguate, the Rio Puerco within the Santa Fe National Forest, and all other perennial reaches of tributaries to the Rio Puerco including the Rio San Jose in Cibola County from the USGS gaging station at Correo upstream to Horace Springs.

A. Designated Uses: coldwater fishery, domestic water supply, fish culture, irrigation, livestock and wildlife watering, and primary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, total inorganic nitrogen (as N) shall be less than 2.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 20 C (68 F), total chlorine residual shall be less than 0.002 mg/l, total phosphorus (as P) shall be less than 0.1 mg/l, and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-108. The main stem of the Rio Grande from Angostura Diversion Works upstream to Cochiti Dam.

A. Designated Uses: irrigation, livestock and wildlife watering, secondary contact recreation, coldwater fishery, and warmwater fishery.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 9.0, temperature shall be less than 25 C (77 F), and total chlorine residual shall be less than 0.002 mg/l.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-108.5 Perennial reaches of Las Huertas Creek.

A. Designated Uses: coldwater fishery, irrigation, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 25 C (77 F), and total chlorine residual shall be less than 0.002 mg/l.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-109. Cochiti Reservoir.

A. Designated Uses: livestock and wildlife watering, warmwater fishery, coldwater fishery, and primary contact recreation.

B. Standards:

1. At any sampling site: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 25 C (77 F), turbidity shall be less than 25 NTU, and total chlorine residual shall be less than 0.002 mg/l.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-110. The Santa Fe River and its tributaries from Cochiti Reservoir upstream to the outfall of the Santa Fe wastewater treatment facility.

A. Designated Uses: irrigation, livestock and wildlife watering, marginal coldwater fishery, secondary contact recreation, and warmwater fishery.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 4.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 30 C (86 F), and turbidity shall be less than 50 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

2-111. The main stem of the Rio Grande from the headwaters of Cochiti Reservoir upstream to Taos Junction Bridge, Embudo Creek from its mouth on the Rio Grande upstream to the junction of the Rio Pueblo and the Rio Santa Barbara, the Santa Cruz River below Santa Cruz Dam, the Rio Tesuque below the Santa Fe National Forest and the Pojoaque River below Nambe Dam.

A. Designated Uses: irrigation, livestock and wildlife watering, marginal coldwater fishery, secondary contact recreation, and warmwater fishery.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.6, temperature shall be less than 22 C (71.6 F), and turbidity shall be less than 50 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

3. At mean monthly flows above 100 cfs, the monthly average concentration for: TDS shall be less than 500 mg/l, sulfate shall be less than 150 mg/l, and chloride shall be less than 25 mg/l.

2-112. The perennial reaches of Rio Vallecitos and its tributaries, and Rio del Oso, and El Rito Creek above the town of El Rito.

A. Designated Uses: domestic water supply, irrigation, high quality coldwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l; conductivity shall be less than 300 umhos; dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; total inorganic nitrogen (as N) shall be less than 1.0 mg/l; pH shall be within the range of 6.6 to 8.8; temperature shall be less than 20 C (68 F); total chlorine residual shall be less than 0.002 mg/l; total organic carbon shall be less than 7 mg/l; total phosphorus (as P) shall be less than 0.1 mg/l; and turbidity shall be less than 10 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-113. The Rio Chama from its mouth on the Rio Grande upstream to Abiquiu Reservoir, the Rio Tusas, the Rio Ojo Caliente, Abiquiu Creek, and El Rito Creek below the town of El Rito.

A. Designated Uses: irrigation, livestock and wildlife watering, marginal coldwater fishery, warmwater fishery, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 31 C (87.8 F).

NMED Exhibit 87

FILED WITH

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

2-114. Abiquiu Reservoir.

A. Designated Uses: irrigation storage, livestock and wildlife watering, primary contact recreation, coldwater fishery, and warmwater fishery.

B. Standards:

1. At any sampling site: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 25 C (77 F), and total chlorine residual shall be less than 0.002 mg/l.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-115. The Rio Chama from the headwaters of Abiquiu Reservoir upstream to El Vado Reservoir and the Rio Gallina and Rio Puerco de Chama north of State Highway 96.

A. Designated Uses: irrigation, livestock and wildlife watering, coldwater fishery, warmwater fishery, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 26 C (78.8 F), and total chlorine residual shall be less than 0.002 mg/l.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-116. All perennial reaches of tributaries to the Rio Chama above Abiquiu Reservoir except the Rio Gallina and Rio Puerco de Chama north of State Highway 96 and the main stem of the Rio Chama from the headwaters of El Vado Reservoir upstream to the New Mexico-Colorado line.

A. Designated Uses: domestic water supply, fish culture, high quality coldwater fishery, irrigation, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l; conductivity shall be less than 500 umhos (1,000 umhos for Coyote Creek); dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; total inorganic nitrogen (as N) shall be less than 1.0 mg/l; pH shall be within the range of 6.6 to 8.8; temperature shall be less than 20 C (68 F); total chlorine residual shall be less than 0.002 mg/l; total organic carbon shall be less than 7 mg/l; total phosphorus (as P) shall be less than 0.1 mg/l; and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-117. El Vado and Heron Reservoirs.

A. Designated Uses: irrigation storage, wildlife and livestock watering, primary contact recreation, and coldwater fishery.

B. Standards:

1. At any sampling site: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 20 C (68 F), and total chlorine residual shall be less than 0.002 mg/l, and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-118. Perennial tributaries to the Rio Grande in Bandelier National Monument and their headwaters in Sandoval County, all perennial reaches of tributaries to the Rio Grande in Santa Fe County unless included in other segments.

A. Designated Uses: domestic water supply, high quality coldwater fishery, irrigation, livestock and wildlife watering, municipal and industrial water supply, and secondary contact recreation.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-119. The main stem of the Rio Grande from Taos Junction Bridge upstream to the New Mexico-Colorado line, the Red River from its mouth on the Rio Grande upstream to the mouth of Placer Creek, and the Rio Pueblo de Taos from its mouth on the Rio Grande upstream to Los Cordovas.

A. Designated Uses: coldwater fishery, fish culture, irrigation, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 20 C (68 F), and total chlorine residual shall be less than 0.002 mg/l, and turbidity shall be less than 50 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-120. The Red River upstream of the mouth of Placer Creek, all tributaries to the Red River, and all other perennial reaches of tributaries to the Rio Grande in Taos and Rio Arriba counties unless included in other segments.

A. Designated Uses: domestic water supply, fish culture, high quality coldwater fishery, irrigation, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l; conductivity shall be less than 400 umhos (500 umhos for the Rio Fernando de Taos); dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; total inorganic nitrogen (as N)

2-200. PECOS RIVER BASIN.

2-201. The main stem of the Pecos River from the New Mexico-Texas line upstream to the USGS gaging station near Malaga.

A. Designated Uses: irrigation, livestock and wildlife watering, secondary contact recreation, and warmwater fishery.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to. 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

3. At all flows above 50 cfs: TDS shall be less than 20,000 mg/l, sulfate shall be less than 3,000 mg/l, and chloride shall be less than 10,000 mg/l.

2-202. The main stem of the Pecos River from the USGS gaging station near Malaga upstream to Lower Tansil Dam,[1] including the Black River, the Delaware River and Blue Spring.

A. Designated Uses: industrial water supply, irrigation, livestock and wildlife watering, secondary contact recreation, and warmwater fishery.

B. Standards:

1. In any single sample, dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 9.0, and temperature shall be less than 34 C (93.2 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

3. At all flows above 50 cfs: TDS shall be less than 8,500 mg/l, sulfate shall be less than 2,500 mg/l, and chloride shall be less than 3,500 mg/l.

2-203. The main stem of the Pecos River from Lower Tansil Dam upstream to Avalon Dam, including Tansil Lake.

A. Designated Uses: industrial water supply, livestock and wildlife watering, primary contact recreation, and warmwater fishery.

B. Standards:

1. At any sampling site: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 34 C (93.2 F), and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-204. The main stem of the Pecos River from Avalon Dam upstream to Brantley Dam, including Avalon Reservoir.

A. Designated Uses: irrigation storage, livestock and wildlife watering, secondary contact recreation, and warmwater fishery.

B. Standards:

1. At any sampling site: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

2-205. Brantley Reservoir.

A. Designated Uses: irrigation storage, livestock and wildlife watering, primary contact recreation, and warmwater fishery.

B. Standards:

1. At any sampling site: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-206. The main stem of the Pecos River from the headwaters of Brantley Reservoir upstream to Acme, including flow from below the perennial reaches of the Rio Penasco, the Rio Hondo, and the Rio Felix which enters the main stem of the Pecos River.

A. Designated Uses: irrigation, livestock and wildlife watering, secondary contact recreation, and warmwater fishery.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

3. At all flows above 50 cfs: TDS shall be less than 14,000 mg/l, sulfate shall be less than 3,000 mg/l, and chloride shall be less than 6,000 mg/l.

2-207. The main stem of the Pecos River from Acme upstream to Sumner Dam.

A. Designated Uses: fish culture, irrigation, limited warmwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

3. At all flows above 50 cfs: TDS shall be less than 8,000 mg/l, sulfate shall be less than 2,500 mg/l, and chloride shall be less than 4,000 mg/l.

2-208. Perennial reaches of the Rio Penasco and its tributaries above Dunken, and perennial reaches of Bonito Creek below Angus, the Rio Ruidoso below Seeping Springs Lakes, and Agua Chiquita.

A. Designated Uses: fish culture, irrigation, livestock and wildlife watering, coldwater fishery, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 30 C (86 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-209. Eagle Creek above Alto Reservoir, Bonito Creek upstream of Angus, and the Rio Ruidoso and its tributaries above Seeping Springs Lakes.

A. Designated Uses: domestic water supply, fish culture, high quality coldwater fishery, irrigation, livestock and wildlife watering, municipal and industrial water supply, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l; conductivity shall be less than 600 umhos in Eagle Creek, 1,100 umhos in Bonito Creek, and 1,500 umhos in the Rio Ruidoso; dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; total inorganic nitrogen (as N) shall be less than 1.0 mg/l; pH shall be within the range of 6.6 to 8.8; temperature shall be less than 20 C (68 F); total chlorine residual shall be less than 0.002 mg/l; total organic carbon shall be less than 7 mg/l; total phosphorus (as P) shall be less than 0.1 mg/l; and turbidity shall be less than 10 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-210. Sumner Reservoir.

A. Designated Uses: irrigation storage, livestock and wildlife watering, primary contact recreation, and warmwater fishery.

B. Standards:

1. At any sampling site: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 32.2 C (90 F), and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-211. The main stem of the Pecos River from the headwaters of Sumner Reservoir upstream to Anton Chico.

A. Designated Uses: fish culture, irrigation, limited warmwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

3. At all flows above 50 cfs: TDS shall be less than 3,000 mg/l, sulfate shall be less than 2,000 mg/l, and chloride shall be less than 400 mg/l.

2-211.3 MacAllister Lake.

A. Designated Uses: coldwater fishery, secondary contact recreation, and livestock and wildlife watering.

B. Standards:

1. At any sampling site: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 25 C (77 F), and total chlorine residual shall be less than 0.002 mg/l.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

2-211.5 Storrie Lake.

A. Designated Uses: coldwater fishery, warmwater fishery, primary contact recreation, livestock and wildlife watering, and irrigation storage.

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER
1991 MAY 29 AM 10:26

B. Standards:

1. At any sampling site: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 20 C (68 F), total chlorine residual shall be less than 0.002 mg/l, and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-212. The Gallinas River and all its tributaries above the diversion for the Las Vegas municipal reservoir and perennial reaches of Tecolote Creek and its perennial tributaries.

A. Designated Uses: domestic water supply, high quality coldwater fishery, irrigation, livestock and wildlife watering, municipal and industrial water supply, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l; conductivity shall be less than 300 umhos except conductivity shall be less than 450 umhos in Wright Canyon Creek; dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; total inorganic nitrogen (as N) shall be less than 1.0 mg/l; pH shall be within the range of 6.6 to 8.8; temperature shall be less than 20 C (68 F); total chlorine residual shall be less than 0.002 mg/l; total phosphorus (as P) shall be less than 0.1 mg/l; and turbidity shall be less than 10 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-213. The main stem of the Pecos River from Anton Chico upstream to one river mile below the bridge on State Highway 223, and perennial reaches of the Gallinas River from its mouth upstream to the diversion for the Las Vegas municipal reservoir.

A. Designated Uses: irrigation, livestock and wildlife watering, marginal coldwater fishery, and secondary contact recreation.

NMED Exhibit 87

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 30 C (86 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml (see 1-103.B).

3. At all flows above 10 cfs: TDS shall be less than 250 mg/l, sulfate shall be less than 25 mg/l, and chloride shall be less than 5 mg/l.

2-214. Cow Creek and all its tributaries and the main stem of the Pecos River from one river mile below the bridge on State Highway 223 upstream to its headwaters, including all tributaries thereto.

A. Designated Uses: domestic water supply, fish culture, high quality coldwater fishery, irrigation, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l; conductivity shall be less than 300 umhos; dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; total inorganic nitrogen (as N) shall be less than 1.0 mg/l; pH shall be within the range of 6.6 to 8.8; temperature shall be less than 20 C (68 F); total chlorine residual shall be less than 0.002 mg/l; total organic carbon shall be less than 7 mg/l; total phosphorus (as P) shall be less than 0.1 mg/l; and turbidity shall be less than 10 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-300. CANADIAN RIVER BASIN.

2-301. The main stem of the Canadian River from the New Mexico-Texas line upstream to Ute Dam, and any flow which enters the main stem from Revuelto Creek.

A. Designated Uses: irrigation, limited warmwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 32.2 C (90 F), and TDS shall be less than 6,500 mg/l at flows above 25 cfs.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-302. Ute Reservoir.

A. Designated Uses: livestock and wildlife watering, municipal and industrial water supply, primary contact recreation, and warmwater fishery.

B. Standards:

1. At any sampling site: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, turbidity shall be less than 25 NTU and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-303. The main stem of the Canadian River from the headwaters of Ute Reservoir upstream to Conchas Dam and Ute Creek and its perennial tributaries.

A. Designated Uses: irrigation, limited warmwater fishery, livestock and wildlife watering, and secondary contact recreation.

NMED Exhibit 87

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-304. Conchas Reservoir.

A. Designated Uses: irrigation storage, livestock and wildlife watering, primary contact recreation and warmwater fishery.

B. Standards:

1. At any sampling site: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 32.2 C (90 F), and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-305. The main stem of the Canadian River from the headwaters of Conchas Reservoir upstream to the New Mexico-Colorado line, and Conchas River and any flow from below the perennial reaches of the Mora River, Cimarron River, Vermejo River, Chicorica Creek which enters the main stem of the Canadian River, and perennial reaches of Raton and Una de Gato creeks.

A. Designated Uses: irrigation, limited warmwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 32.2 C (90 F), and TDS shall be less than 3,500 mg/l at flows above 10 cfs.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-305.3 Perennial reaches of the Mora River from the USGS gaging station near Shoemaker upstream to Mora, all perennial reaches of tributaries to the Mora River downstream from State Highway 518 in San Miguel and Mora counties, perennial reaches of Ocate Creek and its tributaries downstream of Ocate, and perennial reaches of Rayado Creek downstream of Miami Lake diversion in Colfax County.

A. Designated Uses: marginal coldwater fishery, warmwater fishery, secondary contact recreation, irrigation, and livestock and wildlife watering.

B. Standards:

1. At any sampling site: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, temperature shall be less than 25 C (77 F), total chlorine residual shall be less than 0.002 mg/l, and pH shall be within the range of 6.6 to 8.8.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-305.5 Charette Lakes.

A. Designated Uses: coldwater fishery, warmwater fishery, secondary contact recreation, livestock and wildlife watering.

B. Standards:

1. At any sampling site: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 20 C (68 F), and total chlorine residual shall be less than 0.002 mg/l.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml.

2-306. The Mora River and its tributaries above Mora, all tributaries to the Mora River upstream from State Highway 518, Coyote Creek, the Cimarron River above State Highway 21 in Cimarron, all tributaries to the Cimarron River, Rayado Creek above Miami Lake diversion, Ocate Creek and its tributaries upstream of Ocate, and all other tributaries to the Canadian River northwest and north of U.S. Highway 64 in Colfax County unless included in other segments.

A. Designated Uses: domestic water supply, irrigation, high quality coldwater fishery, livestock and wildlife watering, municipal and industrial water supply, and secondary contact recreation.

2-400. SAN JUAN RIVER BASIN.

2-401. The main stem of the San Juan River from the point where the San Juan leaves New Mexico and enters Colorado upstream to U.S. Highway 64 at Blanco, and any flow which enters the San Juan River from the Mancos and Chaco Rivers.

A. Designated Uses: municipal and industrial water supply, irrigation, livestock and wildlife watering, secondary contact recreation, marginal coldwater fishery, and warmwater fishery.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-402. La Plata River from its confluence with the San Juan River upstream to the New Mexico-Colorado line.

A. Designated Uses: irrigation, limited warmwater fishery, marginal coldwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-403. The Animas River from its confluence with the San Juan upstream to U.S. Highway 550 at Aztec.

A. Designated Uses: municipal and industrial water supply, irrigation, livestock and wildlife watering, marginal coldwater fishery, secondary contact recreation, and warmwater fishery.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 27 C (80.6 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-404. The Animas River from U.S. Highway 550 upstream to the New Mexico-Colorado line.

A. Designated Uses: coldwater fishery, irrigation, livestock and wildlife watering, municipal and industrial water supply, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 20 C (68 F), total phosphorus (as P) shall be less than 0.1 mg/l, and total chlorine residual shall be less than 0.002 mg/l.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-405. The main stem of the San Juan River from U.S. Highway 64 at Blanco upstream to the Navajo Dam.

A. Designated Uses: high quality coldwater fishery, irrigation, livestock and wildlife watering, municipal and industrial water supply, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l; conductivity shall be less than 400 umhos/cm (at 25 C); dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; total inorganic nitrogen shall be less than 1.0 mg/l (as N); pH shall be within the range of 6.6 to 8.8; temperature shall be less than 20 C (68 F); total chlorine residual shall be less than 0.002 mg/l; total organic carbon shall be less than 7 mg/l; total phosphorus (as P) shall be less than 0.1 mg/l; and turbidity shall be less than 10 NTU.

2-406. Navajo Reservoir in New Mexico.

A. Designated Uses: coldwater fishery, warmwater fishery, irrigation storage, livestock and wildlife watering, municipal and industrial water storage, and primary contact recreation.

B. Standards:

1. At any sampling site: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 20 C (68 F), total phosphorus (as P) shall be less than 0.1 mg/l, total chlorine residual shall be less than 0.002 mg/l, and turbidity shall be less than 25 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

3. The open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders.

2-407. The Navajo and Los Pinos Rivers in New Mexico.

A. Designated Uses: coldwater fishery, irrigation, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 20 C (68 F), total phosphorus (as P) shall be less than 0.1 mg/l; and total chlorine residual shall be less than 0.002 mg/l.

2-500. GILA RIVER BASIN.

2-501. The main stem of the Gila River from the New Mexico-Arizona line upstream to State Highway 464 in Red Rock.

A. Designated Uses: irrigation, limited warmwater fishery, livestock and wildlife watering, and primary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 32.2 C (90 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-502. The main stem of the Gila River from State Highway 464 in Red Rock upstream to Gila Hot Springs and perennial reaches of tributaries to the Gila River below the town of Cliff.

A. Designated Uses: industrial water supply, irrigation, livestock and wildlife watering, marginal coldwater fishery, primary contact recreation, and warmwater fishery.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 5.0 mg/l, pH shall be within the range of 6.6 to 8.8, and temperature shall be less than 28 C (82.4 F).

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

2-503. The main stem of the Gila River from Gila Hot Springs upstream to the headwaters and all perennial tributaries to the Gila River at or above the town of Cliff.

A. Designated Uses: domestic water supply, high quality coldwater fishery, irrigation, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l; conductivity shall be less than 300 umhos for the main stem of the Gila River above Gila Hot Springs and 400 umhos for other reaches; dissolved oxygen shall be greater than 6.0 mg/l or 85% of

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-804. The Mimbres River upstream of the USGS gaging station at Mimbres and all perennial tributaries thereto.

A. Designated Uses: irrigation, domestic water supply, high quality coldwater fishery, livestock and wildlife watering, and secondary contact recreation.

B. Standards:

1. In any single sample: un-ionized ammonia (as N) shall not exceed 0.02 mg/l, conductivity shall be less than 300 umhos; dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; total inorganic nitrogen (as N) shall be less than 1.0 mg/l; pH shall be within the range of 6.6 to 8.8; temperature shall be less than 20 C (68 F); total chlorine residual shall be less than 0.002 mg/l; total organic carbon shall be less than 7 mg/l; total phosphorus (as P) shall be less than 0.1 mg/l; and turbidity shall be less than 10 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 100/100 ml; no single sample shall exceed 200/100 ml (see 1-103.B).

2-805. Perennial reaches of the Sacramento River (Sacramento-Salt Flat Closed Basin) and all perennial tributaries thereto.

A. Designated Uses: domestic and municipal water supply, livestock and wildlife watering, marginal coldwater fishery, and secondary contact recreation.

B. Standards:

1. In any single sample: dissolved oxygen shall be greater than 6.0 mg/l, pH shall be within the range of 6.6 to 8.8, temperature shall be less than 25 C (77 F), and turbidity shall be less than 10 NTU.

2. The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml; no single sample shall exceed 400/100 ml (see 1-103.B).

PART 3

3-100. DEFINITIONS.

A. "Acute toxicity" means toxicity involving a stimulus severe enough to induce a response in 96 hours of exposure or less. Acute toxicity is not always measured in terms of lethality, but may include other toxic effects that occur within a short time period.

B. "Attainable use" means a use of a surface Water of the State which has water quality and all other characteristics necessary to support and maintain the use, as specified in Section 3-101 of these standards, or which would support and maintain the use after the implementation of water quality standards as specified in Section 1-101.B of these standards.

C. "Best management practices" means schedules of activities, prohibitions of certain practices, implementation of maintenance procedures, or other measures or practices selected by the State or a designated management agency to achieve control of non-point sources of water pollutants.

D. "cfs" means cubic feet per second.

E. "Chronic toxicity" means toxicity involving a stimulus that lingers or continues for a relatively long period relative to the life span of an organism. Chronic effects include, but are not limited to, lethality, growth impairment, behavioral modifications, disease and reduced reproduction.

F. "Coldwater fishery" means a stream reach, lake or impoundment where the water temperature and other characteristics are suitable for the support or propagation or both of coldwater fishes such as brown, cutthroat, brook, or rainbow trout.

G. "Designated use" means those uses specified in Part 2 of "Water Quality Standards for Interstate and Intrastate Streams in New Mexico" for each water body or segment whether or not they are being attained.

H. "Dissolved" means a constituent of a water sample which will pass through a 0.45 micrometer pore-size membrane filter under a pressure differential not exceeding one atmosphere. The "dissolved" fraction is also termed "filterable residue."

I. "Domestic water supply" means a surface water that may be used for drinking or culinary purposes after disinfection.

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

1991 MAY 29 AM 10: 26

J. "Ephemeral stream" means a stream or reach of a stream that flows briefly only in direct response to precipitation or snowmelt in the immediate locality; its channel bed is always above the water table of the region adjoining the stream.

K. "Existing use" means those uses actually attained in a water body whether or not they are included in the water quality standards.

L. "Fecal coliform bacteria" means the portion of the coliform group which is present in the gut or the feces of warmblooded animals. It generally includes organisms which are capable of producing gas from lactose broth in a suitable culture medium within 24 hours at 44.5 $\pm$ 0.2 C.

M. "Fish culture" means production of coldwater or warmwater fishes in a hatchery or rearing station.

N. "Flow," relative to the four definitions of streams herein, means natural flow ensuing from the earth's hydrologic cycle, i.e., atmospheric precipitation resulting in surface and, or, ground-water runoff. Natural in-stream flow may be interrupted or eliminated by dams and diversions.

O. "High quality coldwater fishery" means a perennial stream reach in a minimally disturbed condition which has considerable aesthetic value and is a superior coldwater fishery habitat. A stream reach to be so categorized must have water quality, stream bed characteristics, and other attributes of habitat sufficient to protect and maintain a propagating coldwater fishery (i.e., a population of reproducing salmonids).

P. "Intermittent stream" means a stream or reach of a stream that flows only at certain times of the year, such as when it receives flow from springs, melting snow, or localized precipitation. Syn: temporary stream, seasonal stream.

Q. "Interrupted stream" means a stream that contains perennial reaches with intervening intermittent or ephemeral reaches. Ant: continuous stream.

R. "Interstate waters" means all surface waters which cross or form a part of the border between States.

S. "Intrastate waters" means all surface waters of the State which are not interstate waters.

T. "LC-50" means the concentration of a substance that is lethal to 50% of the test organisms within a defined time period. The length of the time period, which may vary from 24 hours to one week or more, depends on the test method selected to yield the information desired.

U. "Limited warmwater fishery" means a stream reach where intermittent flow may severely limit the ability of the reach to sustain a

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER
1991 MAY 29 AM 10: 27

natural fish population on a continuous annual basis; or a stream where historical data indicate that water temperature may routinely exceed 32.2 C (90 F).

V. "Limiting nutrient" means the nutrient or combination of nutrients available in minimal quantities with respect to the growth requirements of algae and higher aquatic plants and upon which the growth of these organisms is therefore dependent.

W. "Marginal coldwater fishery" means a stream reach, lake or impoundment known to support a coldwater fish population during at least some portion of the year, even though historical data indicates that the maximum temperature in the stream may exceed 20 C (68 F).

X. "Micrograms per liter (ug/l)" means micrograms of solute per liter of solution; equivalent to parts per billion when the specific gravity of the solution = 1.000.

Y. "Milligrams per liter (mg/l)" means milligrams of solute per liter of solution; equivalent to parts per million when the specific gravity of the solution = 1.000.

Z. "Natural causes" means those causal agents which would affect water quality in the absence of man's actions. Natural causes do not include point source discharges, nonpoint source pollution or any other culturally induced impairment of the chemical, physical, biological or radiological integrity of water.

AA. "Nonpoint Source Pollution" means the alteration of surface waters by land management or land-use activities which are not regulated as point sources and which degrade the quality or adversely affects the biological community inhabiting the waters.

BB. "NTU" means nephelometric turbidity units based on a standard method using formazin polymer or its equivalent as the standard reference suspension. Nephelometric turbidity measurements expressed in units of NTU are numerically identical to the same measurements expressed in units of FTU (formazin turbidity units).

CC. "Perennial stream" means a stream or reach of a stream that flows continuously throughout the year in all years; its upper surface, generally, is lower than the water table of the region adjoining the stream. Syn: permanent stream, live stream.

DD. "Picocurie (pCi)" means a measure of radioactivity equal to the quantity of a radioactive substance in which the rate of disintegrations is 2.22 per minute.

EE. "Point source" means any discernible, confined, and discrete conveyance from which pollutants are or may be discharged into a water body, but does not include return flows from irrigated agriculture.

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER
1991 MAY 29 AM 10: 27

FF. "Primary Contact" means any recreational or other water use in which there is prolonged and intimate contact with the water, such as swimming and water skiing, involving considerable risk of ingesting water in quantities sufficient to pose a significant health hazard.

GG. "Secondary contact" means any recreational or other water use in which contact with the water may occur and in which the probability of ingesting appreciable quantities of water is minimal, such as fishing, wading, commercial and recreational boating and any limited seasonal contact.

HH. "Segment" means a water quality standards segment, the surface waters of which have common hydrologic characteristics or flow regulation regimes, possess common natural physical, chemical, and biological characteristics, and exhibit common reactions to external stresses, such as the discharge of pollutants.

II. "TDS" means total dissolved solids, also termed "total filterable residue."

JJ. "Technology-based controls" means the application of technology-based effluent limitations as required under Section 301(b) of the Clean Water Act.

KK. "Total" means a constituent of a water sample which is analytically determined without filtration.

LL. "Total inorganic nitrogen" means the sum of nitrate nitrogen, nitrite nitrogen, and total ammonia nitrogen.

MM. "Toxic pollutant" means those pollutants, or combination of pollutants, including disease-causing agents, which after discharge and upon exposure, ingestion, inhalation or assimilation into any organism, either directly from the environment or indirectly by ingestion through food chains, will cause death, disease, behavioral malfunctions (including malfunctions in reproduction) or physical deformations in such organisms or their offspring.

NN. Tubidity" is an expression of the optical property in water that causes incident light to be scattered or absorbed rather than transmitted in straight lines.

OO. "Warmwater fishery" means a stream reach, lake or impoundment where the water temperature and other characteristics are suitable for the support and propagation of warmwater fishes such as large-mouth black bass, small-mouth black bass, crappie, white bass, bluegill, flathead catfish, or channel catfish.

PP. "Water," for purposes of these standards, means all surface waters including waters situated wholly or partly within or bordering upon the State, whether public or private, except private waters that do not combine with other surface or subsurface water.

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

1991 MAY 29 AM 10:27

QQ. "Water contaminant" means any substance which alters the physical, chemical or biological qualities of water.

RR. "Watercourse" means any river, creek, arroyo, canyon, draw, or wash, or any other channel having definite banks and beds with visible evidence of the occasional flow of water. Syn: stream.

SS. "Waters of the State" means all interstate and intrastate waters including natural ponds and lakes, playa lakes, reservoirs, perennial streams and their tributaries, intermittent streams, sloughs, prairie potholes and wetlands.

TT. "Water pollutant" means a water contaminant in such quantity and of such duration as may with reasonable probability injure human health, animal or plant life or property, or to unreasonably interfere with the public welfare or the use of property.

UU. "Water quality-based controls" means effluent limitations, as provided under Section 301(b)(1)(C) of the Clean Water Act, which are developed and imposed on point-source dischargers in order to protect and maintain applicable water quality standards. These controls are more stringent than the technology-based effluent limitations required under other paragraphs of Section 301(b).

VV. "Wetlands" means those areas which are inundated or saturated by surface or ground water at a frequency and duration sufficient to support, and under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions in New Mexico.

STATE RECORDS CENTER

1991 MAY 29 AM 10:27

3-101. STANDARDS[1] APPLICABLE TO ATTAINABLE OR DESIGNATED USES UNLESS OTHERWISE SPECIFIED IN PART 2.

A. Coldwater Fishery: Un-ionized ammonia (as N) shall not exceed 0.03 mg/l, dissolved oxygen shall be greater than 6.0 mg/l, temperature shall be less than 20 C (68 F), total chlorine residual shall not exceed 0.004 mg/l, and pH shall be within the range of 6.6 to 8.8. The acute and chronic standards set out in Section 3-101.J are applicable to this use.

B. Domestic Water Supply: Waters designated for use as domestic water supplies shall not contain substances in concentrations that create a lifetime cancer risk of more than one cancer per 100,000 exposed persons. The following numeric standards shall not be exceeded:

Dissolved arsenic	0.05 mg/l
Dissolved barium	1. mg/l
Dissolved cadmium	0.010 mg/l
Dissolved chromium	0.05 mg/l
Dissolved lead	0.05 mg/l
Total mercury	0.002 mg/l
Dissolved nitrate (as N)	10. mg/l
Dissolved selenium	0.05 mg/l
Dissolved silver	0.05 mg/l
Dissolved cyanide	0.2 mg/l
Dissolved uranium	5.0 mg/l
Radium-226 + radium-228	30.0 pCi/l

C. High Quality Coldwater Fishery: Dissolved oxygen shall be greater than 6.0 mg/l or 85% of saturation, whichever is greater; temperature shall be less than 20 C (68 F); pH shall be within the range of 6.6 to 8.8; un-ionized ammonia (as N) shall not exceed 0.02 mg/l; total chlorine residual shall not exceed 0.004 mg/l; total phosphorus (as P) shall be less than 0.1 mg/l;[2] total inorganic nitrogen (as N) shall be less than 1.0 mg/l;[2] total organic carbon shall be less than 7 mg/l; turbidity shall be less than 10 NTU (25 NTU in certain reaches where natural background prevents attainment of lower turbidity); and conductivity (at 25 C) shall be less than a limit varying between 300 umhos/cm and 1,500 umhos/cm depending on the natural background in particular stream reaches (the intent of this standard is to prevent excessive increases in dissolved solids which would result in changes in stream community structure). The acute and chronic standards set out in Section 3-101.J are applicable to this use.

D. Irrigation (or Irrigation Storage): The monthly logarithmic mean of fecal coliform bacteria shall not exceed 1,000/100 ml; no single sample shall exceed 2,000/100 ml. The following numeric standards shall not be exceeded:

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER

1991 OCT 11 PM 1:52

Dissolved aluminum	5.0	mg/l
Dissolved arsenic	0.10	mg/l
Dissolved boron	0.75	mg/l
Dissolved cadmium	0.01	mg/l
Dissolved chromium	0.10	mg/l
Dissolved cobalt	0.05	mg/l
Dissolved copper	0.20	mg/l
Dissolved lead	5.0	mg/l
Dissolved selenium	0.13	mg/l
Dissolved selenium in presence of >500 mg/l SO_4	0.25	mg/l
Dissolved vanadium	0.1	mg/l
Dissolved zinc	2.0	mg/l

E. Limited Warmwater Fishery: Standards are the same as for "Warmwater Fishery" except on a case by case basis, the dissolved oxygen may reach a minimum of 4.0 mg/l or maximum temperatures may exceed 32.2 C. The acute and chronic standards set out in Section 3-101.J are applicable to this use.

F. Marginal Coldwater Fishery: Standards are the same as for "Coldwater Fishery" except on a case by case basis, the dissolved oxygen may reach a minimum of 5.0 mg/l or maximum temperatures may exceed 25 C and the pH may range from 6.6 to 9.0. The acute and chronic standards set out in Section 3-101.J are applicable to this use.

G. Primary Contact Recreation: The monthly logarithmic mean of fecal coliform bacteria shall not exceed 200/100 ml, no single sample shall exceed 400/100 ml; the open water shall be free of algae in concentrations which cause nuisance conditions or gastrointestinal or skin disorders; pH shall be within the range of 6.6 to 8.8; and turbidity shall be less than 25 NTU.

H. Warmwater Fishery: Un-ionized ammonia (as N) shall not exceed 0.06 mg/l, dissolved oxygen shall be greater than 5 mg/l, temperature shall be less than 32.2 C (90 F), and pH shall be within the range of 6.0 to 9.0 and total chlorine residual shall not exceed 0.008 mg/l. The acute and chronic standards set out in Section 3-101.J are applicable to this use.

I. Fish culture and municipal and industrial water supply and storage are also designated in particular stream reaches where these uses are actually being realized. However, no numeric standards apply uniquely to these uses. Water quality adequate for these uses is ensured by the general standards and numeric standards for bacterial quality, pH, and temperature which are established for all stream reaches listed in Part 2 of the standards.

J. The following schedule of numeric standards and equations for the substances listed shall apply to the subcategories of fisheries identified in Section 3-101:

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER
1991 MAY 29 AM 10: 27

Chronic Criteria[3]

Dissolved aluminum		87.0	(10^{-3}) mg/l
Dissolved beryllium		5.3	(10^{-3}) mg/l
Total mercury		0.012	(10^{-3}) mg/l
Dissolved selenium		5.0	(10^{-3}) mg/l
Dissolved silver		0.12	(10^{-3}) mg/l
Total cyanide		5.2	(10^{-3}) mg/l
Total chlordane		0.0043	(10^{-3}) mg/l
Dissolved cadmium[5]	e(0.7852[ln(hardness)]-3.49)		(10^{-3}) mg/l
Dissolved chromium[6]	e(0.819[ln(hardness)+1.561)		(10^{-3}) mg/l
Dissolved copper	e(0.8545[ln(hardness)]-1.465)		(10^{-3}) mg/l
Dissolved lead	e(1.273[ln(hardness)]-4.705)		(10^{-3}) mg/l
Dissolved nickel	e(0.846[ln(hardness)]+1.1645)		(10^{-3}) mg/l
Dissolved zinc	e(0.8473[ln(hardness)]+0.7614)		(10^{-3}) mg/l

Acute Criteria[4]

Dissolved aluminum		750	(10^{-3}) mg/l
Dissolved beryllium		130	(10^{-3}) mg/l
Total mercury		2.4	(10^{-3}) mg/l
Dissolved selenium		20.0	(10^{-3}) mg/l
Dissolved silver	e(1.72[ln(hardness)]-6.52)		(10^{-3}) mg/l
Total cyanide		22.0	(10^{-3}) mg/l
Total chlordane		2.4	(10^{-3}) mg/l
Dissolved cadmium	e(1.128[ln(hardness)]-3.828)		(10^{-3}) mg/l
Dissolved chromium[6]	e(0.819[ln(hardness)+3.688)		(10^{-3}) mg/l
Dissolved copper	e(0.9422[ln(hardness)]-1.464)		(10^{-3}) mg/l
Dissolved lead	e(1.273[ln(hardness)]-1.46)		(10^{-3}) mg/l
Dissolved nickel	e(0.76[ln(hardness)]+4,02		(10^{-3}) mg/l
Dissolved zinc	e(0.8473[ln(hardness)]+0.8604)		(10^{-3}) mg/l

K. Livestock and Wildlife Watering: The following numeric standards shall not be exceeded:

Dissolved aluminum	5.0	mg/l
Dissolved arsenic	0.02	mg/l
Dissolved boron	5.0	mg/l
Dissolved cadmium	0.05	mg/l
Dissolved chromium[6]	1.0	mg/l
Dissolved cobalt	1.0	mg/l
Dissolved copper	0.5	mg/l
Dissolved lead	0.1	mg/l
Total mercury	0.01	mg/l
Dissolved selenium	0.05	mg/l
Dissolved vanadium	0.1	mg/l
Dissolved zinc	25.0	mg/l
Radium-226 + radium-228	30.0	pCi/l

NMED Exhibit 87

FILED WITH
STATE RECORDS CENTER
1991 MAY 29 AM 10: 27

[1]For waters with more than a single attainable or designated use the applicable criteria are those which will protect and sustain the most sensitive use.

[2]As the need arises, the State shall determine for specified stream segments or relevant portions thereof whether the limiting nutrient for the growth of aquatic plants is nitrogen or phosphorus. Upon such a determination the waters in question shall be exempt from the standard for the nutrient found to be not limiting. Until such a determination is made, standards for both nutrients shall apply. If co-limitation is found, the waters in question shall be exempt from the total inorganic nitrogen standard. The State shall make available a list of those waters for which the limiting nutrient has been determined.

[3]The chronic criteria shall be applied to the arithmetic mean of four samples collected on each of four consecutive days. Chronic criteria shall not be exceeded more than once every three years.

[4]The acute criteria shall be applied to any single grab sample. Acute criteria shall not be exceeded.

[5]For numeric standards dependent on hardness, hardness (as mg $CaCO_3$/l) shall be determined as needed from available verifiable data sources including, but not limited to, the U.S. Environmental Protection Agency's STORET water quality database.

[6]The criteria for chromium shall be applied to an analysis which measures both the trivalent and hexavalent ions.

NMED Exhibit 87

NMED Exhibit 87

capping the range at 220 is consistent with the highest hardness concentration used in toxicity tests. The new equations apply at hardness concentrations from 0 to 220 mg/L, and the criteria values for a hardness of 220 ug/L applies at higher hardness concentrations. The criteria values for a hardness of 25 ug/L apply at hardnesses less than 25 mg/L because no compelling basis exists for limiting the application of the proposed criteria to hardness of 25 mg/L and above, and because the criteria were based in part on toxicity studies conducted in waters softer than 25 mg/L.

520. The Commission adopts CMI and LANS/DOE's proposal to update the hardness-based acute and chronic aquatic life criteria for dissolved cadmium based on EPA's criteria derivation and recalculation procedures.

521. The current acute and chronic standards for dissolved cadmium in New Mexico are based on EPA's 2001 criteria update. The proposed changes are based on a more recent review technical review and update of the 2001 revised cadmium standards that resulted in new cadmium acute and chronic equations adopted by the State of Colorado in 2005 and approved by EPA.

522. The proposed change follows EPA's guidance for developing numeric criteria for the protection of aquatic life (USEPA, 1985). Updating the criteria as proposed retains the level of protection intended by EPA guidance for deriving numeric criteria for aquatic life designated uses.

523. The Commission adopts CMI and LANS/DOE's proposal to update the hardness-based acute and chronic aquatic life criteria for dissolved zinc based on EPA's criteria derivation and recalculation procedures.

524. The acute and chronic standards for zinc are based on EPA's 1996 criteria update. The proposed changes for zinc equations are based on a more recent review of the updated zinc standards adopted by the State of Colorado, a subsequent review of the EPA recalculation procedure, additional literature searches in 2008 as part of a site-specific zinc standards evaluation for Colorado streams, and additional data from

recently available studies conducted by the International Lead-Zinc Research Organization (ILZRO).

525. The proposed change follows EPA's guidance for developing numeric criteria for the protection of aquatic life (USEPA, 1985). Updating the criteria as proposed retains the level of protection intended by EPA guidance for deriving numeric criteria for aquatic life designated uses.

526. The Commission adopts CMI's proposal to add acute and chronic criteria for dissolved manganese because the criteria rely on updated scientific information and are consistent with EPA's 1985 Guidelines.

527. Neither EPA nor New Mexico currently has manganese ambient water quality standards for the protection of aquatic life. Manganese can be a metal of concern in the west, where manganese deposits are present in the Rocky Mountain and Great Basin Regions. Additional sources of manganese come from iron manufacture industry, volcanic activity, and use of fertilizers. These sources, combined with the natural deposits, can contribute to elevated concentrations of manganese in watersheds with no apparent adverse effect on aquatic biota.

528. The proposed criteria follow the manganese criteria adopted in Colorado, which were developed based on available literature and toxicity testing conducted jointly by industry and the Colorado Division of Wildlife. These hardness-based equations were developed based on the EPA standards derivation procedure, were adopted by the Colorado Water Quality Control Commission in 2000, and have been approved by EPA for use in Colorado.

J. Use-Specific Numeric criteria.

(1) Notes applicable to the Table of Numeric Criteria in paragraph (2):

(a) Where the letter "a" is indicated in a cell, the criterion is hardness-based and can be referenced in Subsection I of 20.6.4.900 NMAC.

(b) Where the letter "b" is indicated in a cell, the criterion can be referenced in Subsection C of 20.6.4.900 NMAC.

(c) Criteria are in µg/L unless otherwise indicated.

(d) Abbreviations are as follows: CAS – Chemical Abstracts Service (see definition for "CAS Number" in 20.6.4.7 NMAC); DWS – domestic water supply; Irr – irrigation; LW – livestock watering; WH – wildlife habitat; HH-OO – human health-organism only; C – cancer-causing; P – persistent.

NMED Exhibit 88

Acrolein	107-02-8	18				3.0	3.0		
Carbaryl	63-25-2					2.1	2.1		
Chlorpyrifos	2921-88-2					0.083	0.041		
Demeton	8065-48-3						0.1		
Guthion	86-50-0						0.01		
Malathion	121-75-5						0.1		
Methoxychlor	72-43-5						0.03		
Mirex	2385-85-5						0.001		
Parathion	56-38-2					0.065	0.013		
Tributyltin (TBT)	Various					0.46	0.072		

EPA Determination: *The EPA's approval of aquatic life criteria for acrolein, cadmium, carbaryl, chloride, chlorpyrifos, demeton, iron, guthion, malathion, methoxychlor, mirex, parathion, and tributyltin are subject to consultation pursuant to Section 7(a)(2) of the ESA. The EPA is taking no action on these revised aquatic life criteria, pending the conclusion of ESA consultation. The criteria for acrolein, cadmium, carbaryl, chloride, chlorpyrifos, demeton, iron, guthion, malathion, methoxychlor, mirex, parathion, and tributyltin are not effective for CWA purposes until approved by the EPA. See Section V for additional information regarding the completion of the ESA consultation.*

K. The criteria for total ammonia consider sensitive freshwater mussel species in the family Unionidae, freshwater non-pulmonate snails, and *Oncorhynchus* spp. (a genus of fish in the family Salmonidae), hence further protecting the aquatic community. The total ammonia criteria magnitude is measured as Total Ammonia Nitrogen (TAN) mg/L. TAN is the sum of and TAN mg/L magnitude is derived as a function of pH and temperature (EPA 2013).

L. The acute aquatic life criteria for TAN (mg/L) was derived by the EPA (2013) as the one-hour average concentration of TAN mg/L that shall not be exceeded more than once every three years on average. The EPA acute criterion magnitude was derived using the following equation:

$$\text{Acute TAN Criterion Magnitude for 1-hour average} = \text{MIN}\left(\left(\frac{0.275}{1+10^{7.204-pH}}+\frac{39}{1+10^{pH-7.204}}\right),\left(0.7249\text{x}\left(\frac{0.0114}{1+10^{7.204-pH}}+\frac{1.6181}{1+10^{pH-7.204}}\right)\text{x}\left(23.12\times 10^{0.036(20-T)}\right)\right)\right)$$

T (temperature °C) and pH are defined as the paired values associated with the TAN sample

(1) Temperature and pH-dependent values of the acute TAN criterion magnitude – when *Oncorhynchus* spp. absent.

	Temperature (°C)

M. The chronic aquatic life criteria for TAN (mg/L) was derived by the EPA (2013) as a thirty-day rolling average concentration of TAN mg/L that shall not be exceeded more than once every three years on average. In addition, the highest four-day average within the 30-day averaging period should not be more than 2.5 times the CCC (e.g., 2.5 x 1.9 mg TAN/L at pH 7 and 20°C, or 4.8 mg TAN/L) more than once in three years on average. The EPA chronic criterion magnitude was derived using the following equation:

Chronic TAN Criterion Magnitude for 30-day average=

$$0.8876 \times \left(\frac{0.0278}{1+10^{7.688-pH}} + \frac{1.1994}{1+10^{pH-7.688}}\right) \times \left(2.126 \times 10^{0.028\times(20-MAX(T,7))}\right)$$

'T' (temperature °C) and pH are defined as the paired values associated with the 'TAN sample.

Temperature and pH-Dependent Values of the Chronic TAN Criterion Magnitude.

[20.6.4.900 NMAC - Rp 20 NMAC 6.1.3100, 10/12/2010; A, 10/11/2002; A, 5/23/2005; A, 7/17/2005; A, 12/1/2010; A, 3/2/2017; A, 4/23/2022]

EPA Determination:

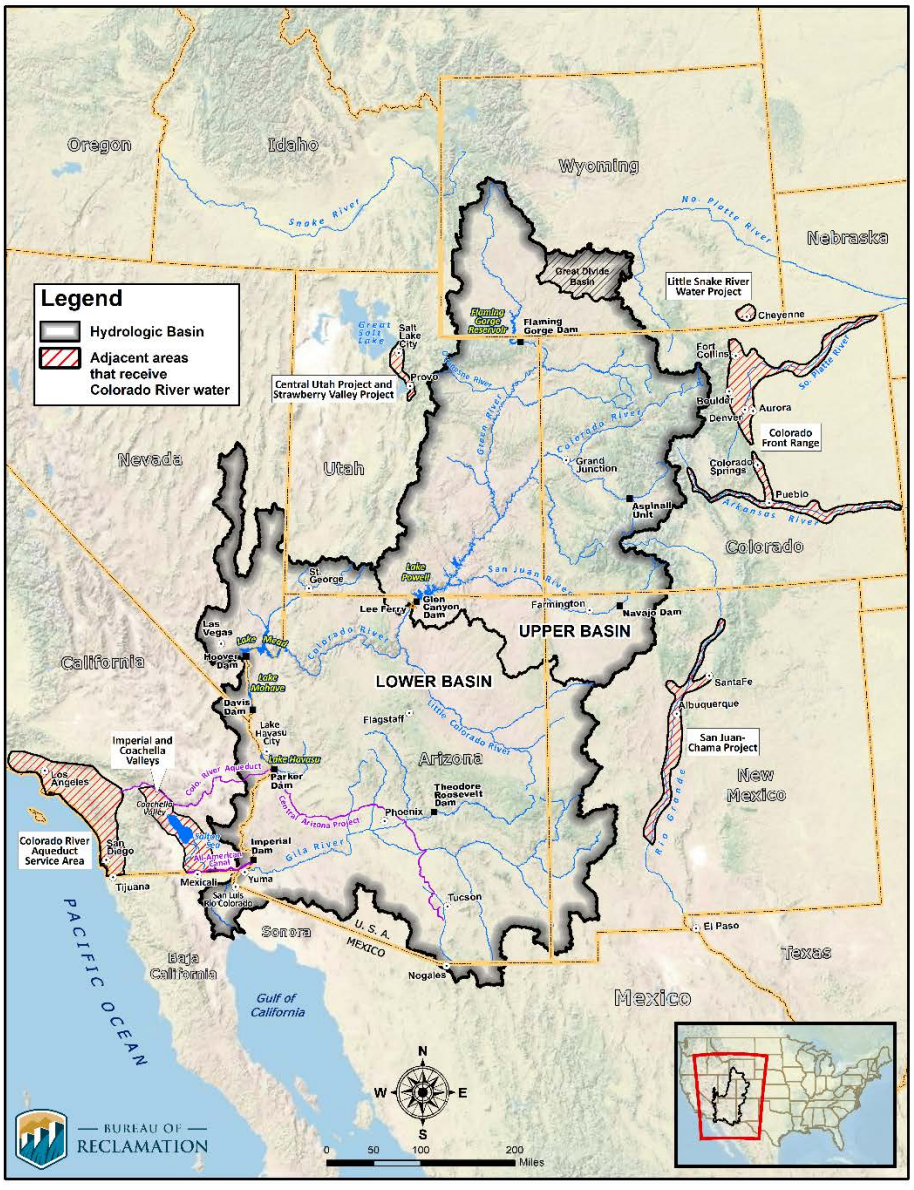
As part of its 2020 triennial review, the NMED proposed, and the Commission adopted the EPA's updated § 304(a) recommended acute and chronic aquatic life criteria for Total Ammonia Nitrogen (TAN). The associated revisions to 20.6.4.900(K), (L) and (M) NMAC, including the equations, temperature and pH-dependent values in the associated tables are all consistent with the values in EPA's current nationally recommended freshwater ammonia criteria. However, the EPA acknowledges that the value of 3.0 for pH 7.9 and 17°C in (L)(1), should be 6.0 when the equation for the Acute TAN Criterion Magnitude for 1-hour average is applied. This is a typographical error that is also present in EPA's Ammonia 2013 aquatic life criteria document and the EPA cautions NMED to beware of the difference in the criteria and correct in their next revision. Since the acute criterion equation is correct, this typographical error is nonsubstantive. These revisions are consistent with the EPA's recommended § 304(a) criteria and with language in 40 CFR §131.20(a). However, the EPA approval of aquatic life criteria is subject to consultation pursuant to Section 7(a)(2) of the ESA. The EPA is taking no action on the revised ammonia aquatic life criteria and narrative in 20.6.4.900(K), (L) and (M) NMAC and these provisions are not effective for CWA purposes until approved by the EPA. See Section V for additional information regarding the completion of the ESA consultation.

IV. Provisions the EPA Is Disapproving

[RESERVED]

V. Additional Considerations

Endangered Species Act Consultation



The EPA's approval of revised WQS and associated aquatic life criteria are subject to the consultation requirement of Section 7(a)(2) of the Endangered Species Act[14] (ESA). Under Section 7(a)(2) of the ESA, the EPA has the obligation to ensure that its approval of modifications to the *New Mexico Standards for Interstate and Intrastate Waters* (20.6.4 NMAC) will not jeopardize the continued existence of threatened and endangered species and critical habitat in New Mexico.

The Colorado River Basin

TRANSMITTAL LETTERS

The Federal Water Pollution Control Act requires that at least once every three years the Basin States review water quality standards relating to the salinity of the Colorado River. The states collectively initiated this review under the direction of the Forum.

With the adoption of this final review, copies are being sent to the Colorado River Basin State Governors listed below for inclusion within their individual state water quality standards.

SUMMARY

This document is a review of the water quality standards for salinity in the Colorado River. Section 303 of the Clean Water Act amendments to the Federal Water Pollution Control Act require that water quality standards are reviewed every three years. Accordingly, the seven-state Colorado River Basin Salinity Control Forum has reviewed the existing state-adopted and EPA-approved water quality standards for salinity consisting of numeric criteria and a Plan of Implementation. Upon adoption by the Forum, this Review will be submitted to the governors of each of the Basin States for inclusion in their state water quality standards.

The Forum recommends no change in the numeric salinity criteria at the three stations located on the lower main stem of the Colorado River. The numeric criteria at these stations will remain:

Station	Salinity in mg/L[1]
Below Hoover Dam	723
Below Parker Dam	747
At Imperial Dam	879

The Plan of Implementation is intended to maintain the salinity concentrations at or below the numeric criteria while the Basin States continue to use the waters of the Colorado River. The Colorado River Basin Salinity Control Act requires the implementation of salinity control programs to reduce the salinity of the Colorado River. Reducing the salinity of the Colorado River water reduces economic impacts to its users. While the Plan of Implementation included in this Review provides high confidence that the numeric criteria will not be exceeded during the review period, the Forum will continue to evaluate opportunities for additional salinity control that will increase economic and environmental benefits realized in the Colorado River Basin.

The Forum's Plan of Implementation includes:

1. Construction of salinity control measures by Reclamation, USDA (Natural Resources Conservation Service), and BLM to the extent that those measures remain viable and appropriately cost effective.

2. State implementation of the Forum's adopted policies for effluent limitations under the National Pollutant Discharge Elimination System (Appendix B of this Review).

3. Implementation of non-point source management plans developed by the states and approved by EPA.

Item 1 of the plan listed above is to be implemented by federal agencies in conjunction with state, local and private participants. The Forum works jointly with federal agencies on developing measures to be implemented. Items 2 and 3 are primarily implemented by the Colorado River Basin states.

[1] Flow-weighted average annual salinity concentration which is defined as the total annual salt load divided by the total annual streamflow.

NMED Exhibit 90

To date the program has implemented more than 1.33 million tons of annual salinity control. The current Plan of Implementation, approved by the Forum, anticipates that an additional 51,700 tons of annual salinity control be implemented over the next three years. Reclamation's numerical modeling indicates that with this implementation there is a 6 percent probability of exceeding the numeric criteria over the next three years. If current program funding levels were to continue through 2040 a total of 1.49 million tons of annual control would be achieved. With an increase of salinity control implementation to 9,000 tons annually under Reclamation's Basinwide Program, a total of 1.55 million tons of salinity control would be implemented by 2040 with a 9 percent probability of exceeding the numeric criteria between now and 2040. The Salinity Control Program continues to be a successful federal and state partnership that has environmental and economic benefits for users of Colorado River water.

NMED Exhibit 90

PURPOSE OF THE REVIEW

The *2023 Review: Water Quality Standards for Salinity, Colorado River System* (Review) is prepared and submitted in response to Section 303(c) of Public Law (P.L.) 92-500 (Clean Water Act) by the seven state Colorado River Basin Salinity Control Forum (Forum) on behalf of the governors of their respective states. This review of the water quality standards includes the numeric criteria and the Plan of Implementation developed and adopted by the Forum. This is the 17th review conducted by the Forum. Section 303(c)(1) of the Clean Water Act requires that:

> The governor of a state or the state water pollution control agency of such state shall from time to time (but at least once each three-year period beginning with the date of enactment of the Federal Water Pollution Control Act Amendments of 1972) hold public hearings for the purpose of reviewing applicable water quality standards and, as appropriate, modifying and adopting standards. Results of such review shall be made available to the Administrator [of the Environmental Protection Agency].

The scope of this Review is limited to the portion of the Colorado River Basin (Basin) above Imperial Dam and how this area of the Basin is in compliance with the water quality standards approved by the United States Environmental Protection Agency (EPA) in 1975 (Standards). This Review focuses on the 2024 to 2026 period (review period) and evaluates the appropriateness of the Standards in the Basin. Background information and activities regarding historical actions relative to the development and adoption of salinity standards are contained in the Forum report, *Water Quality Standards for Salinity, Including Numeric Criteria and Plan of Implementation for Salinity Control, Colorado River System*, Colorado River Basin Salinity Control Forum, June 1975.

Below Imperial Dam, salinity is controlled as a federal responsibility to meet the terms contained within Minute No. 242 titled "Permanent and Definitive Solution to the International Problem of the Salinity of the Colorado River" to the Mexican Water Treaty of 1944. Minute No. 242 requires that measures be taken to assure that Colorado River water delivered to Mexico upstream from Morelos Dam will have an average annual salinity concentration of no more than 115 ± 30 parts per million total dissolved solids (TDS) higher than the average annual flow-weighted salinity concentration of the Colorado River water arriving at Imperial Dam.

Nothing in this Review shall be construed to alter, amend, repeal, interpret, modify or be in conflict with the provisions of the Boulder Canyon Project Act (45 Stat. 1057), the Boulder Canyon Project Adjustment Act (54 Stat. 774), the Colorado River Basin Project Act (82 Stat. 885), the Colorado River Compact, the Colorado River Storage Project Act (70 Stat. 105), the Upper Colorado River Basin Compact, or the Treaty with the United Mexican States (Treaty Series 994).

NMED Exhibit 90

HISTORY AND BACKGROUND

The Colorado River Basin Salinity Control Program (Program) is a unique cooperative watershed-scale effort between several federal agencies and seven states designated to meet national, international, and state water quality objectives. The Forum participates with federal, state, and local agencies and private participants to ensure the successful execution of the triennial Plan of Implementation through on-the-ground activities and encouraging legislative support for federal funding.

The Basin is 242,000 square miles[2] (approximately 155 million acres) of the western United States and a small portion of northern Mexico. Currently, about 40 million[3] people in the seven western states of Arizona, California, Nevada (Lower Basin States) and Colorado, New Mexico, Utah, and Wyoming (Upper Basin States), collectively referred to as the Basin States, rely on the Colorado River and its tributaries to provide some, if not all, of their municipal water needs. Additionally, water from the Colorado River system is utilized to irrigate nearly 5.5 million acres of land[4] in the Basin, producing some 15 percent of the nation's crops and about 13 percent of its livestock, which combined generate many billions of dollars a year in economic benefits.

The Colorado River also serves as the lifeblood for thirty[5] federally recognized Native American Indian tribes, seven National Wildlife Refuges, four National Recreation Areas and eleven National Park units. Hydropower facilities along the Colorado River supply more than 4,200 megawatts of electrical capacity to help meet the power needs of the West and reduce the use of fossil fuels. Finally, the Colorado River is vital to Mexico, supporting a thriving agricultural industry in the San Luis and Mexicali Valleys and providing municipal water supplies for communities in the Mexican States of Sonora and Baja California.

The Colorado River system is operated in accordance with the Law of the River[6], which apportions a total of 16.5 million acre-feet (maf) between the Basin States and Mexico. Currently, the 10-year (2011 through 2020) basin-wide average historical natural flow[7] of 13.5 maf is less than the consumptive uses and losses in the Basin, which have averaged 14.6 maf.[8]

---

[2] Colorado River System, Consumptive Uses and Losses Report, 1996-2000, Bureau of Reclamation.

[3] About 40 million people were estimated to be within the hydrologic boundaries of the Basin in the United States, as well as in the adjacent areas of the Basin States that receive Colorado River water, in 2015. See Colorado River Basin Water Supply and Demand Study - Technical Report C, U.S. Bureau of Reclamation, 2012.

[4] It is estimated that there were 5.5 million irrigated acres in the hydrologic boundaries of the Basin in the United States, as well as in the adjacent areas of the Basin States that receive Colorado River water, in 2015 based on interpolated acreage data from Scenario A Current Projections. See Colorado River Basin Water Supply and Demand Study - Technical Report C, U.S. Bureau of Reclamation, 2012.

[5] Reclamation, Draft Supplemental Environmental Impact Statement, Near-term Colorado River Operations, April 2023.

[6] The treaties, compacts, decrees, statutes, regulations, contracts and other legal documents and agreements applicable to the allocation, appropriation, development, exportation, and management of the waters of the Colorado River Basin are often collectively referred to as the "Law of the River."

[7] Natural flow represents the flow that would have occurred at the location had depletions and reservoir regulation not been present upstream of that location. This value was provided by the U.S. Bureau of Reclamation.

[8] Basinwide consumptive use and losses estimated over the period 2011-2020, including the 1944 Treaty delivery to Mexico, reservoir evaporation, and other losses due to operational inefficiencies as estimated by Reclamation.

Salinity-caused impacts have long been a major concern in the United States and Mexico. The salinity in the river generally increases as it flows downstream. The Colorado River has carried an average salt load of approximately 9 million tons annually past Hoover Dam, the uppermost location at which numeric criteria have been established.

The salts in the Colorado River system are naturally occurring and pervasive. Many of the saline sediments of the Basin were deposited in prehistoric marine environments. Salts contained within the sedimentary rocks are easily eroded, dissolved, and transported into the river system.

In a 1971 study[9], EPA analyzed salt loading in the Basin and divided it into two categories, naturally occurring and human-caused. EPA concluded that about half (47 percent) of the salinity concentration measured at Hoover Dam is from natural sources, including salt contributions from saline springs, groundwater discharge into the river system (excluding irrigation return flows), erosion and dissolution of sediments, and the concentrating effects of evaporation and transpiration[10]. Other natural sources include salt contributions from non-point (excluding irrigated agriculture) or unidentified sources, or from the vast, sparsely populated regions of the Basin, many of which are administered by the United States Bureau of Land Management (BLM) or other governmental agencies. Of the land within the Basin, about 75 percent is owned and administered by the federal government or held in trust for Indian tribes. The greatest portion of the naturally occurring salt load originates on these federally owned and administered lands.

EPA estimated that out of Basin exports (3 percent), agricultural irrigation (37 percent), reservoir evaporation and phreatophyte use (12 percent), and municipal and industrial uses (1 percent) account for 53 percent of the salinity concentration in water arriving at Hoover Dam. Much of the salt load contribution from irrigated agriculture is from federally developed irrigation projects. Other human activities, including livestock grazing, wildlife management, logging, mining, oil exploration, road building, recreation and urbanization can influence the rate of natural salt movement from rock formations and soils to the river system.

In 1972, the federal government enacted the Clean Water Act mandating efforts to develop and maintain water quality standards in the United States. At the same time, Mexico and the United States engaged in discussions to address the issue of increasing salinity in the Colorado River water being delivered to Mexico. The Basin States established the Forum in 1973. The Forum is composed of representatives from each of the Basin States appointed by the governors of the respective states. The Forum was created for interstate cooperation and to provide the states with the information necessary to comply with Section 303(a) and (b) of the Clean Water Act.

EPA promulgated a regulation[11] in December 1974 which set forth a basin-wide salinity control policy for the Basin. This regulation established a standards procedure and required the Basin States to adopt and submit for approval to EPA water quality standards for salinity, including numeric criteria and a Plan of Implementation, consistent with the policy stated in the regulation. As described in the Numeric Criteria section below, in compliance with the regulation, the Forum

[9] The Mineral Quality Problem in the Colorado River, Summary Report, Environmental Protection Agency, Regions VIII and IX, 65pp., 1971.
[10] Note the EPA study also identified that about 66% of the total salt load arriving at Hoover Dam was from natural sources. A recent USGS study confirms this amount estimating that 68% of the salt load is from natural sources (see Tillman, F.D. et al, A Review of Current Capabilities and Science Gaps in Water Supply Data, Modeling, and Trends for Water Availability Assessments in the Upper Colorado River Basin. *Water*, 2022, 14, 3813.
[11] EPA Regulation – 40 CFR, Part 120

NMED Exhibit 90

selected three numeric criteria stations on the main stem of the lower Colorado River as being appropriate points to measure the salinity concentrations of the river. These stations are located at the following points: (1) below Hoover Dam, (2) below Parker Dam, and (3) at Imperial Dam. The Forum also adopted a water quality standard for the Colorado River Basin including both a Plan of Implementation and numeric criteria.

The Colorado River Basin Salinity Control Act (P.L. 93-320) (1974) (Act) established the Colorado River Basin Salinity Control Program under Title II to address the concerns raised by EPA. The Act also created the Colorado River Basin Salinity Control Advisory Council to advise the federal agencies regarding administration of the Program. P.L. 93-320 has been amended several times since its original enactment. P.L. 98-569 (1984) authorized the United States Department of Agriculture's (USDA) on-farm program. P.L. 104-20 (1995) created the United States Bureau of Reclamation's (Reclamation) Basinwide Salinity Control Program (Basinwide Program). The Federal Agriculture Improvement and Reform Act (P.L. 104-127) (1996) (1996 Farm Bill) authorized up-front cost sharing by the Basin States and modified the USDA authorities, including the use of the Environmental Quality Incentives Program (EQIP). P.L. 106-459 (2000) increased the appropriation ceiling. The Food, Conservation, and Energy Act of 2008 (P.L. 110-246) (2008 Farm Bill) created the Basin States Program (BSP). The Agricultural Improvement Act of 2018 (P.L. 115-334) continued the authorization of EQIP.

UNDERSTANDING THE SALINITY OF THE COLORADO RIVER

In general, the salinity concentration of the water in the Colorado River increases from the headwaters to the terminus in the Gulf of California, known in Mexico as the Sea of Cortez. Much of the salt is picked up in the Upper Basin, and some tributary streams average higher concentrations of salt than the main stem.

As with most large rivers, the natural flow of the Colorado River increases from its headwaters to its terminus. Today, however, the flow of the Colorado River decreases below Hoover Dam due to diversions. Imperial Dam is the last major diversion point for uses in the United States. In normal years, 1.5 maf is scheduled to pass Imperial Dam for deliveries to Mexico.

Reclamation has developed a map of the Basin showing the average flows and the corresponding salinity concentrations for the years 2017-2021. This map is provided for general illustrative purposes as Figure 1. The average flow of the Colorado River and its important tributaries are indicated by the width of the line, and the salinity concentrations are illustrated by colors coded to ranges in TDS.

NMED Exhibit 90

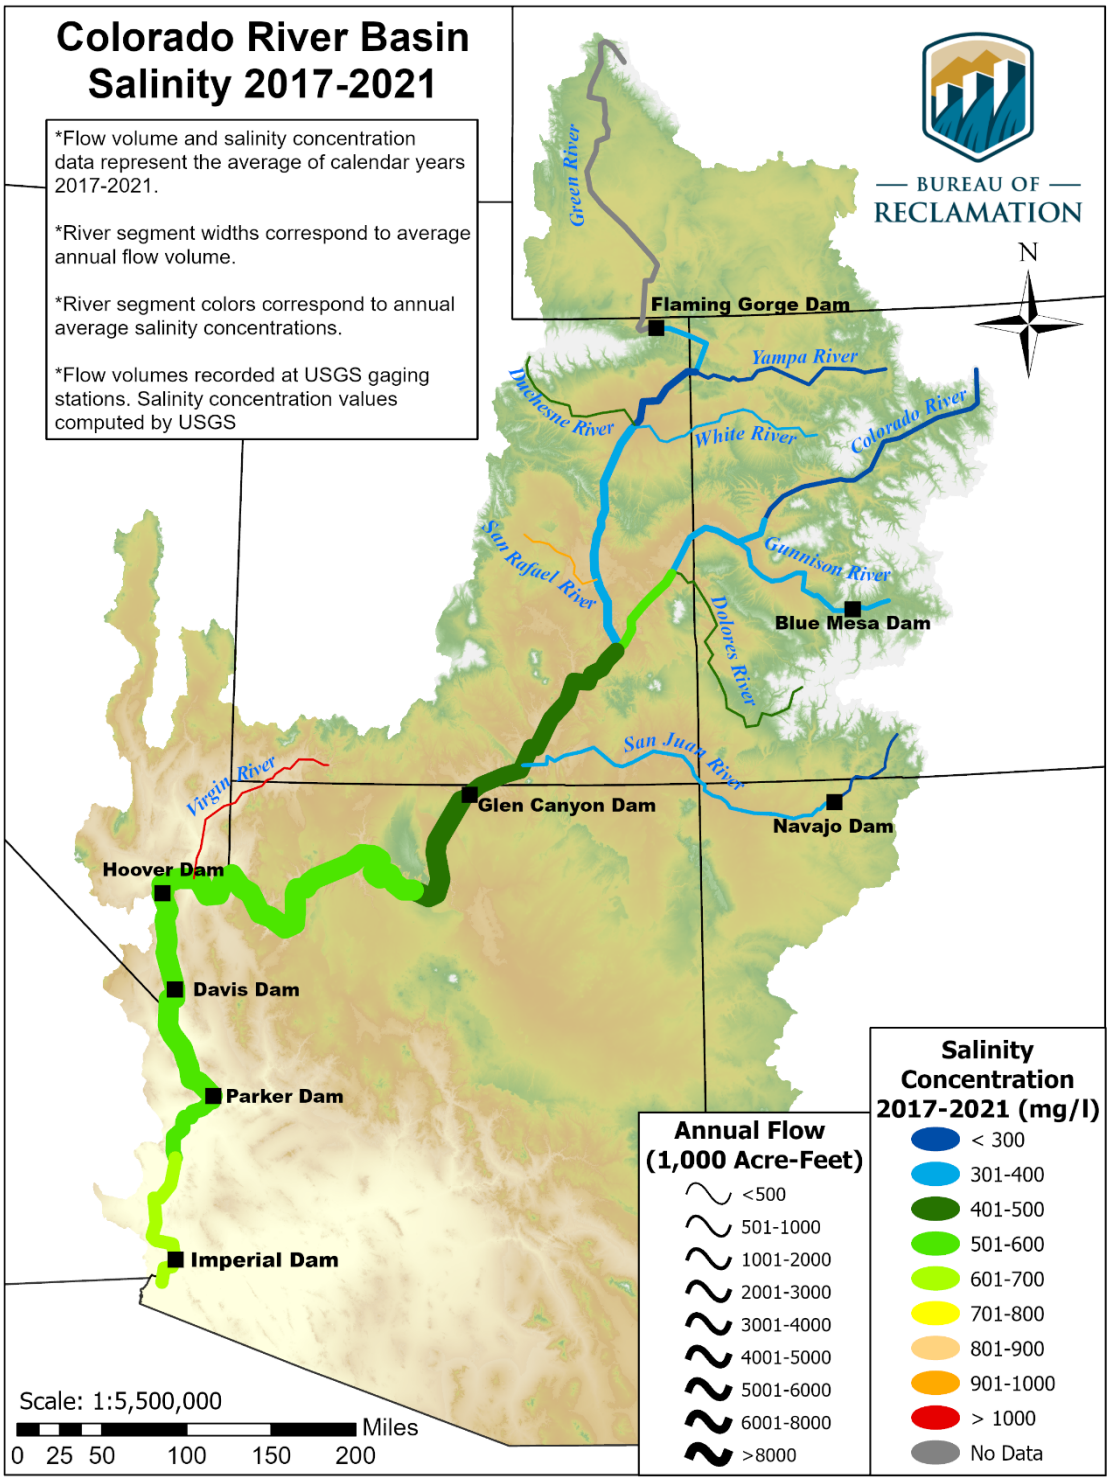

Figure 1 - 2017-2021 Average generalized flow and salinity concentrations across the Colorado River Basin.

In general, over the last thirty years the salinity concentrations have decreased at all three of the numeric criteria stations (see Figure 2). The values for the observed flow-weighted average salinity at the Numeric Criteria Stations are provided in Appendix A. In this Review, the terms "salinity," "TDS" and "concentration," each in mg/L, are used interchangeably.

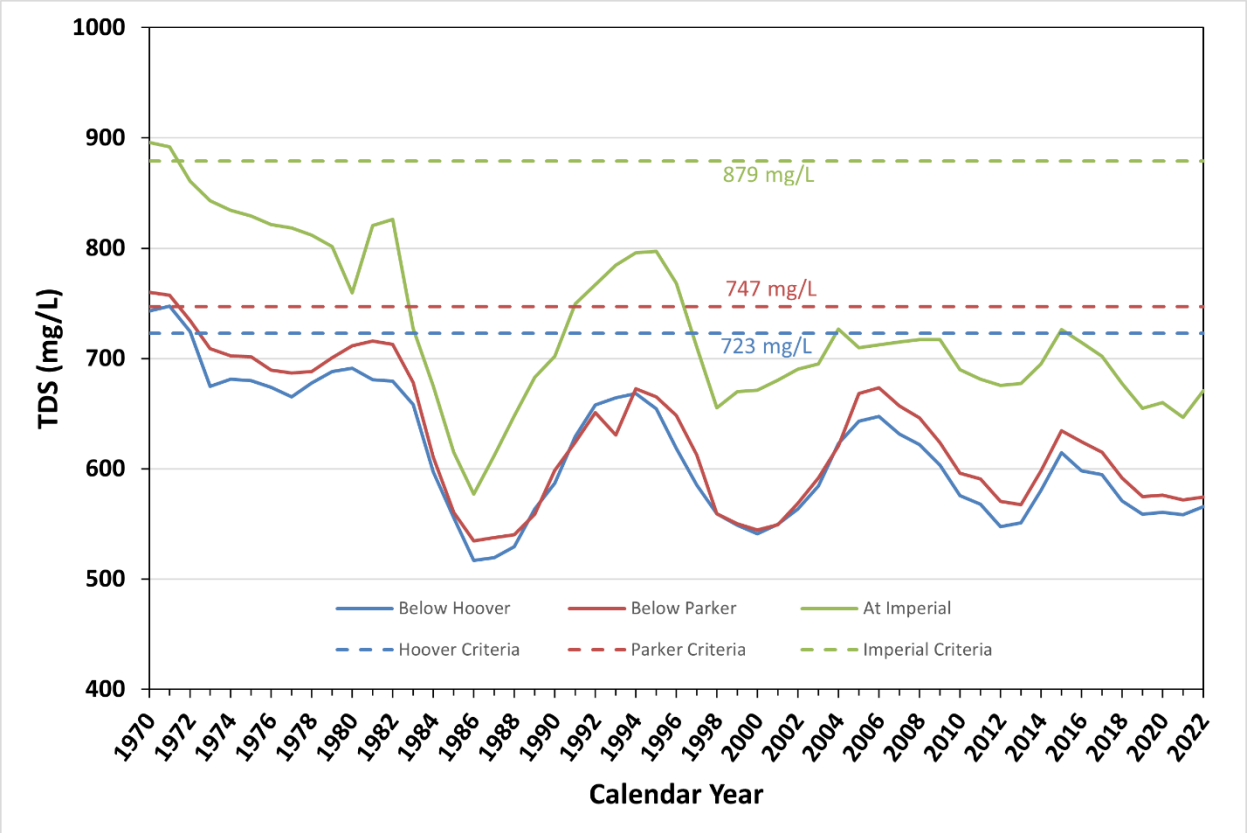

Figure 2 - Flow weighted average annual salt concentrations at Numeric Criteria Stations.

PROVISION FOR REVIEWING AND REVISING THE STANDARD

The Colorado River water quality standards for salinity and the approach taken by the Basin States in complying with the standards are unique. The salinity concentrations that are projected in the future have not been shown to have adverse effects on human health or wildlife. Thus, the Program is different from most other water quality standard compliance programs. The standards adopted by the Forum and the Basin States and approved by EPA consist of the numeric criteria and the Plan of Implementation. The numeric criteria portion of the water quality standards is established to protect against increases in economic damages to infrastructure and crop production. The Plan of Implementation is designed to maintain the flow-weighted average annual salinity at or below the numeric criteria for the benefit of future generations in states reliant on the Colorado River.

NMED Exhibit 90

The Program is a basin-wide coordinated effort among federal, state, and local agencies, and participants to control salt loading. The Forum, in its statement of "Principles and Assumptions for Development of Colorado River Salinity Standards and Implementation Plan," approved by the Forum on September 20, 1974, stated under Principle 7:

> The Plan of Implementation shall be reviewed and modified as appropriate from time to time, but at least once every three years. At the same time, the (numeric) standards, as required by Section 303 (c) (1) of P.L. 92-500, shall be reviewed for the purpose of modifying and adopting standards consistent with the plan so that the Basin States may continue to develop their compact-apportioned waters while providing the best practicable water quality in the Colorado River Basin.[12]

NUMERIC CRITERIA

EPA promulgated a regulation that set forth a salinity control policy for the Basin. This policy required that the flow-weighted average annual salinity in the lower main stem of the Colorado River be maintained at or below the 1972 levels. The points in the lower main stem of the Colorado River where the flow-weighted average annual salinity is measured are at the following three stations: 1) below Hoover Dam, 2) below Parker Dam, and 3) at Imperial Dam. The basis for selecting these stations is their proximity to key diversion facilities on the lower Colorado River. Nevada diverts main stem water from Lake Mead for use in the Las Vegas area. The Metropolitan Water District of Southern California and the Central Arizona Project divert water from Lake Havasu, impounded behind Parker Dam, for millions of water users in southern California and central Arizona, respectively. The large agricultural areas in the Imperial and Coachella Valleys in California and the Yuma area in Arizona are served by diversions at Imperial Dam.

The numeric criteria for each of those stations as established in 1972 are as follows:

Below Hoover Dam	723 mg/L
Below Parker Dam	747 mg/L
At Imperial Dam	879 mg/L

While the federal regulations provide for temporary increases above the numeric criteria levels if sufficient control measures are included in the Plan of Implementation, no temporary increases are anticipated during this review period.

The Forum believes the Review is the appropriate setting to recommend any changes to the numeric criteria. The Forum finds the current numeric criteria are adequate for the next three years and recommends no changes at this time. Because of the potential economic benefit to the Basin, the Forum believes there is justification to maintain salinity levels below the numeric criteria and remove additional salt from the Colorado River, thus saving several hundred million dollars in annual damages.

[12] Water Quality Standards for Salinity, Including Numeric Criteria and Plan of Implementation for Salinity Control, Colorado River System, Colorado River Basin Salinity Control Forum, 1975 Review, p. 133.

NMED Exhibit 90

PLAN OF IMPLEMENTATION

General

The Plan of Implementation is designed to keep the flow-weighted average annual salinity concentrations at or below the 1972 numeric criteria levels for the benefit of future generations in states reliant on the Colorado River. Measures in place are currently controlling 1.33 million tons of salt annually. The Plan of Implementation would implement practices to control an additional 51,700 tons of salt per year by 2026. With the Plan of Implementation as proposed in this Review in place, the probability of exceeding the numeric criteria during the review period is small based on Reclamation computer model simulations. The analysis indicates the probability of exceeding the numeric criteria with the Plan of Implementation in place in any of the next three years at the Hoover Dam, Parker Dam and Imperial Dam stations is 6 percent. This low probability of exceedance was an important factor in the Forum's decision to adopt the Plan of Implementation accompanying this Review.

The Plan of Implementation is composed of many actions contemplated by the federal and state agencies and includes projects that remove the required salt tonnage to meet the Plan goal. This will principally be accomplished by reducing the salt contributions to the Colorado River from existing sources and minimizing future increases in salt load caused by human activities. For this Review, the Plan of Implementation can be briefly summarized as follows:

1. Implementation of salinity control measures by Reclamation, Natural Resources Conservation Service (NRCS), the BSP and BLM to the extent that those measures remain viable and appropriately cost effective.

2. Pumping operations at the Paradox Valley Unit (PVU) were suspended in March 2019 following earthquake activity. Brine injection was resumed on an interim basis in June 2022 at the rate of about 65,000 tons per year. Concerns about seismic activity have called into question the remaining useful life of the existing brine injection well. Reclamation did not select a brine disposal alternative in its Environmental Impact Statement published in 2020. Because the brine injection well is presently functioning, through the review period (2024-2026), for modeling purposes, 65,000 tons of annual salinity control will be shown for PVU. However, because a new brine disposal alternative has not yet been identified, in order to represent the uncertainty of future PVU operations, for modeling purposes herein, the injection rate is reduced by 20%, or 13,000 tons per year for each year from 2027 through 2031 after which zero tons of salinity control is used thereafter through 2040. This is not a statement of the Forum's position on the need for continued salinity control at the PVU but simply a recognition of the uncertainty with continued operations of the injection well between now and 2040.

3. Application of the Forum-adopted policies by each of the states. (The texts of the policies are included in Appendix B, and a list of National Pollutant Discharge Elimination System (NPDES) permits issued pursuant to these policies is found in Appendices C and D of this Review.)

NMED Exhibit 90

4. Implementation of non-point source management plans developed by the states in collaboration with stakeholders (including, but not limited to, landowners as well as state, federal and local agencies), and approved by EPA (see the State Water Quality Management Plans section of this Review).

The Forum participates with federal, state, and local agencies and private participants to ensure the Plan of Implementation is executed. The Forum also urges Congress to appropriate the funds needed for implementation and recommends legislative changes when necessary.

Constructed Measures

Congress enacted Public Law 93-320 in June of 1974 with the Forum's support. Title II of the Public Law created a water quality program for addressing salinity in the Colorado River in the United States above Imperial Dam. Primary responsibility for Title II was given to the Secretary of the Interior, with Reclamation being instructed to investigate and build the Paradox Valley, Grand Valley, Las Vegas Wash and Crystal Geyser salinity control units. The Secretary of Agriculture was also instructed to support the effort within existing authorities.

Public Law 93-320 has been amended several times. The amendments directed the Secretary of the Interior and the Secretary of Agriculture to give preference to the salinity control units with the least cost per unit of salinity reduction. The amendments established a BLM program, a voluntary on-farm salinity control program to be implemented by USDA (including the voluntary replacement of incidental fish and wildlife values foregone as a result of the on-farm measures) and the Basin States Program. Through implementation of these programs, many cost-effective salt-load reducing activities have been accomplished.

USDOI-Reclamation

The Act was amended by P.L. 104-20 to authorize the Basinwide Program. The Basinwide Program uses a competitive process that has greatly increased the federal cost effectiveness of salinity control. Reclamation may implement a variety of effective salinity control measures, but most projects concentrate on improving the efficiency of off-farm irrigation delivery systems. Reclamation solicits applications through a Notice of Funding Opportunity (NOFO) process for projects that will reduce the salinity of the Colorado River. Reclamation evaluates and ranks each application and awards grants to the highest-ranking applications. Cost effectiveness is the prime criteria in the evaluation[13]. The timing of the NOFO is based on the need for more salinity control projects, and it relates to the amount of federal appropriation Reclamation receives to implement its portion of the Program. P.L. 104-20 and P.L. 106-459 increased the authorization ceiling for Reclamation's salinity control program.

USDA-NRCS

The NRCS program generally concentrates on improving on-farm systems. NRCS salinity activities fall mainly under the authorities of EQIP. EQIP for Colorado River salinity control was authorized and initially funded under the 1996 Farm Bill and reauthorized by the Agricultural

[13] Criteria included with documentation for each funding announcement (https:/usbr.gov/us/progact/salinity/index.html)

NMED Exhibit 90

Improvement Act of 2018 (P.L. 115-334) (2018). NRCS accepts applications under EQIP and evaluates, ranks, and selects those applications that best meet the goals of the salinity control program. Based on the applications, NRCS provides technical and financial assistance to the producers. Under the Agricultural Improvement Act of 2018, NRCS may also now enter into EQIP contracts with "water management entities" including states, irrigation districts, and similar entities to implement water conservation and efficiency practices. NRCS also offers financial assistance for voluntary replacement of fish and wildlife values forgone.

USDOI - BLM

The goal of the BLM program is to reduce the mobilization of salts to the Colorado River from BLM administered public lands. Salt reduction is achieved by controlling both point and non-point sources of salt contributions, recognizing that the majority of salt derived from public lands is of non-point source origin. Salt loading from non-point sources is mainly reduced by minimizing soil erosion.

Basin States Program

Public Law 110-246 amended the Act and created the Basin States Program (BSP) through which money from the Lower Colorado River Basin Development Fund and the Upper Colorado River Basin Fund (Basin Funds) is used for cost sharing in Reclamation and NRCS salinity control programs. These are administered by Reclamation in consultation with the Colorado River Basin Salinity Control Advisory Council. Cost share on federal appropriations expended by both Reclamation and NRCS for salinity control in the Basin is required by the Act. The money for the Basin Funds comes from levies assessed on users of power generated within the Basin. The required cost share on the original salinity control units of Paradox, Grand Valley and Las Vegas Wash is 25 percent of the project cost. Salinity control units and programs implemented subsequent to the original units require a 30 percent cost share from the Basin Funds.

For cost-share dollars generated by the federal expenditures under the Basinwide Program, Reclamation expends the required cost-share funding, together with appropriated funds in the Basinwide Program, through a public grant process. BSP funding generated by federal appropriations expended in EQIP is managed by Reclamation to administer the BSP and to enter into the following agreements: (1) with irrigation entities to implement salinity projects through the NOFO, (2) other federal agencies for studies and research, (3) the states of Colorado, Utah and Wyoming to fund approved salinity control activities, and (4) other entities for approved salinity control activities and salinity control projects. Each of the state agencies has the same goal of providing salinity control in the most cost-effective manner. The cost-share aspects of the BSP have proven very useful as a means of achieving additional cost-effective salinity control. The BSP complements the NRCS and Reclamation programs in a comprehensive manner and facilitates local water user participation.

<u>Accomplishments and Future Control</u>

The Plan of Implementation recognizes that the Forum, participating federal agencies and the Basin States each have specific responsibilities for addressing salinity on the Colorado River. The

NMED Exhibit 90

Forum, in conjunction with the Colorado River Basin Salinity Control Advisory Council, will continue to provide overall coordination and a continuing review of salinity conditions and program effectiveness, and will advise the participating federal agencies regarding the implementation of salinity control efforts.

To date, it is estimated that the Program has reduced the annual salt loading in the Colorado River by approximately 1,332,400 tons, resulting in approximately 103 - 120 mg/L reduction in salinity concentrations in the Lower Basin. Figures 3 – 5 show the comparison of measured salinity levels as compared to what salinity levels would have been without implementation of the Program at the three numeric criteria stations. Table 1 gives a brief summary of the measures that have been implemented to date, the areas where those measures have occurred, and the tons of salt controlled per year associated with each area. Figure 6 shows the salinity areas where these measures have been implemented.

TOTAL			**1,332,400**

** See discussion relative the modeling of future PVU operations found on page 10

*BLM Nonpoint Source controls not included herein

The Plan of Implementation assumes that measures currently in place continue to operate through the review period (2024 - 2026) and beyond. Improved water delivery and irrigation systems will need to be continually maintained and efficiently operated to provide reliable salinity control. Much of the financial burden of O&M and replacement of irrigation systems falls to salinity program participants who are the agricultural producers in the Basin. The Forum acknowledges the need for producers to maintain their improved irrigation practices through continued efforts and financial investment. The same is true for the non-agricultural measures as well. The best example may be the Paradox Valley Unit (PVU). The expected life and continued effectiveness of the PVU project is a matter of study by Reclamation and the Forum. As described on page 10, because a brine disposal replacement alternative has not yet been identified, for modeling herein it is presumed that the project will not provide any control beginning in 2027.

It should be noted that Table 1 includes 14,600 tons of salinity control implemented by BLM through the plugging of abandoned, flowing oil and gas wells. Most of BLM's salinity control activities center around efforts to reduce saline soil erosion such as improving grazing and watershed management efforts, or mitigation after oil and gas development, fire, or OHV damage. Therefore, activities are more of an offset to ongoing causes of salinity rather than an improvement from 1972 conditions when the Program was initiated. As such, though critically important to the Program and the overall water quality of the Colorado River System, these activities are not included in Tables 2 and 3 which show potential gains or improvements over 1972 conditions.

NMED Exhibit 90

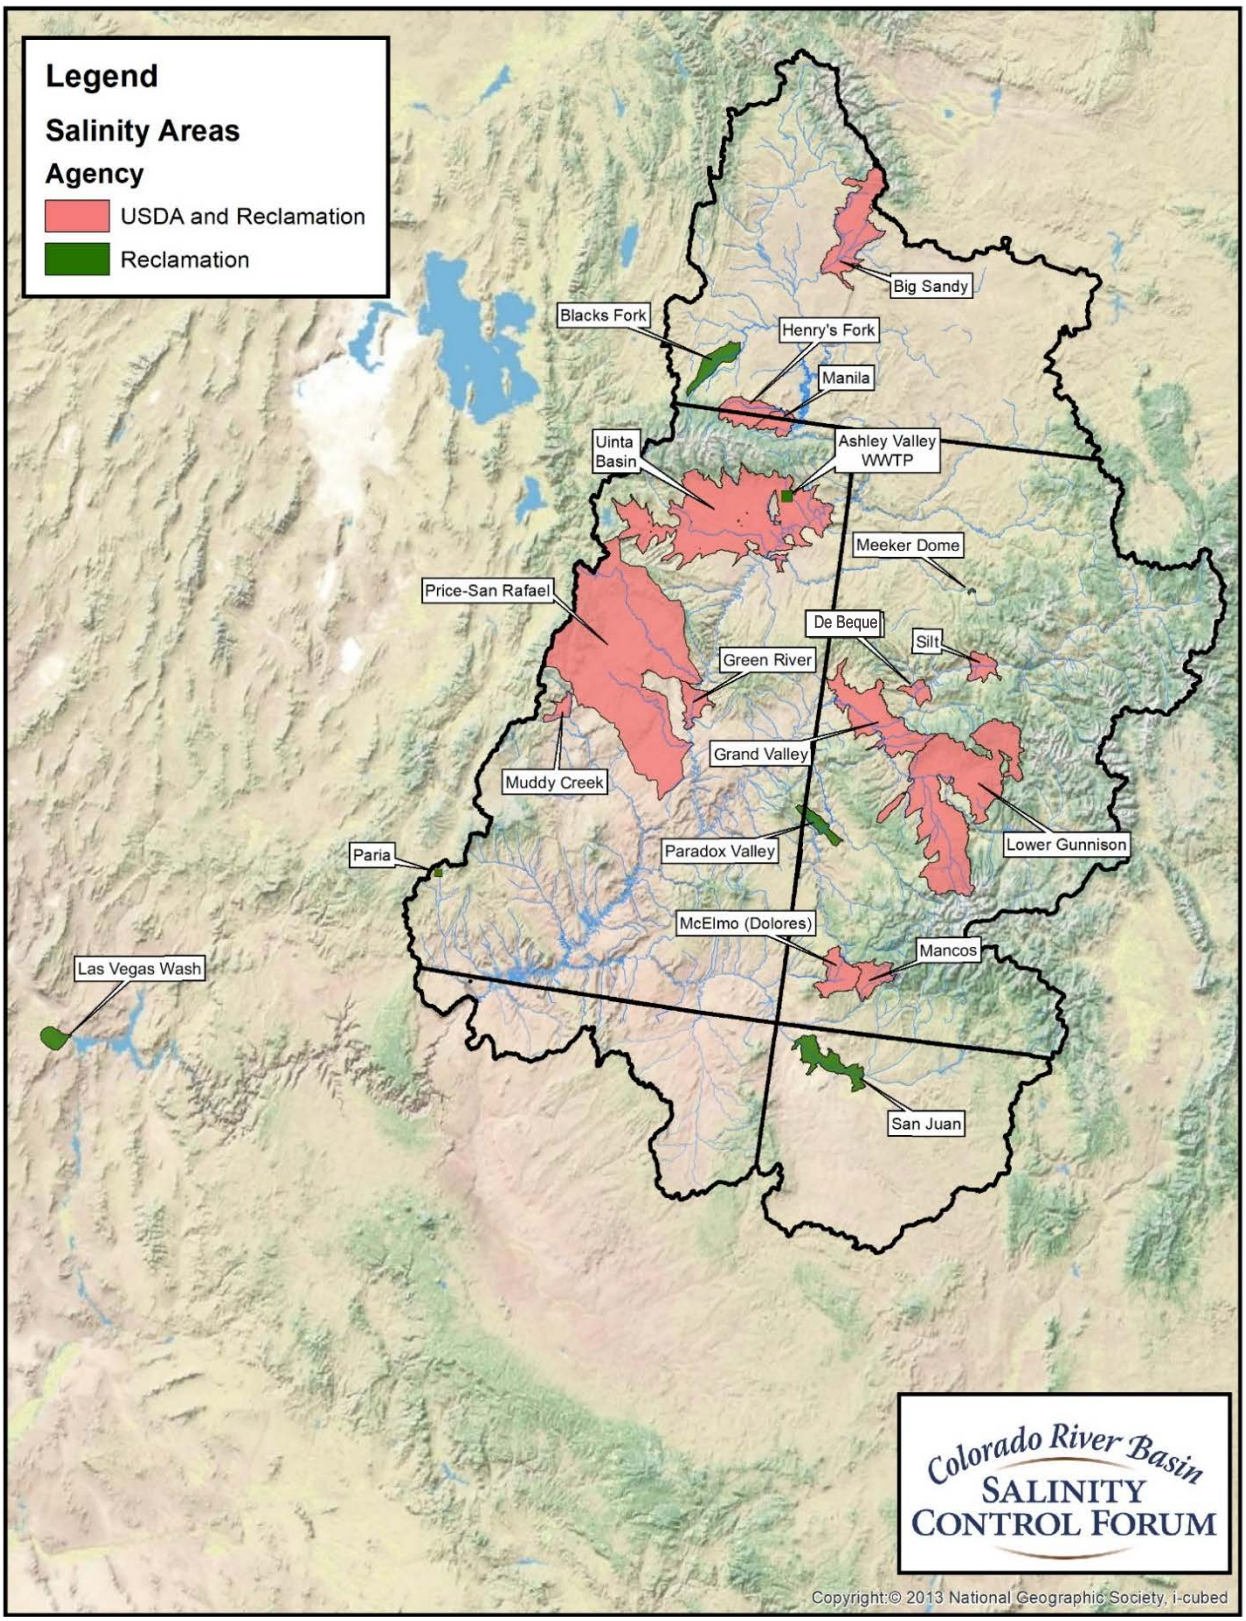

Figure 6 - Colorado River Basin Salinity Control Areas

The Plan of Implementation anticipates the continuation of the Program through the period of the Review. As presented in Table 2, it is anticipated that an additional 51,700 tons annually will be controlled by the Program as set forth in the 2023 Plan of Implementation, resulting in a total of 1,384,100 tons of annual reduction by 2026.

Table 2 - Additional Controls - Plan of Implementation 2026**

Funding Source		Tons/Year as of 2026
RECLAMATION (Basinwide Program)*		22,200
BASIN STATES PROGRAM (BSP)		7,900
USDA NRCS (EQIP)		21,600
TOTAL**		**51,700**

*Includes cost-share dollars from Basin States Program
** BLM Nonpoint Source controls not included herein

This Plan of Implementation mainly focuses on the improvement of agricultural practices in the Upper Colorado River Basin. These improvements include both on-farm and off-farm activities. The majority of the salt reduction will occur in established salinity project areas, but some will occur outside those areas. Table 3 provides existing and some potential salinity control project areas and an estimate of the potential salt reductions for both on- and off-farm projects that could occur in those areas.

Table 3 - Remaining Potential Salinity Control (2024-2040)*

Project Area	Total Tons/year	Percent remaining
Big Sandy	35,660	33%
West Blacks Fork	26,900	96%
Grand Valley	211,460	43%
Green River	10,400	76%
Henrys Fork	16,120	89%
Lower Gunnison	473,100	63%
Mancos	15,000	63%
Manila	11,100	32%
McElmo (Dolores)	39,940	41%
Muddy Creek	8,060	62%
Paria	30	2%
Price-San Rafael	38,490	18%
San Juan	9,330	15%
Silt	9,460	78%
Uinta	68,800	24%
USDA Tier 2	6,610	41%
Nonpoint Sources*		
TOTAL**	**980,460**	

*BLM Nonpoint Source controls not included
**Saline Groundwater Sources not included

The potential additional controllable salt remaining in all the identified areas is estimated to be 980,460 tons annually, and thus the potential available tons exceed the 51,700 tons of additional annual salinity control identified by the Plan of Implementation. Additional salinity control areas may be identified in the future.

Forum Policies and NPDES Permits

Important components of the Plan of Implementation are the Forum policies and NPDES permits which guide Basin States activities associated with the control of salt discharge to the Colorado River. In 1977, the Forum adopted the Policy for Implementation of Colorado River Salinity Standards through the NPDES Permit Program. This policy provides guidance for the regulation of municipal and industrial point source discharges of saline water. In 1980, the Forum adopted a policy to encourage the use of brackish and/or saline waters for industrial purposes where it is environmentally sound and economically feasible. A third policy dealing with intercepted groundwater was adopted by the Forum in 1982. In 1988, the Forum adopted a fourth policy which addresses the salinity of water discharges from fish hatcheries. The Forum subsequently updated its NPDES policy in 2002 to clarify the Forum policies for consistent implementation among the Basin States. In 2015, a Forum subcommittee found that the States are consistently implementing the policies. These policies are found in Appendix B of this report.

Each of the states has adopted the Forum policies presented in Appendix B. Salinity discharge requirements for these permits are evaluated and practicable controls are required during the permit process. A listing of NPDES permits and level of compliance of discharge facilities within the Basin are presented in Appendix C. Some NPDES permits are issued by the various EPA Regions in the Basin for federal facilities and Native American tribes without NPDES primacy. The State of New Mexico does not yet have NPDES primacy; therefore, EPA Region 6 issues NPDES permits in New Mexico, which are certified by the New Mexico Environment Department. Forum policies also apply to EPA-issued NPDES permits and hence, become a part of the Plan of Implementation. The NPDES permits issued by EPA can be found in Appendix D of this report. During the period of this Review, the status of implementation of NPDES permits and water quality management plans in each of the states follows:

State Water Quality Management Plans

ARIZONA

Scope

The Colorado River enters Arizona and the Lower Basin near Page and travels through the Grand Canyon before turning southward at Lake Mead (Hoover Dam) and flowing to the Gulf of California. There are four major drainages in Arizona's portion of the Basin which are regulated under the NPDES program: 1) the Little Colorado River; 2) the Virgin River; 3) the Bill Williams River, formed by the Big Sandy and the Santa Maria Rivers at Alamo Lake, which empties into the Colorado River above Parker Dam; and 4) the Gila River, which joins the Colorado River below Imperial Dam. Because the Gila River is below Imperial Dam, facilities that discharge to the Gila River or its tributaries do not require conformance with the Forum policies.

NMED Exhibit 90

NPDES Permitting

The Water Quality Division of the Arizona Department of Environmental Quality (ADEQ) administers the Arizona Pollutant Discharge Elimination System (AZPDES) program on non-Indian country lands. All permits for domestic wastewater and industrial discharges, with direct river discharges, are written in conformance with associated Forum policies. ADEQ continues to evaluate and revise other discharge permits as information becomes available.

Currently there are 25 active individual discharge permit holders in Arizona's non-tribal portion of the Colorado River system. Of these, 20 permits are for municipal or domestic wastewater discharges. The other 5 permits are for industrial discharges related to fish hatcheries, mines, water treatment or water delivery. Additionally, there are 3 inactive permits that were terminated or expired since the 2020 triennial review. A specific listing of the individual permits and the status of compliance with Forum policies is contained in Appendix C.

There are currently 22 stream segments and lakes in the Basin that are listed in the state's 2022 Section 303(d) list as impaired in the following watersheds: Bill Williams (3), Colorado River Grand Canyon (9), Colorado River Lower Gila (4), Little Colorado River (6). No waters are currently listed for salinity, which only applies to the Colorado River. The primary causes of impairment are selenium (8), mercury (8), suspended sediment (3), *E. Coli* (3), ammonia (2), copper (1), beryllium (1), and dissolved oxygen (1). Complete assessment information can be found on ADEQ's website.

Watershed Planning

ADEQ's TMDL Program and the Water Quality Improvement Grant Program utilize comprehensive watershed-based plans, which contain EPA's required nine elements, to help focus funding to those areas and projects that have the greatest chance for improving water quality. These plans contain implementation strategies for many of the impaired waters, as well as Best Management Practices to address existing and potential issues in the watershed.

Work plans are developed to secure grant funding under the Clean Water Act, Section 319(h) for watershed level planning and implementation. The work plans identify and coordinate efforts by state, federal and local agencies, along with watershed groups and private citizens, to reduce or prevent nonpoint source pollution through the use of Best Management Practices and "on-the-ground" projects.

CALIFORNIA

Note that California administers NPDES permits similar to other states, but it does not currently have any active NPDES permits which discharge in the Colorado River Basin.

NMED Exhibit 90

COLORADO

Scope

Colorado's portion of the Colorado River Basin is comprised of six major drainages: 1) the main stem of the Colorado River from the continental divide to the Utah border, 2) the Roaring Fork River Basin, 3) the Yampa/White River Basin which flows to the Green River in Utah, 4) the Gunnison River Basin, 5) the Dolores River which flows to the main stem in Utah, and 6) the San Juan Basin which flows into New Mexico and then to the main stem in Utah.

NPDES Permitting

The Colorado Department of Public Health and Environment, Water Quality Control Division (CDPHE, WQCD), administers the NPDES permitting program in the Colorado River Basin, with the exception that EPA issues permits for point source discharges on the Southern Ute and Ute Mountain Ute Reservations, as well as for federally owned lands such as National Parks. This would include permits for discharges to groundwater that would contribute salinity to the Colorado River system through a hydrologic connection to surface waters. Permits for industrial and municipal discharges are written in conformance with the associated Forum policies. Colorado continues to issue stormwater permits to construction of oil and gas development sites and related infrastructure (e.g. roads) of one or more acres of disturbance, even though the Energy Policy Act had exempted this activity from the requirement to obtain a permit at the federal level.

Currently there are more than 300 active discharge permits and permit certifications in the Colorado portion of the Colorado River Basin where the salinity requirements have been addressed. A specific listing of these permits is contained in Appendix C.

Water Quality Assessments and TMDLs

The waters in Colorado's portion of the Colorado River Basin, particularly at higher elevation, are generally of good quality. Based on the 2022 303(d) List of Impaired Waters, there are 195 water quality impaired stream segments in the Colorado River Basin in Colorado (Gunnison River Basin: 70 impaired segments; Upper and Lower Colorado River Basin: 91 impaired segments; San Juan River Basin: 34 impaired segments). Of these, a significant majority in the lower ends of these basins are impaired for selenium. Water quality impairments in the mountainous portions of these basins are due to high concentrations of metals, primarily caused by the remnants of historic mining activities. No waters are currently listed for salinity related impacts.

The lower portions of each of these basins are underlain by bedrock deposits of the cretaceous period, most notably Mancos Shale and Dakota Sandstone. The Mancos Shale is a marine deposit and, as such, contains significant amounts of readily soluble constituent materials, including selenium. Groundwater which leaches to the relatively impermeable shale deposits tends to dissolve selenium and, as it flows atop the bedrock strata toward surface drainages, carries elevated levels of dissolved selenium with it. Various anthropogenic activities like sand and gravel extraction and agricultural and urban landscape irrigation accelerate the mobilization and transport of selenium from shale and shale-derived soil to surface water.

NMED Exhibit 90

Given the selenium impairments, CDPHE, WQCD prioritized developing selenium Total Maximum Daily Loads (TMDLs) for several impaired tributaries within the Colorado River basin. One of the primary reasons for prioritizing these TMDLs is the impact the selenium loading is having on threatened and endangered fish habitat. Additional water quality monitoring and TMDL development for tributaries from Glenwood Springs to the Utah state line is underway with completion targeted for 2024. Activities are also ongoing to address the nonpoint source contributions that will be identified in these TMDLs. Many BMPs that are implemented to address the selenium nonpoint source contributions are anticipated to reduce salinity as well.

Watershed Planning - Colorado River Basin Selenium/Salinity Nonpoint Source Activities

CDPHE, WQCD supported watershed- and regional-scale water quality planning and BMP implementation for selenium and salinity reduction in the Basin. While the focus has been on selenium, control techniques for selenium are generally thought to reduce salinity loading because seepage and deep percolation of water into the local Mancos Shale and associated soils is a primary source of both salt and selenium loading. Numerous projects for selenium and salinity control are ongoing in the Basin with a primary emphasis in the Lower Gunnison which was the largest contributing tributary. The Gunnison River Basin Selenium Management Program, which was developed in response to the 2009 USFWS Gunnison Basin Programmatic Biological Opinion, provides details of past, current, and planned selenium control projects. Selenium reductions associated with this program are attributed to previous and on-going off-farm and on-farm salinity control efforts implemented through the Colorado River Basin Salinity Control Program, Environmental Quality Incentives Program, National Irrigation Water Quality Program, Natural Resources Conservation Service Regional Conservation Partnership Program, Colorado Department of Natural Resources Species Conservation Trust Program, and Colorado Nonpoint Source Program Clean Water Act Section 319. The Colorado Nonpoint Source Program provided funding assistance for additional irrigation lateral piping in the Basin and continues to work with local communities and producers to support implementation of BMPs. USGS studies have shown that irrigation efficiency efforts are contributing to a downward trend in selenium loading (https://pubs.er.usgs.gov/ publication/sir20185001) and this downward trend was reflected in the removal of the Lower Gunnison segment (COGULG02) from the 2022 303(d) List of Impaired Waters by the Colorado Water Quality Control Commission.

NEVADA

Scope

The Basin within Nevada consists of three major tributaries: 1) the Virgin River, 2) the Muddy River, and 3) the Las Vegas Wash. All of these tributaries flow into Lake Mead and provide nearly all of the inflow to the river from Nevada.

NPDES Permitting

The Nevada Division of Environmental Protection is the EPA delegated authority for the issuance of NPDES Permits. As of December 31, 2022, there were 52 active discharge permits in the Nevada portion of the Colorado River System. The largest dischargers, the City of Las Vegas with a permitted discharge maximum flow of up to 101 mgd (91 mgd from the Water Pollution Control Facility and 10 mgd from the Durango Hills Facility), the Clark County Water Reclamation

NMED Exhibit 90

District with a permitted discharge maximum flow of up to 150 mgd, the City of Henderson with a permitted discharge maximum flow of up to 48 mgd (40 mgd from the Kurt R. Segler Water Reclamation Facility and 8 mgd from the Southwest Water Reclamation Facility), and the City of North Las Vegas with a permitted discharge maximum flow up to 25 mgd. The quality of the water affected by these permits is closely monitored and all necessary programs to protect water quality standards are being implemented. Nevada continues to apply the policies adopted by the Forum.

Water Quality Management Planning

Area-wide water quality management planning duties and powers have been vested to certain counties and entities. The Clark County Board of Commissioners was designated the Area-Wide Water Quality Management Planning organization within Clark County. The initial 208 Plan was adopted by the Clark County Board of Commissioners in 1978 and was approved by the EPA. Since that time, several 208 Plan revisions have been made as needed to address changing needs.

NEW MEXICO

Scope

New Mexico's portion of the Basin above Imperial Dam is comprised of two major drainages: 1) the Rio Puerco, which is a tributary of the Little Colorado River, and 2) the San Juan River, which is a major tributary of the Colorado River.

NPDES Permitting

The NPDES program is administered by the EPA Region 6 in the State of New Mexico, including Tribal Nations and except for facilities on the Navajo Nation which are issued by EPA Region 9. The New Mexico Environment Department (NMED) Surface Water Quality Bureau (SWQB) assists the EPA Region 6 in implementing the Clean Water Act Section 402 NPDES permit program by reviewing federal permits and preparing Section 401 certifications to certify that the permit also complies with New Mexico law. Permits for industrial and municipal discharges are written in conformance with the associated Forum policies. The State of New Mexico adopts the standards of the Forum by reference in the Water Quality Standards for Interstate and Intrastate Surface Waters at 20.6.4.54 NMAC. Currently, there are 35 discharge permits (active and inactive) in the New Mexico portion of the Basin, of which EPA Region 6 administers 22 permits and EPA Region 9 administers 13 Navajo Reservation permits. Of these, 18 permits (14 state, 4 Navajo Nation) are for industrial discharges and 16 permits (6 state, 1 Jicarilla Apache, 9 Navajo Nation) are associated with municipal wastewater discharges.

Water Quality Assessment and TMDLs

The New Mexico Water Quality Control Commission currently adopts the water quality framework developed and proposed by the NMED which includes the State of New Mexico Water Quality Management Plan and the New Mexico Nonpoint Source Management Plan. Both plans cover the entire state, except for tribal and pueblo lands which are under the jurisdiction of the respective Tribes and Pueblos. Much of the Basin in New Mexico falls within the Navajo Nation boundary.

NMED Exhibit 90

The following TMDLs have been adopted by the New Mexico Water Quality Control Commission and approved by EPA within the New Mexico portion of the Basin at this time:

Gallegos Canyon (San Juan to Navajo boundary) selenium
San Juan River (Animas River to Canon Largo) sedimentation, *E.coli*
Animas River (San Juan River to Estes Arroyo) temperature, *E.coli*
Animas River (San Juan River to Estes Arroyo) total nitrogen, total phosphorus
Animas River (Estes Arroyo to Southern Ute) *E.coli*, total phosphorus
La Plata River (McDermott Arroyo to CO border) *E.coli*
La Plata River (McDermott Arroyo to CO border) dissolved oxygen
La Plata River (San Juan River to McDermott Arroyo) sedimentation, *E.coli*
San Juan River (Navajo and at Hogback to Animas River) *E.coli*

The most recent San Juan Basin Surface Water Quality Survey was conducted in 2017 and 2018 by the NMED SWQB. These data were assessed to determine the current impairments and de-listing, and for the future TMDL development. These surveys are normally scheduled throughout the various watersheds and basins in the state on a 7- to 8-year cycle. The NMED SWQB in coordination with the EPA and Navajo Nation currently conducts additional water quality sampling as a result of the 2015 Gold King Mine Spill.

Watershed Planning

Work plans have been developed and grant funding secured under Clean Water Act Section 319(h) for watershed-associated development, riparian area restoration, certification of Section 404 permits, spill response and treatment of abandoned mines. The work plans identify and coordinate efforts by state, federal and local agencies, along with other groups and private citizens, to reduce or prevent non-point source pollution and implement Best Management Practices to reduce nonpoint source pollutants. The NMED and the San Juan Watershed Group, an unincorporated citizen and interagency group funded by the Section 319(h) program, are working to improve water quality in the San Juan River by implementing Best Management Practices for non-point source contributors of nutrients and *E. coli*. State Revolving Loan Funds and other funds are authorized and available for use in funding salinity control projects. State actions in support of salinity control include: 1) inclusion of salinity control measures in the Section 208 plans, 2) dissemination of information on salinity sources and control, 3) consultation with industries on potential salinity reduction measures, 4) implementation of Forum policy through NPDES permits, and 5) maintaining a continuous water quality planning program whereby new or additional salinity control measures can be addressed. Funding associated with the 2015 Gold King Mine Spill is also used to conduct San Juan River Watershed conferences where on-going watershed restoration and sampling efforts are presented.

UTAH

Scope

Utah's portion of the Colorado River Basin is comprised of ten major sections: 1) the main stem of the Colorado River from the Colorado border to the Arizona Border in Lake Powell, 2) the

NMED Exhibit 90

Green River Basin from the Wyoming state line in Flaming Gorge Reservoir to the confluence with the Colorado River, 3) the Duchesne River Basin, 4) the lower Yampa and White River Basins which flow to the Green River in Utah, 5) the Price and San Rafael River Basins, 6) the Dirty Devil and Escalante Rivers, 7) the lower portion of the San Juan River Basin which flows into the main stem of the Colorado River in Utah, 8) the Paria River, 9) the Kanab Creek Basin to the Arizona State Line, and 10) the Virgin River Basin to the Arizona state line.

NPDES Permitting

The Utah Division of Water Quality (DWQ) within the Utah Department of Environmental Quality administers the NPDES permitting program in Utah. Permits for industrial and municipal discharges within the Colorado River Basin are written in conformance with the associated Forum policies and are available for viewing online at the UPDES Permitting Program webpage.

As of December 31, 2022, there are 71 discharge permits as issued by DWQ in the Utah portion of the Colorado River Basin. Of these, 32 are for municipal discharges and 39 are for industrial discharges, of which 7 industrial permits have been recently terminated. A specific listing of the individual permits and their compliance status is presented in Appendix C. Multiple discharge permits for coal mining operations in Utah were developed to offset salinity contributions from industrial sources in accordance with the Forum policy initially adopted as part of the 2002 Triennial Review. The salinity-offset project plans have been finalized previously, with projects implemented to offset salinity contributions in excess of the one-ton-per-day requirement from those facilities.

Water Quality Assessments and TMDLs

The waters in Utah's portion of the Colorado River Basin are generally of good quality; however, there are 29 assessment units currently listed as impaired for impacts from TDS according to the 303(d) list presented in the 2022 Integrated Report. These segments are generally in the lower reaches of the respective basins and are the result of a combination of natural salt loadings and agricultural drainage. TMDLs have been developed for a number of assessment units to address past impairments from TDS and can be viewed on DWQ's Approved TMDL webpage.

Watershed Planning

Utah's Watershed Management Program is focused on protecting and restoring the water quality of its streams, lakes, and groundwater resources by employing the following key elements: Stewardship, Monitoring and Assessment, Coordination, and Watershed Planning. Although projects exist in other regions, currently the Upper Colorado Basin region in Utah has no watershed planning projects in progress to specifically address Total Dissolved Solids. The Basin Plans for the Utah State Water Plan include water quality as part of the process, and these plans are updated periodically.

WYOMING

Scope

NMED Exhibit 90

Wyoming's portion of the Basin is comprised of two major mainstream drainages: 1) the Little Snake River, which is a tributary of the Yampa River in Colorado, and 2) the Green River, which empties into Flaming Gorge Reservoir on the Wyoming-Utah border.

NPDES Permits

Currently there are 28 active discharge permits in the Wyoming portion of the Colorado River system. All permits for industrial and municipal discharges are written in conformance with Forum policies. Of the 28 permits, 11 are for industrial discharges related to fish hatcheries, coal mines, power plants or oil and gas production facilities and 17 of the permits are associated with municipal wastewater discharges. These facilities serve a total population of approximately 50,000 people. A specific listing of the individual permits and compliance status is contained in Appendix C.

Water Quality Assessments and TMDLs

The waters in the Upper Colorado River Basin within Wyoming are generally of good quality. There are currently 14 streams and river segments identified as impaired within the Basin in Wyoming's 2020 Integrated 305(b) and 303(d) Report. Of these, two segments are impaired for salinity-related impacts; Bitter Creek in the Green River Basin and Muddy Creek in the Little Snake River Basin both are listed as impaired for chloride.

Other water quality impairments in the Green River Basin include sedimentation/siltation, *E. coli*/fecal coliform, and pH. Other water quality impairments in the Little Snake River Basin include physical substrate habitat alterations, nutrients, temperature, selenium, and heavy metals. A web map of the assessed waterbodies, which includes summary information and links to fact sheets, assessment reports, TMDLs, and more is available on WDEQ's Water Quality Assessment webpage under the "Reports" tab.

There are eight completed TMDLs within the Basin that are not directly associated with salinity concerns. Water quality monitoring and data analysis by WDEQ are ongoing in Bitter Creek to support future development of TMDLs or alternative approaches. A TMDL for Muddy Creek is not scheduled for development at this time.

Watershed Planning

Watershed planning and restoration activities continue for several of the impaired waterbodies within the Green River and Little Snake River Basins. In the past five years, two nine-element watershed-based plans were published by local conservation districts and approved for use in the competitive proposal process for Section 319(h) water quality implementation projects.

Local Conservation Districts serve a key leadership role in planning and implementation in Wyoming, and detailed information on their efforts in the Green and Little Snake River Basins can be found in the 2018 Wyoming Watersheds Progress Report, prepared by the Wyoming Association of Conservation Districts. A new report is under development and anticipated to be published within the next year.

NMED Exhibit 90

In 2010, the Wyoming Water Development Commission (WWDC) revised the Green River Basin Plan, which includes the Little Snake River Drainage. The plan updated information about the current uses and projected future uses of water in the Basin and includes other useful information such as irrigated lands delineation, hydrologic modeling of major streams, estimated availability of surface and groundwater for future use, and recommendations and strategies for facing current and future water use challenges.

In 2018, the WWDC published an updated Environmental and Recreational Water Use Analysis to accompany the 2010 basin plan. The study identified a consistent viewpoint and accounting process for environmental and recreational water demands to help guide river basin planning efforts moving forward. More information on planning and implementation in the Green and Little Snake River Basins is presented below.

Green River Basin:
In 2018, the Sublette County Conservation District completed a nine-element watershed-based plan to address the sediment impairment in a segment of the Little Sandy River within the Green River basin. The plan identifies ways that excessive erosion and sedimentation in the impaired segment could be addressed through best management practices and river restoration.

Sweetwater County Conservation District completed a stream restoration project on Bitter Creek in 2018 that stabilized a headcut by replacing a failing drop structure with an improved structure that promotes channel stability.

In 2021, the Sweetwater County Conservation District completed a nine-element watershed-based plan to address the fecal coliform impairments in Bitter and Killpecker Creeks and discuss the chloride issues in Bitter Creek (within the Green River basin). The plan provides planning and methodology to improve water quality within the Bitter Creek watershed, which includes Killpecker Creek. As shown above, the WDEQ continues to assess the chloride impairment, therefore a detailed plan to address this component will come at a later date.

Other entities have also been actively pursuing stream and river restoration projects in the Green River Basin. The Wyoming Game and Fish Department (WGFD) and Trout Unlimited continue to restore segments of the New Fork River and the Green River. These projects are supported by Section 319(h) funding, as well as numerous other local, state, and federal funding sources.

Little Snake River Basin:
Coordinated resource management in the Little Snake River Basin led to successful restoration of three impaired waterbodies in the Muddy Creek watershed through improved grazing management, stream stabilization projects, and wetlands development. These efforts were applauded on EPA's Nonpoint Source Success Story website. Little Snake River Conservation District continues to lead restoration activities on other impaired waterbodies in the basin, including erosion and sediment reduction projects in the Little Snake River.

NMED Exhibit 90

CONCLUSION AND ADOPTION OF THE STANDARDS

The water quality standards for salinity control in the Colorado River consist of two components: the numeric criteria and the Plan of Implementation. No changes have been made to the numeric criteria since their adoption by the seven Basin States in 1975 and subsequent approval by EPA. Following their 2023 triennial review process, the Forum again concludes that the numeric criteria are appropriate and recommends no changes. The Forum also finds that the updated Plan of Implementation is adequate for maintaining salinity concentrations below the numeric criteria through 2026, thus providing significant benefits to the Colorado River Basin. If the Plan of Implementation is executed successfully, the probability of exceeding the numeric criteria is estimated to be 6 percent in any given year of the review period, thereby providing a measurable improvement to the quality of the Colorado River.

The Program cannot be successful without the cooperation of many agencies and governments at the local, state, and federal levels. First, the Program relies on landowners to implement cost-effective salinity control measures. Second, the Program is dependent on a multitude of agreements among the seven Basin States which have always been accomplished by consensus. Lastly, the Program depends on the three federal agencies that implement salinity control, as well as other federal agencies such as the United States Fish & Wildlife Service, United States Geological Survey and EPA. Based on their involvement in the preparation of this Review, it is expected that cooperating federal agencies will support the Plan of Implementation and its programs.

In June of 2023, the Forum adopted the proposed 2023 Review for public comment. During the summer of 2023, the Forum and the seven Basin States solicited comments on the Review from the public and cooperating agencies. Each state used its own comment solicitation method, and the Forum posted the proposed 2023 Review on its website. No public comments were received. At the Forum meeting held on October 24, 2023, the Forum approved this 2023 Review.

With the approval of this Review by the Forum, each of the seven Basin States will include these standards as a part of their own water quality standards through their respective procedures. The states will obtain approval of their water quality standards from EPA based on their respective regions. The State of New Mexico will submit its triennial review to EPA Region 6 in Dallas, Texas; Colorado, Utah and Wyoming will submit to EPA Region 8 in Denver, Colorado; and Arizona, California and Nevada will submit to EPA Region 9 in San Francisco, California. It is anticipated that EPA will fully support this salinity control effort by approval of each state's submittals.

FUTURE PROGRAM

As described in earlier sections of this report, the water quality standard for salinity in the Colorado River Basin is expected to be met during the review period (over the next three years, 2024-2026). Given average hydrology in the Basin, the probability of exceeding the numeric criteria, while putting into practice the outlined Plan of Implementation, is well within the established water quality standard. Nonetheless, as water development continues to occur throughout the Basin, salinity concentrations and the associated economic damages are projected to increase. Therefore,

NMED Exhibit 90

this section analyzes the comparative changes in Colorado River salinity under different implementation scenarios from the present through 2040. The efforts of the Program are to minimize downstream economic damages while the states continue to use water from the Colorado River. This effort is increasingly challenging as economic damage levels and costs increase over time, thus placing greater burdens on Program implementation.

Reclamation used its Colorado River Simulation System (CRSS) model to project salinity levels for the period 2023 through 2040 with the varying levels of Program implementation. The CRSS model simulates 33 separate hydrologic traces for each year (1988-2020) and then calculates the average annual salinity. A detailed description of the CRSS model and the model runs made for this Review are found in Appendix E.

The Forum requested that Reclamation analyze the effects on the salinity of the Colorado River for four levels of program implementation (tons of salt removed). The Forum chose the levels of implementation based on different assumptions regarding federal funding, state cost share and the tons of salt available for future control. These scenarios require different levels of anticipated funding to support implementation. For each modeled scenario, 65,000 tons of salinity control was modeled for PVU through 2026 following a ramp down of 20% (13,000 tons) per year from 2027 through 2031 after which there was modeled no salinity control at PVU through 2040.

Scenario 1 shows no additional salinity control measures implemented after 2023. Also included in this scenario is the modeled ramping down and loss of salinity control at PVU described above. Hence, Table 1 shows 1,332,400 tons of present salinity control but Scenario 1 shows no additional salinity control at 1.27 million tons due to the loss of salinity control at PVU.

Scenario 2 shows controls associated with current and projected limited program funding levels through 2040. Reclamation's Basinwide program maintains a funding level of $10 million in 2023 and then funding levels of $8.4 million through 2040. NRCS funding follows the agency's 3-year funding plan for 2024-2026 and is reduced to $12 million through 2029 and then $10 million through 2040.

Scenario 3 shows the same funding levels for NRCS as Scenario 2 and a funding level of $10.7 million for Reclamation through 2026 and then a fixed rate of implementation of 9,000 tons per year thereafter.

Scenario 4 shows controls associated with controlling the maximum potential identified salt load by 2040 (Table 3) and is shown as an upper bound, not a practical plan of implementation.

Table 4 shows the four scenarios modeled by Reclamation with the tons of annual salinity control in place by the year 2040.

NMED Exhibit 90

Table 4 - Plan of Implementation Levels Modeled by CRSS

Description	Total Control
Scenario 1 - No Additional Controls beyond 2023 (does not implement the Plan of Implementation identified herein)	1.27M tons
Scenario 2 - Controls associated with limited program funding levels through 2040	1.49M tons
Scenario 3 - Controls associated with fixed implementation through 2040	1.55M tons
Scenario 4 - Controls associated with controlling maximum potential identified salt load by 2040	2.21M tons

Note: "No additional controls" contemplates some continuing O&M expenditures to maintain existing facilities.

Note: Uses the 2023 Review scenarios with 0 tons Paradox controls for 2031-2040

The modeling shows that the difference between no additional salinity controls (Scenario 1) and the proposed plan of implementation of 1.55 million tons (Scenario 3) is 27 mg/L at Imperial Dam by the year 2040. These values are summarized in Figures 7, 8 and 9 and Table 5 below for the three numeric criteria points.

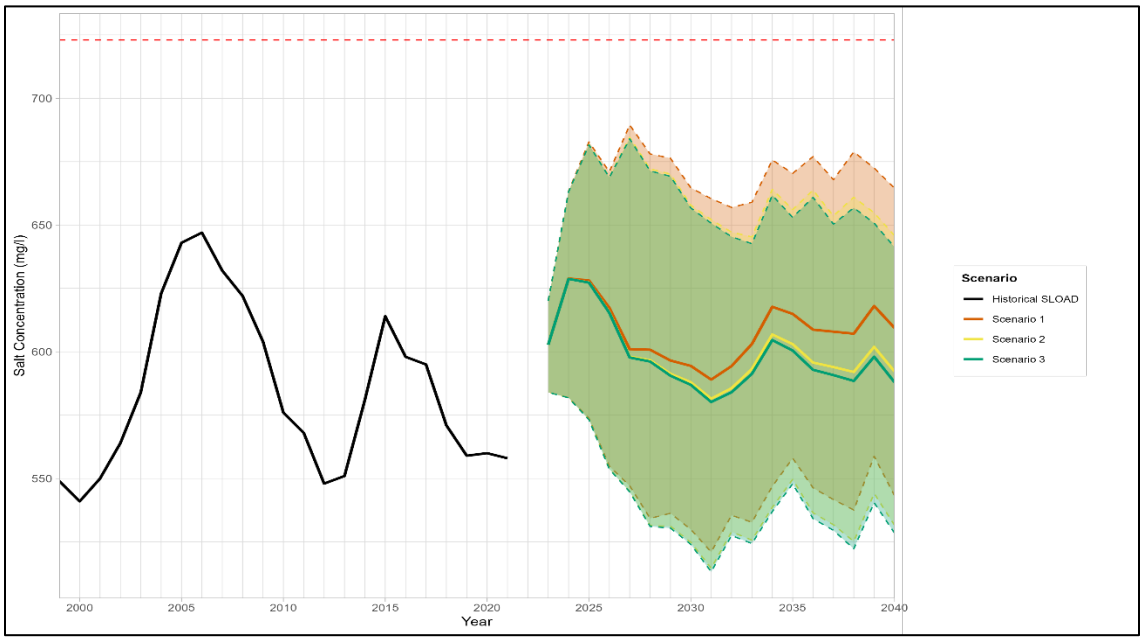

Figure 7 - Projected average annual salinity concentration below Hoover Dam. The colored solid lines are the mean values, and the shaded cloud area represents the 10th to 90th percentiles of each scenario's annual values. The black line represents the historical observed concentration from the SLOAD program. The red dotted line represents the numeric criteria.

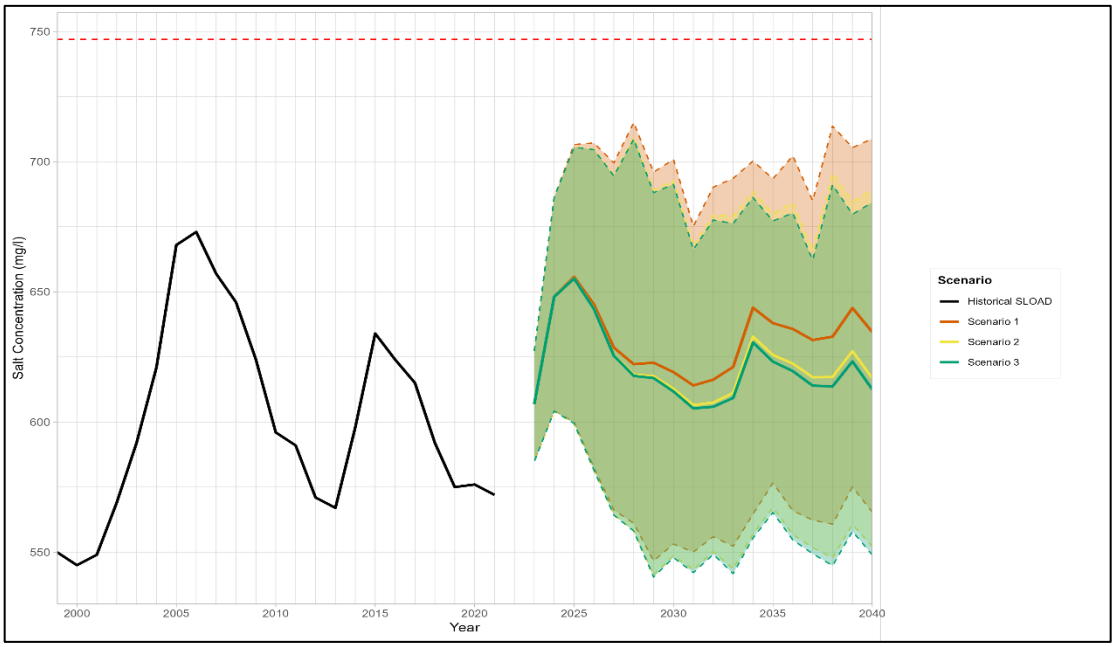

Figure 8 - Projected average annual salinity concentration below Parker Dam. The colored solid lines are the mean values, and the shaded cloud area represents the 10th to 90th percentiles of each scenario's annual values. The black line represents the historical observed concentration from the SLOAD program. The red dotted line represents the numeric criteria.

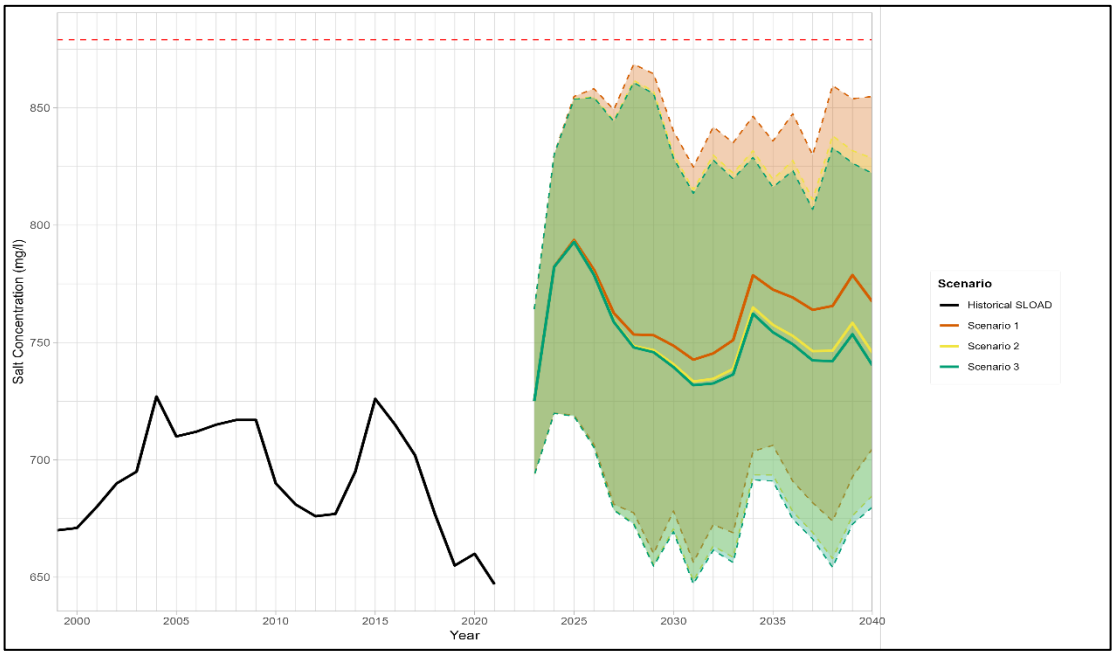

Figure 9 - Projected average annual salinity concentration at Imperial Dam. The colored solid lines are the mean values, and the shaded cloud area represents the 10th to 90th percentiles of each scenario's annual values. The black line represents the historical observed concentration from the SLOAD program. The red dotted line represents the numeric criteria.

To further understand the impacts of reducing the salinity concentrations in the Lower Basin, the Forum used Reclamation's Salinity Economic Impact Model (SEIM), which is described in Appendix F, to estimate damages under the four implementation alternatives. Damage estimates for each alternative are listed in Table 5 under the heading "Total Quantified Damages." Estimated damage reductions resulting from lower salinity concentrations projected under each alternative were derived by subtracting the "Total Quantified Damages" from the base case of 1.27M tons removed, or $447 million of annual damages. These estimates are listed in Table 5 as "Annual Damage Reductions." The SEIM model only estimates damages to the Lower Basin that can be reasonably *quantified* at the present time (see Appendix F). In addition to the currently *unquantified* damages in the Lower Basin, there are also benefits from the Program in the Upper Basin that have yet to be quantified. The SEIM was updated for the 2023 Review. Reclamation's consultant completed a review and update of the SEIM including updates to input data and cost functions where possible. Major changes included updates to residential impact functions, agricultural crop salinity thresholds, unified methods for calculating agricultural leaching and water utility costs. In 2022, the SEIM Committee, a subgroup of state and federal work group members, updated crop prices, price indices, water blending data and population projections to the latest available information.

Table 5 – Annual Damages and Damage Reductions

Alternative	Salinity Reduction at Imperial Dam in 2040 (mg/L)	Total Quantified Damages ($M)	Annual Damage Reductions as Compared to No Additional Future Controls Beyond 2020 ($M)
1.27M tons removed	--	447	--
1.49M tons removed	21	397.4	49.6
1.55M tons removed	27	385.1	61.9
2.21M tons removed	90	239.9	207.1

All damage and reduced-damage estimates correspond to year 2040.

Note: Uses the 2023 Review scenarios with 0 tons Paradox controls for 2031-2040

From these calculations, it can be seen that as more salinity control is implemented and the concentrations at the numeric criteria points are reduced, the *quantified* economic damages projected to be experienced annually by users in the Lower Basin are also reduced. For example, as indicated in Table 5, with the additional 280,000 tons of control (the difference between the 1.27 million ton and 1.55 million ton alternatives) annually, the *quantified* economic damages to agricultural and municipal and industrial water users are reduced by approximately $61.9 million annually. If the Plan of Implementation is implemented, then the probability of exceeding the numeric criteria values at the three stations is about 9 percent.

NMED Exhibit 90

While it is essential to continue to maintain salinity concentrations at or below the numeric criteria, the Forum will continue to focus on opportunities to further reduce future economic damages. The Forum believes a more robust salinity control program is needed to achieve the reductions indicated in Table 5. Two of the challenges facing the Forum in pursuing such a program are finding cost effective salinity control projects and acquiring the necessary funding to implement those projects. Persistent drought has reduced Colorado River flows thereby reducing power production which reduces the cost-share dollars available for Program funding. The Forum is committed to continue working with the federal agencies to identify cost effective projects. The Forum is also committed to working with the federal agencies and Congress to seek additional appropriations and to generate the cost share revenues needed to support additional federal expenditures. The Forum determines that all of the alternatives evaluated above are economically justifiable. However, given the current financial constraints, the Forum, for this review period, will pursue a Program designed to remove at least 1.55 million tons annually by the year 2040. This may require legislation to alter the states' cost share or other actions to meet the identified Program levels.

1 Determined by the USGS from data collected by Reclamation and USGS

2 2021-2022 values are provisional

Salinity concentrations are based on TDS as the sum of constituents whenever possible. The sum of constituents is defined to include calcium, magnesium, sodium, chloride, sulfate, a measure of the carbonate equivalent of alkalinity and, if measured, silica and potassium.

APPENDIX B

Forum Policies

POLICY FOR IMPLEMENTATION OF COLORADO RIVER SALINITY STANDARDS THROUGH THE NPDES PERMIT PROGRAM

Adopted by
The Colorado River Basin Salinity Control Forum

February 28, 1977
Revised October 30, 2002

In November 1976, the United States Environmental Protection Agency Regional Administrators notified each of the seven Colorado River Basin states of the approval of the water quality standards for salinity for the Colorado River System as contained in the document entitled "Proposed Water Quality Standards for Salinity Including Numeric Criteria and Plan of Implementation for Salinity Control, Colorado River System, June 1975, and the supplement dated August 25, 1975. The salinity standards including numeric criteria and a plan of implementation provide for a flow weighted average annual numeric criteria for three stations in the lower main stem of the Colorado River: below Hoover Dam, below Parker Dam, and at Imperial Dam.

In 1977, the states of the Colorado River Basin adopted the "Policy for Implementation of Colorado River Salinity Standards through the NPDES Permit Program." The plan of implementation is comprised of a number of federal and non-federal projects and measures to maintain the flow- weighted average annual salinity in the Lower Colorado River at or below numeric criteria at the three stations as the Upper and Lower Basin states continue to develop their compact-apportioned waters. One of the components of the Plan consists of the placing of effluent limitations, through the National Pollutant Discharge Elimination System (NPDES) permit program, on industrial and municipal discharges.

NPDES Policy for Municipal and Industrial Discharges of Salinity in the Colorado River

The purpose of this policy is to provide more detailed guidance in the application of salinity standards developed pursuant to Section 303 and through the NPDES permitting authority in the regulation of municipal and industrial sources. (See Section 402 of the Federal Water Pollution Control Act.) The objective of the policy, as provided in Sections I.A. and I.B., is to achieve "no salt return" whenever practicable for industrial discharges and an incremental increase in salinity over the supply water for municipal discharges. This policy is applicable to discharges that would have an impact, either direct or indirect on the lower main stem of the Colorado River System. The lower main stem is defined as that portion of the River from Hoover Dam to Imperial Dam.

In October, 2002, the Forum substantially amended the NPDES policies relating to industrial discharges but made no changes to the procedures for municipal discharges. In the printing of the 2002 Review, however, the section relating to municipal discharges and an additional appendix entitled “Guidance on New Construction Determination” were inadvertently omitted. Both errors have been corrected in this printing and the Forum reaffirms the validity of all of the policies as they appear in this document.

NMED Exhibit 90

NPDES Policies Separately Adopted by the Forum

The Forum developed a separate and specific policy for the use of brackish and/or saline waters for industrial purposes on September 11, 1980. The Forum addressed the issue of intercepted ground water and adopted a specific policy dealing with that type of discharge on October 20, 1982. On October 28, 1988, the Forum adopted a specific policy addressing the water use and discharge associated with fish hatcheries. Each of these separately adopted policies is attached hereto.

NPDES Policies for Specified Industrial Discharges – 2002 Amendments

On October 30, 2002, the Forum amended this policy for implementation of Colorado River salinity standards through the NPDES permit program in order to address the following three additional types of industrial discharges: (1) water that has been used for once-through noncontact cooling water purposes; (2) new industrial sources that have operations and associated discharges at multiple locations; and (3) "fresh water industrial discharges" where the discharged water does not cause or contribute to exceedances of the salinity standards for the Colorado River System. This policy was also amended to encourage new industrial sources to conduct or finance one or more salinity-offset projects in cases where the permittee has demonstrated that it is not practicable to prevent the discharge of all salt from proposed new construction.

Discharges Of Once-Through Noncontact Cooling Water

Section I.C. of this policy has been added to address discharges of water that has been used for once-through noncontact cooling water purposes. The policy for such discharges shall be to permit these uses based upon a finding that the returned water does not contribute to the loading or the concentration of salts in the waters of the receiving stream beyond a *de minimis* amount. A *de minimis* amount is considered, for purposes of this policy, as an average annual increase of not more than 25 milligrams per liter (mg/L) in total dissolved solids measured at the discharge point or outfall prior to any mixing with the receiving stream in comparison to the total dissolved solids concentration measured at the intake monitoring point of the cooling process or facility. This policy is not intended to supersede any other water quality standard that applies to the receiving stream, including but not limited to narrative standards promulgated to prohibit impairment of designated uses of the stream. It is the intent of the Forum to permit the return of once-through noncontact cooling water only to the same stream from which the water was diverted. Noncontact cooling water is distinguished from blowdown water, and this policy specifically excludes blowdown or any commingling of once-through noncontact cooling water with another waste stream prior to discharge to the receiving stream. Sections I.A. and I.B. of this policy govern discharges of blowdown or commingled water.

New Industrial Sources with Operations and Discharges at Multiple Locations under Common or Affiliated Ownership or Management

Recently there has been a proliferation of new industrial sources that have operations and associated discharges at multiple locations. An example is the recent growth in the

NMED Exhibit 90

development of energy fuel and mineral resources that has occurred in the Upper Colorado River Basin. This type of industrial development may involve the drilling of relatively closely spaced wells into one or more geological formations for the purpose of extracting oil, gas or minerals in solution. Large-scale ground water remediation efforts involving multiple pump and treat systems operating for longer than one year may share similar characteristics. With such energy and mineral development and ground water remediation efforts there is the possibility of a single major industrial operation being comprised of numerous individual point source discharges under common or affiliated ownership or management that produce significant quantities of water as a waste product or byproduct over a long period. Given the large areal scope of these types of major industrial sources and the often elevated concentrations of salinity in their produced water, the total amount of salt loading that they could generate may be very large in comparison to the Forum's past and present salt removal projects. Relatively small quantities of this produced water could generate one ton per day in discharges to surface waters. Since salinity is a conservative water quality constituent, such discharges of produced water, if uncontrolled, could have an adverse effect on achieving the adopted numeric salinity standards for the Colorado River System.

These kinds of major industrial sources strain the conventional interpretation of the industrial source waiver for new construction set forth in Section I.A.1.a. of this policy, which authorizes a discharge of salinity from a single point source of up to one ton per day in certain circumstances. The Forum adopted this provision in 1977, well before most of the new major industrial sources that have operations and discharges at multiple locations began to appear in the Colorado River Basin. A new category of industrial sources is, therefore, warranted. NPDES permit requirements for New Industrial Sources with Operations and Discharges at Multiple Locations under Common or Affiliated Ownership or Management are set forth in Section I.D. of this policy. These new requirements are intended to apply to new industrial sources with operations that commence discharging after October 30, 2002.

For purposes of interpreting this policy, "common or affiliated ownership or management" involves the authority to manage, direct, superintend, restrict, regulate, govern, administer, or oversee, or to otherwise exercise a restraining or directing influence over activities at one or more locations that result in a discharge of salinity into the Colorado River System. Common or affiliated ownership or management may be through the ownership of voting securities or may be indicated where individual sources are related through one or more joint ventures, contractual relationships, landlord/tenant or lessor/lessee arrangements. Other factors that indicate two or more discharging facilities are under common or affiliated ownership or management include: sharing corporate executive officers, pollution control equipment and responsibilities, common workforces, administrative functions, and/or payroll activities among operational facilities at different locations.

Fresh Water Industrial Discharges

Sections I.A. and I.B. of this policy have been amended to allow the permitting authority to authorize "fresh water industrial discharges" where the discharged water does not cause

NMED Exhibit 90

or contribute to exceedances of the adopted numeric salinity standards for the Colorado River System. Different end-of-pipe concentrations of salinity as shown in Table 1 of the policy, are appropriate for discharges to tributaries depending upon their location within the Basin. The concept of "benchmark concentrations" has been developed in order to address this need for different end-of-pipe concentrations. These benchmark concentrations are not to be interpreted as water quality standards. Rather, they are intended to serve solely for the establishment of effluent limits for implementing the waiver for "fresh water discharges." The allowance for freshwater discharges is intended to preserve flows from discharges in the Basin, which do not cause significant degradation of existing ambient quality with respect to salinity. Operations or individual discharges that qualify for the freshwater waiver shall not be subject to any further limitation on salt loading under this policy.

Salinity-Offset Projects

This policy has been amended to allow the permitting authority to authorize industrial sources of salinity to conduct or finance one or more salinity-offset projects when the permittee has determined that it is not practicable: (i) to prevent the discharge of all salt from proposed new construction; (ii) to reduce the salt loading to the Colorado River to less than one ton per day or 366 tons per year; or (iii) the proposed discharge is of insufficient quality in terms of TDS concentrations that it could be considered "fresh water" as defined below. Presently, the permitting authority can consider the costs and availability of implementing off-site salinity control measures to mitigate the adverse impacts of the permitted salt load. It is not intended that the applicant be required to develop or design an off-site salinity control project or establish a salt bank, but rather to assess the costs of conducting or buying into such projects where they are available. In the future the Forum or another entity may create a trading/banking institution to facilitate the implementation of a salinity-offset program, basin-wide. This would allow industrial sources to conduct or finance the most cost effective project available at the time an offset project is needed regardless of the project's location in the Basin.

NMED Exhibit 90

NPDES PERMIT PROGRAM POLICY
FOR IMPLEMENTATION OF COLORADO RIVER SALINITY STANDARDS

I. Industrial Sources

The Salinity Standards state that "The objective for discharges shall be a no-salt return policy whenever practicable." This is the policy that shall be followed in issuing NPDES discharge permits for all new industrial sources, and upon the reissuance of permits for all existing industrial sources, except as provided herein. The following addresses those cases where "no discharge of salt@ may be deemed not to be practicable.

A. New Construction

1. "New construction@ is defined as any facility from which a discharge may occur, the construction of which is commenced after October 18, 1975. (Date of submittal of water quality standards as required by 40 CFR 120, December 11, 1974.) Attachment 1 provides guidance on new construction determination. "A new industrial source with operations and discharging facilities at multiple locations under common or affiliated ownership or management@ shall be defined for purposes of NPDES permitting, as an industrial source that commenced construction on a pilot, development or production scale on or after October 30, 2002.

   a. The permitting authority may permit the discharge of salt upon a satisfactory demonstration by the permittee that:

      i. It is not practicable to prevent the discharge of all salt from the new construction or,

      ii. In cases where the salt loading to the Colorado River from the new construction is less than one ton per day or 366 tons per year, or

      iii. The proposed discharge from the new construction is of sufficient quality in terms of TDS concentrations that it can be considered "fresh water" that would have no adverse effect on achieving the adopted numeric standards for the Colorado River System. The permitting authority may consider a discharge to be fresh water if the maximum TDS concentration is: (i) 500 mg/L for discharges into the Colorado River and its tributaries upstream of Lees Ferry, Arizona; or, (ii) 90% of the applicable in-stream salinity standard at the appropriate benchmark monitoring station for discharges into the Colorado River downstream of Lees Ferry as shown in Table 1, below

NMED Exhibit 90

Table 1

	Benchmark Monitoring Station	Applicable Criteria	Freshwater Discharge (mg/L)
1	Colorado River at Lees Ferry, Arizona	N/A	500
2	Colorado River below Hoover Dam	723	650
3	Colorado River below Parker Dam	747	675
4	Colorado River at Imperial Dam	879	790

b. Unless exempted under Sections I.A.1.a.ii. or iii., above, the demonstration by the applicant must include information on the following factors relating to the potential discharge:

i. Description of the proposed new construction.

ii. Description of the quantity and salinity of the water supply.

iii. Description of water rights, including diversions and consumptive use quantities.

iv. Alternative plans that could reduce or eliminate salt discharge. Alternative plans shall include:

(A) Description of alternative water supplies, including provisions for water reuse, if any;

(B) Description of quantity and quality of proposed discharge;

(C) Description of how salts removed from discharges shall be disposed of to prevent such salts from entering surface waters or groundwater aquifers;

(D) Costs of alternative plans in dollars per ton of salt removed; and

NMED Exhibit 90

(E) Unless the permitting authority has previously determined through prior permitting or permit renewal actions that it is not practicable to prevent the discharge of all salt from the new construction in accordance with Section I.A.1.a.i., the applicant must include information on project options that would offset all or part of the salt loading to the Colorado River associated with the proposed discharge or that would contribute to state or interstate salinity control projects or salt banking programs.

v. A statement as to the one plan among the alternatives for reduction of salt discharge that is recommended by the applicant and also information as to which of the other evaluated alternatives are economically infeasible.

vi. Such other information pertinent to demonstration of non- practicability as the permitting authority may deem necessary.

c. In determining what permit conditions shall be required under I.A.1.a.i., above, the permit issuing authority shall consider, but not be limited to the following:

i. The practicability of achieving no-discharge of salt from the new construction.

ii. Where "no discharge" is determined not to be practicable:

(A) The impact of the total proposed salt discharge of each alternative on the lower main stem in terms of both tons per year and concentration.

(B) Costs per ton of salt removed from the discharge for each plan alternative.

(C) Capability of minimizing salinity discharge.

(D) If applicable under I.A.1.b.(iv)(E), costs and practicability of offsetting all or part of the salt load by the implementation of salt removal or salinity control projects elsewhere in the Colorado River Basin. The permittee shall evaluate the practicability of offsetting all or part of the salt load by comparing such factors as the cost per ton of salt removal for projects undertaken by the Colorado River Basin Salinity Control Forum and the costs in damages associated with increases in salinity concentration against the permittee's cost in conducting or buying into such projects where they are available.

NMED Exhibit 90

iii. With regard to subparagraphs, (b) and (c) above, the permit issuing authority shall consider the compatibility of state water laws with either the complete elimination of a salt discharge or any plan for minimizing a salt discharge.

B. Existing Facilities or any discharging facility, the construction of which was commenced before October 18, 1975

1. The permitting authority may permit the discharge of salt upon a satisfactory demonstration by the permittee that it is not practicable to prevent the discharge of all salt from an existing facility.

2. The demonstration by the applicant must include, in addition to that required under Section I.A.1.b the following factors relating to the potential discharge:

a. Existing tonnage of salt discharged and volume of effluent.

b. Cost of modifying existing industrial plant to provide for no salt discharge.

c. Cost of salt minimization.

3. In determining what permit conditions shall be required, the permit issuing authority shall consider the items presented under I.A.1.c.(ii), and in addition; the annual costs of plant modification in terms of dollars per ton of salt removed for:

a. No salt return.

b. Minimizing salt return.

4. The no-salt discharge requirement may be waived in those cases where:

a. The discharge of salt is less than one ton per day or 366 tons per year; or

b. The permitting authority determines that a discharge qualifies for a "fresh water waiver" irrespective of the total daily or annual salt load. The maximum TDS concentration considered to be fresh water is 500 mg/L for discharges into the Colorado River and its tributaries upstream of Lees Ferry, Arizona. For discharges into the Colorado River downstream of Lees Ferry the maximum TDS concentration considered to be afresh water shall be 90% of the applicable in-stream standard at the appropriate benchmark monitoring station shown in Table 1, above.

C. Discharge of Once-Through Noncontact Cooling Water

1. Definitions:

NMED Exhibit 90

a. The terms "noncontact cooling water" and "blowdown@ are defined as per 40CFR 401.11 (m) and (n).

b. "Noncontact cooling water" means water used for cooling that does not come into direct contact with any raw material, intermediate product, waste product or finished product.

c. "Blowdown" means the minimum discharge of recirculating water for the purpose of discharging materials contained in the water, the further buildup of which would cause concentration in amounts exceeding limits established by best engineering practice.

d. "Salinity" shall mean total dissolved solids as the sum of constituents.

2. Permits shall be authorized for discharges of water that has been used for once-through noncontact cooling purposes based upon a finding that the returned water does not contribute to the loading of salts or the concentration of salts in the waters of the receiving stream in excess of a *de minimis* amount.

3. This policy shall not supplant nor supersede any other water quality standard of the receiving stream adopted pursuant to the Federal Clean Water Act, including but not limited to impairment of designated uses of the stream as established by the governing water quality authority having jurisdiction over the waters of the receiving stream.

4. Noncontact cooling water shall be distinguished from blowdown, and Section 1.C. of this policy specifically excludes blowdown or any commingling of once-through noncontact cooling water with another waste stream prior to discharge to the receiving stream. Sections I.A. and I.B of this policy shall in all cases govern discharge of blowdown or commingled water.

5. Once-through noncontact cooling water shall be permitted to return only to the same stream from which the water was diverted.

6. Because the increase in temperature of the cooling water will result in some evaporation, a *de minimis* increase in the concentration of dissolved salts in the receiving water may occur. An annual average increase in total dissolved solids of not more than 25 milligrams per liter (mg/L) measured at the intake monitoring point, as defined below, of the cooling process or facility, subtracted from the effluent total dissolved solids immediately upstream of the discharge point to the receiving stream, shall be considered *de minimis*.

7. At the time of NPDES discharge permit issuance or reissuance, the permitting authority may permit a discharge in excess of the 25 mg/L increase based upon a satisfactory demonstration by the permittee pursuant to Section 1.A.1.a.

NMED Exhibit 90

8. Once-through demonstration data requirements:

   a. Description of the facility and the cooling process component of the facility.

   b. Description of the quantity, salinity concentration and salt load of intake water sources.

   c. Description of the discharge, covering location, receiving waters, quantity of salt load and salinity concentration of both the receiving waters and the discharge.

   d. Alternative plans for minimizing salt discharge from the facility which shall include:

      i. Description of alternative means to attain no discharge of salt.

      ii. Cost of alternative plans in dollars per ton of salt removed from discharge.

      iii. Such other information pertinent to demonstration of non- practicability as the permitting authority may deem necessary.

9. If, in the opinion of the permitting authority, the database for the salinity characteristics of the water source and the discharge is inadequate, the permit will require that the permittee monitor the water supply and the discharge for salinity. Such monitoring program shall be completed in two years and the permittee shall then present the once-through demonstration data as specified above.

10. All new and reissued NPDES permits for once-through noncontact cooling water discharges shall require at a minimum semiannual monitoring of the salinity of the intake water supply and the effluent, as provided below.

    a. The intake monitoring point shall be the point immediately before the point of use of the water.

    b. The effluent monitoring point shall be prior to the discharge point at the receiving stream or prior to commingling with another waste stream or discharge source.

    c. Discrete or composite samples may be required at the discretion of the permitting authority, depending on the relative uniformity of the salinity of the water supply.

    d. Analysis for salinity may be either total dissolved solids or electrical conductivity where a satisfactory correlation with total dissolved solids has

NMED Exhibit 90

been established. The correlation shall be based on a minimum of five different samples.

D. Discharges of Salinity from a New Industrial Source with Operations and Discharging Facilities at Multiple Locations

1. The objective for discharges to surface waters from a new industrial source with operations and discharging facilities at multiple locations shall be to assure that such operations will have no adverse effect on achieving the adopted numeric salinity standards for the Colorado River System.

2. NPDES permit requirements for a new industrial source with operations and discharging facilities at multiple locations shall be defined, for purposes of establishing effluent limitations for salinity, as a single industrial source if these facilities meet the criteria:

   a. The discharging facilities are interrelated or integrated in any way including being engaged in a primary activity or the production of a principle product; and

   b. The discharging facilities are located on contiguous or adjacent properties or are within a single production area e.g. geologic basin, geohydrologic basin, coal or gas field or 8 digit hydrologic unit watershed area; and

   c. The discharging facilities are owned or operated by the same person or by persons under common or affiliated ownership or management.

3. The permitting authority may permit the discharge of salt from a new industrial source with operations and discharging facilities at multiple locations if one or more of the following requirements are met:

   a. The permittee has demonstrated that it is not practicable to prevent the discharge of all salt from the industrial source. This demonstration by the applicant must include detailed information on the factors set forth in Section I.A.1.b of the Policy for implementation of Colorado River Salinity Standards through the NPDES permit program; with particular emphasis on an assessment of salinity off-set options that would contribute to state or interstate salinity control projects or salt banking programs and offset all or part of the salt loading to the Colorado River associated with the proposed discharge.

   b. In determining what permit conditions shall be required under I.A.1.a.i., above, the permit issuing authority shall consider the requirement for an offset project to be feasible if the cost per ton of salt removal in the offset project options (i.e. the permittee's cost in conducting or buying into such projects where they are available) is less than or equal to the cost per ton of

NMED Exhibit 90

salt removal for projects undertaken by the Colorado River Basin Salinity Control Forum or less than the cost per ton in damages caused by salinity that would otherwise be cumulatively discharged from the outfalls at the various locations with operations controlled by the industrial source; or

c. The pemittee has demonstrated that one or more of the proposed discharges is of sufficient quality in terms of TDS concentrations to qualify for a "fresh water waiver" from the policy of "no salt return, whenever practical.@ An individual discharge that can qualify for a fresh water waiver shall be considered to have no adverse effect on achieving the adopted numeric salinity standards for the Colorado River System.

4. For the purpose of determining whether a freshwater waiver can be granted, the quality of water discharged from the new industrial source with operations and discharging facilities at multiple locations, determined as the flow weighted average of salinity measurements at all outfall points, must meet the applicable benchmark concentration in accordance with Section I.A.1.a.iii., as set forth above.

5. Very small-scale pilot activities, involving 5 or fewer outfalls, that are sited in areas not previously developed or placed into production by a new industrial source operations and discharges at multiple locations under common or affiliated ownership or management, may be permitted in cases where the discharge of salt from each outfall is less than one ton per day or 366 tons per year. However, no later than the date of the first permit renewal after the pilot activities have become part of a larger industrial development or production scale effort, all discharging facilities shall be addressed for permitting purposes as a single industrial source with operations and discharges at multiple locations under common or affiliated ownership or management.

6. The public notice for NPDES permits authorizing discharges from operations at multiple locations with associated outfalls shall be provided promptly and in the most efficient manner to all member states in the Colorado River Basin Salinity Control Forum in relation to this policy.

II. Municipal Discharges

The basic policy is that a reasonable increase in salinity shall be established for municipal discharges to any portion of the Colorado River stream system that has an impact on the lower main stem. The incremental increase in salinity shall be 400 mg/L or less, which is considered to be a reasonable incremental increase above the flow weighted average salinity of the intake water supply.

F. The permitting authority may permit a discharge in excess of the 400 mg/L incremental increase at the time of issuance or reissuance of a NPDES discharge permit, upon satisfactory demonstration by the permittee that it is not practicable to attain the 400 mg/L limit.

NMED Exhibit 90

G. Demonstration by the applicant must include information on the following factors relating to the potential discharge:

1. Description of the municipal entity and facilities.

2. Description of the quantity and salinity of intake water sources.

3. Description of significant salt sources of the municipal wastewater collection system, and identification of entities responsible for each source, if available.

4. Description of water rights, including diversions and consumptive use quantities.

5. Description of the wastewater discharge, covering location, receiving waters, quantity, salt load, and salinity.

6. Alternative plans for minimizing salt contribution from the municipal discharge. Alternative plans should include:

   a. Description of system salt sources and alternative means of control.

   b. Cost of alternative plans in dollars per ton, of salt removed from discharge.

7. Such other information pertinent to demonstration of non-practicability as the permitting authority may deem necessary.

H. In determining what permit conditions shall be required, the permit issuing authority shall consider the following criteria including, but not limited to:

1. The practicability of achieving the 400 mg/L incremental increase.

2. Where the 400 mg/L incremental increase is not determined to be practicable:

   a. The impact of the proposed salt input of each alternative on the lower main stem in terms of tons per year and concentration.

   b. Costs per ton of salt removed from discharge of each alternative plan.

   c. Capability of minimizing the salt discharge.

NMED Exhibit 90

D. If, in the opinion of the permitting authority, the data base for the municipal waste discharger is inadequate, the permit will contain the requirement that the municipal waste discharger monitor the water supply and the wastewater discharge for salinity. Such monitoring program shall be completed within 2 years and the discharger shall then present the information as specified above.

E. Requirements for establishing incremental increases may be waived in those cases where the incremental salt load reaching the main stem of the Colorado River is less than one ton per day or 366 tons per year. Evaluation will be made on a case-by-case basis.

F. All new and reissued NPDES permits for all municipalities shall require monitoring of the salinity of the intake water supply and the wastewater treatment plant effluent in accordance with the following guidelines:

Treatment Plant Design Capacity	Monitoring Frequency	Type of Sample
<1.0 MGD*	Quarterly	Discrete
1.0 - 5.0 MGD	Monthly	Composite
>5.0 - 50.0 MGD	Weekly	Composite
50.0 MGD	Daily	Composite

1. Analysis for salinity may be either as total dissolved solids (TDS) or be electrical conductivity where a satisfactory correlation with TDS has been established. The correlation should be based on a minimum of five different samples.

2. Monitoring of the intake water supply may be at a reduced frequency where the salinity of the water supply is relatively uniform.

NMED Exhibit 90

Attachment 1

Guidance on New Construction Determination

For purposes of determining a new construction, a source should be considered new if by October 18, 1975, there has not been:

I. Significant site preparation work such as major clearing or excavation; and/or

II. Placement, assembly or installation of unique facilities or equipment at the premises where such facilities or equipment will be used; and/or

III. Any contractual obligation to purchase unique facilities or equipment. Facilities and equipment shall include only the major items listed below, provided that the value of such items represents a substantial commitment to construct the facility:

A. structures; or
B. structural materials; or
C. machinery; or
D. process equipment; or
E. construction equipment.

IV. Contractual obligation with a firm to design, engineer, and erect a completed facility (i.e., a turnkey plant).

NMED Exhibit 90

POLICY FOR USE OF
BRACKISH AND/OR SALINE WATERS
FOR INDUSTRIAL PURPOSES

Adopted by
The Colorado River Basin Salinity Control Forum

September 11, 1980

The states of the Colorado River Basin, the Federal Executive Department, and the Congress have all adopted as a policy that the salinity in the lower main stem of the Colorado River shall be maintained at or below the flow-weighted average values found during 1972, while the Basin states continue to develop their compact-apportioned waters. In order to achieve this policy, all steps which are practical and within the framework of the administration of states' water rights must be taken to reduce the salt load of the river. One such step was the adoption in 1975 by the Forum of a policy regarding effluent limitations for industrial discharges with the objective of "no-salt return" wherever practicable. Another step was the Forum's adoption in 1977 of the "Policy for Implementation of Colorado River Salinity Standards through the NPDES Permit Program." These policies are part of the basinwide plan of implementation for salinity control which has been adopted by the seven Basin states.

The Forum finds that the objective of maintaining 1972 salinity levels would be served by the exercise of all feasible measures including, wherever practicable, the use of brackish and/or saline waters for industrial purposes.

The summary and page 32 of the Forum's 1978 Revision of the Water Quality Standards for Salinity state: AThe plan also contemplates the use of saline water for industrial purposes whenever practicable,...@ In order to implement this concept and thereby further extend the Forum's basic salinity policies, the Colorado River Basin states support the Water and Power Resources Service (WPRS) appraisal study of saline water collection, pretreatment and potential industrial use.

The Colorado River Basin contains large energy resources which are in the early stages of development. The WPRS study should investigate the technical and financial feasibility of serving a significant portion of the water requirements of the energy industry and any other industries by the use of Basin brackish and/or saline waters. The Forum recommends that:

I. The Colorado River Basin states, working with federal agencies, identify, locate and quantify such brackish and/or saline water sources.

II. Information on the availability of these waters be made available to all potential users.

III. Each state encourage and promote the use of such brackish and/or saline waters, except where it would not be environmentally sound or economically feasible, or would significantly increase consumptive use of Colorado River System water in the state above that which would otherwise occur.

NMED Exhibit 90

IV. The WPRS, with the assistance of the states, encourages and promotes the use of brackish return flows from federal irrigation projects in lieu of fresh water sources, except where it would not be environmentally sound or economically feasible, or would significantly increase consumptive use of Colorado River System water.

V. The WPRS considers a federal contribution to the costs of industrial use of brackish and/or saline water, where cost-effective, as a joint private-government salinity control measure. Such activities shall not delay the implementation of the salinity control projects identified in Title II of P.L. 93-320.

NMED Exhibit 90

POLICY FOR IMPLEMENTATION OF COLORADO RIVER SALINITY STANDARDS THROUGH THE NPDES PERMIT PROGRAM FOR INTERCEPTED GROUND WATER

Adopted by
The Colorado River Basin Salinity Control Forum

October 20, 1982

The States of the Colorado River Basin in 1977 agreed to the APolicy for Implementation of Colorado River Salinity Standards through the NPDES Permit Program@ with the objective for industrial discharge being Ano-salt return@ whenever practicable. That policy required the submittal of information by the applicant on alternatives, water rights, quantity, quality, and costs to eliminate or minimize the salt discharge. The information is for use by the NPDES permit-issuing agency in evaluating the practicability of achieving Ano-salt@ discharge.

There are mines and wells in the Basin which discharge intercepted ground waters. The factors involved in those situations differ somewhat from those encountered in other industrial discharges. Continued development will undoubtedly result in additional instances in which permit conditions must deal with intercepted ground water.

The discharge of [1]intercepted ground water needs to be evaluated in a manner consistent with the overall objective of Ano-salt return@ whenever practical. The following provides more detailed guidance for those situations where ground waters are intercepted with resultant changes in ground-water flow regime.

I. The Ano-salt@ discharge requirement may be waived at the option of the permitting authority in those cases where the discharged salt load reaching the main stem of the Colorado River is less than one ton per day or 366 tons per year. Evaluation will be made on a case-by-case basis.

II. Consideration should be given to the possibility that the ground water, if not intercepted, normally would reach the Colorado River System in a reasonable time frame. An industry desiring such consideration must provide detailed information including a description of the topography, geology, and hydrology. Such information must include direction and rate of ground-water flow; chemical quality and quantity of ground water; and the location, quality, and quantity of surface streams and springs that might be affected. If the information adequately demonstrates that the ground water to be intercepted normally would reach the river system in a reasonable time frame and would contain approximately the same or greater salt load than if intercepted, and if no significant localized problems

[1]The term Aintercepted ground water@ means all ground water encountered during mining or other industrial operations.

NMED Exhibit 90

would be created, then the permitting agency may waive the Ano-salt@ discharge requirement.

III. In those situations where the discharge does not meet the criteria in I or II above, the applicant will be required to submit the following information for consideration:

A. Description of the topography, geology, and hydrology. Such information must include the location of the development, direction and rate of ground-water flow, chemical quality and quantity of ground water, and relevant data on surface streams and springs that are or might be affected. This information should be provided for the conditions with and without the project.

B. Alternative plans that could substantially reduce or eliminate salt discharge. Alternative plans must include:

1. Description of water rights, including beneficial uses, diversions, and consumptive use quantities.

2. Description of alternative water supplies, including provisions for water reuse, if any.

3. Description of quantity and quality of proposed discharge.

4. Description of how salts removed from discharges shall be disposed of to prevent their entering surface waters or ground-water aquifers.

5. Technical feasibility of the alternatives.

6. Total construction, operation, and maintenance costs; and costs in dollars per ton of salt removed from the discharge.

7. Closure plans to ensure termination of any proposed discharge at the end of the economic life of the project.

8. A statement as to the one alternative plan for reduction of salt discharge that the applicant recommends be adopted, including an evaluation of the technical, economic, and legal Practicability of achieving no discharge of salt.

9. Such information as the permitting authority may deem necessary.

IV. In determining whether a Ano-salt@ discharge is Practicable, the Permit-issuing authority shall consider, but not be limited to, the water rights and the technical, economic, and legal practicability of achieving no discharge of salt.

NMED Exhibit 90

V. Where Ano-salt@ discharge is determined not to be Practicable the permitting authority shall, in determining permit conditions, consider:

A. The impact of the total proposed salt discharge of each alternative on the lower main stem in terms of both tons per year and concentration.

B. Costs per ton of salt removed from the discharge for each plan alternative.

C. The compatibility of state water laws with each alternative.

D. Capability of minimizing salinity discharge.

E. The localized impact of the discharge.

F. Minimization of salt discharges and the preservation of fresh water by using intercepted ground water for industrial processes, dust control, etc. whenever it is economically feasible and environmentally sound.

NMED Exhibit 90

POLICY FOR IMPLEMENTATION OF COLORADO RIVER SALINITY STANDARDS THROUGH THE NPDES PERMIT PROGRAM FOR FISH HATCHERIES

Adopted by
The Colorado River Basin Salinity Control Forum

October 28, 1988

The states of the Colorado River Basin in 1977 adopted the APolicy for Implementation of Colorado River Salinity Standards through the NPDES Permit Program.@ The objective was for Ano-salt return@ whenever practicable for industrial discharges and an incremental increase in salinity over the supply water for municipal discharges. The Forum addressed the issue of intercepted ground water under the 1977 policy, and adopted a specific policy dealing with that type of discharge.

A specific water use and associated discharge which has not been here-to-fore considered is discharges from fish hatcheries. This policy is limited exclusively to discharges from fish hatcheries within the Colorado River Basin. The discharges from fish hatcheries need to be addressed in a manner consistent with the 1977 and 1980 Forum policies.

The basic policy for discharges from fish hatcheries shall permit an incremental increase in salinity of 100 mg/L or less above the flow weighted average salinity of the intake supply water. The 100 mg/L incremental increase may be waived if the discharged salt load reaching the Colorado River system is less than one ton per day, or 366 tons per year. Evaluation is to be made on a case-by-case basis.

I. The permitting authority may permit a discharge in excess of the 100 mg/L incremental increase at the time of issuance or reissuance of a NPDES discharge permit. Upon satisfactory demonstration by the permittee that it is not practicable to attain the 100 mg/L limit.

II. Demonstration by the applicant must include information on the following factors relating to the potential discharge:

   A. Description of the fish hatchery and facilities.

   B. Description of the quantity and salinity of intake water sources.

   C. Description of salt sources in the hatchery.

   D. Description of water rights, including diversions and consumptive use quantities.

   E. Description of the discharge, covering location, receiving waters, quantity salt load, and salinity.

NMED Exhibit 90

F. Alternative plans for minimizing salt discharge from the hatchery. Alternative plans should include:

1. Description of alternative means of salt control.

2. Cost of alternative plans in dollars per ton, of salt removed from discharge.

G. Such other information pertinent to demonstration of non-practicability as the permitting authority may deem necessary.

III. In determining what permit conditions shall be required, the permit-issuing authority shall consider the following criteria including, but not limited to:

A. The practicability of achieving the 100 mg/L incremental increase.

B. Where the 100 mg/L incremental increase is not determined to be practicable:

1. The impact of the proposed salt input of each alternative on the lower main stem in terms of tons per year and concentration.

2. Costs per ton of salt removed from discharge of each alternative plan.

3. Capability of minimizing the salt discharge.

IV. If, in the opinion of the permitting authority, the database for the hatchery is inadequate, the permit will contain the requirement that the discharger monitor the water supply and the discharge for salinity. Such monitoring program shall be completed within two years and the discharger shall then present the information as specified above.

V. All new and reissued NPDES permits for all hatcheries shall require monitoring of the salinity of the intake water supply and the effluent at the time of peak fish population.

A. Analysis for salinity may be either as total dissolved solids (TDS) or be electrical conductivity where a satisfactory correlation with TDS has been established. The correlation should be based on a minimum of five different samples.

NMED Exhibit 90

APPENDIX C

States NPDES Permits List

LEGEND

NPDES PERMITS
EXPLANATION CODES

COLORADO RIVER BASIN SALINITY CONTROL FORUM
January 1, 2020, through December 31, 2022

NPDES permits are reviewed under two different criteria under Forum policy; these being municipal and industrial. In order for a permittee to be in compliance under the municipal criteria, the increase in concentration between inflow and outflow cannot be greater than 400 mg/L. Forum industrial criteria requires that no industrial user discharges more than 1.00 ton/day. Under Forum policy there can be granted exceptions to these limitations by the states. The following gives an explanation of the current status of the NPDES permits. Because at any given time many of the permits identified in this list are being reviewed, reissued, and/or terminated, and new discharge permits are being filed, this list must be considered as being subject to frequent change.

MUNICIPAL

(M) Municipal user in compliance with Forum policy.

(M-A) Municipal user in compliance with the 400 mg/L incremental increase provision.

(M-B) Municipal user in compliance with the 1 ton per day or 366 tons per year provision for intermittent discharges.

(M-1)* Permit has expired or been revoked. No discharge.

(M-2) Permittee did not discharge during the reporting period.

(M-3) Measurement of TDS is not currently required, but the state and/or EPA plans to require measurements of both inflow and outflow when the permit is reissued.

Measurements of inflow are not consistent with Forum policy;

(M-4A) Therefore, it is not known whether or not this municipal user is in compliance.

(M-4B) However, since outflow concentration is less than 500 mg/L it is presumed that this permit is not in violation of the ≤400 mg/L increase.

(M-5) Permittee is in violation of Forum policy in that there is an increase in concentration of >400 mg/L over the source waters. No provision has been made allowing this violation of Forum policy.

(M-5A) The state and/or EPA is currently working to bring permittee into compliance.

(M-5B) Though discharge is >400 mg/L over source waters, in keeping with Forum policy the permittee has demonstrated the salt reduction is not practicable and the requirement has been waived.

(M-6) This permit requires no discharge or discharge only under rare and extreme hydrologic conditions. Thus, flow and concentration measurements are not required.

(M-7) Insufficient data to know the current status of this permit.

---

* Permits that have been expired or revoked and listed with the M-1 and I-1 explanation codes shall be removed from the NPDES list during the subsequent triennial review.

INDUSTRIAL

(I) Industrial user in compliance with Forum policy.

(I-A) Industrial user in compliance with the Forum's salinity offset policy.

(I-B) Industrial user in compliance with the 1 ton per day or 366 tons per year provision for intermittent discharges.

(I-1)* Permit has expired or been revoked. No discharge.

(I-2) Permittee did not discharge during the reporting period.

(I-3) Measurement of TDS is not currently required, but the state and/or EPA plans to require measurements of both volume and concentration of outflow when the permit is reissued.

(I-4) Either concentration or volume of outflow are not currently being reported, thus the permittee is in violation of Forum policy. It is not known if the discharge is in excess of the <1.00 ton/day requirement.

(I-5) Permittee is in violation of Forum policy in that discharge of salts is >1.00 ton/day. No provision has been made allowing this violation of Forum policy.

(I-5A) The state and/or EPA is currently working to bring permittee into compliance.

(I-5B) Though discharge is >1.00 ton/day, in keeping with Forum policy the permittee has demonstrated the salt reduction is not practicable and the requirement has been waived.

(I-5C) The use of ground water under this permit is for geothermal energy and only heat is extracted. The intercepted salt and water are naturally tributary to the Colorado River System and hence, this discharge does not increase salt in the river. The permit is covered by the Forum's policy on intercepted ground waters.

(I-5D) This permit is in compliance with the Forum's policy for fish hatcheries. The use of the water is a one-time pass through, and the incremental increase in salinity is ≤ 100 mg/l.

(I-5E) This permit is for the interception and passage of ground waters and thus is excepted under the Forum's policy on intercepted ground waters.

(I-6) This permit requires no discharge or discharge only under rare and extreme hydrologic conditions. Thus, flow and concentration measurements are not required.

(I-7) Insufficient data to know the current status of this permit.

NMED Exhibit 90

LEGEND (continued)

NPDES PERMITS
REACH DEMARCATIONS

COLORADO RIVER BASIN SALINITY CONTROL FORUM

In order to provide a better understanding of the location of the various NPDES permits and the geographical sequence in the Colorado River System, each of the following NPDES permits is identified with a Colorado River reach number. The reach numbers have their origin in the old CRSS river model. Though this model is no longer used, the reach numbers assist in understanding the general location of the permits. The reaches are defined as:

100	Upper Main Stem	from headwaters of Colorado River to Colorado River near Cameo
190	Taylor Park	from headwaters of Gunnison River to above Blue Mesa Reservoir
200	Blue Mesa	from above Blue Mesa Reservoir to below Blue Mesa Dam
210	Morrow Point	from below Blue Mesa Dam to Crystal Reservoir
220	Lower Gunnison	from Crystal Reservoir to confluence with Colorado River
300	Grand Valley	from Colorado River near Cameo to confluence with Green River
310	Dolores River	from headwaters of Dolores River to confluence with Colorado River
401	Fontenelle	from headwaters of Green River to Green River near Green River, WY
411	Flaming Gorge	from Green River near Green River, WY to confluence with White and Duchesne Rivers
500	Yampa River	from headwaters of Yampa River to confluence with Green River
510	White River	from headwaters of White River to confluence with Green River
600	Green River	Green River from confluence with White and Duchesne Rivers to confluence with Colorado River
610	Duchesne River	from headwaters of Duchesne River to confluence with Green River
700	Lake Powell	Colorado River from confluence of with Green River to Lees Ferry
710	San Rafael River	from headwaters of San Rafael River to confluence with Green River
801	Upper San Juan River	from headwaters of San Juan River to San Juan near Bluff
802	Lower San Juan River	from San Juan near Bluff to confluence with Lake Powell
900	Glen Canyon to Lake Mead	Colorado River from Lees Ferry to backwaters of Lake Mead
905	Virgin River	from headwaters of Virgin River to backwaters of Lake Mead
910	Lake Mead	from backwaters of Lake Mead to Colorado River below Hoover Dam
920	Lake Mohave	Colorado River from below Hoover Dam down to I-40 bridge
930	Lake Havasu	Colorado River from I-40 bridge to below Parker Dam
940	Parker Dam to Imperial Dam	Colorado River from below Parker Dam to above Imperial Dam
945	Imperial Dam	Colorado River from above Imperial Dam to Gila and Yuma users

EPA NPDES Permits List

LEGEND

NPDES PERMITS
EXPLANATION CODES

COLORADO RIVER BASIN SALINITY CONTROL FORUM
January 1, 2020, through December 31, 2022

NPDES permits are reviewed under two different criteria under Forum policy; these being municipal and industrial. In order for a permittee to be in compliance under the municipal criteria, the increase in concentration between inflow and outflow cannot be greater than 400 mg/L. Forum industrial criteria requires that no industrial user discharges more than 1.00 ton/day. Under Forum policy there can be granted exceptions to these limitations by the states. The following gives an explanation of the current status of the NPDES permits. Because at any given time many of the permits identified in this list are being reviewed, reissued, and/or terminated, and new discharge permits are being filed, this list must be considered as being subject to frequent change.

MUNICIPAL

(M) Municipal user in compliance with Forum policy.

(M-A) Municipal user in compliance with the 400 mg/L incremental increase provision.

(M-B) Municipal user in compliance with the 1 ton per day or 366 tons per year provision for intermittent discharges.

(M-1)* Permit has expired or been revoked. No discharge.

(M-2) Permittee did not discharge during the reporting period.

(M-3) Measurement of TDS is not currently required, but the state and/or EPA plans to require measurements of both inflow and outflow when the permit is reissued.

Measurements of inflow are not consistent with Forum policy;

(M-4A) Therefore, it is not known whether or not this municipal user is in compliance.

(M-4B) However, since outflow concentration is less than 500 mg/L it is presumed that this permit is not in violation of the ≤400 mg/L increase.

(M-5) Permittee is in violation of Forum policy in that there is an increase in concentration of >400 mg/L over the source waters. No provision has been made allowing this violation of Forum policy.

(M-5A) The state and/or EPA is currently working to bring permittee into compliance.

(M-5B) Though discharge is >400 mg/L over source waters, in keeping with Forum policy the permittee has demonstrated the salt reduction is not practicable and the requirement has been waived.

(M-6) This permit requires no discharge or discharge only under rare and extreme hydrologic conditions. Thus, flow and concentration measurements are not required.

(M-7) Insufficient data to know the current status of this permit.

---

* Permits that have been expired or revoked and listed with the M-1 and I-1 explanation codes shall be removed from the NPDES list during the subsequent triennial review.

INDUSTRIAL

(I) Industrial user in compliance with Forum policy.

(I-A) Industrial user in compliance with the Forum's salinity offset policy.

(I-B) Industrial user in compliance with the 1 ton per day or 366 tons per year provision for intermittent discharges.

(I-1)* Permit has expired or been revoked. No discharge.

(I-2) Permittee did not discharge during the reporting period.

(I-3) Measurement of TDS is not currently required, but the state and/or EPA plans to require measurements of both volume and concentration of outflow when the permit is reissued.

(I-4) Either concentration or volume of outflow are not currently being reported, thus the permittee is in violation of Forum policy. It is not known if the discharge is in excess of the <1.00 ton/day requirement.

(I-5) Permittee is in violation of Forum policy in that discharge of salts is >1.00 ton/day. No provision has been made allowing this violation of Forum policy.

(I-5A) The state and/or EPA is currently working to bring permittee into compliance.

(I-5B) Though discharge is >1.00 ton/day, in keeping with Forum policy the permittee has demonstrated the salt reduction is not practicable and the requirement has been waived.

(I-5C) The use of ground water under this permit is for geothermal energy and only heat is extracted. The intercepted salt and water are naturally tributary to the Colorado River System and hence, this discharge does not increase salt in the river. The permit is covered by the Forum's policy on intercepted ground waters.

(I-5D) This permit is in compliance with the Forum's policy for fish hatcheries. The use of the water is a one-time pass through, and the incremental increase in salinity is ≤ 100 mg/l.

(I-5E) This permit is for the interception and passage of ground waters and thus is excepted under the Forum's policy on intercepted ground waters.

(I-6) This permit requires no discharge or discharge only under rare and extreme hydrologic conditions. Thus, flow and concentration measurements are not required.

(I-7) Insufficient data to know the current status of this permit.

NMED Exhibit 90

LEGEND (continued)

NPDES PERMITS
REACH DEMARCATIONS

COLORADO RIVER BASIN SALINITY CONTROL FORUM

In order to provide a better understanding of the location of the various NPDES permits and the geographical sequence in the Colorado River System, each of the following NPDES permits is identified with a Colorado River reach number. The reach numbers have their origin in the old CRSS river model. Though this model is no longer used, the reach numbers assist in understanding the general location of the permits. The reaches are defined as:

100	Upper Main Stem	from headwaters of Colorado River to Colorado River near Cameo
190	Taylor Park	from headwaters of Gunnison River to above Blue Mesa Reservoir
200	Blue Mesa	from above Blue Mesa Reservoir to below Blue Mesa Dam
210	Morrow Point	from below Blue Mesa Dam to Crystal Reservoir
220	Lower Gunnison	from Crystal Reservoir to confluence with Colorado River
300	Grand Valley	from Colorado River near Cameo to confluence with Green River
310	Dolores River	from headwaters of Dolores River to confluence with Colorado River
401	Fontenelle	from headwaters of Green River to Green River near Green River, WY
411	Flaming Gorge	from Green River near Green River, WY to confluence with White and Duchesne Rivers
500	Yampa River	from headwaters of Yampa River to confluence with Green River
510	White River	from headwaters of White River to confluence with Green River
600	Green River	Green River from confluence with White and Duchesne Rivers to confluence with Colorado River
610	Duchesne River	from headwaters of Duchesne River to confluence with Green River
700	Lake Powell	Colorado River from confluence of with Green River to Lees Ferry
710	San Rafael River	from headwaters of San Rafael River to confluence with Green River
801	Upper San Juan River	from headwaters of San Juan River to San Juan near Bluff
802	Lower San Juan River	from San Juan near Bluff to confluence with Lake Powell
900	Glen Canyon to Lake Mead	Colorado River from Lees Ferry to backwaters of Lake Mead
905	Virgin River	from headwaters of Virgin River to backwaters of Lake Mead
910	Lake Mead	from backwaters of Lake Mead to Colorado River below Hoover Dam
920	Lake Mohave	Colorado River from below Hoover Dam down to I-40 bridge
930	Lake Havasu	Colorado River from I-40 bridge to below Parker Dam
940	Parker Dam to Imperial Dam	Colorado River from below Parker Dam to above Imperial Dam
945	Imperial Dam	Colorado River from above Imperial Dam to Gila and Yuma users

APPENDIX E

Colorado River Simulation System
Model Description

COLORADO RIVER SIMULATION SYSTEM
MODEL DESCRIPTION

The Colorado River Simulation System (CRSS) is the official long-term basin-wide planning model used by Reclamation's Upper Colorado and Lower Colorado Regions to simulate future Colorado River system conditions. The model framework used for this process is commercial software called RiverWare™, a generalized river basin modeling software package developed by the University of Colorado through a cooperative arrangement with Reclamation, the Tennessee Valley Authority, and the U.S. Army Corps of Engineers.

CRSS was originally developed by Reclamation in the early 1970s and was implemented in RiverWare™ in 1996. The model projects future river and reservoir conditions on a monthly timestep over a period of decades into the future. CRSS has been used for most major modeling studies on the Colorado River, including several National Environmental Policy Act Environmental Impact Statements (EIS), the Colorado River Interim Guidelines for Lower Basin Shortages and Coordinated Operations for Lake Powell and Lake Mead EIS. CRSS was also the primary modeling tool for system projections in Reclamation's Colorado River Basin Water Supply and Demand Study under WaterSMART.

There are numerous inputs to, and assumptions made by, CRSS with respect to future conditions on the Colorado River. The input data for CRSS includes hydrologic inflows, various physical process parameters such as the evaporation rates for each reservoir, initial reservoir conditions, and the future diversion and depletion schedules for entities in the Basin States and for Mexico. These future schedules are based on demand and depletion projections prepared and submitted by the Basin States. The rules of operation of the Colorado River mainstream reservoirs, including Lakes Powell and Mead, are also provided as input to the model. These sets of operating rules describe how water is released and delivered under various hydrologic and system conditions.

As the period of analysis increases, the uncertainty in these inputs and assumptions also increases. Therefore, a large amount of uncertainty in the corresponding outputs is expected. Consequently, CRSS is not used to predict future conditions, but rather to simulate what might occur. CRSS is especially useful in making a relative comparison between hydrologic and salinity concentration impacts from different alternatives by holding constant most inputs, as well as other key modeling assumptions, so as to isolate the differences due to each alternative. Additionally, sensitivity analyses that answer the question, "What is the sensitivity of the output to a particular set of inputs or assumptions?" are commonly performed.

Future conditions of the Colorado River system are most sensitive to assumptions with respect to future inflows. Because it is impossible to predict the actual future inflows into the system, a range of possible future inflows are analyzed and used to quantify the probability of occurrences of particular events (e.g., higher or lower lake elevations). This technique involves running multiple hydrologic sequences for each scenario or operational alternative. These sequences can be derived from a number of techniques. Depending on the project and planning period, Reclamation has used techniques based on the historical observed natural flow record (1906-2020), the paleo record derived from tree-rings (762-2005), and 112 downscaled Global Climate Model (GCM) projections based on 16 unique GCMs. For this Review, the index sequential method (ISM) was

NMED Exhibit 90

applied to the 1988-2020 "Stress Test" period to generate 33 different future inflow scenarios. The drier "Stress Test" hydrology has become standard in recent CRSS water supply studies. Previous Reviews have used the wetter 1906-present "full record" and "Pluvial Removed" hydrologies.

The CRSS RiverWare™ model includes a salinity module to analyze salinity concentrations throughout the Colorado River Basin. The salinity model simulates the effects of water development projects and the salinity control program (SCP) on future salinity concentration levels in the Colorado River. The salinity control criteria are purposely designed to be long-term and non-degradational goals, rather than exceedance standards such as those used for industry or drinking water. Efforts of the SCP are designed to meet the criteria by implementing, as needed, the most cost-effective salinity control projects. This ensures that the salinity control numeric criteria will continue to be met in the future, even with the salinity impacts produced by increasing Upper Basin depletions.

The model assumes salinity is a conservative water quality parameter, and reservoirs are modeled as fully mixed systems. Salinity module inputs include salinity accompanying hydrologic inflows, initial reservoir salinity concentrations, estimates of salt loading due to agricultural return flows and salt removed by salinity control projects. Model results simulate annual average salinity concentrations at the numeric criteria stations downstream of Hoover Dam and Parker Dam and at Imperial Dam and can be used to analyze the probability of exceeding the numeric criteria in future years.

The salinity module within CRSS is intended for long-term (15 to 20 years) simulation and it is highly sensitive to initial conditions during the first 10 to 12 years.

Modeling Assumptions for the 2023 Triennial Review

The following lists major modeling assumptions in a bulleted format for the 2023 Triennial Review. These assumptions reflect the January 2022 version of CRSS. Documents referenced in these assumptions include the *Colorado River Interim Guidelines for Lower Basin Shortages and Coordinated Operations of Lake Powell and Lake Mead Final Environmental Impact Statement* (FEIS, 2007A), *Record of Decision* (ROD) *for Colorado River Interim Guidelines for Lower Basin Shortages and the Coordinated Operations for Lake Powell and Lake Mead* (Interim Guidelines, 2007B), Colorado River Basin Water Supply and Demand Study (Basin Study, 2012), Colorado River Lower Basin Drought Contingency Plan (LB DCP, 2019), Minute No. 323 to the 1944 U.S. Mexico Water Treaty (Minute 323, 2017), and the Prairie and Rajagopalan (2007) article entitled "A basin wide stochastic salinity model." Refer to these documents for additional detail regarding specific assumptions. All runs were performed using the CRSS long-term planning model.

Key Assumptions Common to All Scenarios Updated Since the 2020 Triennial Review

- Simulations run from January 2023 through December 2040 at a monthly time step
- Initial conditions for all reservoirs are 2022 end-of-calendar year (EOCY) observed values
    - Initial reservoir salt concentrations are December 2022 downstream flow weighted annual average concentrations from SLOAD. A high December 2022 Lees Ferry concentration, used to initialize Lake Powell concentration, explains the early spike in simulation results.
    - Intentionally Created Surplus (ICS) initial balances were updated for January 2023
- Continued Upper Basin Drought Response Operations and other elements of the Upper

NMED Exhibit 90

Basin DCP are not modeled.

- Future water demands for the Upper Division States are based on depletion projections from the 2016 Upper Colorado River Commission (UCRC) Demand Schedule for the Upper Colorado River Division States ("2016 Schedule", 2016).
    - Incorporation of the 2016 schedule required a redesign of layout of Upper Basin water users in CRSS. The new layout more clearly distinguishes between current agriculture uses and future projected growth. Over successive changes to CRSS and its demand schedules agricultural growth uses had been mixed up with present level uses. Growth in agricultural use is modeled at fixed salinity pickup concentrations so high projections of growth, not supported by current trends in agricultural use, resulted in a large increase in salinity loading at the beginning of model simulations. The new schedule and layouts result in approximately 500,000 tons less salt entering the Upper Basin and brings concentration projections in line with historical averages.
    - Reclamation incorporated the 2016 Schedule for the first time in the January 2021 CRSS official model run. The Upper Division States and UCRC assisted with the representation of this new schedule in CRSS. During this process, the need for additional refinements to the representation of Upper Colorado River Basin water use in CRSS was identified. Reclamation is currently working with the Upper Division States and UCRC on such refinements.
- Water Quality Improvement Projects (WQIP) have been updated to reflect historical and projected control levels.

Other Assumptions Common to All Scenarios

- Future hydrologic inflows are generated at 29 separate inflow points or nodes in the Colorado River watershed using the Indexed Sequential Method (Interim Guidelines EIS, Chapter 4.2.5). This technique is applied to the 33-year (1988 through 2020) historical record of calculated natural flows to produce 33 hydrologic inflow sequences or traces for each scenario.
- Future salinity concentrations are generated at 20 nodes in the Colorado River watershed using Reclamation's nonparametric natural salt model. The natural salt model includes annual total flow-salt mass (Upper Basin) and intervening flow-salt mass (Lower Basin) regressions built with 1991-2020 natural flow and salt mass data. The natural salt model provides salt mass based on flows. Salt concentrations are computed from flow and salt mass. Prairie and Rajagopalan (2007) describes the methods used in the basin-wide salinity modeling framework.
- Annual salt loading values from agriculture are assumed constant throughout the simulation horizon. Variations in salt mass resulting from variation in flow conditions (high and low) are not considered; therefore, when computing natural salt, we expect negative natural salt values.
- Salt concentrations on reaches are limited to their historical minimum and maximums with the remainder being stored for later release when concentrations are again within these bounds.
- Future water demands for the Lower Division States (during Normal Conditions) are according to the schedules provided for the 2007 FEIS for the 2007 Interim Guidelines modeling with updates to Nevada's demands in May 2019.
- For 2023-2026, Lake Powell and Lake Mead are operated according to the 2007 Interim Guidelines, LB DCP, and Minute 323. For modeling purposes, these operations are assumed to continue through 2040.
    - Lower Basin and Mexico shortages and surpluses are specified in the 2007 Interim

NMED Exhibit 90

Guidelines and Minute 323, respectively.
    - LB DCP contributions and Mexico Binational Water Scarcity Contingency Plan savings are specified in the LB DCP and Minute 323, respectively
- Lake Mohave, Lake Havasu, Taylor Park and Fontenelle reservoirs are operated in accordance with their existing rule curves (2007 FEIS, Appendix A). The Aspinall Unit, Flaming Gorge, and Navajo are operated according to their existing RODs (Basin Study).
- Yuma Desalting Plant is assumed to not operate.

APPENDIX F

Salinity Economic Impact Model Description

SALINITY ECONOMIC IMPACT MODEL DESCRIPTION

SEIM Background

The Salinity Economic Impact Model (SEIM) estimates the annual quantified damages (economic impacts) incurred in metropolitan and agricultural areas in the Lower Colorado River Basin (LCRB) that depend, either wholly or in part, on Colorado River water.

The SEIM is the current version of a salinity model that was originally developed in the late 1980s by the Milliken Chapman Research Group, Inc. (Lohman, 1988) to quantify the economic impacts of salinity from projects improving water efficiency in the Lower Colorado River Basin. Strategies to improve agricultural water efficiency included concrete-lining canals and retrofitting flood irrigation systems with drip or sprinkler irrigation systems. Prior to the use of salinity models such as the SEIM, the impacts of the salinity reduction on the economies of Lower Colorado River water users were unknown.

The model development in the 1980s was funded by the Bureau of Reclamation to quantify the efforts of the Colorado River Basin Salinity Control Advisory Council (Advisory Council). The Advisory Council's function is to:

> *"…advise the Secretaries of the Departments of the Interior and Agriculture…on all matters relating to efficient and timely planning and execution of salinity control measures…specified in the Colorado River Basin Salinity Control Act."*

The original salinity model estimated the economic impact due to salinity by considering five economic sectors that may be impacted by high-salinity Colorado River water. Over time, the original salinity model was updated and modified as new data became available. Brummer and Yahnke (1999) provided improved agricultural economic impact procedures for all areas except the Metropolitan Water District (MWD) service area. The MWD service area improvements are documented in MWD and Bureau of Reclamation (1999) and included updated procedures and data across all economic sectors.

A second salinity model was developed in the early 2000s based on this revised salinity model to improve the representation of the Central Arizona portion of the original model and support salinity economic impact analysis for the Central Arizona Salinity Study (Bureau of Reclamation, 2003). From 2003 until 2016, these two salinity models were run in tandem whenever an economic impact analysis was needed. In 2016, these two models were combined into a single Excel workbook model or the SEIM.

Beginning in 2015, the SEIM was reviewed by representatives from Arizona, California, and Nevada to provide recommendations on redefining model regions and updating data for use in the 2017 Triennial Review. Another objective of the SEIM review was to improve usability, efficiency, and transparency of the SEIM.

In 2020, Daniel B. Stephens & Associates, Inc. (DBS&A) completed a review of SEIM and updated the model, input data and cost functions where possible (2019a, 2019b, 2020). Major

NMED Exhibit 90

changes included updates to residential impact functions, agricultural crop salinity thresholds, unified methods for calculating agricultural leaching and water utility costs. DBS&A recommend regular updates to input data. In 2022, the SEIM Committee, a subgroup of state and federal work group members, updated crop prices, price indices, water blending data and population projections. Additional updates for non-MWD regions included crop acreages, treatment plant capacities, and industrial water use. MWD also updated recycled water use data.

SEIM Methodology

The SEIM estimates the economic impact attributed to areas receiving Colorado River water with salinity levels greater than a baseline value of 500 mg/L[1] total dissolved solids (TDS) or areas increasing local TDS concentrations due to blending with Colorado River Water higher than 500 mg/L on residential water-using appliances, the treatment and infrastructure replacement costs in the commercial, industrial, and water utilities sectors, and income losses to agriculture. It also estimates the additional costs related to meeting California water quality standards for groundwater and recycled water use in the MWD service area. The model does not calculate an absolute value of the economic impacts due to salinity. Rather, the model estimates salinity impacts from the baseline condition (500 mg/L) and then calculates the change in economic impacts when salinity concentrations rise above or decline below the baseline condition. A few subareas, such as the North West subarea within MWD, typically do not receive Colorado River supplies. As a result, these subareas are not affected by changing Colorado River salinity levels and do not contribute damages to the overall total in the model.

Where possible, published cost data have been used in the SEIM. Crop prices and crop yields were obtained from the United States Department of Agriculture's National Agricultural Statistics Service (USDA-NASS). Five-year (2017 – 2021) averages of state-level crop prices and yields were used unless the county-level crop prices were available. In sectors where new cost data are not available, historical cost data have been indexed to 2021 prices. The Consumer Price Index (CPI) is used for residential and commercial prices (Federal Reserve Bank of St. Louis, 2022a). The Gross Domestic Product Implicit Price Deflator (GDPDef) is used for agricultural prices and revenues (Federal Reserve Bank of St. Louis, 2022b). The Producer Price Index (PPI) was used to estimate salinity costs in the industrial, agricultural (leaching costs only), utilities, groundwater, and recycling economic sectors (Bureau of Labor Statistics, 2022).

Reclamation uses the Colorado River Simulation System (CRSS) to project future salinity levels in the river. These projections incorporate the effect of current and future salinity control projects implemented mainly in the Upper Colorado River Basin through the Colorado River Basin Salinity Control Forum (Forum). In addition to these projected salinity concentrations, SEIM model inputs include projected population, housing, and employment statistics along with projected residential, commercial, and industrial water demands obtained from Forum members. The model currently projects annual economic impacts due to elevated salinity for any year between 2020 and 2040.

The SEIM accepts projected salinity concentrations from the CRSS at three diversion points along the mainstem of the Lower Colorado River. Quantified damages due to salinity concentration are

[1] U.S. EPA's secondary drinking water quality standard

NMED Exhibit 90

estimated for seven economic sectors across five regions. Table 1 summarizes the diversion points, economic sectors and regions that are included in the SEIM.

Table 2 lists the regions and their subareas as represented in the model. It should be noted that some subarea names are county names and the subarea may not include the entire county, only the portion that received Lower Colorado River mainstem waters. The SEIM estimates the annual quantitative damages by diversion point and economic sector for each region and subarea listed above. Table 3 presents the impacted items that are included in each economic sector's categories.

Table 1
Names of Locations, Damage Sectors, and Regions Included in SEIM

Diversion Points	Economic Sectors	Regions
Hoover Dam	Agriculture	Central Arizona
Parker Dam	Residential	Mainstem Arizona
Imperial Dam	Commercial	Mainstem Nevada
	Utility	Mainstem California, Non-MWD
	Industrial	MWD Service Area
	Groundwater[2]	
	Recycling**Error! Bookmark not defined.** & POTW	

Table 2
Subareas within Each Region in SEIM

Region	Subarea
Central Arizona	Phoenix AMA[3], Pinal AMA, Tucson AMA
Mainstem Arizona	Mohave County, La Paz County, Yuma County
Mainstem Nevada	Clark County
Mainstem California Non-MWD	Imperial County, San Bernardino County, Riverside County
MWD	Northwest, Los Angeles, West Basin, Central Basin, San Gabriel, Chino Basin, Orange County, Western Riverside, San Diego, Eastern Riverside

Table 3
Economic Sector Impact Category Items Included in the SEIM

Economic Sector	Impact Category Items
Residential	Water Pipes, Water Heater, Faucet, Garbage Disposal, Clothes Washer, Dishwasher, Water Softener, Detergent
Commercial	Sanitary, Cooling, Irrigation, Kitchen, Laundry, Misc.
Industrial	Process Water, Cooling Tower, Boiler, Sanitation, Irrigation
Water Utilities	Treatment Plant, Distribution System

[2] Only applies to MWD Service Area

[3] These are active management areas (AMA) in Central Arizona in which groundwater use is strictly regulated by the Arizona Department of Water Resources. Nearly 80% of Arizona's population resides in these 3 AMAs.

NMED Exhibit 90

Groundwater	Direct Recharge, Indirect Recharge, Incidental Recharge
Recycled Water	Irrigation, Direct Groundwater Recharge, Indirect Groundwater Recharge
Agriculture	**MWD Subareas Crops:** Strawberry, Nursery, Cut Flowers, Misc. Vegetable, Citrus, Avocado, Vineyard, Pasture/grain, Deciduous, Field Crops **All Other Subareas Crops:** Head Lettuce, Leaf Lettuce, Romaine Lettuce, Broccoli, Cauliflower, Alfalfa Hay, Onions, Avocados, Cantaloupe, Carrots, Oranges, Tangerines, Lemon/Limes, Grapefruit, Table Grapes, Potatoes, Corn, Wheat, Cotton, Barley, Olives, Honeydews, Tomatoes, Leaching Management Costs

The SEIM estimates damages (economic impact) on residential, industrial, commercial, water utility, and agriculture sectors, as well as on groundwater and recycled water. A general description

NMED Exhibit 90

of how each sector is calculated in the SEIM model is provided below.

Figure 1 presents a map of the regions included in the SEIM with shading indicating the portion of each subarea that receives Colorado River mainstem waters, along with the economic sectors impacted within each respective subarea.

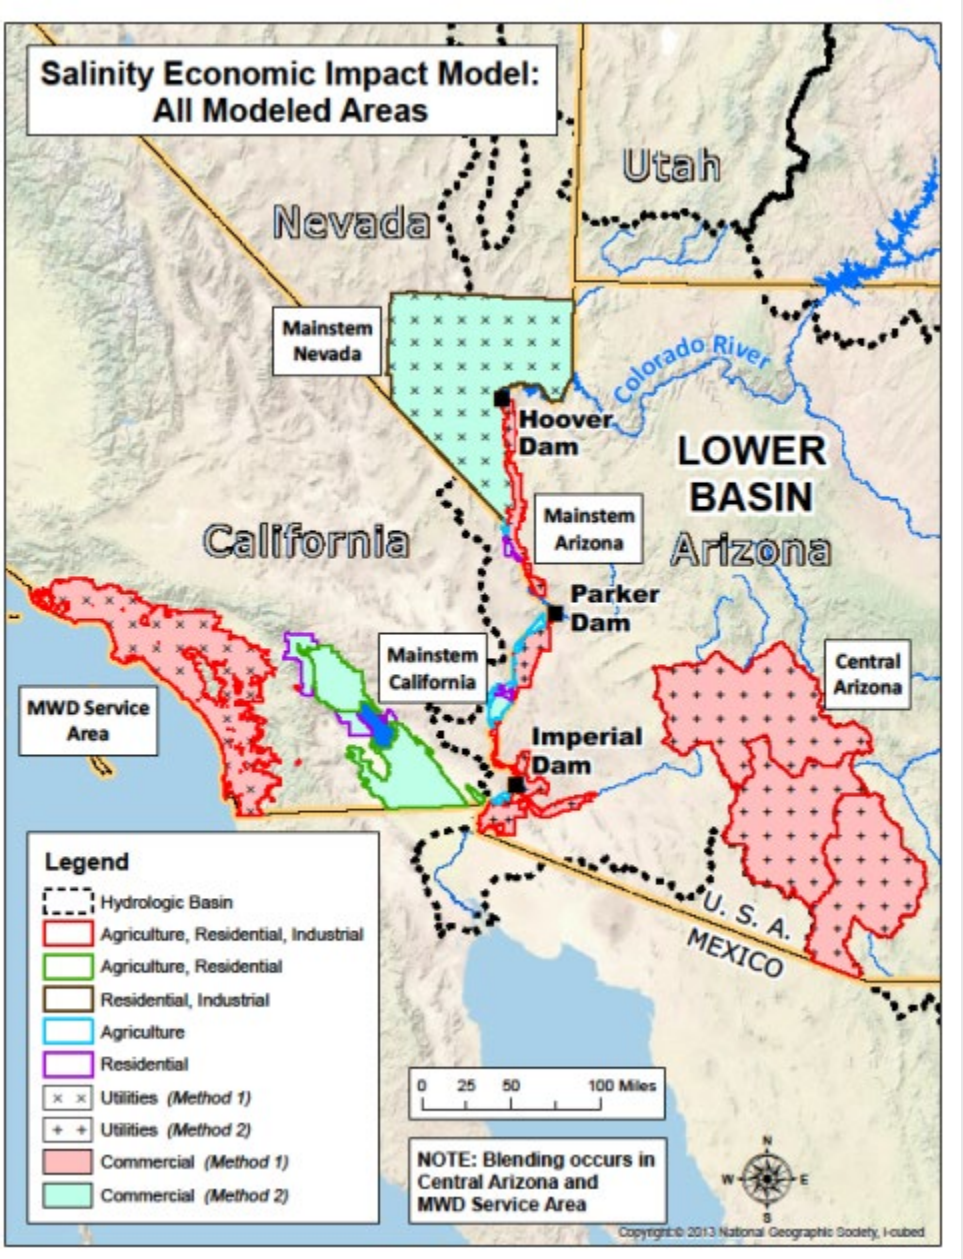

Figure 1 – Economic Sectors for the Regions Included in the SEIM

Residential Damage Calculation

The SEIM model estimates increased annual cost for each subarea based on the reduced useful life of water-using appliances and fixtures from increased average annual salinity, the household adoption rate of appliances and fixtures, the cost of an appliance or fixture, and the number of households. Some additional costs are based on the share of households adopting practices that

NMED Exhibit 90

avoid salinity costs. Input data and useful life functions based on given salinity values are documented in the DBS&A technical memorandums (2019a, 2019b, 2020).

Commercial Damage Calculation

Commercial damages are calculated for six different water use categories: sanitary, cooling, irrigation, kitchens, laundries, and others. The former version of the model calculated costs differently for Mainstem Nevada and Mainstem CA compared to the rest of the areas. The 2020 SEIM was updated so that all subareas use the same method (DBS&A, 2020). The economic costs are calculated based on the water use categories and the estimated costs of using water with an increased TDS concentration.

Industrial Damage Calculation

Salinity damages are estimated in the SEIM for eight major types of industrial water use. Damage functions developed for these categories are applied to the amount of industrial water use by category for each subarea in the model. Industries with processes requiring better quality water have larger costs associated with increasing salinity.

Water Utilities Damage Calculation

The SEIM estimates the damages to water utilities as the total capital cost for water treatment. The former version of the model calculated costs differently for MWD, Mainstem Nevada and Mainstem CA compared to the rest of the areas. The 2020 SEIM was updated so that all subareas use the same method (DBS&A, 2020). The method uses total water treatment plant capacity and estimates unit cost for affected water treatment capital. This new method does not include distribution costs which were deemed to be minimal assuming that treated water corrosivity is stabilized prior to entering the distribution system.

Agriculture Damage Calculation

Agriculture damages are estimated in the SEIM through changes in gross revenue due to reduced crop yields of salt-sensitive crops. Crop yield functions for the most common types of agriculture were developed or used from available research. The number of acres and current crop price per acre were updated with best available data in the current SEIM model. The gross crop revenue is estimated based on the crop yield per acre at a given salinity level and the price per acre for that crop. The revenue computed in the SEIM from the projected salinity concentrations is compared to the revenue computed from baseline conditions to determine the change in revenue from increases in salinity for each subarea in the model. Subareas with more acres of crops sensitive to salinity changes have the largest amount of damages from reduced crop yields.

Groundwater, Recycling and Wastewater

The SEIM calculates the costs of removing salts to maintain water quality requirements for groundwater and recycled water that are used extensively in the MWD service area. MWD estimates the amount of water and wastewater that drains into the groundwater system and the amount that is used for recycled water purposes. Salinity cost functions (costs to desalt these sources of water) are used to estimate the costs at given salinity levels.

SEIM Results

NMED Exhibit 90

The latest SEIM, Version 2.1, dated 2/17/23, was used during the 2023 Triennial Review to estimate quantified damages in the Lower Colorado River Basin. Table 4 presents the diversion point projected salinity concentrations from CRSS and the SEIM average annual quantified damages for the years 2023 and 2040. Table 5 presents the annual reduction in salinity concentration and quantified damages as of 2040, relative to Scenario 1, at each diversion point and as a LCRB total. Scenarios represented in Tables 4 and 5 are as follows:

- 2023 Conditions: Salinity controls as of 2023.
- Scenario 1 - No additional controls beyond 2023 (does not implement the Plan of Implementation identified herein)
- Scenario 2 - Controls associated with limited program funding levels through 2040
- Scenario 3 - Controls associated with fixed implementation through 2040
- Scenario 4 - Controls associated with controlling maximum potential identified salt load by 2040

NMED Exhibit 90

Table 4
Average Annual Colorado River Salinity Concentrations and Annual Quantified Damages, 2023 and 2040

2023							
	Average Annual Concentration (mg/L)			Average Annual Quantified Damages ($ millions)			
Scenario	Hoover	Parker	Imperial	Hoover	Parker	Imperial	Total
Scenario 1	603	607	725	$28.1	$134.7	$185.3	$348.1
Scenario 2	603	607	725	$28.1	$134.7	$185.3	$348.1
Scenario 3	603	607	725	$28.1	$134.7	$185.3	$348.1
Scenario 4	602	607	725	$27.8	$134.7	$185.3	$347.8

2040[4]							
	Average Annual Concentration (mg/L)			Average Annual Quantified Damages ($ millions)			
Scenario	Hoover	Parker	Imperial	Hoover	Parker	Imperial	Total
Scenario 1	609	635	767	$36.3	$185.6	$225.2	$447.0
Scenario 2	592	617	746	$30.8	$160.9	$205.8	$397.4
Scenario 3	588	613	740	$29.5	$155.4	$200.2	$385.1
Scenario 4	538	561	677	$13.0	$84.0	$142.8	$239.9

[4] Scenarios assume 0 tons Paradox controls for 2027-2040

Table 4 shows that average annual salinity concentrations and average annual quantified damages due to salinity at the three key locations (Hoover, Parker, and Imperial) will increase between 2023 and 2040 if no additional controls are built.

Table 5
<u>Reduction</u> in Average Annual Colorado River Salinity Concentration and Annual Quantified Damages in 2040, Relative to Scenario 1 ("No Additional Controls Beyond 2023")

2040[4]							
	Annual Concentration Reduction relative to Scenario 1 (mg/L)			Annual Quantified Damage Reduction relative to Scenario 1 ($ millions)			
Alternative	Hoover	Parker	Imperial	Hoover	Parker	Imperial	Total
Scenario 1	0	0	0	$0.0	$0.0	$0.0	$0.0
Scenario 2	17	18	21	$5.5	$24.7	$19.4	$49.6
Scenario 3	21	22	27	$6.7	$30.2	$25.0	$61.9
Scenario 4	71	74	90	$23.3	$101.5	$82.4	$207.1

NMED Exhibit 90

Table 5 shows that all scenarios with funding and salinity controls greater than 2023 levels (i.e., Scenarios 2, 3, and 4) would reduce average annual salinity concentrations and annual quantified damages relative to Scenario 1, which would hold funding and salinity control at 2023 levels. For example, Scenario 3 (Controls associated with fixed implementation through 2040) would reduce 2040 average annual salinity concentrations by 22 mg/L at Parker, relative to Scenario 1, and would reduce 2040 total annual quantified damages by $62 million, relative to Scenario 1.

STATE OF NEW MEXICO
WATER QUALITY CONTROL COMMISSION

IN THE MATTER OF:

PETITION FOR REGULATORY CHANGE TO
ADOPT AMENDMENTS TO 20.6.4 NMAC –
Standards For Interstate and Intrastate Surface Waters **WQCC 25-75 (R)**

DIRECT TECHNICAL TESTIMONY OF NATHANIEL REYNOLDS

I. INTRODUCTION

My name is Nathaniel Reynolds, and I am presenting this written testimony (**NMED Exhibit 91)** on behalf of the Department concerning proposed changes to numerical Water Quality Standards (WQS or Standards) codified at Title 20, Chapter 6, Part 4, of the New Mexico Administrative Code (20.6.4 NMAC).

My testimony will provide the technical basis and reasoning for proposed amendments to water quality criteria in 20.6.4.900(D) NMAC including:

- Updating the primary contact criterion for total microcystins, and
- Updating the primary contact criterion for cylindrospermospin.

II. QUALIFICATIONS

I am currently employed by the New Mexico Environment Department (NMED) Surface Water Quality Bureau (SWQB) Monitoring and Standards Section (MASS) as a Senior Water Quality Standards Scientist and have held this position since November 2024. I am responsible for evaluating proposed water quality standards and preparing technical water quality standards demonstrations for New Mexico's surface waters in accordance with the New Mexico Water Quality Act (WQA) and the federal Clean Water Act (CWA). I also serve as the Harmful Algal Blooms (HABs) Outreach Coordinator, and an integral member of the initial HABs program

development team. In this role I convened the New Mexico Harmful Algal Blooms Work Group to address HABs in the state with lake managers, governmental agencies and researchers and began a HABs response monitoring strategy and HABs public safety efforts. In July 2026, my efforts in collaboration with the rest of the MASS HABs team culminated in the release of the Department's formalized HAB Advisory Program which included a HAB Advisory Guidance document establishing thresholds for advisories, actions to be taken by resource managers and the recreating public, and a HAB Advisory Map to quickly, clearly, and concisely communicate HAB events and risk to the public.

I hold a Bachelor of Science degree in Chemistry from Loyola University New Orleans. Prior to working for NMED SWQB, I worked in land management with various agencies. From October 2022 to November 2023, I served at the Resource Conservation District of the Santa Monica Mountains collecting biological and fish community data and conducting riparian habitat and lagoon monitoring, water quality testing, and vegetation surveys. Before that, I conducted wildlife monitoring surveys to comply with the National Environmental Policy Act (NEPA) and the Endangered Species Act (ESA) in the Seqouia National Forest with the Great Basin Institute. From May 2021 to November 2021 I was a biological technician at the Carson National Forest where I performed headwater stream restoration and monitoring; assisted in Burned Area Emergency Response (BAER) assessments; assisted with the permit process on varying projects related to acequia construction, watershed restoration, permit compliance, and long-term monitoring; cultivated relationships in collaborative efforts with organizations such as the Albuquerque Wildlife Federation and Trout Unlimited; and participated in cattle exclosure construction, canopy cover surveys, silviculture project monitoring, *E. coli* sampling, safety hazard analysis,

archeological surveys, hosting volunteer events, and data management. An accurate and up-to-date copy of my resume is included as **NMED Exhibit 92**.

III. Proposed Primary Contact Criteria Amendments

In May 2019, the U.S. Environmental Protection Agency (EPA) published its nationally recommended Human Health Recreational Ambient Water Quality Criteria for Microcystins and Cylindrospermopsin (**NMED Exhibit 93**). The EPA based the new criteria on the latest scientific knowledge about the potential human exposure risk effects and the toxins' adverse effects to the liver and kidney as well as the reproductive, respiratory, and digestive systems. These effects range from acute short-term to chronic long-term health effects. The WQCC adopted numeric criteria for the State's designated recreational primary contact use for cyanotoxins affiliated with HABs during the 2020 Triennial Review. In the Department's original petition for the 2020 Triennial Review, the Department proposed:

> "a maximum of 8 micrograms per liter (µg/L) for total microcystins, and a maximum of 15 µg/L for cylindrospermopsin."

However, the San Juan Water Commission (SJWC) suggested that "NMED should justify the proposed duration as "maximum" for the cyanotoxins or change it to a monthly statistic similar to *E. coli* bacteria." The Department responded in its amended petition by proposing revised criteria based on EPA's recommended recurrence frequency, which was adopted by the WQCC as follows:

> ". . .a single sample of total microcystins of 8 µg/L with no more than three exceedances within a 12-month period and a single sample of cylindrospermopsin of 15 µg/L with no more than three exceedances within a 12-month period. . ."

NMED used EPA's Draft Technical Support Document (TSD) for Microcystin and Cylindrospermopsin (**NMED Exhibit 94**) during the 2020 Triennial Review. EPA has now finalized the TSD, which states "EPA recommends that each state or authorized tribe documents the recurrence frequency in the state or tribal water quality standards *or supporting documents*" (emphasis added) **(NMED Exhibit 95).** EPA also affirms that, "[s]tates and authorized tribes may adopt one or both of the national CWA Section 304(a) recommended criteria into their state or tribal water quality standards (WQS) or may use the recommended criteria magnitude values as the basis for swimming advisories and related public notification purposes." In response to the criteria adopted during the 2020 Triennial Review, as well as increasing temperatures, longer growing seasons, and the Bureau's responsive monitoring to recent algae blooms, in 2025 SWQB launched a preliminary Harmful Algal Blooms (HABs) Advisory Program, in collaboration with the New Mexico Department of Health (NMDOH), resource management agencies, and other stakeholders, which is designed to determine and communicate risks associated with HABs to the public quickly and clearly. The Bureau learned a lot from that inaugural year, so in July 2026, SWQB established a *HABs Advisory Program Guidance* document **(NMED Exhibit 96)** that uses documented advisory thresholds, including total microcystin and cylindrospermopsin concentrations, to assign a recreational or swimming advisory status to lakes and other waterbodies, inform the HAB Advisory Map, and notify the public about current health risks[1].

The Department recommends removing the frequency and duration in 20.6.4.900(D) NMAC while preserving the magnitude (i.e., EPA's swimming advisory recommendations) to read:

D. Primary contact: The following criteria apply to this use:

[1] The HABs Advisory Map is available at: https://www.env.nm.gov/surface-water-quality/habs/.

(1) [~~The monthly geometric mean of~~] E. coli bacteria (monthly geometric mean) [~~of~~] 126 cfu/100 mL or MPN/100 ml[~~,~~].

(2) [~~a single sample of~~]E. coli bacteria (single sample) [~~of~~] 410 cfu/100 mL or MPN/100 mL[~~,~~].

(3) [~~a single sample of~~]total microcystins (single sample) [~~of~~] 8 µg/L[~~ with no more than three exceedances within a 12-month period and~~].

(4) [~~a single sample of~~]cylindrospermopsin (single sample) [~~of~~] 15 µg/L[~~ with no more than three exceedances within a 12-month period, and~~].

(5) pH [~~within the range of~~] 6.6 to 9.0[~~ apply to this use. The results for E. coli may be reported as either colony forming units (CFU) or the most probable number (MPN) depending on the analytical method used.~~]

After the Department reformatted this subsection in the proposed rules attached to the Amended Petition, staff realized the Department neglected to retain the references to "single sample" for total microcystins and cylindrospermopsin that were in the proposed rules filed with the original Petition. Therefore, NMED proposes including the language in green above for clarity.

Currently, the Department is using EPA's recommended criteria magnitude values for advisories and related public notification purposes. The SWQB also assesses water quality data against the criteria according to the *Comprehensive Assessment and Listing Methodology* (CALM)[2] and its associated appendices to determine if a waterbody is attaining its uses, including primary contact recreation (20.6.4.12 NMAC). The methodologies contained within the CALM cover the decision-making process for both listing and delisting causes of impairment and the CWA § 303(d)/§ 305(b) Integrated Report (IR) **(NMED Exhibit 30)** details designated use impairment by assessment unit (i.e., waterbody or stream reach). Available microcystin and cylindrospermopsin data are integral to the Department's advisory and impairment determination processes, but each process requires different frequency and duration collection strategies and

[2] https://www.env.nm.gov/surface-water-quality/calm/

considerations. In addition, EPA recognizes in its Final Technical Support Document **(NMED Exhibit 95)** that there are multiple environmental factors that can cause variability in bloom formation and toxin production, and it is appropriate for states to consider a pattern of multiple excursions within a recreational season as well as a pattern of excursions in multiple years (i.e., more than one year) when determining whether the primary contact recreation use is attained.

Therefore, the Department proposes to strike the frequency and duration components for microcystin and cylindrospermopsin from 20.6.4.900(D) NMAC because SWQB has documented the recurrence frequency and duration in supporting documents like the *HABs Advisory Program Guidance* and CALM, similar to other pollutants. SWQB staff with monitoring, assessment, and water quality standards expertise regularly review and update these supporting documents and SWQB issues a public review and comment period for the CALM every two years prior to data assessment. We are still learning about HABs in New Mexico and improving our local dataset to better understand the temporal nature of cyanotoxins and recurrence intervals that may impair the recreational contact use. Documenting sampling and assessment details in supporting documents such as these that are routinely updated by subject matter experts when new information and data become available, which is especially important with emerging contaminants like microcystin and cylindrospermopsin, provides the Department flexibility to ensure SWQB's HAB Advisory Program and CWA § 303(d)/§ 305(b) IR assessment methods are aligned with the current state of knowledge and research, available New Mexico-specific data, evolving methodologies, and best practices.

IV. CONCLUSION

The Department recommends that the Commission adopt the proposed amendments to the Standards filed with the Department's First Amended Petition (**NMED Exhibit 27**), with the

additions of "…(single sample)" as discussed above, and based on the testimony of SWQB's witnesses.

This concludes my direct technical testimony.

PROFESSIONAL EXPERIENCE

New Mexico Environment Department:
Water Quality Standards Scientist: December 2023- Present
Prepared technically and scientifically defensible demonstrations, evaluating proposed amendments for testimony before the Water Quality Control Commission on regulatory changes to water quality standards, in accordance with various State and Federal acts and regulations, reviewed and developed technical reports, briefings, and work plans, managed specific tasks, performed water data collection and analysis, reviewed and developed water quality standards amendments, including Use Attainability Analyses, temporary standards, site-specific criteria, and other scientific studies to support changes to designated uses or water quality criteria, supported and provided technical assistance to outside entities on "third-party proposals" to amend water quality standards. Initiated Harmful Algal Bloom Advisory Program which included creating a working group, monitoring for cyanobacteria and associated cyanotoxins, drafting of NMED's first Harmful Algal Bloom Advisory Guidance.

California Conservation Corps and AmeriCorps Watershed Stewards Program:
Corpsmember: October 2022- November 2023
Served at the Resource Conservation District of the Santa Monica Mountains. With the biology department, collected field data including snorkel surveys for Steelhead Trout, electrofishing and PIT tagging, riparian habitat monitoring, Benthic Macroinvertebrate sample collection, water quality testing, Western Pond Turtle trapping and monitoring, amphibian surveys, lagoon monitoring, seining for Tidewater Gobies, Oak tree monitoring, vegetation surveys, and tree planting. Working with organizational partners, performed data management and report writing, program management, grant budgeting, equipment management, leading volunteers, and public outreach.

Great Basin Institute:
Wildlife Crew Member: May 2022-September 2022
Planned and performed Spotted Owl and Goshawk surveys in the Sequoia Complex Fire scar. Navigation and safety in high intensity burn scar. Understanding and implementing survey protocols as pertaining to the project. Used audio calling to find and establish primary activity centers of birds. Follow up surveys to determine reproductive status of the birds, attempting to establish whether both a male and female are present and find any nests or offspring.

PROFESSIONAL EXPERIENCE

Carson National Forest:
Natural Resources Biological Technician (Seasonal): May 2021-November 2021
Engaged in headwater stream restoration and monitoring utilizing a variety of low impact structures. Assisted in Burned Area Emergency Response assessment for burn severity, soil stability, and potential flooding. Acted as a biological resource advisor on the 2021 Rainbow Family Gathering incident. Gained expertise in permitting by assisting in all stages of the permit process on varying projects from the original consultation for acequia construction to NEPA surveys to implementation of watershed restoration structures, compliance on bridge construction, and long-term monitoring. Cultivated relationships in collaborative efforts with organizations such as the Albuquerque Wildlife Federation and Trout Unlimited. Participated in cattle exclosure construction, canopy cover surveys, silviculture project monitoring, E. coli sampling, safety hazard analysis, wading, archeological surveys, hosted volunteer events, on and off-road driving, UTV operation, and data management.

Valles Caldera National Preserve:
Entomology and Plant Ecology Intern: May 2017 - August 2017 (Comparable to GS-5 40hrs/wk)
Performed electro-shock fish surveys, rangeland monitoring, field identification of plants and vegetation monitoring, invasive plant surveys, invasive plant removal including chemical applications, thistle classification, plant identification, Douglas Fir bark beetle kill surveys, seeding, pheromone traps, pitfall traps, bug sorting and pinning.

Loyola University New Orleans:
Research Assistant: June 2014 - May 2018
Designed and executed synthesis experiments in an organic chemistry lab. Created and maintained detailed lab notebook records documenting all actions, times, and discussion of results. Techniques include 60 MHz and 400 MHz NMR spectroscopy, mass spectrometry, thin layer and column chromatography, Suzuki-Miyaura coupling reactions, recrystallization, precipitation reactions.

Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin

Prepared by:

U.S. Environmental Protection Agency
Office of Water (4304T)
Health and Ecological Criteria Division
Washington, DC

EPA Document Number: 822-R-19-001
Date: May 2019

NMED Exhibit 93

NOTICES

This document has been drafted and approved for publication by the Health and Ecological Criteria Division, Office of Science and Technology, United States Environmental Protection Agency, and is approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

NMED Exhibit 93

FOREWORD

Section 304(a) of the Clean Water Act (CWA) requires the Administrator of the U.S. Environmental Protection Agency (EPA) to publish water quality criteria that accurately reflect the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare that might be expected from the presence of pollutants in any body of water, including ground water.

The EPA is publishing these recommended values under CWA 304(a) for states to consider as the basis for swimming advisories for notification purposes in recreational waters to protect the public. The EPA envisions that if states decide to use the values as swimming advisory values they might do so in a manner similar to their current recreational water advisory programs. Alternatively, states may consider using these same values when adopting new or revised water quality standards (WQS). If adopted by states as WQS and approved by the EPA under CWA 303(c), the WQS could be used for all CWA purposes. States may also wish to consider using these values as both swimming advisory values and WQS.

This document has undergone an EPA intra-agency peer-review process. The Health and Ecological Criteria Division, Office of Science and Technology, Office of Water, U.S. Environmental Protection Agency has completed the final review and the document is approved for publication. The values were derived using the existing peer-reviewed and published science on the adverse human health effects of the toxins including previous EPA analysis, such as the EPA's *Health Effects Support Document for the Cyanobacterial Toxin Microcystins* and *Health Effects Support Document for the Cyanobacterial Toxin Cylindrospermopsin* (HESDs), and the EPA's *Drinking Water Health Advisory for the Cyanobacterial Microcystin Toxins* and *Drinking Water Health Advisory for the Cyanobacterial Toxin Cylindrospermopsin* (Drinking Water Health Advisories) (U.S. EPA 2015a, 2015b, 2015c, 2015d). The EPA used established criteria methodologies (U.S. EPA 2000) and recreation-specific exposure parameters from the EPA's *Exposure Factors Handbook* (EFH) (U.S. EPA 2011) to derive these values. Detailed information that can be found in the EPA's HESDs and Drinking Water Health Advisories is summarized in this document.

The term "water quality criteria" is used in two sections of the CWA section 304(a)(1) and section 303(c)(2). The term has a different legal meaning in each section. In section 304, the term represents a non-regulatory, scientific assessment of effects on human health or aquatic life. The criteria recommendations presented in this document are such a scientific assessment. If the state or authorized tribe adopts water quality criteria associated with specific designated uses as WQS under section 303, and approved by the EPA, they become applicable CWA WQS in ambient waters within that state or tribe. Water quality criteria adopted in state or tribal WQS could have the same numerical values as criteria developed by the EPA under section 304. Alternatively, states and authorized tribes may derive numeric criteria based on other scientifically defensible methods, but the criteria must be protective of designated uses. States and tribes can adopt criteria into their standards. When approved by the EPA, the criteria become Clean Water Act-applicable WQS. Guidelines to assist in modifying the criteria recommendations presented in this document are contained in the Water Quality Standards Handbook (U.S. EPA 2012).

This document provides recommendations only. It does not establish or affect legal rights or obligations. It does not establish a binding norm and cannot be finally determinative of the issues addressed. Agency decisions in any particular situation will be made by applying the CWA and EPA regulations on the basis of specific facts presented and scientific information then available.

1.0 EXECUTIVE SUMMARY

Cyanobacteria, also commonly referred to as blue-green algae, are photosynthetic bacteria that are ubiquitous in nature and are found in surface waters. Environmental conditions that promote excessive growth of cyanobacteria in surface waters can lead to situations in which cyanobacterial cell density is high, known as blooms. Nitrogen and phosphorus levels, the ratio of nitrogen to phosphorus, water temperature, organic matter availability, light attenuation, pH, and water column stratification are environmental factors that play an important role in the development of cyanobacterial blooms and their production of cyanotoxins. Some cyanobacteria, but not all, have the ability to produce toxins. The toxin-producing cyanobacteria contain genes that confer the ability to produce toxins and are referred to as toxigenic cells. The abundance of toxigenic cyanobacteria can vary within the overall cyanobacteria population, between waterbody to waterbody, and over time within a single waterbody.

Microcystins can be produced by a variety of toxigenic cyanobacteria genera, including *Microcystis*, *Anabaena*, *Dolichospermum, Nostoc*, *Oscillatoria*, *Fischerella*, *Planktothrix*, and *Gloeotrichia*. Some of these species can be distributed through the water column, concentrate in the upper layers, or form surface scums depending on environmental conditions. More than 100 microcystin congeners exist, which vary based on amino acid composition. The majority of toxicological data on the effects of microcystins are available for microcystin featuring leucine and arginine (microcystin-LR), which is also a frequently monitored congener. Microcystins are water soluble and tend to remain contained within the toxigenic cyanobacterial cell until the cell breaks and they are released into the water. Microcystins typically have a half-life of four to 14 days in surface waters or may persist longer, depending on factors such as photodegradation, bacteria, and the presence of organic matter. Microcystins can persist even after a toxigenic cyanobacterial bloom is no longer visible.

Cylindrospermopsin can be produced by a variety of toxigenic cyanobacteria species, including *Cylindrospermopsis raciborskii*, *Aphanizomenon*, *Anabaena*, *Lyngbya wollei*, and *Raphidiopsis*. Some of these species tend not to form visible surface scums, and the highest concentrations of total cyanobacterial cells typically occur below the water surface. Two congeners of cylindrospermopsin, as well as two structural analogs, have been identified. Cylindrospermopsin can be retained within the cell or released into the water. The biodegradation of cylindrospermopsin in natural water bodies is a complex process that can be influenced by many environmental factors, including toxin concentration, water temperature, sunlight, and the presence of cell pigments and bacteria. Half-lives of 11 to 15 days and up to eight weeks have been reported for cylindrospermopsin in surface waters.

This document for microcystins and cylindrospermopsin focuses on the human health risks associated with incidental ingestion while recreating in freshwaters containing these harmful cyanotoxins. The recommended cyanotoxin values apply to freshwaters with the recreational designated use. The toxins that are produced by cyanobacteria growing in freshwaters can enter estuarine and marine waters as waters containing the toxins flow downstream. The EPA recognizes that there may be circumstances where harmful cyanobacterial blooms (also known as harmful algal blooms or HABs) can impact downstream marine and estuarine waters. This document provides information on occurrence and incidental ingestion in estuarine and marine waters for states to consider but does not provide recommendations for those waters. Exposure to cyanobacteria and their toxins can also occur through non-recreational pathways such as consumption of cyanotoxin-contaminated drinking water and food (including fish), and during bathing or showering. This document does not address or provide recommendations for non-recreational exposures.

NMED Exhibit 93

The EPA is publishing these recommended values for microcystins[1] and cylindrospermopsin under the Clean Water Act (CWA) section 304(a) for states to consider as the basis for swimming advisories for notification purposes to protect public health in recreational waters. The EPA envisions that if states decide to use the values as swimming advisory values, they would do so in a manner similar to their current recreational water advisory programs. Alternatively, states may consider using these same values when adopting new or revised water quality standards (WQS). If adopted as WQS and approved by the EPA under the CWA section 303(c), the WQS could be used for all CWA purposes. States may also wish to consider using these values as both swimming advisory values and WQS.

The recommended values in this document leverage the information that the EPA collected and evaluated in its *Health Effects Support Document for the Cyanobacterial Toxin Microcystins* and *Health Effects Support Document for the Cyanobacterial Toxin Cylindrospermopsin* (HESDs), and the EPA's *Drinking Water Health Advisory for the Cyanobacterial Microcystin Toxins* and *Drinking Water Health Advisory for the Cyanobacterial Toxin Cylindrospermopsin* (Drinking Water Health Advisories) (U.S. EPA 2015a, 2015b, 2015c, 2015d).

The EPA evaluated the health effects of microcystins and derived a reference dose (RfD) in its 2015 *Health Effects Support Document for the Cyanobacterial Toxin Microcystins* (U.S. EPA 2015d). Exposure to elevated levels of microcystins can potentially lead to liver damage. The critical study for the derivation of the microcystins RfD was conducted by Heinze (1999) based on rat exposure to microcystin-LR in drinking water. The critical effect from this study was slight to moderate liver lesions with necrosis and increased liver weight and enzymes associated with tissue damage. The EPA established the RfD based on microcystin-LR and used it as a surrogate for other microcystin congeners. Monitoring and toxicity studies suggest that the microcystin-LR is the most frequently occurring congener and is more toxic than other congeners of microcystin evaluated (Loftin et al. 2016b; U.S. EPA 2015d; Ito et al. 2002; Rinehart et al. 1994; Vesterkvist and Meriluoto 2003; WHO 1999). The EPA used the RfD to derive its previously published Drinking Water Health Advisories for microcystins (U.S. EPA 2015a) and the recommended values in this document. The dose and critical effects that the EPA used from Heinze (1999) to establish the RfD are supported by a Guzman and Solter (1999) study, also conducted in rats.

The EPA evaluated the health effects of cylindrospermopsin and derived an RfD in its 2015 *Health Effects Support Document for the Cyanobacterial Toxin Cylindrospermopsin* (U.S. EPA 2015c). The kidneys and liver appear to be the primary target organs for cylindrospermopsin toxicity. The critical study that the EPA used to derive the cylindrospermopsin RfD was conducted by Humpage and Falconer (2002, 2003) based on drinking water exposure to mice. Adverse effects on the kidneys were manifested by decreases in urinary protein concentration and increased relative kidney weight. Upon considering all effects observed by Humpage and Falconer (2002, 2003), increased relative kidney weight was considered the most appropriate basis for quantitation (U.S. EPA 2015c). The EPA used the RfD to derive its previously published Drinking Water Health Advisories for cylindrospermopsin (U.S. EPA 2015b).

Based on available noncancer health effects information, the EPA is recommending values protective of primary contact recreation as follows:

[1] Microcystins comprise a class of over 100 congeners and unless specified otherwise, "microcystins" refers to total microcystins.

NMED Exhibit 93

- For microcystins, the recommended recreational value is 8 micrograms (μg)/liter (L).
- For cylindrospermopsin, the recommended recreational value is 15 μg/L.

These values are based on the exposure experienced by recreating children due to their higher exposures compared with other age groups. Given that toxigenic cyanobacterial blooms typically are seasonal events, recreational exposures are likely to be episodic, and may be short term in nature. The EPA recommends that if used as a swimming advisory to protect swimmers at a beach, these values not be exceeded on any single day. If used as a water quality criterion for assessment and listing purposes, the EPA recommends a maximum of three excursions across a recreational season and observation of that pattern across multiple years to reflect seasonal dynamics and occurrence patterns of HABs.

At this time, available data are insufficient to develop quantitative recreational values for total cyanobacterial cell density related to inflammatory health endpoints. The reported epidemiological relationships between cell density exposure and specific health outcomes (e.g., dermal symptoms, eye/ear irritation, fever, gastrointestinal (GI) illness, and respiratory symptoms) are not consistent. The uncertainties related to the epidemiological study differences, such as study size, species and strains of cyanobacteria present, and the total cyanobacterial cell densities associated with significant health effects, do not provide sufficient information to determine a consistent association between total cyanobacterial densities associated with adverse inflammatory health effects. The EPA recognizes that some states have included total cyanobacterial cell density values as an important part of their HAB management strategy. Available information on health endpoints, cell density, and guidelines developed by other authorities on total cyanobacteria cells is described in the Effects Characterization section of the document (section 7.5) and in Appendix D.

Because the EPA's recommendations in this document are cyanotoxin concentrations, it can be helpful for risk-management purposes to understand how this relates to toxigenic cyanobacteria in the waterbody, as the abundance of toxigenic cells in a water body affects the amount of cyanotoxin produced. The number of toxigenic cyanobacteria relative to the number of total cyanobacteria can vary in time and space. Quantifying the abundance of toxigenic cyanobacteria is a better predictor of potential toxin production compared to quantifying total cyanobacteria. The EPA presents a toxigenic cell number based on the number of toxigenic cells that could produce microcystins equivalent to the recommended magnitude. The Effects Characterization section also describes gene-based detection methods (i.e., quantitative polymerase chain reaction (qPCR)) that can target and quantify the toxigenic subpopulation of cyanobacteria that are present in a waterbody.

NMED Exhibit 93

2.0 INTRODUCTION AND BACKGROUND

Section 304(a) of the CWA requires the Administrator of the EPA to publish water quality criteria that accurately reflect the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare that might be expected from the presence of pollutants in any body of water.

Currently there are no U.S. federal water quality criteria or regulations for cyanobacteria or cyanotoxins in drinking water under the Safe Drinking Water Act (SDWA) or in ambient waters under the CWA. No cyanotoxins are included on EPA's priority pollutant list.[2] In 2015, the EPA published non-regulatory Drinking Water Health Advisories (U.S. EPA 2015a, 2015b) to provide information for public health officials or other interested groups on two cyanotoxins (microcystins and cylindrospermopsin) that can affect drinking water quality but are not regulated under SDWA.

The EPA is publishing these recommended values for microcystins and cylindrospermopsin under the CWA section 304(a) for states to consider as the basis for swimming advisories for notification purposes to protect public health in recreational waters. The EPA envisions that if states decide to use the values as swimming advisory values, they would do so in a manner similar to their current recreational water advisory programs. Alternatively, states may consider using these same values when adopting new or revised WQS. If adopted as WQS and approved by the EPA under the CWA section 303(c), the WQS could be used for all CWA purposes. States may also wish to consider using these values as both swimming advisory values and WQS.

The EPA-recommended values in this document leverage the information that the EPA collected and evaluated in its *Health Effects Support Document for the Cyanobacterial Toxin Microcystins* and *Health Effects Support Document for the Cyanobacterial Toxin Cylindrospermopsin* (HESDs), and its *Drinking Water Health Advisory for the Cyanobacterial Microcystin Toxins* and *Drinking Water Health Advisory for the Cyanobacterial Toxin Cylindrospermopsin* (Drinking Water Health Advisories) (U.S. EPA 2015a, 2015b, 2015c, 2015d).

This document for microcystins and cylindrospermopsin focuses on the human health risks associated with incidental ingestion while recreating in freshwaters containing these harmful cyanotoxins. The recommended cyanotoxin values apply to freshwaters with the recreational designated use. The toxins that are produced by cyanobacteria growing in freshwaters can enter estuarine and marine waters as waters containing the toxins flow downstream. The EPA recognizes that there may be circumstances where harmful cyanobacterial blooms (also known as HABs) can impact downstream marine and estuarine waters. This document provides information on occurrence and incidental ingestion in estuarine and marine waters for states to consider but does not provide recommendations for those waters. Exposure to cyanobacteria and their toxins can also occur through non-recreational pathways such as consumption of cyanotoxin-contaminated drinking water and food (including fish), and during bathing or showering. This document does not address or provide recommendations for non-recreational exposures.

International and State Guidelines

The World Health Organization (WHO 2003a) published a series of guideline values for recreational exposure to cyanobacteria associated with incremental severity and probability of health effects at increasing densities of total cyanobacteria and corresponding concentrations of chlorophyll *a* (if

[2] https://www.epa.gov/sites/production/files/2015-09/documents/priority-pollutant-list-epa.pdf

cyanobacteria dominate) (Table 2-1). The WHO also considered the potential for liver damage by microcystins in deriving the recommended total cyanobacterial cell densities. Potential concentrations of microcystins that could be associated with each guidance level are discussed in the WHO document. However, it should be noted that actual microcystin concentrations at each WHO action level could vary depending on the composition of toxigenic strains in the cyanobacterial community present and the dominant species of microcystin producer present in a bloom. For example, at a total cyanobacterial cell density of 100,000 cells/milliliter (mL), an estimated microcystin concentration of 20 µg/L could occur assuming all cells present are toxin-producing *Microcystis* species and the average cellular toxin content was 0.2 picogram (pg) microcystin per cell (WHO 2003a). Microcystin concentrations could range from 50 to 100 µg/L, or higher, if another toxin-producing species, such as *Planktothrix*, is present at the same cell density.

Table 2-1. WHO (2003a) Recreational Guidance/Action Levels for Cyanobacteria, Chlorophyll *a*, and Estimated Corresponding Microcystin Level

Relative Probability of Acute Health Effects	Cyanobacteria (cells/mL)	Chlorophyll *a* (µg/L)	Estimated Corresponding Microcystin Levels (µg/L)
Low	≤ 20,000	≤ 10	< 10[a]
Moderate	> 20,000–100,000	> 10–50	2–4 to 20[a,b]
High	> 100,000	> 50	> 20

[a] WHO estimated that 2 to 4 µg microcystins/L may be expected, with 10 µg/L possible, at a cell density of 20,000 cells/mL if microcystin-producing cyanobacteria are dominant.

[b] At 100,000 cyanobacterial cells/mL, a concentration of 20 µg microcystins/L is likely if the bloom consists of *Microcystis* and has an average toxin content of 0.2 pg/cell.

For these guidelines, the WHO recommended values that included the potential health effects from exposure to total cyanobacteria because it was "unclear whether all important cyanotoxins had been identified and that the health outcomes observed after recreational exposure could be related to cyanobacterial substances other than the well-known cyanotoxins" (WHO 2003a). The different guideline levels were an effort to distinguish between irritative or inflammatory-response symptoms associated with total cyanobacterial cells and the more severe hazard of exposure to elevated concentrations of cyanotoxins, particularly microcystins. The cell-associated inflammatory responses are represented by the low probability of adverse health effects category of ≤ 20,000 cells/mL, corresponding to ≤ 10 µg/L chlorophyll *a* if cyanobacteria dominate. According to the WHO, as the density of cyanobacteria increase above that level, the probability of inflammatory responses increases, and the potential for more severe adverse health effects associated with exposure to the cyanotoxins also increases. The WHO high-risk category includes both > 100,000 cells/mL, corresponding to 50 µg/L of chlorophyll *a*, if cyanobacteria dominate, and > 20 µg/L microcystin levels. Health effects at this level are expected to be primarily due to the toxic effects of microcystins. Very high densities of cells occurring in scums—for example, > 10 million cells/mL or > 5,000 chlorophyll *a*—can be associated with very high concentrations of toxin, for example 2,000 µg/L of microcystins in the top 4 cm of a water body (WHO 2003a). Scums that accumulate along the shoreline due to wind can be associated with a thousand-fold higher density of cells (WHO 2003a).

The WHO guideline value development was informed by results from a review conducted by Chorus and Bartram (1999). A primary study identified in this review was a prospective epidemiology study by Pilotto et al. (1997), which evaluated health effects after recreational exposure to total cyanobacteria and reported associations between total cyanobacterial cell densities and health. Pilotto et al. (1997) found a

significant association among recreators exposed to greater than 5,000 cells/mL. The WHO chose a guideline level of 20,000 cells/mL to represent the upper bound of the "low probability of adverse health effects" category (WHO 2003a). While the association among recreators exposed to greater than 5,000 cells/mL for more than one hour and one or more symptoms reported in Pilotto et al. (1997) was statistically significant, the WHO states that they represented less than 30 percent of the individuals exposed (Chorus and Bartram 1999). Therefore, the level of health effect and the small number of people affected at 5,000 cells/mL were not considered by the WHO to be a basis to justify action (WHO 2003a).

The WHO pointed out that the potential concentration of microcystins could vary depending on the composition of toxigenic strains within the overall cyanobacterial community present and the dominant species of microcystin producer present in a bloom. The WHO states that, at the same cyanobacterial cell density, cyanotoxin levels could approximately double if *Planktothrix agardhii* were the dominant member of the community.

Many countries have adopted the multiple parameters that the WHO discusses for recreational waters including cell density, biovolume, and cyanotoxin concentration (see Table 2-2). Some international authorities have multiple action levels. For brevity, Table 2-2 presents the guideline reflecting the lowest concentration of microcystins or density of cyanobacterial cells or narrative guidelines that recommended or triggered a health protective action for countries that have adopted action levels. For a more complete list of guideline or action levels and recommended actions for international jurisdictions, see Appendix A. The EPA did not identify any recreational guideline levels for cylindrospermopsin established by other international regulatory authorities.

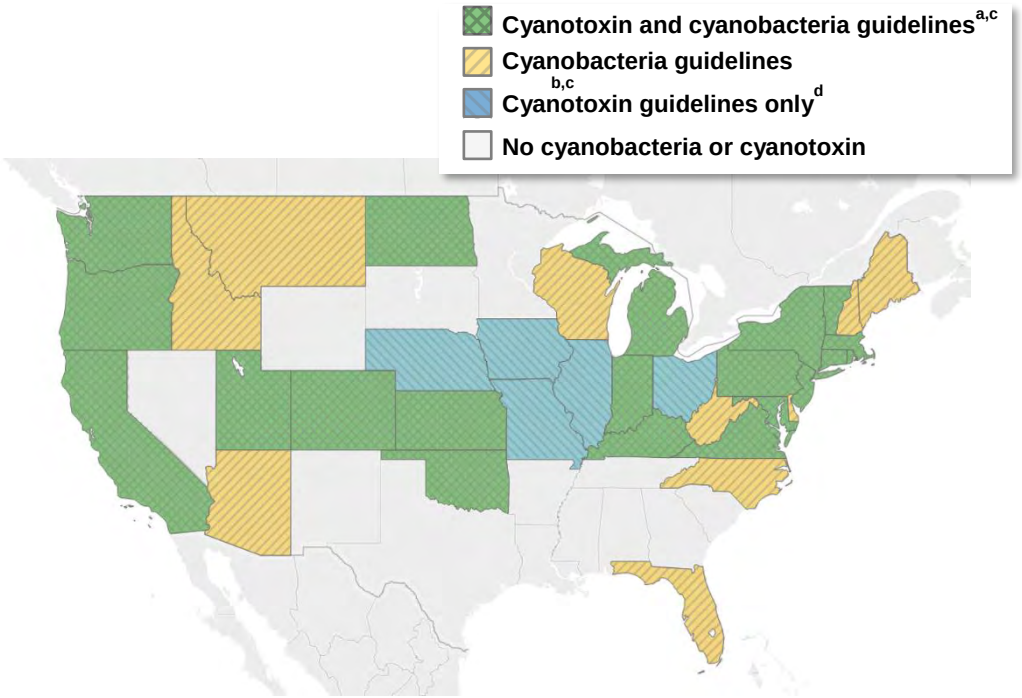
Table 2-2. International Recreational Water Guideline or Action Levels for Cyanobacteria and Microcystins

Jurisdiction	Lowest Recreational Water Guideline/Action Level[a]	Reference
Australia[b]	microcystins (total): $\geq$ 10 µg/L or *Microcystis aeruginosa* (total): $\geq$ 500 to < 5,000 cells/mL or cyanobacteria (total): $\geq$ 0.4 to < 4 mm^3/L (where a known toxin producer is dominant in the total biovolume) or total biovolume of all cyanobacterial material $\geq$ 10 mm^3/L (where known toxins are not present)	Australian Government National Health and Medical Research Council (2008)
Canada	microcystins (total): ≥ 20 µg/L (expressed as microcystin-LR) or cyanobacteria (total): ≥ 100,000 cells/mL	Health Canada (2012)
Cuba	cyanobacteria: > 1 of the species known as potentially toxic or phytoplankton cells: > 20,000 – to < 100,000 cells/mL, > 50 percent of cells cyanobacteria	German Federal Environment Agency (2012)[c]
Czech Republic	cells: > 20,000 cells/mL	German Federal Environment Agency (2012)[c]
Denmark	chlorophyll *a*: > 50 µg/L, dominated by cyanobacteria or visible surface scum	German Federal Environment Agency (2012)[c]
European Union	appropriate monitoring must be implemented if there is a risk of proliferation of algae. Member state authorities responsible must take management measures and provide information immediately if a proliferation of cyanobacteria (or blue algae) occurs.	European Parliament and the Council of the European Union (2006)
Finland	algae (includes cyanobacteria): detected	German Federal Environment Agency (2012)[c]

NMED Exhibit 93

Jurisdiction	Lowest Recreational Water Guideline/Action Level[a]	Reference
France[b]	microcystins: > 25 µg/L or cyanobacteria: > 20,000 to < 100,000 cells/mL (± 20 percent)	German Federal Environment Agency (2012)[c]
Germany	Secchi Disk reading > 1 m and (microcystins): ≥ 10 µg/L or chlorophyll *a* (with dominance by cyanobacteria): ≥ 40 µg/L or biovolume: ≥ 1 mm^3/L)	German Federal Environment Agency (2012)[c]
Hungary	microcystins: ≥ 4 to < 10 µg/L or cell count: ≥ 20,000 to < 50,000 cells/mL or chlorophyll *a* (with dominance by cyanobacteria): ≥ 10 to < 25 µg/L	German Federal Environment Agency (2012)[c]
Italy[b]	microcystin-LR: > 20 µg/L equivalents or cyanobacterial cell count for cyanotoxin-producing species other than those that produce microcystins (e.g., cylindrospermopsin) > 100,000 cells/mL (± 20 percent) or transparency ≤ 1 m and total phosphorus > 20 µg/L and total cyanobacterial cell count > 2,000 to ≤ 20,000 cells/mL (± 20 percent) or transparency ≥ 1 m and total phosphorus > 20 µg/L and total cyanobacterial cell count ≤ 2,000 cells/mL	Funari et al. (2017)
Netherlands	chlorophyll *a*: ≥ 12.5 to ≤ 75 µg/L or biovolume (cyanobacterial cell count): ≥ 2.5 to ≤ 15 mm^3/L	German Federal Environment Agency (2012)[c]
New Zealand[b]	microcystins (total): ≥ 12 µg/L or cyanobacteria (benthic): 20−50 percent coverage of potentially toxigenic cyanobacteria attached to substrate or cyanobacteria (total): > 0.5 to < 1.8 mm^3/L (biovolume equivalent of potentially toxic cyanobacteria) or cyanobacteria (total): > 0.5 to < 10 mm^3/L (biovolume equivalent of the combined total of all cyanobacteria)	Wood et al. (2008)
Poland	visible blooms	German Federal Environment Agency (2012)[c]
Scotland[b]	chlorophyll *a*: ≥ 10 µg/L with dominance of cyanobacteria or cyanobacteria: ≥ 20,000 cells/mL	Scottish Government Health and Social Care Directorates Blue-Green Algae Working Group (2012)
Spain	cyanobacteria proliferation potential (low)	German Federal Environment Agency (2012)[c]
Turkey	microcystin-LR: > 25 µg/L equivalents or cells: ≥ 20,000 to 100,000 cells/mL	German Federal Environment Agency (2012)[c]
World Health Organization (WHO)	cyanobacteria: 20,000 cells/mL or chlorophyll *a*: 10 µg/L (approximately 2-4 µg microcystins/L, assuming cyanobacteria dominance)	Chorus and Bartram (1999); WHO (2003a)

[a] More details are provided in Appendix A.



[b] The lowest guideline values for each quantitative parameter (i.e., cyanotoxin concentration, cyanobacterial cell density, biovolume) are not associated with the same action level. For example, for Australia, the lowest cyanobacterial cell density and biovolume criteria trigger the green level surveillance mode, and the lowest cyanotoxin concentration triggered the red level action mode.

[c] Following the VIIIth International Conference on Toxic Cyanobacteria, the German Federal Environmental Agency compiled and published in 2012 regulatory approaches to the assessment and management of cyanotoxin risks based on contributions by member countries.

NMED Exhibit 93

As of March 2018, approximately 35 U.S. states have implemented cyanobacterial HAB guidelines for recreational waterways. As graphically shown in Figure 2-1, five states have quantitative or qualitative cyanotoxin guidelines only, and 20 states have quantitative guidelines for cyanotoxins, as well as either quantitative or qualitative guidelines for total cyanobacterial cell density. Qualitative guidelines for cell density use visual inspection rather than quantitative detection methods. In addition, 10 states had quantitative guidelines for cyanobacterial cell density only or had qualitative guidelines for cyanobacteria only. Seven states have guideline levels that address toxin-producing cyanobacteria as a proportion of the total cyanobacterial population or include a toxin-specific cyanobacteria cell density (California, Idaho, Maryland, New York, New Hampshire, Oregon, and Virginia). The Karuk Tribe, located in California, developed cell-based values for posting cyanotoxin public health warnings for the tribe's recreational waters (Kann 2014). Its values were based on the site-specific relationships between the cell densities of *Microcystis* and the level of microcystins observed in Karuk waters. For example, in the Klamath River, at 20,000 cells *Microcystis*/mL, the probability of exceeding 4 µg/L microcystins was 55 percent, while at 5,000 cells/mL there were no exceedances. Because the probability of exceeding the microcystins benchmark rapidly increased at cell densities above 5,000 *Microcystis*/mL, the Karuk Tribe uses that value to inform decision-making for health warnings (Kann 2014).

Figure 2-1. State Guidelines for Cyanotoxins and Cyanobacteria in Recreational Water by Type and Scope of Guidelines

[a] Includes states with quantitative cyanotoxin guidelines as well as either quantitative or qualitative cyanobacteria guidelines.

[b] Includes states that either have quantitative cyanobacteria guidelines only or qualitative guidelines only.

[c] The EPA found that Texas and North Carolina published guidelines in the past, but the guidelines were no longer on their websites.

[d] Missouri has presence/absence testing for cyanotoxins and quantitative thresholds.

For brevity, Table 2-3 lists the lowest recreational water guideline or narrative guidelines or action levels for microcystins, cylindrospermopsin, or total cyanobacteria that trigger or recommend a health protective action for U.S. states. For a more complete list of state guideline or action levels see

NMED Exhibit 93

Appendix B. Parameters and values used as the basis for guidelines varied across states, as did the methodologies for developing the values.

Table 2-3. State Guideline or Action Levels for Microcystins, Cylindrospermopsin, and Cyanobacterial Cells in Recreational Water

State	Lowest Recreational Water Guideline or Action Level[a]	Reference
Arizona	Blue-green algae (mean value based on a minimum of two sample events within one peak season): 20,000 cells/mL and Chlorophyll *a* result (mean value based on a minimum of two sample events within one peak season) in target range	Arizona Department of Environmental Quality (2008)
California	Microcystins: 0.8 µg/L	Butler et al. (2012); Cyanobacteria Harmful Algal Bloom Network (2016a, 2016b)
	Cylindrospermopsin: 1 µg/L	
	Toxin-producing cyanobacteria: 4,000 cells/mL	
	Site-specific indicators of cyanobacteria (e.g., blooms, scums, mats)	
Colorado	Microcystin-LR: ≥ 10 µg/L and < 20 µg/L	Colorado Department of Public Health and Environment (2016)
	Cylindrospermopsin: ≥ 7 µg/L	
	Potentially toxic algae are visible	
Connecticut[b]	Combination of visual inspection, cell counts: Visual rank category 2: Blue-green algae cells > 20,000 cells/mL and < 100,000 cells/mL	Connecticut Department of Public Health (CDPH) and Connecticut Energy and Environmental Protection (CDEEP) (CDPH and CDEEP 2017; CDEEP 2017)
Delaware	Thick green, white, or red scum on surface of pond	Delaware Department of Natural Resources and Environmental Control: Division of Water (2016)
Florida	Cyanobacteria bloom	Florida Department of Environmental Protection (2019)
Idaho	*Microcystis* or *Planktothrix*: > 40,000 cells/mL	IDEQ (2015)
	Sum of all potentially toxigenic taxa: ≥ 100,000 cells/mL	
Illinois	Microcystin-LR: > 10 µg/L	Illinois Environmental Protection Agency (2018); Illinois Environmental Protection Agency (2013)
Indiana	Blue-green algae: 100,000 cells/mL	Indiana Department of Environmental Management (2018)
	Microcystin-LR: 4 µg/L	
	Cylindrospermopsin: 8 µg/L	
Iowa	Microcystin: ≥ 20 µg/L	Iowa Environmental Council (2018)
Kansas	Cyanobacteria: ≥ 80,000 and < 250,000 cells/mL	Kansas Department of Health and Environment (2015a); Kansas Department of Health and Environment (2015b)
	Microcystin: ≥ 4 and < 20 µg/L	
Kentucky	Blue-green algae: > 100,000 cells/mL	Kentucky Department for Environmental Protection (2014)

State	Lowest Recreational Water Guideline or Action Level[a]	Reference
	Microcystins: > 20 µg/L	Commonwealth of Kentucky Department for Environmental Protection Division of Water (2015)
Maine	Secchi disk reading < 2 meters caused by algae	Maine Department of Environmental Protection (2013)

Washington	Bloom is forming or a bloom scum is visible (toxic algae may be present); cyanotoxin levels do not exceed thresholds	Hardy and Washington State Department of Health (2008); Hardy and Washington State Department of Health (2011)
	Microcystins: 6 µg/L	
	Cylindrospermopsin: 4.5 µg/L	
West Virginia	Blue-green algal blooms observed and monitored	West Virginia Department of Health and Human Resources (2015)
Wisconsin	Cyanobacteria: > 100,000 cells/mL	Wisconsin Department of Natural Resources (2012); Wisconsin Department of Health Services (2016)
	Visible scum layer	Werner and Masnado (2014) ; Wisconsin Department of Health Services (2016)

[a] More details are provided in Appendix B.
[b] Connecticut states "based on US EPA's draft recreational criterion, CT DPH suggests a cyanotoxin threshold of 4 µg/L microcystin."
[c] The EPA found that Texas published guidelines in the past, but the guidelines were no longer on its website.

NMED Exhibit 93

3.0 NATURE OF THE STRESSORS

This section describes cyanobacteria and cyanobacterial blooms that have the potential to produce microcystins and cylindrospermopsin. It also describes the chemical and physical properties, sources and occurrence information in different media, environmental fate, and toxicokinetics for the cyanotoxins. The information in this section is based on information the EPA presented in its HESDs and Drinking Water Health Advisories (U.S. EPA 2015a, 2015b, 2015c, 2015d). The EPA conducted supplemental literature searches in September 2015 to capture new references related to the following topics:

- Levels of human exposure to cylindrospermopsin or microcystins through recreational water activities.
- Health effects for humans or animals exposed to cylindrospermopsin or microcystins.
- State and international safety levels or criteria for microcystins or cylindrospermopsin.
- Recreational exposure ingestion rates for children's age groups.
- Incidents of pet or livestock adverse health effects, including mortality, due to exposure to cyanotoxins.

For detailed information on these supplemental literature searches and the five research questions that correspond to the bullets above, see Appendix C.

Cyanobacteria are a group of microorganisms that naturally occur in freshwater and marine environments and can be found at higher densities in eutrophic or nutrient-enriched water bodies. Many cyanobacteria are capable of producing toxins, referred to as cyanotoxins, which can adversely affect human health. Under the right conditions of water temperature, light, pH, nutrient availability, and other factors, cyanobacteria can reproduce rapidly, forming what are commonly referred to as cyanobacterial HABs. Other microorganisms can form HABs, but for the purpose of this document the usage of "HABs" refers to cyanobacterial HABs unless otherwise specified.

3.1 Cyanobacteria and Cyanobacterial Blooms

Cyanobacteria are photosynthetic prokaryotes (Seckbach and Oren 2007) and are ubiquitous in the environment. Cyanobacteria smaller than 2.0 µm are known as picocyanobacteria (Jakubowska and Szeląg-Wasielewska 2015). The chloroplast, found in photosynthetic eukaryotes like algae and plants, evolved from an endosymbiotic relationship with cyanobacteria (Kutschera and Niklas 2005). Ecologists historically grouped cyanobacteria, often referred to as "blue-green algae," with eukaryotic algae because they contain chlorophyll *a* and can perform oxygenic photosynthesis. However, cyanobacteria are prokaryotes (i.e., no discrete membrane-bound nucleus or membrane-bound subcellular organelles) and are genetically related to other bacteria in the eubacteria domain. Taxonomically, they are classified in the phylum Cyanobacteria or Cyanophyceae (Carmichael 2008; O'Neil et al. 2012).

Cyanobacteria, including picocyanobacteria, can produce bioactive compounds including toxins, which can be harmful. These biomolecules include hepatotoxic, neurotoxic, and cytotoxic compounds and compounds that can result in allergic reactions (Burkholder and Glibert 2006; Carmichael 1994; Jaiswal et al. 2008; Jakubowska and Szeląg-Wasielewska 2015; Śliwińska-Wilczewska et al. 2018; Volk and

NMED Exhibit 93

Mundt 2007). Studies have shown that exposure to cyanobacterial cells can cause health effects that are independent of the cyanotoxins; this information is detailed in Appendix D.

Under certain conditions, cyanobacteria possessing the toxin synthesis genes, also referred to as toxigenic cyanobacteria, begin producing cyanotoxins. Numerous biotic and abiotic factors can influence not only the dominance of cyanobacteria within the overall phytoplankton community, but also the proportion of toxigenic cyanobacteria relative to non-toxin-producing cyanobacteria (Davis et al. 2009; Hyenstrand et al. 1998; McCarthy et al. 2009; Neilan et al. 2013; Gobler et al. 2016). Multiple species of cyanobacteria are capable of producing the same toxin, such as the microcystins, which can pose a risk to human and animal health (Crawford et al. 2017). Although scientists have observed a generalized relationship between cyanobacteria density or chlorophyll *a* and cyanotoxin concentration, these relationships are affected by the dominance of the toxin-producing cyanobacteria within the overall cyanobacterial community (Zhang et al. 2014; Loftin et al. 2016b).

Members of the genera *Microcystis*, *Dolichospermum* (*Anabaena*), *Nostoc*, *Fischerella*, *Planktothrix* (formerly *Oscillatoria*), and *Gloeotrichia* can produce microcystins (Carey et al. 2012b; Codd et al. 2005; Duy et al. 2000; Stewart et al. 2006c). *Microcystis aeruginosa* occurs mostly at the surface with higher light intensities and in shallow lakes. Kosten et al. (2012) surveyed 143 shallow lakes along a latitudinal gradient (between 5–55°S and 38–68°N) from subarctic Europe to southern South America. *Microcystis* have been documented to occur in blooms on all continents except Antarctica and often dominate phytoplankton assemblages in the summer (O'Neil et al. 2012). *Microcystis* have been documented throughout the United States (Carmichael 2001; Jacoby et al. 2000). Species of cyanobacteria, like *Microcystis*, that occur at or near the surface due to buoyancy and wind, can accumulate on shores and bays where they can form scums (Australian Government National Health and Medical Research Council 2008; WHO 2003b).

Cylindrospermopsin can be produced by a number of cyanobacterial species including *Raphidiopsis raciborskii* (formerly Cylindrospermopsis raciborskii),[3] *Aphanizomenon flos-aquae*, *Aphanizomenon gracile*, *Aphanizomenon ovalisporum*, *Umezakia natans*, *Anabaena bergii*, *Anabaena lapponica*, *Anabaena planctonica*, *Lyngbya wollei*, *Raphidiopsis curvata*, and *Raphidiopsis mediterranea* (B-Béres et al. 2015; Kokocinski et al. 2013; McGregor et al. 2011; Moreira et al. 2013). These species do not tend to form visible surface scums and the highest concentrations of cyanobacterial cells occurs below the water surface (Falconer 2005).

Cylindrospermopsin-producing cyanobacteria occur in tropical or subtropical regions, as well as warmer temperate regions. For example, *Cylindrospermopsis raciborskii* occurs in freshwater ponds, rivers, reservoirs, and eutrophic lakes and has been found in Australia, Asia, Europe, Africa, and South, Central, and North America (Fuentes et al. 2010). According to a survey conducted in Florida in 1999 from June to November, the most frequently observed toxigenic cyanobacteria were *Microcystis* (43.1 percent), *Cylindrospermopsis* (39.5 percent), and *Anabaena* (28.7 percent) (Burns 2008).

Research indicates that cyanotoxins can confer competitive advantage for survival and replication and are associated with physiological functions of cyanobacterial cell signaling, nutrient uptake, iron scavenging, maintenance of homeostasis, and protection against oxidative stress (Holland and Kinnear 2013). Cylindrospermopsin production provides a competitive advantage to cyanobacteria when phosphorus becomes scarce. Bar-Yosef et al. (2010) observed that when phosphorus is scarce, the

[3] Cyanobacteria taxonomy is continuously being revised. The genus *Cylindrospermopsis* has been renamed to *Raphidiopsis*. This document mostly maintains the genus name of *Cylindrospermopsis.*

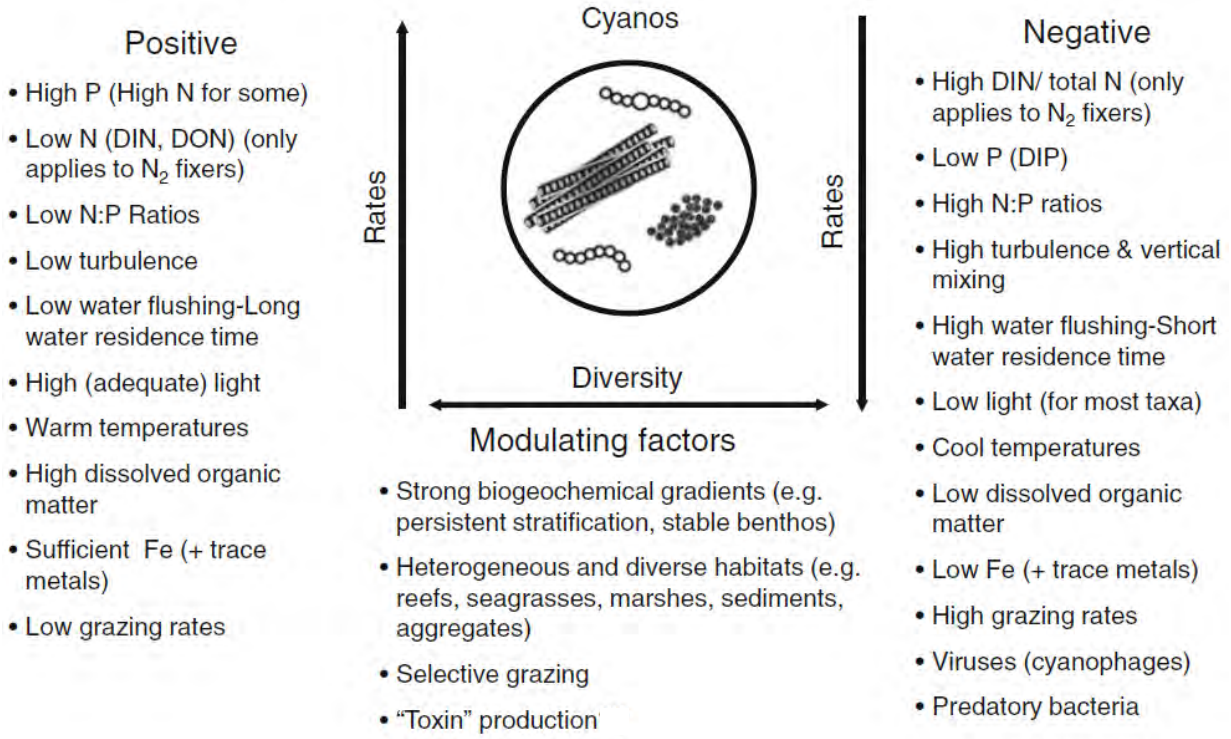
NMED Exhibit 93

cyanobacterium *Aphanizomenon ovalisporum* releases cylindrospermopsin, which causes other microorganisms to release alkaline phosphatase, a compound that will increase available free phosphorus. Subsequently, *Aphanizomenon* can gain access to phosphorus made available by other microorganisms while simultaneously conserving the energy and resources required to express and excrete alkaline phosphatase (Bar-Yosef et al. 2010). The precise ecological function of microcystins has not been determined conclusively (Zurawell et al. 2005). Studies comparing wild-types and mutants of a microcystin-producing species, examining the genes involved in microcystin biosynthesis, and evaluating *Microcystis* colony size have suggested that microcystins play important physiological roles in cyanobacteria, including colony formation (Kaplan et al. 2012; Zurawell et al. 2005). Gobler et al. (2007) observed decreased zooplankton grazing when toxigenic *Microcystis* were actively producing microcystin. Although cyanotoxins can negatively affect humans and other animals, research suggests that the primary functions of cyanotoxins are in cyanobacterial physiology and microbial ecology.

Cyanobacteria can regulate their buoyancy; thus, they can actively seek water depths with optimal growth conditions and will enlarge their gas vesicles to adapt to turbulent conditions. When weather conditions shift from turbulent to strongly stratified, excessively buoyant cells may accumulate at the surface because the regulation of buoyancy takes a few days (Australian Government National Health and Medical Research Council 2008, WHO 2003b). When the rate of cyanobacterial cell growth exceeds the loss rate for a population, positively buoyant, floating cyanobacterial cells can also accumulate at the surface (Falconer 1998). This accumulation can form a visibly colored scum on the water surface, which can contain more than 10,000 cells/mL (Falconer 1998). Scums can pose an elevated health risk to recreational users. The floating scum can be concentrated by prevailing winds in certain surface water areas, especially at the shore as is the case for *Microcystis*. Scums have frequently been reported to accumulate cells and cyanotoxin concentration by a factor of 1,000 or more, with million-fold accumulations resulting in pea soup consistency (Australian Government National Health and Medical Research Council 2008; WHO 2003b).

The microbial community can be complex and variable. It can consist of multiple different species and strains of cyanobacteria and other microbes. Microbial interactions can occur within blooms, such as competition and adaptation between toxic and nontoxic cyanobacterial strains, as well as impacts from viruses and zooplankton grazers like *Daphnia* (large generalist grazers), copepods, and cladocerans (Ger et al. 2014). Each of these microbial-related factors can cause fluctuations in bloom development and composition.

3.1.1 Environmental Factors Influencing Occurrence of Cyanobacteria and Cyanotoxins



A variety of physical, chemical, and environmental factors can influence both cyanobacteria proliferation and toxin production, including nutrient (e.g., nitrogen and phosphorus) concentrations, water temperature, light levels, and pH. Other factors include water turbulence, mixing, and flushing, oxidative stressors, and interactions with other biota (e.g., viruses, bacteria, and animal grazers), as well as their combined effects (Paerl and Otten 2013a, 2013b). See Figure 3-1.

Total cyanobacterial density in a bloom and cyanotoxin concentration are not always closely related. Cyanotoxin concentrations depend on the dominance and diversity of species and strains within the bloom along with environmental and ecosystem influences on bloom dynamics (Chorus et al. 2000; Hitzfeld et al. 2000; WHO 1999). Cyanotoxin production can vary among strains and clones of a single species (Carmichael 1994; Utkilen and Gjølme 1992) and within and between blooms (Codd and Bell 1985). Growth phase also can influence cyanotoxin production (Jaiswal et al. 2008). Biomass and toxin production do not necessarily coincide (section 7.5.2.3). Francy et al. (2016) modeled the relationship of

NMED Exhibit 93

environmental variables compared to cyanotoxin levels. They demonstrated that some environmental factors such as measures of the algal community (e.g., phycocyanin, cyanobacterial biovolume, and cyanobacterial gene concentrations) and pH are strongly correlated with microcystin concentrations.

Figure 3-1. Environmental Factors Influencing Total Cyanobacterial Blooms, Reproduced from Paerl and Otten (2013b)

Cyanotoxins can be found inside the cell (i.e., intracellular) or external to the cell in the water (i.e., extracellular). The proportion of intracellular versus extracellular cyanotoxin can vary. Extracellular microcystins (either dissolved in water or bound to other materials) typically are less than 30 percent of the total microcystin concentration in source water (Graham et al. 2010). Most of the microcystins are intracellular and released into the water when the toxigenic cyanobacterial cells rupture or die. Cylindrospermopsin can be retained within the cyanobacterial cell or released. The ratio of intracellular to extracellular cyanotoxin can change depending on the growth phase with as much as 50 percent of cylindrospermopsin produced by *Cylindrospermopsis raciborskii* released extracellularly (Griffiths and Saker 2003).

A complex interplay of environmental factors dictates the spatial and temporal changes in the concentration of cyanobacterial cells and their toxins with respect to the dominant species. Factors such as the amount and timing of nutrient supply (i.e., nutrient concentration and nutrient loading), the relative proportions of nutrients (i.e., nitrogen to phosphorus ratio), dissolved organic matter availability, temperature, and light attenuation, as well as other physico-chemical processes, can play a role in shaping cyanobacterial bloom composition and cyanotoxin production (Paerl and Huisman 2008; Paerl and Otten 2013b).

Some cyanobacteria possess toxin genes that enable them to produce toxins, while other cyanobacteria do not contain toxin genes and therefore cannot produce toxins. For example, cyanobacteria that can produce microcystins contain a collection of genes, called "*mcy*" genes, that when expressed produce

NMED Exhibit 93

microcystins. Multiple species of cyanobacteria can contain this set of genes. Together these species comprise microcystin-producing toxigenic cyanobacteria. Ten genes are in the microcystin gene cluster, *mcyA* through *mcyJ* (Tillett et al. 2000). Different researchers have studied the occurrence and prevalence of these genes within cyanobacteria populations.

Environmental factors can provide competitive advantages to *Microcystis* relative to other phytoplankton (Jacoby et al. 2000; Marmen et al. 2016). Evidence suggests that these environmental factors also affect the relative abundance of microcystin-producing strains and non-microcystin-producing strains (Marmen et al. 2016). *Microcystis* thrive in warmer temperatures, with optimal growth and photosynthesis occurring above 25°C (O'Neil et al. 2012). A Japanese study between May and November 2006 found that the toxin-producing species, *Microcystis aeruginosa*, dominated in months with relatively higher water temperatures, while the non-toxin-producing species, *M. wesenbergii*, dominated in months with lower water temperatures (Imai et al. 2009). The genetic composition of the bloom can also influence the degree of toxicity associated with an algal bloom. Lee et al. (2015) found that *Microcystis* typically comprised less than one percent of the total cyanobacterial abundance in Vancouver Lake, Washington, but the majority of the *Microcystis* cells contained the toxin-producing gene. Despite comprising a small percentage of the total cyanobacterial community in this lake, *Microcystis* were the sole microcystin-producing cyanobacteria and were responsible for microcystin concentrations that exceeded the WHO guidelines several times throughout the sampling period. In addition, increases in phosphate concentrations were associated with increases in both toxigenic and non-toxigenic *Microcystis* and with toxin production. The authors note that quantifying *Microcystis mcyE* gene (one of the genes responsible for toxin production) copy number, rather than relying solely on visual cell counts, might be a better estimate of overall cyanotoxin concentration (Lee et al. 2015).

Zhang et al. (2015) observed that low flow conditions favored total cyanobacteria and higher flow conditions favored green algae. Loftin et al. (2016a) suggest that low stream flow, shallow depth, and high water-column light penetration in Piedmont streams favored periphyton occurrence (mixture of algae, cyanobacteria, heterotrophic bacteria, and detritus).

Phytoplankton competition and food web interactions occur as blooms develop, persist, and decline, thereby impacting cyanotoxin concentrations in surface waters. In addition, potential warming of surface waters and changes in precipitation could result in changes in ecosystem dynamics that lead to more frequent formation of cyanobacteria blooms and their associated toxins (Paerl et al. 2011; Paerl and Huisman 2008; Paerl and Otten 2013b).

3.1.1.1 Nutrients

Nutrients, particularly nutrient over-enrichment, are key environmental drivers that influence the proportion of cyanobacteria in the phytoplankton community, the cyanobacterial biovolume, cyanotoxin production, and the impact that cyanobacteria may have on ecosystem function and water quality (Yang et al. 2016a; Beaulieu et al. 2013; Paerl et al. 2011). Cyanobacteria have been shown to dominate the phytoplankton communities in eutrophic lakes (Downing et al. 2001; Monchamp et al. 2014). Phosphorus loading has been linked to the proliferation of cyanobacteria and the shift toward cyanobacterial dominance of the phytoplankton community (O'Neil et al. 2012). However, it is important to consider both phosphorus and nitrogen when considering the occurrence of toxigenic cyanobacterial blooms. Cyanobacterial toxin concentrations are also associated with nutrient levels (Wang et al. 2002); however, different cyanobacteria species use organic and inorganic nutrient forms differently. Dolman et al. (2012) found that total cyanobacterial biomass was higher in lakes with above-

average nitrogen and phosphorus concentrations and that concentrations of all cyanotoxin groups were higher in lakes with higher total nitrogen and total phosphorus concentrations.

Paerl (2008) demonstrated that nitrogen and phosphorus additions, both independently and together, can stimulate primary productivity and *Cylindrospermopsis raciborskii* biomass. Elevated nitrogen and phosphorus loading can enhance the growth and cyanotoxin levels of *Microcystis* blooms and microcystin synthetase gene expression (Gobler et al. 2007; O'Neil et al. 2012; Marmen et al. 2016). Gobler et al. (2007) found that *Microcystis* dominance and toxin production was stimulated by elevated nitrogen and suppressed by nitrogen limiting conditions. Toxin production may cause the inhibition of grazing by mesozooplankton and further accumulation of cyanobacterial cells. Willis et al. (2015) found the highest growth rates for environmental isolates of *Cylindrospermopsis raciborskii* were observed with the addition of nitrogen.

The relative abundance of nitrogen and phosphorus can be an important consideration in regards to toxigenic cyanobacterial blooms. Loadings of nitrogen, or phosphorus, or both, to water bodies from agricultural, industrial, and urban sources influences the development of total cyanobacterial blooms and are associated with cyanotoxin production (Paerl et al. 2011). Smith (1983) was the first to describe a strong relationship between the relative amounts of nitrogen and phosphorus in surface waters and toxigenic cyanobacterial blooms. Smith proposed that cyanobacteria should be superior competitors under conditions of nitrogen limitation because of their unique capacity for nitrogen fixation, although many cyanobacteria like *Microcystis* that produce toxins do not fix nitrogen. Many toxigenic cyanobacterial blooms are comprised of non-nitrogen-fixing genera and in the presence of elevated phosphorus, nitrogen can be a limiting factor for biomass proliferation and microcystin production (Gobler et al. 2007). Schindler et al. (2008) demonstrated that lower nitrogen inputs relative to phosphorus loadings can lead to dominance of nitrogen-fixing cyanobacteria in mesocosm- and ecosystem-scale experiments in prairie and boreal lakes. Otten et al. (2012) reported higher average microcystin concentrations and a higher prevalence of toxigenic *Microcystin* biomass at sites that had narrower TN:TP ratios (< 20) in Lake Taihu, China. Fortin et al. (2015) demonstrated that the dominance of *Microcystis* depended on the ratio of nitrogen to phosphorus, with a (mass) ratio 11:1 resulting in the highest abundance of *Microcystis*, whereas the concentrations of each nutrient were significant factors affecting the amount of biomass that could be generated.

Cyanotoxin concentration can be related to cyanobacterial cell abundance, which is facilitated by nutrient availability (Welker 2008), so nutrient concentration can be correlated to cyanotoxin concentration. Yuan et al. (2014; 2015) developed nutrient thresholds related to microcystin concentrations, cyanobacterial biovolume, and chlorophyll *a*. Nutrient availability, environmental conditions, and ecosystem interactions can affect the production and amount of toxins that cells produce and release (Bar-Yosef et al. 2010; Dolman et al. 2012; Graham et al. 2004; Paerl et al. 2001). For example, both nitrogen and phosphorus have been shown to promote the production of microcystins during bloom events (Davis et al. 2009; Gobler et al. 2016; Ha et al. 2009). Horst et al. (2014) found a significant positive relationship between cellular microcystin amounts and nitrate concentration with nitrogen limitation related to lower cell quotas of microcystin. Ha et al. (2009) found that microcystin concentrations were highly associated with *mcyA* gene copies and that high concentrations of nitrates and ammonium increased microcystin production by promoting the growth of toxigenic *Microcystis*. Elevated phosphorus has been shown to favor toxigenic strains over non-toxin strains coupled with higher intracellular toxin concentrations (Boopathi and Ki 2014; Burford et al. 2016).

Soluble phosphates and nitrates may also result in the increased production of microcystins (ILS 2000; O'Neil et al. 2012; Paerl and Scott 2010; Wang et al. 2010). Davis et al. (2009) found that growth rates

NMED Exhibit 93

of toxigenic *Microcystis* were higher than nontoxic strains as temperature increased in the presence of elevated soluble phosphorus and that toxigenic cells contained more copies of the gene *mcyD* under these conditions. The authors conclude that lakes experiencing this combination of factors could experience more toxic blooms (Davis et al. 2009). In the Sacramento-San Joaquin delta in California nitrogen and phosphorus are available in non-limiting amounts and facilitate persistence of total cyanobacterial blooms (Berg and Sutula 2015). A study by Lehman et al. (2015) characterizes nitrogen sources of a *Microcystis* bloom in the San Francisco Estuary using stable isotopes. They reported that ammonium from the Sacramento River was the likely sole source of the nitrogen for most of the bloom, overriding nitrate contributions from the San Joaquin River.

Jacoby et al. (2000) characterized multiple physical and chemical environmental factors associated with blooms in the summer of 1994 and 1995 at Steilacoom Lake, Washington. The dominance of *Microcystis aeruginosa* in the lake was associated with low nitrogen-to-phosphorus ratios and low nitrate-nitrogen with sufficient ammonium-nitrogen. Microcystin concentrations were positively correlated with increasing soluble reactive phosphorus concentrations with the highest microcystin concentrations associated with a low ratio of soluble nitrogen to soluble reactive phosphorus (less than five). The authors reported that microcystin production per gram cyanobacterial biomass was not consistent, thus no relationship was found between *Microcystis aeruginosa* abundance and microcystin concentration. A significant positive relationship between total phosphorus concentrations and total cyanobacteria densities was observed in both years of the study (Jacoby et al. 2000).

During bloom events, nutrients on a local scale are incorporated into the production of biomass and decrease in the water column within the bloom, even in eutrophic water bodies. Kuniyoshi et al. (2013) showed that phosphate deficiency resulting from exponential biomass production can result in approximately seven-fold increase in microcystin synthesis. Bar-Yosef et al. (2010) reported that cylindrospermopsin-producing *Aphanizomenon* excrete cylindrospermopsin when phosphorus-limiting conditions occur within the bloom, to induce other cells to produce and excrete alkaline phosphatase, thus increasing availability of extracellular inorganic phosphate. Cylindrospermopsin is energetically cheaper for the cell to produce relative to alkaline phosphatase (Raven 2010) and coupled with a high-affinity phosphorus uptake protein also found in these cells, allows *Aphanizomenon* to increase rapidly, outcompeting other cyanobacteria and dominate a bloom (Bar-Yousef et al. 2010). Preußel et al. (2014) observed that cylindrospermopsin is actively released from *Aphanizomenon ovalisporum* cells subjected to phosphorus limitation, a condition that occurs during the exponential biomass production in a bloom event.

Eutrophic systems already subject to bloom events are prone to further expansion of these blooms due to additional nitrogen inputs, especially if these nutrients are available from internal sources. As the trophic state increases, aquatic systems absorb higher concentrations of nitrogen (Paerl and Huisman 2008; Paerl and Otten 2013b). Recent surveys of cyanobacterial and algal productivity in response to nutrient pollution across geographically diverse eutrophic lakes, reservoirs, estuarine and coastal waters, and in different experimental enclosures of varying sizes demonstrate that greater stimulation is routinely observed in response to both nitrogen and phosphorus additions. Further, this evidence suggests that nutrient co-limitation is widespread (Elser et al. 2007; Lewis et al. 2011; Paerl et al. 2011). These results suggest that reductions in nutrient concentration would reduce eutrophication and cyanobacterial bloom expansion. For example, analysis of observational data collected at high spatial scales support the idea that controlling total phosphorus and total nitrogen could reduce the frequency of high microcystin contamination events by reducing the biomass of total cyanobacteria in the system (Orihel et al. 2012; Scott et al. 2013; Yuan et al. 2014). In addition, reduction of phosphorus in the absence of concurrent

reductions in nitrogen loading may not effectively control the growth, toxicity, or both of cyanobacteria such as *Microcystis* (Gobler et al. 2016). Study authors concluded that reduction of specific nutrient species, such as soluble forms of nitrogen and phosphorus, could reduce the dominance of toxigenic cyanobacteria in the lake microbial community, which could, in turn, decrease the incidences of elevated toxin levels (Davis et al., 2010; Gobler et al. 2016).

3.1.1.2 Temperature

Cyanobacterial blooms commonly occur from spring to early fall in various regions of the United States (Wynne and Stumpf 2015). Conditions such as elevated water temperatures and increased vertical stratification in lakes and reservoirs can support proliferation of total cyanobacteria (Paerl and Huisman 2008). The increasing body of laboratory and field data (Carey et al. 2012a; De Senerpont Domis et al. 2007; Huisman et al. 2005; Jeppesen et al. 2009; Kosten et al. 2012; Reynolds 2006; Wagner and Adrian 2009; Weyhenmeyer 2001) suggest that an increase in temperature may influence cyanobacterial dominance in phytoplankton communities. Some cyanobacteria have higher optimal growth temperatures compared with other phytoplankton and can proliferate at higher water temperatures by outcompeting these other phytoplankton groups (Elliott 2010; Paerl et al. 2011). Warmer water temperatures favor surface bloom-forming cyanobacterial genera because they are heat-adapted, and their maximal growth rates occur at relatively high temperatures, with optimum growth temperatures ranging from 30 to 35°C and optimum microcystin production ranging from 20 to 25°C (Giannuzzi 2018; Reynolds 2006; Robarts and Zohary 1987; WHO 2003b). As the growth rates of the eukaryotic taxa decline in response to warming water temperature, cyanobacterial growth rates reach their optima. Davis et al. (2009) found in four U.S. lakes that concurrent increases in temperature and phosphorus concentrations yielded the highest growth rates of toxic *Microcystis* cells, which led them to conclude that eutrophication and warm temperatures may promote the growth of toxic, rather than nontoxic, populations of *Microcystis* leading to blooms with higher microcystin content.

Cyanobacteria are typically known to proliferate in warm water environments such as tropical and temperate lakes and rivers, but they can also proliferate in cooler water environments under mesophilic and psychrophilic conditions (Seckback and Oren 2007). Cyanobacteria are also found in Antarctic habitats where they play a significant role in microbial ecosystem dynamics by providing fixed carbon via photosynthesis (Singh and Elster 2007). Cyanobacteria can grow in these extreme environments because they can adapt to survive freeze/thaw cycles and they can metabolize at near 0°C (Singh and Elster 2007).

The increase in water column stability associated with higher temperatures, less flow, and shallower water can also favor total cyanobacteria growth (Carey et al. 2012a; Wagner and Adrian 2009). In a study of 143 shallow lakes sampled along a latitudinal transect ranging from subarctic Europe to southern South America, Kosten et al. (2012) reported the percentage of cyanobacteria relative to total phytoplankton biovolume increased steeply with temperature in the lakes. The series of conditions most likely to result in cyanobacterial dominance begin with elevated winter–spring rainfall and runoff, followed by protracted periods of summer drought where temperatures, vertical stratification, and water residence times all increase simultaneously (Paerl and Otten 2013b).

Indirectly, warming can increase nutrient concentrations by enhancing mineralization (Gudasz et al. 2010; Kosten et al. 2009; Kosten et al. 2010) by temperature- or anoxia-mediated sediment phosphorus release (Jensen and Andersen 1992; Søndergaard et al. 2003). Thus, increases in temperature can indirectly increase cyanobacterial biomass through its effect on nutrient concentrations. Others have suggested that warmer conditions may raise total phytoplankton biomass through an alteration of top-

down regulation by selective grazing that favors larger size phytoplankton species and cyanobacterial blooms (Jeppesen et al. 2009; Jeppesen et al. 2010; Teixeira-de Mello et al. 2009). The relationship between temperature and cyanobacterial dominance can be explained not only through a temperature-related effect on the competitive advantage of cyanobacteria, but also by factors such as the percent area covered and the volume of the lake taken up by submerged macrophytes (Carey et al. 2012a; Kosten et al. 2012).

Cylindrospermopsis raciborskii was first identified in the tropics but has also been increasingly found in temperate regions since it was first found in North America in 1955 (Hong et al. 2006). *Cylindrospermopsis raciborskii* blooms are most likely to occur between the temperatures of 25 to 32°C but can sustain biomass at temperatures as low as 11°C (Antunes et al. 2015). In Florida, *C. raciborskii* was found to be the dominant cyanobacteria species in one lake all year round (Burns 2008). In 2006, *C. raciborskii* was detected in lakes in southern Louisiana (Fuentes et al. 2010). Conditions promoting its growth were shallow, warm surface water (over 30°C) and low light intensities. The highest densities of *C. raciborskii* were observed from June through August with densities ranging from 37,000 cells/mL to more than 160,000 cells/mL. In a study of two lakes directly connected to Lake Michigan, Hong et al. (2006) found low levels of *C. raciborskii* only in the late summer, and these were associated with elevated bottom water temperatures and phosphorus concentrations.

3.1.1.3 Sunlight

Sunlight availability and turbidity can have a strong influence on the cyanobacteria species that predominate, as well as the depth at which they occur (Carey et al. 2012a; Falconer 2005). The authors (Carey et al. and Falconer) found a greater proportion of the total phytoplankton biovolume attributable to cyanobacteria in lakes with high rates of light absorption. They could not establish cause and effect from their field data, but other controlled experiments and field data have demonstrated that light availability can affect the competitive balance among a large group of shade-tolerant species of cyanobacteria, primarily *Oscillatoriales* and other phytoplankton species (Scheffer et al. 1997; Smith 1986).

3.1.1.4 pH Levels

Total cyanobacterial blooms intensify and persist at pH levels between six and nine (Caraco and Miller 1998; WHO 2003a). Kosten et al. (2012) noted that pH affected cyanobacteria abundance in lakes along a latitudinal transect from Europe to southern South America. The percentage of cyanobacteria in the 143 shallow lakes sampled highly correlated with pH, increasing as the pH increased. Shapiro (1984) hypothesized that cyanobacteria have a competitive advantage over other phytoplankton species because they are efficient users of carbon dioxide in water. When dissolved carbon dioxide is high (low pH), conditions favor growth and replication of the green algal colonies over the blue-green cyanobacteria (Caraco and Miller 1998; Shapiro 1984). At alkaline pH levels, inorganic carbon is present as carbonate anion rather than as carbon dioxide, carbonic acid, or bicarbonate anion. This situation favors the growth of cyanobacteria because they can carry out photosynthesis when the levels of dissolved carbon dioxide are very low (high pH). The blue-green algae have a much higher photosynthetic demand for the dissolved carbon dioxide allowing them to out compete the green algae for the limited supply (Caraco and Miller 1998; Shapiro 1984). Thus, a higher water column pH can correlate with a higher proportion of cyanobacteria in an algal bloom.

The Caraco and Miller (1998) study suggests that pH and dissolved carbon dioxide, although chemically linked, are also independent factors in bloom dynamics because, even when dissolved carbon dioxide in

water is mechanically enriched, an alkaline pH still favors growth of the cyanobacteria over the green algae if nutrient inputs are constant.

3.2 Cyanotoxins

Much of the information and the studies summarized in this section for microcystins and cylindrospermopsin are described in detail in the EPA's HESDs and Drinking Water Health Advisories for microcystins and cylindrospermopsin (U.S. EPA 2015a, 2015b, 2015c, 2015d). The EPA's HESDs established the scientific basis for the EPA Drinking Water Health Advisories and also informed the EPA in developing these ambient water quality criteria (AWQC) or swimming advisories. This section summarizes the information that is provided in more detail in the EPA's HESDs. Additional information can be found in the EPA's HESDs for microcystins and cylindrospermopsin (U.S. EPA 2015c, 2015d).

3.2.1 Chemical and Physical Properties

Structurally, microcystins are monocyclic heptapeptides that contain seven amino acids joined end to end and then head to tail to form cyclic compounds that are comparatively large; molecular weights range from approximately 800 to 1,100 g/mole for the different congeners (e.g., microcystin-LR is 995.17 g/mole). The cyclic peptides include more than 100 congeners of microcystins (Niedermeyer 2014). Figure 3-2 provides the structure of microcystin where X and Y represent variable amino acids. Although substitutions mostly occur in positions X and Y, other modifications have been reported for all the amino acids (Puddick et al. 2015).

The microcystin congeners are named based on their two variable amino acids (Carmichael et al. 1988). For example, microcystin-LR, the most common congener (Carmichael 1992). The letters used to identify the variable amino acids are the standard single letter abbreviations for the amino acids found in proteins. The variable amino acids are usually the L-amino acids as found in proteins. In Figure 3-2, which shows the structure of microcystin-LR, leucine is in the X position and arginine is in the Y position. Table 3-1 lists the most common microcystin congeners, including the amino acids in the X and Y positions.

There are other variants of microcystins besides those that arise because of the two interchangeable amino acids on the microcystin ring. For example, demethylated congeners have been observed in Europe; Wejnerowski et al. (2018) identified demethylated forms of microcystin-RR and microcystin-LR in a toxigenic cyanobacterial bloom in Poland. Observations of demethylated microcystins suggest that more than 200 microcystin congeners are possible.

NMED Exhibit 93

Figure 3-2. Structure of Microcystin (Kondo et al. 1992)

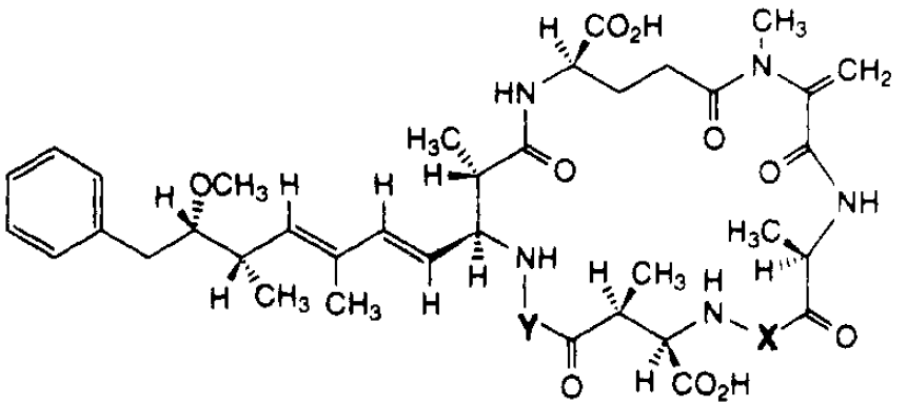


Table 3-1. Abbreviations for Selected Microcystins (Yuan et al. 1999)

Microcystin Congeners	Amino Acid in X	Amino Acid in Y
Microcystin-LR	Leucine	Arginine
Microcystin-RR	Arginine	Arginine
Microcystin-YR	Tyrosine	Arginine
Microcystin-LA	Leucine	Alanine
Microcystin-LY	Leucine	Tyrosine
Microcystin-LF	Leucine	Phenylalanine
Microcystin-LW	Leucine	Tryptophan

The preponderance of toxicological data on the effects of microcystins result from tests using the microcystin-LR congener. Toxicity data suggest that microcystin-LR is as potent as or more potent than other studied microcystins and that the most toxic microcystins are those with the more hydrophobic L-amino acids (e.g., -LA, -LR, and -YR); the least toxic are those with hydrophilic amino acids, such as microcystin-RR (U.S. EPA 2015d; Ito et al. 2002; Rinehart et al. 1994; Vesterkvist and Meriluoto 2003; WHO 1999). Data on the -RR, -YR, and -LA congeners, however, are limited, and toxicity values cannot be derived for them. Therefore, values developed from data specific to microcystin-LR can represent other present microcystin congeners.

Table 3-2 provides chemical and physical properties of microcystin-LR. Microcystins are water soluble. In aquatic environments, the cyclic peptides tend to remain contained within the cyanobacterial cell and are released in substantial amounts only when the cell walls are broken down (cell lysis).

Cylindrospermopsin is a tricyclic alkaloid with the molecular formula of $C_{15}H_{21}N_5O_7S$ (Ohtani et al. 1992) and a molecular weight of 415.43 g/mole. It is a dipolar ion with localized positive and negative charges (Ohtani et al. 1992). The chemical structure of cylindrospermopsin is presented in Figure 3-3(a). Two naturally occurring congeners of cylindrospermopsin have been identified, 7-epi-cylindrospermopsin (the epimer of cylindrospermopsin) and 7-deoxycylindrospermopsin; see Figure 3-3(b) and (c) (de la Cruz et al. 2013; Norris et al. 1999). Recently, Wimmer et al. (2014) identified two new analogs, 7-deoxy-desulfo-cylindrospermopsin and 7-deoxy-desulfo-12-acetylcylindrospermopsin,

NMED Exhibit 93

from the Thai strain of *Cylindrospermopsis raciborskii*. However, it is not clear if these are cylindrospermopsin congeners, precursors, or degradation products.

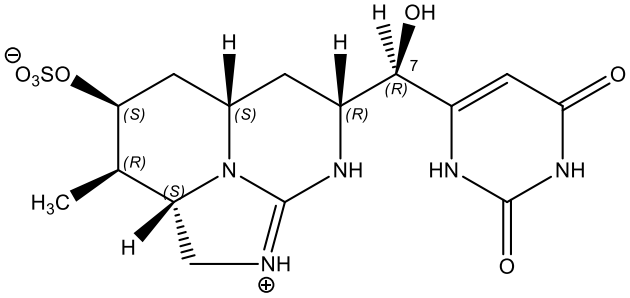

Table 3-2. Chemical and Physical Properites of Microcystin-LR

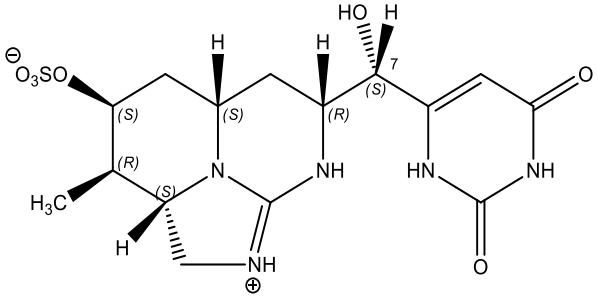
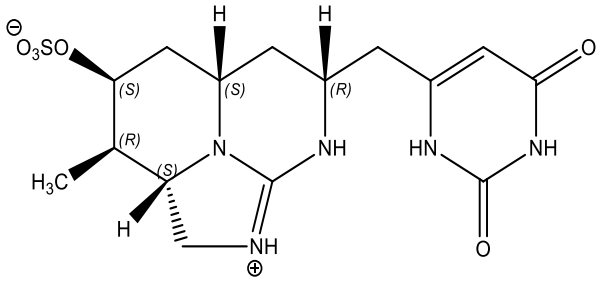
Property	Microcystin-LR
Chemical Abstracts Registry (CAS) Number	101043-37-2
Chemical Formula	$C_{49}H_{74}N_{10}O_{12}$
Molecular Weight	995.17 g/mole
Color/Physical State	Solid
Boiling Point	Not available (N/A)
Melting Point	N/A
Density	1.29 g/cm^3
Vapor Pressure at 25°C	N/A
Henry's Law Constant	N/A
Log Octanol-Water Partition Coefficient (K_{ow})	2.16; -1.41 to 1.67 as pH decreases
Soil Organic Carbon-Water Partition Coefficient (K_{oc})	N/A
Solubility in Water	Highly*
Other Solvents	Ethanol and methanol



Sources: Chemical Book (2012); TOXLINE (2012); Ward and Codd (1999) and McCord et al. (2018) for log K_{ow}.
* Microcystin congeners vary in their relative solubility in water.

Figure 3-3. Structure of Cylindrospermopsin and Structurally Related Cylindrospermopsins (de la Cruz et al. 2013)



(a) Cylindrospermopsin

(b) 7-epi-cylindrospermopsin (the epimer of cylindrospermopsin)

(c) 7-deoxycylindrospermopsin

The physical and chemical properties of cylindrospermopsin are presented in Table 3-3. Cylindrospermopsin is highly soluble in water (Chiswell et al. 1999; Moore et al. 1998). It is isolated for commercial use mostly from *Cylindrospermopsis raciborskii*. Some relevant physico-chemical properties of cylindrospermopsin could not be identified, and no physico-chemical properties were found for the structurally related cylindrospermopsins.

Table 3-3. Chemical and Physical Properties of Cylindrospermopsin

Property	Cylindrospermopsin
CAS Registry Number	143545-90-8
Chemical Formula	$C_{15}H_{21}N_5O_7S$
Molecular Weight	415.43 g/mole
Color/Physical State	White powder

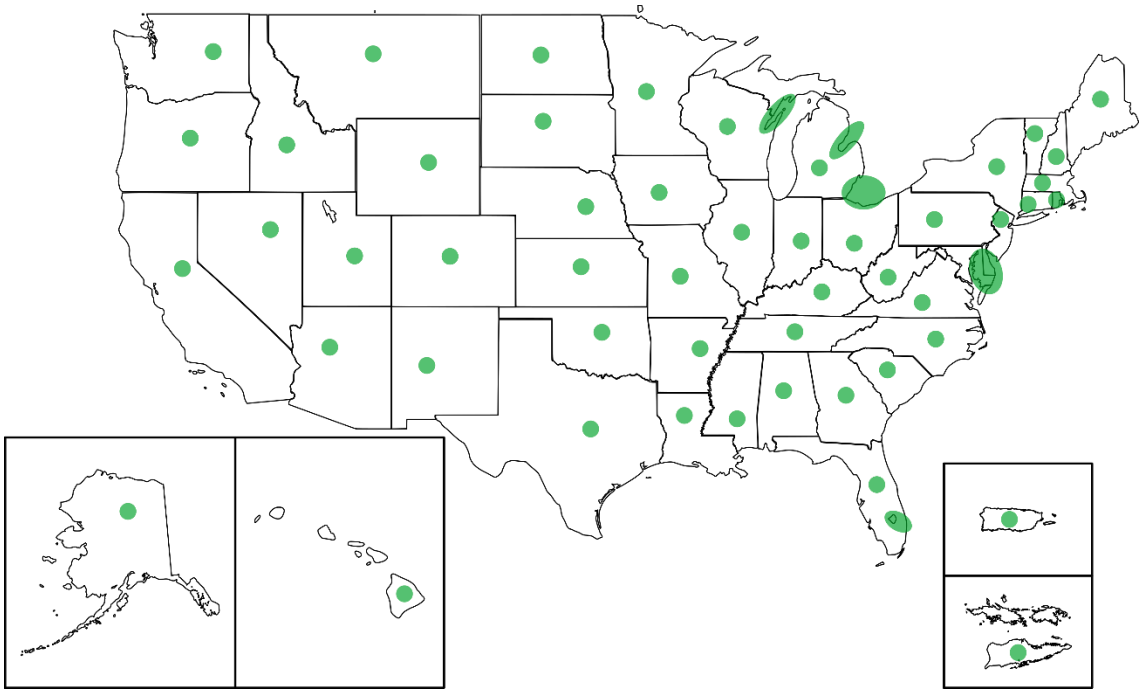
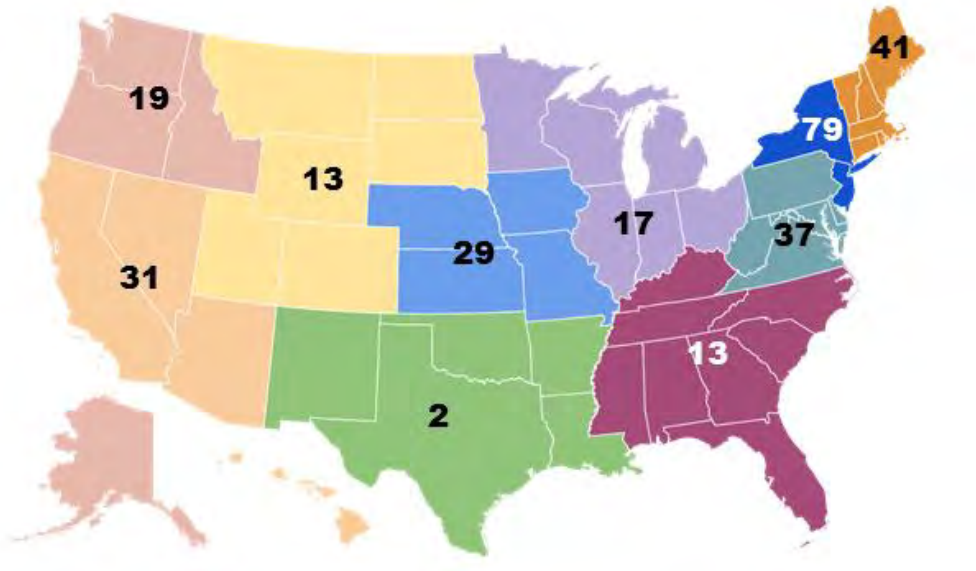
3.2.2 Sources and Occurrence in Surface Waters



Because they are a natural part of algal communities, cyanobacteria are commonly observed in freshwater systems. The occurrence of HABs has been documented in surface waters of all 50 states as well as U.S. territories between 2006 and 2015 as shown in Figure 3-4 (Richlen 2016; WHOI 2016). Figure 3-4 also identifies areas where more widespread HAB problems have occurred (e.g., parts of the Great Lakes).

Figure 3-5 shows the number of 2017 freshwater HAB recreational notices states publicly reported, organized by the EPA region between June 2 and August 1, 2017. To develop this regional summary map, the EPA researched and compiled publicly available reports posted on states' websites between these dates. During that time, states reported at least 281 notices for freshwater HABs with reported microcystin concentrations ranging from not detected (i.e., below the limit of detection) to 382 µg/L. These notices included cautions, warnings, public health advisories, and public health warnings due to

NMED Exhibit 93



the presence of total cyanobacteria, cyanotoxins, or both. These notices can last for multiple days. The review was not exhaustive and might not reflect all the monitoring, beach, or general health advisories (e.g., some advisories at local or county-level may not be posted on the state website). Thus, the number of actual HAB notices during this time might be higher. In addition, many states have only recently begun to monitor HABs, so monitoring may be limited.

Figure 3-4. Generalized Distribution of Cyanobacterial HABs in the United States and Territories

[a] Graphic adapted from a Woods Hole Oceanographic Institute (WHOI) map of HABs that occurred between 2006 and 2015. It reflects input from HAB experts with broad experience in HAB events and reports to the U.S. National Office for Harmful Algal Blooms (Richlen 2016; WHOI 2016). Each state that has experienced one or more cyanobacterial HAB is indicated with a single green dot. Larger green ovals mark areas where more widespread cyanobacterial HAB problems occurred.

Figure 3-5. State-reported HAB Notices by EPA Region, June 2 to August 1, 2017

NMED Exhibit 93

3.2.2.1 Microcystins

Microcystins are the most common cyanotoxins found worldwide and have been reported in surface waters in most of the states in the United States (Funari and Testai 2008; Loftin et al. 2016b; U.S. EPA 2009). Dry-weight concentrations of microcystins in surface freshwater toxigenic cyanobacterial blooms or surface freshwater samples reported worldwide between 1985 and 1996 ranged from 1 to 7,300 µg/g. Water concentrations of extracellular plus intracellular microcystins ranged from 0.04 to 25,000 µg/L. The remainder of this section provides examples of microcystin concentrations reported in ambient waters in the United States.

The EPA (U.S. EPA 2009) reported on the 2007 National Lakes Assessment (NLA), a national probability-based survey of the nation's lakes, ponds, and reservoirs. The NLA provided estimates of the condition of natural and man-made freshwater lakes, ponds, and reservoirs greater than 4 hectares (10 acres) and at least one meter deep. The 2007 NLA study surveyed 1,028 inland lakes and included measured microcystin concentrations, total cyanobacterial cell counts, and chlorophyll *a* concentrations. Microcystins were quantified using enzyme-linked immunosorbent assays (ELISA) with a detection limit of 0.1 µg/L (Loftin et al. 2016b). At each lake site, crews collected samples at a single station located at the deepest point in the lake and at ten stations around the lake perimeter. Due to the design of the survey, samples were taken at random and not necessarily where a bloom was occurring.

The 2007 NLA found that total cyanobacteria were detected in 98 percent of samples and were the dominant member of the phytoplankton community in 76 percent of samples (Loftin et al. 2016b; U.S. EPA 2009). Subsequent analysis indicated that potential microcystin-producing species occurred in 95 percent of samples (Loftin et al. 2016b). Microcystins were the most commonly detected class of cyanotoxins found in 32 percent of lakes in the contiguous United States (Loftin et al. 2016b; U.S. EPA 2009) and 39 percent of streams in the southeastern United States (Loftin et al. 2016a). Microcystins present in lakes ranged from the limit of detection (0.1 µg/L) to 225 µg/L with a mean concentration of 3.0 µg/L (detections only). Approximately 1.1 percent of lake samples exceeded 10 µg/L microcystins, and approximately 27 percent and 44 percent of lakes exceeded the WHO low-risk threshold for cyanobacterial abundance and chlorophyll *a*, respectively (Loftin et al. 2016b).

Lakes in states with microcystins levels > 10 µg/L reported in the 2007 NLA are shown in Table 3-4. The 2007 NLA data show two states (North Dakota and Nebraska) had nine percent of samples above 10 µg/L. Other states including Iowa, Texas, South Dakota, and Utah also had samples that exceeded 10 µg/L, but the frequency of detection was lower. Several of the 2007 NLA samples in North Dakota, Nebraska, and Ohio exceeded 20 µg/L (192, 225, and 78 µg/L, respectively).

In 2012, the EPA expanded on the 2007 NLA to include smaller water bodies in this statistically designed survey. Results represent the population of natural lakes, ponds, and reservoirs across the lower 48 states (not including the Great Lakes or the Great Salt Lake). To be included, in the survey lakes had to be larger than 2.47 acres (1 hectare), at least 3.3 feet (1 meter) deep, with a minimum quarter acre (0.1 hectare) of open water (U.S. EPA 2016). Data were collected from 1,038 lakes selected from a stratified random sample based on ecoregion, state, and surface area in the larger inference population (the set of 111,818 lakes). The NLA used thresholds established by the WHO to determine risk of exposure to cyanotoxins. Microcystins were detected in 39 percent of lakes monitored, but less than one percent exceeded the WHO estimates for microcystins at moderate or high risk of exposure. Less than one percent of lakes are in the most and moderately disturbed condition (i.e., have a high or moderate risk of exposure), and 99 percent are either least disturbed or show no detection of microcystins. Between 2007 and 2012, the percentage of lakes categorized as most disturbed for

microcystins did not change (U.S. EPA 2016), even though there was a significant increase in the detection of microcystins (+9.5 percent).

Table 3-4. States Surveyed as Part of the 2007 NLA with Water Body Microcystin Concentrations above 10 µg/L (U.S. EPA 2009)

State	Number of Sites Sampled	Percentage of Samples with Detection of Microcystins > 10 µg/L	Maximum Detection of Microcystins
North Dakota	38	9.1 percent	192 µg/L
Nebraska	42	9.1 percent	225 µg/L
South Dakota	40	4.9 percent	33 µg/L
Ohio	21	4.5 percent	78 µg/L*
Iowa	20	4.5 percent	38 µg/L*
Utah	26	3.6 percent	15 µg/L*
Texas	51	1.8 percent	28 µg/L*

*Single sample.

The NLA used total cyanobacterial cell counts as an indicator of water quality impacts of microcystins; 15 percent of lakes were classified in the most disturbed condition, 23 percent were classified as moderately disturbed, and 61 percent were classified as least disturbed. Between 2007 and 2012, there was a statistically significant increase (+8.3 percent) in the number of lakes in the most disturbed category for cyanobacterial cell counts. Lakes that were considered most disturbed exceeded the WHO recreational levels of concern (20 µg of microcystins/L).

A survey conducted during the spring and summer of both 1999 and 2000 in more than 50 lakes in New Hampshire found measurable microcystin concentrations in all samples (Haney and Ikawa 2000). Microcystins were analyzed by ELISA and were found in all the lakes sampled with a mean concentration of 0.1 µg/L.

A survey conducted in Florida in 1999 found potential microcystin-producing genera in water samples, including, *Microcystis* (43.1 percent), *Anabaena* (28.7 percent), *Planktothrix* (13.8 percent), *Aphanizomenon* (7.2 percent), and *Coelosphaerium* (3.6 percent) (Burns 2008). Although *Planktothrix* and *Aphanizomenon* were found less frequently than were the other genera, at times they accounted for a significant portion of the cyanobacterial community present. Microcystins were the most commonly found toxins in Florida waters, occurring in all samples analyzed containing cyanotoxins (Burns 2008).

In 2002, the Monitoring and Event Response to Harmful Algal Blooms in the Lower Great Lakes project evaluated the occurrence and distribution of cyanotoxins in the lower Great Lakes region (Boyer 2007). Analysis for total microcystins was performed using protein phosphatase inhibition assay. Microcystins were detected in at least 65 percent of the samples, mostly in Lake Erie, Lake Ontario, and Lake Champlain.

NMED Exhibit 93

A 2004 study of the Great Lakes found high levels of cyanotoxins during the month of August (Makarewicz et al. 2006). Microcystin-LR was analyzed by protein phosphatase inhibition assay (limit of detection of 0.003 µg/L) and was detected at levels of 0.008 µg/L in the nearshore and 0.076 µg/L in the bays and rivers. This study reported higher levels of microcystin-LR (1.6 to 10.7 µg/L) in smaller lakes in the Lake Ontario watershed.

In 2005, Washington State Department of Ecology developed the Ecology Freshwater Algae Program to focus on the monitoring and management of cyanobacteria in Washington lakes, ponds, and streams (WSDE 2012). Microcystin levels ranged from the detection limit (0.05 µg/L) to 4,620 µg/L in 2008, to 18,700 µg/L in 2009, to 853 µg/L in 2010, and to 26,400 µg/L in 2011 (Hamel 2009, 2011, 2012).

In 2006, the U.S. Geological Survey (USGS) conducted a study of 23 lakes in the midwestern United States in which total cyanobacterial blooms were sampled to determine the co-occurrence of cyanotoxins in cyanobacterial blooms (Graham et al. 2010). This study reported that microcystins were detected in 91 percent of the lakes sampled with 17 percent of microcystin-positive samples exceeding 20 µg/L. The researchers also found that cylindrospermopsin co-occurred with microcystins in nine percent of samples (Graham et al. 2010). Mixtures of all the microcystin congeners measured (-LA, -LF, -LR, -LW, -LY, -RR, and -YR) were common. Microcystin-LR and -RR were the dominant congeners detected with mean concentrations of 104 and 910 µg/L, respectively.

The Ohio EPA (2012) has been monitoring inland lakes since 2007 for cyanotoxins. Of the Ohio lakes sampled during the 2007 NLA, 36 percent had detectable levels of microcystins. In 2010, the Ohio EPA sampled Grand Lake St. Marys for cylindrospermopsin, microcystins, and other cyanotoxins. Microcystin levels ranged from below the detection limit (< 0.15 µg/L) to more than 2,000 µg/L. Follow-up samples taken in 2011 for microcystins indicated concentrations exceeded 50 µg/L in August. During the same month, sampling in Lake Erie found microcystin levels exceeding 100 µg/L.

The USGS monitored Lake Houston in Texas from 2006 to 2008 and found microcystins in 16 percent of samples and at concentrations less than or equal to 0.2 µg/L (Beussink and Graham 2011). The USGS also did a study in the Upper Klamath Lake in Oregon in 2007 and detected total microcystin concentrations between 1 µg/L and 17 µg/L (VanderKooi et al. 2010). In 2011, the USGS conducted a study on the upstream reservoirs of the Kansas River to characterize the transport of cyanobacteria and associated compounds (Graham et al. 2012). Concentrations of total microcystins were low in the majority of the tributaries with the exception of Milford Lake, which had higher total microcystin concentrations, some exceeding the Kansas recreational guideline level of 20 µg/L. Upstream from Milford Lake, a cyanobacterial bloom was observed with a total microcystin concentration of 150,000 µg/L. When sampled a week later, total microcystin concentrations were less than 1 µg/L. The study authors indicated that this might be due to dispersion of microcystins through the water column or to other areas, or by degradation of microcystins via abiotic and biological processes. Samples taken during the same time from outflow waters contained total microcystin concentrations of 6.2 µg/L.

In 2008, the National Oceanic and Atmospheric Administration (NOAA) began monitoring for total cyanobacterial blooms in Lake Erie using high temporal resolution satellite imagery. Using the Great Lakes Coastal Forecast System, forecasts of bloom transport are created to estimate the trajectory of the bloom, which are distributed as bulletins to local managers, health departments, researchers, and other stakeholders. To evaluate bloom toxicity, the Great Lakes Environmental Research Laboratory collected samples at six to eight stations each week for 24 weeks, measuring cyanotoxin concentrations as well as chlorophyll biomass and an additional 18 parameters (e.g., nutrients) to improve future forecasts of these blooms. Microcystins were separated into particulate (cell-bound) and dissolved (extracellular) phases

NMED Exhibit 93

(Graham and Jones 2007; Zastepa et al. 2014). In 2014, particulate microcystin concentrations ranged from below detection to 36.7 µg/L. Samples taken in 2015 and 2016 showed particulate microcystin concentration ranges from below detection to 9.19 µg/L and from below detection to 21.26 µg/L, respectively. Particulate microcystin concentrations peaked in August 2014 at all sites. Dissolved microcystin concentrations were also collected at each site in 2014 from September until the end of the sampling period in November, as well as during the field sampling seasons in 2015 and 2016. During the final months of sampling in 2014 (October to November), dissolved microcystin concentrations were detected with peak concentrations of 0.8 µg/L (mean: 0.28 +/- 0.2 µg/L) whereas particulate microcystin concentrations were below detection limits on many dates, indicating that a majority of the microcystins (mean: 72 percent +/- 37 percent) were in the dissolved form, as the bloom declined in intensity. Measured dissolved microcystin concentrations in the following two years ranged from levels below detection to peaks of 0.69 µg/L in September 2015 and 1.76 µg/L in July 2016 (NOAA 2014).

A 2014 survey of southeastern U.S. streams detected microcystins in 39 percent of the samples (29 of 75 sites) (Loftin et al. 2016a). The stream sample concentrations ranged from the minimum reporting limit of 0.1 µg/L to 3.2 µg/L. In some cases, the source of the cyanobacteria in flowing water bodies was traced to an upstream water body such as a lake or reservoir.

From August to October 2015, a bloom identified as *Microcystis aeruginosa* occurred on the Ohio River (ORSANCO 2017). Patches of the bloom covered 636 miles of the river and peaked in late September. The Ohio River Valley Water Sanitation Commission (ORSANCO) collected over 150 river samples, which were analyzed for microcystins. Of the samples collected by ORSANCO, 15 (10 percent) were greater than 6 µg/L. The highest microcystin concentration was 1900 µg/L from a sample collected at river mile 468.8 (Cincinnati, Ohio). No toxins were detected in finished drinking water (tested by utilities and state agencies). Ohio, West Virginia, Kentucky, and Indiana issued recreation notices for the Ohio River as the bloom extended into their areas. Illinois issued a precautionary statement concerning recreation in the river due to concern that the bloom would reach their border. These recreation advisories were lifted after the bloom ended (ORSANCO 2017).

From July 14 to September 14, 2016, an extensive cyanobacterial bloom covering 100 square miles occurred in Utah Lake, Jordan River, and nearby canals. Microcystin-LR concentrations ranged from below the detection limit to 0.23 µg/L, and the highest total microcystin concentration reported was 176 µg/L (Utah Department of Environmental Quality 2016). Both maximum values were from samples collected at the surface near an accumulation of cyanobacteria. Cyanobacteria composition observed during the 2016 bloom varied in both time and space, but was primarily dominated by *Aphanizomenon* or *Dolichospermum*. Other taxa including *Geitlerinema*, *Pseudanabaena*, and *Phormidium* were also observed in significant densities in a few samples (Utah Department of Environmental Quality 2016).

Lake Okeechobee, located north of the Everglades, is the largest freshwater lake in Florida. It is subject to agricultural runoff from adjacent cattle farms and sugar cane fields, which contribute to the formation of massive cyanobacterial blooms (Parker 2016). Water may be pumped out of the lake to the coast through the St. Lucie River and the Caloosahatchee River to prevent the lake level from rising too high after periods of heavy rain (Parker 2016). In July 2016, a 239-square mile cyanobacterial bloom in Lake Okeechobee was discharged and flowed through canals, rivers, and estuaries to the ocean. As a result of the microcystin levels in the river and at the coast, and the visible cyanobacterial scum in the lake and river, a state of emergency was declared in the counties of Martin, St. Lucie, Palm Beach, and Lee. From May 4 to August 4, 2016, the Florida Department of Environmental Protection took approximately 200 water samples from the St. Lucie River and estuary, Caloosahatchee River and estuary, Lake Okeechobee, Indian River Lagoon, and other nearshore marine locations (Florida Department of

NMED Exhibit 93

Environmental Protection 2016). The microcystin concentrations in freshwater were reported in Lake Okeechobee (from not detected to 382.3 µg/L). Elevated levels were also reported in the St. Lucie River and the St. Lucie Canal (from not detected to 80.3 µg/L). Among the cyanobacteria species identified were *Microcystis aeruginosa*, *Scrippsiella trochoidea*, *Planktolyngbya limnetica*, *Dolichospermum circinalis*, and *Plectonema wollei* (Florida Department of Environmental Protection 2016).

3.2.2.2 Cylindrospermopsin

In general, fewer surface water occurrence data were available for cylindrospermopsin compared with microcystins. During blooms, testing for microcystins is much more common than is testing for cylindrospermopsin.

In a 1999 study, *Cylindrospermopsis* was detected in 40 percent of 167 water samples taken from 87 water bodies in Florida (Burns 2008). The actual cylindrospermopsin concentrations were not reported, but all samples containing the organism *Cylindrospermopsis* were positive for the toxin cylindrospermopsin.

In 2005, the U.S. Army Corps of Engineers detected cylindrospermopsin at a maximum concentration of 1.6 µg/L in lake water samples from Oklahoma (Lynch and Clyde 2009).

The USGS detected cylindrospermopsin in nine percent of blooms sampled during a 2006 USGS survey of 23 lakes in the midwestern United States (Graham et al. 2010). The low concentrations of cylindrospermopsin detected (0.12 to 0.14 µg/L) in the study occurred in bloom communities dominated by the genera *Aphanizomenon* or *Anabaena* and *Microcystis*.

The USGS analyzed the stored samples collected during the 2007 EPA NLA (U.S. EPA 2009) and detected cylindrospermopsin in four percent of samples, with a mean concentration 0.56 µg/L and a range from the limit of detection, 0.01 µg/L, to a maximum of 4.4 µg/L (Loftin et al. 2016b). Potential cylindrospermopsin-producing species (*Anabaena*, *Aphanizomenon*, *Cylindrospermopsis*, *Lyngbya*, and *Raphidiopsis*) occurred in 67 percent of samples (Loftin et al. 2016b). Cylindrospermopsins occurred most frequently in the midwestern and south-central United States and parts of Florida.

In Grand Lake in St. Marys, Ohio, cylindrospermopsin concentrations as high as 9 µg/L were reported in 2010 (Ohio EPA 2012).

3.2.3 Estuarine and Marine Waters

In Japan, the Isahaya Reservoir discharges water into Isahaya Bay. The reservoir experiences algal blooms seasonally, with species including nontoxic cyanobacteria as well a microcystin-producing *Microcystis aeruginosa* (Umehara et al. 2012). Water from the reservoir is discharged to the bay after rainfall events, even during periods of *Microcystis aeruginosa* blooms. Between November 2008 and November 2009, Umehara et al. (2012) estimated that 64.5 kilograms (kg) of microcystins were discharged to the bay, of which only 0.7 kg deposited on the floor. The authors speculated that because the majority of microcystins remain in the water, it is likely that they are washed out to other coastal areas with strong tides (Umehara et al. 2012).

In 2007, Miller et al. (2010) confirmed the presence of *Microcystis* and microcystins in Lake Pinto's downstream tributaries within 1 kilometer (km) of Monterey Bay in California after a large cyanobacterial bloom in the lake, and detected microcystins in nearshore marine waters following the

NMED Exhibit 93

rainy season. The same researchers observed sea otters dying from consuming microcystin-contaminated clams, mussels, and oysters near ocean outflows of freshwater systems (Miller et al. 2010). A follow-up study was designed by Gibble and Kudela (2014) to identify the potential pathways leading to microcystin contamination in coastal ecosystems in and around Monterey Bay. They surveyed 21 sites at the land-sea interface in 2010–2011 followed by a survey of four watersheds in 2011–2013. In the first year of a three-year study, microcystins were detected in 15 of 21 freshwater, estuarine, and marine locations. In the two subsequent years, monitoring focused on four major watersheds that feed into Monterey Bay. The authors observed high microcystin concentrations in both autumn and spring seasons and concluded that microcystins are likely present throughout the year and transfer to the coastal environment, with the potential to be a persistent issue in the Monterey Bay area. The authors also correlated anthropogenic nutrient loadings with microcystins. Concentrations ranged from undetectable up to 20 ng/g resin, which translates to approximately 20 parts per billion (ppb) microcystins in the water column.

Otten et al. (2015) used microbial source tracking techniques to trace the source of a toxic *Microcystis* bloom in the Klamath River in Oregon to a single upstream reservoir. The use of assays targeting gene sequences for phycocyanin and microcystin synthase allowed the quantification of total and toxigenic *Microcystis*. Their results showed that large quantities of cyanobacterial cells could withstand passage through hydroelectric installations and transport over 300 km. Microcystin concentrations ranged from 165 µg/L in a reservoir upstream to 3.6 µg/L within the lower estuary less than 1 km from the Pacific Ocean (Otten et al. 2015).

The large cyanobacterial bloom in Lake Okeechobee, Florida, in 2016 (described above) flowed downstream and impacted estuarine and marine waters, resulting in beach closures along the Atlantic (Chaney 2016; Florida Department of Environmental Protection 2016). From May 4 to August 4, 2016, the Florida Department of Environmental Protection sampled freshwater, estuarine waters, and nearshore marine waters. The highest concentration reported (414.3 µg/L) was collected in Martin County at Bathtub Reef, a beach along the Atlantic Ocean. Sampling efforts in estuarine water, for example at a marina in the St. Lucie River, reported a concentration of 78 µg/L. The majority of marine waters sampled had low levels of microcystins (not detected or approximately 1 µg/L).

3.2.4 Other Sources of Microcystins and Cylindrospermopsin

Cyanotoxins have the potential to occur in drinking water, ground water, fish, shellfish, dietary supplements, air, soil, and sediments. These potential sources of cyanotoxins are discussed briefly in section 7.6. Exposure to these toxins in finished drinking water is also characterized in the Drinking Water Health Advisories (U.S. EPA 2015a, 2015b).

3.3 Environmental Fate

Different physical and chemical processes are involved in the persistence, breakdown, and movement of microcystins and cylindrospermopsin in aquatic systems as described below.

3.3.1 Mobility

Microcystins may adsorb onto naturally suspended solids and dried crusts of cyanobacteria. They can precipitate out of the water column and reside in sediments for months (Falconer 1998; Han et al. 2012). A study conducted by the USGS and the University of Central Florida determined that microcystin-LR and cylindrospermopsin did not sorb in sandy aquifers and were transported along with ground water

NMED Exhibit 93

(O'Reilly et al. 2011). The authors suggested that the removal of microcystin-LR was due to biodegradation.

Cyanotoxins that are produced by cyanobacteria growing in freshwaters can enter estuarine and marine waters as waters containing the toxins flow downstream. Studies have demonstrated that toxigenic cyanobacteria can travel long distances in freshwater and can reach estuarine and marine waters from coastal lakes, reservoirs, and rivers (Preece et al. 2017).

In sediments, cylindrospermopsin exhibits some adsorption to organic carbon, with little adsorption observed on sandy and silt sediments (Klitzke et al. 2011). The low adsorption of cylindrospermopsin reduces its residence time in sediments, thus reducing the opportunity for microbial degradation.

3.3.2 Persistence

3.3.2.1 Microcystins

Microcystins are relatively stable and resistant to chemical hydrolysis or oxidation at or near neutral pH. Elevated or low pH or temperatures above 30°C may cause slow hydrolysis. Microcystins have been observed to persist for 21 days to two to three months in solution and up to six months in dry scum (Funari and Testai 2008; Rapala et al. 2006). Environmental conditions such as temperature, pH, presence of light, salinity, and presence of certain aquatic bacteria can influence the rate of microcystin degradation (Schmidt et al. 2014). Microcystins can persist even after a cyanobacterial bloom is no longer visible (Lahti et al. 1997b; Zastepa et al. 2014). In a study by Zastepa et al. (2014), dissolved microcystin-LA was present at a concentration of 20 µg/L or greater for 9.5 weeks even though the *Microcystis* bloom was not visible after five weeks.

In the presence of full sunlight, microcystins undergo photochemical breakdown, but this varies by microcystin congener (Chorus et al. 2000; WHO 1999). Zastepa et al. (2014) suggest that microcystin-LA degrades at a slower rate than microcystin-LR, -RR, and -YR congeners. The presence of water-soluble cyanobacterial cell pigments, in particular phycobiliproteins, enhances this breakdown. Breakdown can occur in as few as two weeks to longer than six weeks, depending on the concentration of pigment and the intensity of the light (Tsuji et al. 1994, 1995).

Several other factors, including pH, wavelength of light (Schmidt et al. 2014), and whether microcystins are dissolved or present in particulate matter (Lahti et al. 1997b) can affect the rate of transformation or photodegradation. According to Tsuji et al. (1994, 1995), microcystin-LR was photodegraded with a half-life of about five days in the presence of 5 mg/L of extractable cyanobacterial pigment. Humic substances can act as photosensitizers and can increase the rate of microcystins breakdown in sunlight. Others have found that high concentrations of humic acids can slow the rate of microcystins transformation by sunlight (Schmidt et al. 2014). In deeper or turbid water, the breakdown rate is slower. Welker and Steinberg (2000) estimated the maximum rate of microcystin-LR degradation in the presence of humic substance photosensitizers. Extrapolating results from their small experimental tubes to a water column of 1 meter, Schmidt et al. (2014) estimated the half-life of microcystin-LR to be 90 to 120 days per meter of water depth in surface waters. The researchers demonstrated that the wavelength of light can also affect degradation rates; complete microcystins degradation was observed within one hour when exposed to 254-nm light and within five days using 365-nm light. According to Lahti et al. (1997b), microcystin-LR follows first-order decay kinetics, with a decimal reduction time of 30 days for dissolved microcystins compared with 15 days for microcystins found in particulate matter. Zastepa et

NMED Exhibit 93

al. (2014) also found that dissolved microcystin-LA persists longer than microcystin-LA in particulates, with in situ half-lives of 15.8 days and 6.5 days, respectively.

Microcystins are susceptible to biodegradation by aquatic bacteria found naturally in surface waters (Jones et al. 1994). Bacteria isolates of *Arthrobacter, Brevibacterium, Rhodococcus, Paucibacter*, and various strains of the genus *Sphingomonas* (*Pseudomonas*) have been reported to be capable of degrading microcystin-LR (de la Cruz et al. 2011; Han et al. 2012). These degradative bacteria have also been found in sewage effluent (Lam et al. 1995), lake water (Cousins et al. 1996; Jones et al. 1994; Lahti et al. 1997b), and lake sediment (Lahti et al. 1997a; Rapala et al. 1994; U.S. EPA 2015a). Lam et al. (1995) reported that the biotransformation of microcystin-LR followed a first-order decay with a half-life of 0.2 to 3.6 days. In a study conducted by Jones et al. (1994) with microcystin-LR in different natural surface waters, microcystin-LR persisted for three days to three weeks; however, more than 95 percent loss occurred within three to four days. A study by Christoffersen et al. (2002) measured half-lives in the laboratory and in the field of approximately one day, driven largely by bacterial aerobic metabolism. These researchers found that approximately 90 percent of the initial amount of microcystins disappeared from the water phase within five days, irrespective of the starting concentration. Other researchers (Edwards et al. 2008) have reported half-lives of four to 14 days, with longer half-lives associated with a flowing stream and shorter half-lives associated with lakes. Microcystin-LR degradation by *Sphingopyxis* species was observed with an optimal degradation rate at pH values between 6.5 and 8.5 (Schmidt et al. 2014). Several studies have demonstrated bacterial degradation of microcystin-LR, but other congeners, such as microcystin-LF or -LA, were not significantly degraded (Zastepa et al. 2014). During periods of high toxigenic cyanobacterial densities, the composition of other bacteria in the community may shift in response. In a study of the San Juan reservoir in Spain, Lezcano et al. (2017) found that several classes, orders, and families of known biodegrading bacteria, such as the *Spirobacillales* order, increased by more than a factor of 1.5 during the peak of a cyanobacterial bloom. The increase in relative abundance suggests that these biodegraders may play a role in microcystins degradation in the environment. Although microcystin-degrading bacteria might be present, initial degradation rates could be slow because the bacteria need time to begin using the toxins as carbon or energy sources (Hyenstrand et al. 2003). Microcystins can accumulate in the water column if these biodegrading bacteria are not present at the time of a toxic bloom (Schmidt et al. 2014). Cousins et al. (1996) demonstrated that microcystin experimentally added into reservoir water has a half-life of three to four days, whereas microcystin spiked into the same matrix but sterilized (so biodegrading bacteria are dead) had no significant change in the 12 days of the experiment. The authors concluded that biodegradation was the primary mechanism of microcystin reductions in the raw reservoir water.

Where rivers discharge to the ocean, freshwater cyanobacteria, cyanotoxins, or both can enter the marine environment (Andersen et al. 1993; Miller et al. 2010). Miller et al. (2010) confirmed the transfer of freshwater microcystins to the marine environment; the researchers found that after introducing *Microcystis* cyanobacteria to a saline environment, cyanobacteria can survive for 48 hours before lysing and releasing microcystins. Microcystin concentrations in these experiments decreased in the range of 44 to 71 percent after one hour in the saline environment, but continued to be detected in the seawater for at least 21 days, based on a detection limit of 0.02 µg/L (Miller et al. 2010).

3.3.2.2 Cylindrospermopsin

Cylindrospermopsin is relatively stable in the dark and at temperatures from 4°C to 50°C for up to five weeks (ILS 2000). Cylindrospermopsin is also resistant to changes in pH and remains stable for up to eight weeks at pH 4, 7, and 10. In the absence of cyanobacterial cell pigments, cylindrospermopsin tends

NMED Exhibit 93

to be relatively stable in sunlight, with a half-life of 11 to 15 days in surface waters (Funari and Testai 2008).

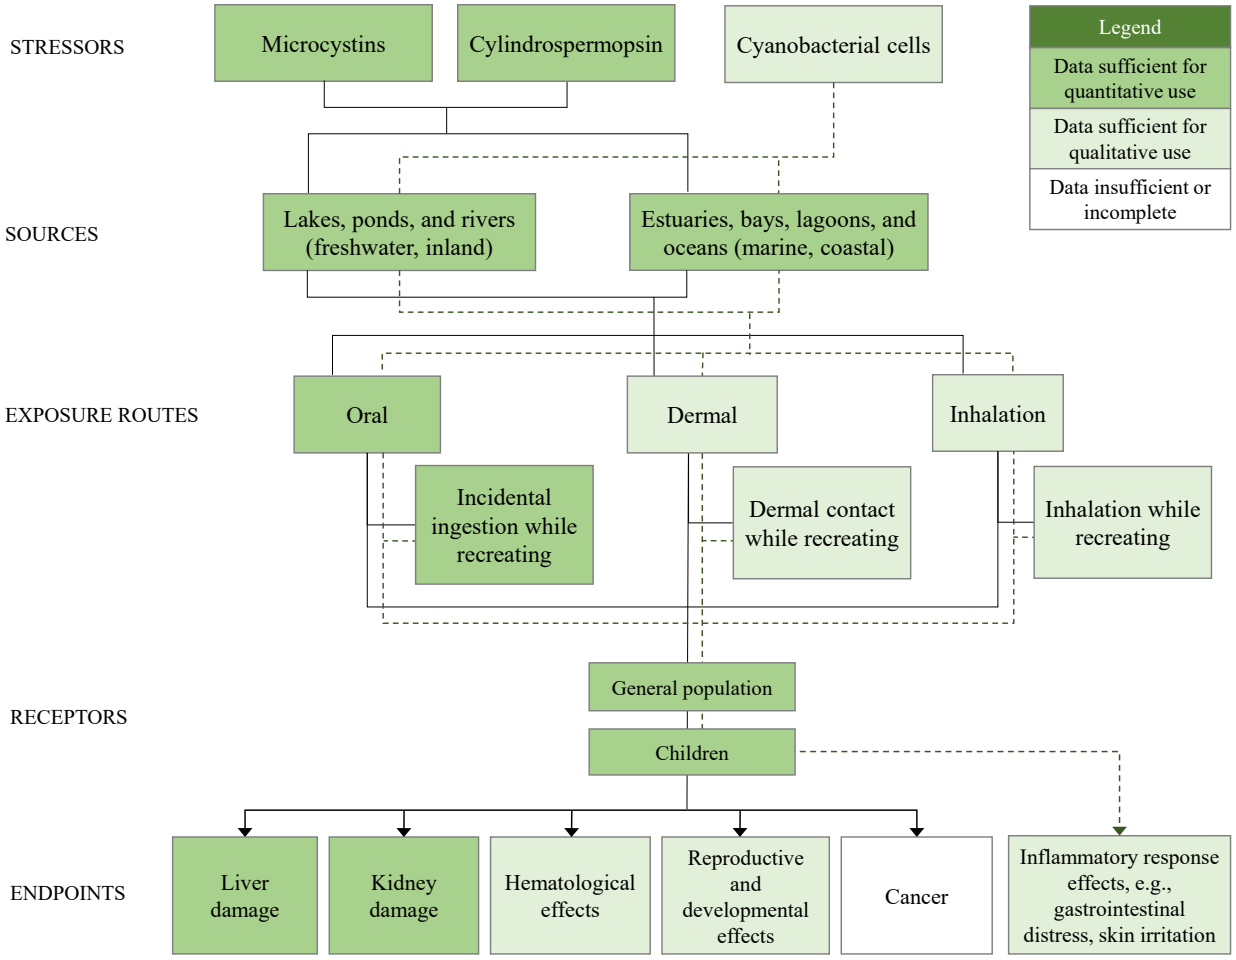
Like microcystins, degradation of cylindrospermopsin increases in the presence of cell pigments such as chlorophyll *a* and phycocyanin, a blue photosynthetic pigment found in cyanobacteria. When exposed to both sunlight and cell pigments, cylindrospermopsin breaks down rapidly—more than 90 percent within two to three days (Chiswell et al. 1999).

Bacteria have been shown to decompose cylindrospermopsin in laboratory studies; the biodegradation is influenced by the cyanotoxin concentration, temperature, and pH. Mohamed and Alamri (2012) reported that *Bacillus* bacteria degraded cylindrospermopsin and that degradation occurred in six days at the highest toxin concentration (300 µg/L) and in seven or eight days at lower concentrations (10 and 100 µg/L, respectively). The biodegradation rate was also reported to depend on temperature and pH, with the highest rates occurring in warm waters (25 and 30°C) and neutral to slightly alkaline conditions (pH 7 and 8). Klitzke and Fastner (2012) confirmed the observations of Mohamed and Alamri (2012), noting that a decrease in temperature from 20 to 10°C slowed down degradation by a factor of 10. They also found that degradation slowed significantly under anaerobic conditions, with half-lives of 2.4 days under aerobic conditions and 23.6 days under anaerobic conditions.

3.4 Toxicokinetics

Limited data are available regarding the toxicokinetics of microcystins in environmental exposure conditions (U.S. EPA 2015d). Available intestinal data indicate that the organic anion transporting polypeptide (OATP) family transporters facilitate the absorption of microcystins from the intestinal tract into liver, brain, and other tissues, as well as their export out of organs and tissues (Cheng et al. 2005; Fischer et al. 2005; Svoboda et al. 2011). However, bile acids and other physiologically relevant substrates compete with microcystins for transporter uptake by the liver (Thompson and Pace 1992); reduction or elimination of liver toxicity has been observed during in vivo or in vitro exposures when microcystin uptake by OATP transporters is limited or inhibited (Hermansky et al. 1990a, 1990b; Runnegar et al. 1995; Runnegar and Falconer 1982; Runnegar et al. 1981). Both in vivo and in vitro studies have shown biliary excretion of microcystins (Falconer et al. 1986; Pace et al. 1991; Robinson et al. 1991), possibly via conjugation with cysteine and glutathione (Kondo et al. 1996). Additional details of microcystin toxicokinetics can be found in the EPA's Drinking Water Health Advisory and HESD for microcystins (U.S. EPA 2015a, 2015d).

Limited toxicokinetic data for cylindrospermopsin are available and are derived from mice intraperitoneal studies and in vivo studies that do not necessarily reflect environmental exposure conditions (U.S. EPA 2015c; Pichardo et al. 2017). Cylindrospermopsin is absorbed from the GI tract (Humpage and Falconer 2003; Shaw et al. 2001; Shaw et al. 2000) and is distributed primarily to the liver but also to the kidneys and spleen (Norris et al. 2001). The metabolism and toxicity of cylindrospermopsin is mediated by hepatic cytochrome P450 (CYP450) enzymes, and the periacinar region of the liver appears to be the main target of toxicity where cylindrospermopsin and its metabolites bind to proteins (Norris et al. 2001; Runnegar et al. 1995; Shaw et al. 2001; Shaw et al. 2000). Elimination of cylindrospermopsin was continuous over a monitoring period of 24 hours, with a large mean total recovery primarily from urine, and to a smaller extent, feces, after 24 hours (Norris et al. 2001). Additional details of cylindrospermopsin toxicokinetics can be found in the EPA's Drinking Water Health Advisory and HESD for cylindrospermopsin (U.S. EPA 2015b, 2015c).



NMED Exhibit 93

4.0 PROBLEM FORMULATION

4.1 Conceptual Model

This conceptual model provides useful information that characterizes and communicates the potential health risks related to exposure to microcystins and cylindrospermopsin in recreational waters. The model depicts the sources of the cyanotoxins in these waters, the recreational routes of exposure for sensitive biological receptors of concern, and the potential assessment endpoints (e.g., effects such as kidney and liver toxicity) (Figure 4-1).

Figure 4-1. Conceptual Model of Exposure Pathways to the Cyanotoxins, Microcystins and Cylindrospermopsin, and Cyanobacteria in Surface Waters While Recreating

4.1.1 Conceptual Model Diagram for Recreational Exposure

The conceptual model is intended to explore potential links of exposure to a contaminant or stressor with the adverse effects and toxicological endpoints important for management goals, including the development of recreational AWQC. Boxes that are shaded darker green indicate pathways that the EPA considered quantitatively in estimating the advisory level, whereas boxes shaded lighter green indicate data were sufficient for qualitative use and the white boxes did not have sufficient data for the EPA to

NMED Exhibit 93

evaluate quantitatively or qualitatively. The solid lines are for the cyanotoxins and the dotted lines are for the cyanobacterial cells.

4.1.2 Factors Considered in the Conceptual Model for Microcystins and Cylindrospermopsin

Stressors

The stressors are microcystins and cylindrospermopsin concentrations in water. These toxins can be produced by cyanobacteria occurring in freshwater. The EPA concluded that although statistically significant associations with adverse health effects occur across a wide range of cyanobacterial cell densities, criteria cannot be derived based on cyanobacterial cell density at this time. Effects related to cyanobacterial cells are discussed in section 7.5.1 and Appendix D.

Sources

Cyanobacteria occur naturally in surface waters, such as lakes, ponds, rivers, estuaries, bays, lagoons, and oceans in or surrounding the United States. Some genera of the cyanobacteria, including *Microcystis*, *Cylindrospermopsis*, *Anabaena*, *Planktothrix*, and *Nostoc*, can produce the cyanotoxins microcystins and cylindrospermopsin. This assessment focuses on cyanotoxins produced by these cyanobacteria in freshwater. These toxins have the potential to affect downstream waters, including coastal areas where surface water containing the toxins discharges into estuarine and marine waters.

Routes of Exposure

Exposure to cyanotoxins from recreational water sources can occur via oral exposure (incidental ingestion while recreating); dermal exposure (contact of exposed parts of the body with water containing cyanotoxins during recreational activities such as swimming, wading, or water skiing); and inhalation exposure to contaminated aerosols (while recreating). The route of exposure considered quantitatively in this assessment is the oral exposure to microcystins and cylindrospermopsin via incidental ingestion while swimming. Inhalation can occur from exposures from personal watercraft and boat spray. Dermal exposure can occur through recreational water contact; however, significant dermal absorption of microcystins and cylindrospermopsin is not expected due to the large size and charged nature of these molecules and the lack of dermal receptor sites capable of uptake (Butler et al. 2012; U.S. EPA 2004; U.S. EPA 2007). Sufficient data to quantify toxicity via the inhalation and dermal exposure routes were not available. The dermal and inhalation routes of exposure are discussed further in the Effects Characterization section (7.4).

Receptors

Anyone who recreates in a water body where cyanotoxins are present could be exposed to cyanotoxins through ingestion, dermal contact, and inhalation of aerosols while recreating in contaminated surface waters. Recreating children can be at greater risk from exposure to microcystins or cylindrospermopsin because they have smaller body mass compared to adults, they spend more time in contact with the water compared to adults, and they incidentally ingest more water than adults while recreating. Therefore, the EPA has determined that childhood is the most vulnerable lifestage due to potential increased exposure while recreating when compared with adults. The EPA evaluates and discusses differences between lifestages in the Effects Characterization section (7.3).

NMED Exhibit 93

While there are examples in the literature and reports of animal poisonings and death due to exposure of cyanotoxins, values protective of animals such as dogs and livestock are not generated in this document. However, section 7.8 discusses some animal-specific issues, including a summary of guidelines that several states have developed for animals.

Endpoints

Available microcystin toxicity data indicate that the primary target organ for microcystins is the liver as described in the EPA's HESD for microcystins (U.S. EPA 2015d).

Available cylindrospermopsin toxicity data are described in the EPA's HESD for cylindrospermopsin (U.S. EPA 2015c). For cylindrospermopsin, the EPA selected kidney effects as the endpoint on which to quantify the measure of effect. However, in both the critical study and the supporting studies there is evidence that cylindrospermopsin can also alter the shape of red blood cells.

Clinical, epidemiological, and outbreak study results (see Appendix D) suggest a link between an increase in adverse inflammatory symptoms among recreators and elevated cyanobacterial cell densities. However, there is considerable uncertainty and variability associated with the epidemiological results, which did not identify consistent effects at similar cyanobacterial densities. Specifically, significant associations occur across a wide range of cell densities; associations vary with different self-reported health endpoints or combined symptom categories. Potential inflammatory health effects related to exposure to total cyanobacterial cells are described in the Effects Characterization section (7.5.1) and in Appendix D, both of which include a discussion of the uncertainties related to associations with cyanobacterial cells.

4.2 Analysis Plan

The EPA's 2000 *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (2000 Human Health Methodology) outlines the Agency's process for deriving AWQC and guides the development of these recreational criteria and swimming advisory recommendations (U.S. EPA 2000).

The 2000 Human Health Methodology includes identifying the population subgroup that should be protected and evaluating cancer and non-cancer endpoints, measures of effect, measures of exposure, and relative source contribution (RSC). In this analysis plan, the EPA describes: (1) the RfD previously derived for microcystins and cylindrospermopsin (measure of effect); (2) the calculation for the recreational criteria; (3) incidental ingestion exposure in terms of volume ingested, duration of exposure, and body weight (measure of exposure) described in the EPA's *Exposure Factors Handbook* (EFH) and data reported in the peer-reviewed scientific literature; and (4) discusses the RSC. These criteria focus on human exposure as a result of primary contact recreation activities, such as swimming, during which immersion and incidental ingestion of ambient water are likely.

The EPA's HESD for microcystins and HESD for cylindrospermopsin (U.S. EPA 2015c, 2015d) provide the health effects basis for the development of the Drinking Water Health Advisories for microcystins and cylindrospermopsin (U.S. EPA 2015a, 2015b), including the basis for estimating the point of departure. To develop its HESDs for microcystins and cylindrospermopsin, the EPA assembled available information on toxicokinetics, acute, short-term, subchronic, and chronic toxicity along with developmental and reproductive toxicity, neurotoxicity, immunotoxicity, genotoxicity, and cancer in

NMED Exhibit 93

humans and animals. For detailed descriptions of the literature search strategies, see the EPA's HESDs for microcystins and cylindrospermopsin (U.S. EPA 2015c, 2015d).

The EPA's HESDs were subject to rigorous internal and external peer review before being finalized in 2015. The information evaluated for these documents also supports the development of the recreational criteria and swimming advisories for microcystins and cylindrospermopsin, which evaluate exposure via recreational water ingestion. The EPA conducted supplemental literature searches to capture new references, including effects related to recreational exposure to cells. For detailed information on the search terms, see Appendix C.

4.2.1 Approach for Recreational AWQC and Swimming Advisory Derivation

The recreational AWQC and swimming advisory recommendations for microcystins and cylindrospermopsin are calculated as described in the 2000 Human Health Methodology and presented in the equation below:

$$\text{Recreational AWQC } (\mu g/L) = \text{RfD} \times \frac{\text{BW}}{\text{IR}}$$

Where:

RfD	=	reference dose (μg/kg body weight/day)
BW	=	mean body weight (kg)
IR	=	ingestion rate (L/day) (discussed in section 4.2.3.1)

4.2.1.1 Magnitude, Duration, and Frequency

Recreational criteria, like other 304(a) criteria, consist of a magnitude, duration, and frequency. Magnitude is the numeric expression of the maximum amount of the contaminant that may be present in a water body that supports the designated use. Duration is the period over which the magnitude is calculated. Frequency of excursion describes the number of times the contaminant may be present above the magnitude over the specified period (duration). A criterion is derived such that the combination of magnitude, duration, and frequency protect the designated use (e.g., primary contact recreation).

4.2.2 Measures of Effect

The EPA's HESDs for microcystins and cylindrospermopsin (U.S. EPA 2015c, 2015d), provide the health effects basis for development of an oral toxicity value or the RfD, including the selection of the critical study and critical endpoints and application of uncertainty factors (UFs). In derivation of the recreational criteria and swimming advisory recommendations, the EPA uses these toxicity values as the measure of effect for oral exposure through incidental ingestion while recreating. The RfDs described in the EPA's HESDs are based on short-term and subchronic studies and therefore are an estimate (with uncertainties spanning perhaps an order of magnitude) of the daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a short-term exposure period.

NMED Exhibit 93

4.2.3 Measures of Exposure

The EPA selected incidental ingestion during primary contact activities (such as swimming) in derivation of the recreational criteria and swimming advisories because data suggest that incidental ingestion can be considered the highest potential exposure pathway for cyanotoxins while recreating. Dorevitch et al. (2011) studied the volume of water ingested during a range of recreational activities in the Chicago Area Waterway System (CAWS) and at a public outdoor swimming pool. Study participants took part in one of the following activities on the CAWS: canoeing, fishing, kayaking, motor boating, or rowing. In the swimming pool, participants took part in canoeing, fishing, kayaking, swimming, or wading/splashing. The results indicate that the odds of ingesting a teaspoon or more of water are significantly higher among swimmers than among those who just immersed their head in a swimming pool or those who participated in the other, more limited contact activities on surface waters. Therefore, the EPA determined that using a swimmer scenario for exposure as the basis for the criteria is protective of these other aquatic activities.

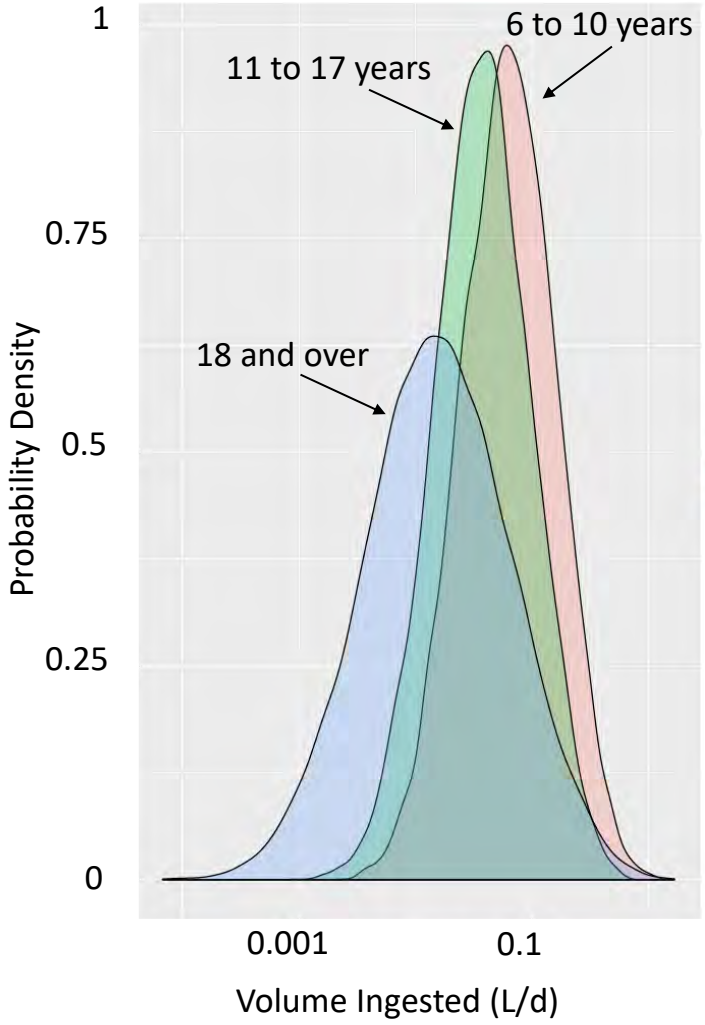
Inhalation exposure occurs during swimming; however, data are not sufficient to quantify health effects resulting from inhalation exposure to cyanotoxins at this time. See section 7.4.1 for a characterization of potential effects from inhalation exposure.

Dermal exposure happens during swimming; however, significant dermal absorption of the toxins microcystins and cylindrospermopsin is not expected due to the large size and charged nature of these molecules (Butler et al. 2012; U.S. EPA 2004; U.S. EPA 2007). Because available data are not sufficient, the EPA is not quantifying effects resulting from dermal exposure to cyanotoxins. See section 7.4.2 for a characterization of dermal exposure to these cyanotoxins.

Dermal exposure to cyanobacterial cells can also result in adverse health effects, such skin rashes, eye irritation, and ear irritation. Because adequate effects data are not available, the EPA is not quantifying effects resulting from exposure to cells at this time; effects are described qualitatively. Available epidemiological study results do not provide consistent associations between cell densities and the inflammatory health endpoints. See section 7.5.1 for a characterization of potential effects from recreational exposure to cyanobacterial cells.

All recreational exposure studies that included both children and adults found that age tended to influence incidental ingestion exposure while recreating. More specifically, children tend to ingest more water and spend more time in the water compared with adults (Dufour et al. 2017; Dufour et al. 2006; Schets et al. 2011; U.S. EPA 2011). Data supporting the selected exposure factors are described in the sections that follow.

The measure of exposure is the 90th percentile of the daily incidental ingestion rate (volume of surface water incidentally ingested per day) and body weight (kg). Both body weight and incidental ingestion while recreating are parameters that vary with age. The EPA's 2000 Human Health Methodology (2000) outlines EPA's process for deriving AWQC and guides the development of these recreational criteria and swimming advisory recommendations.



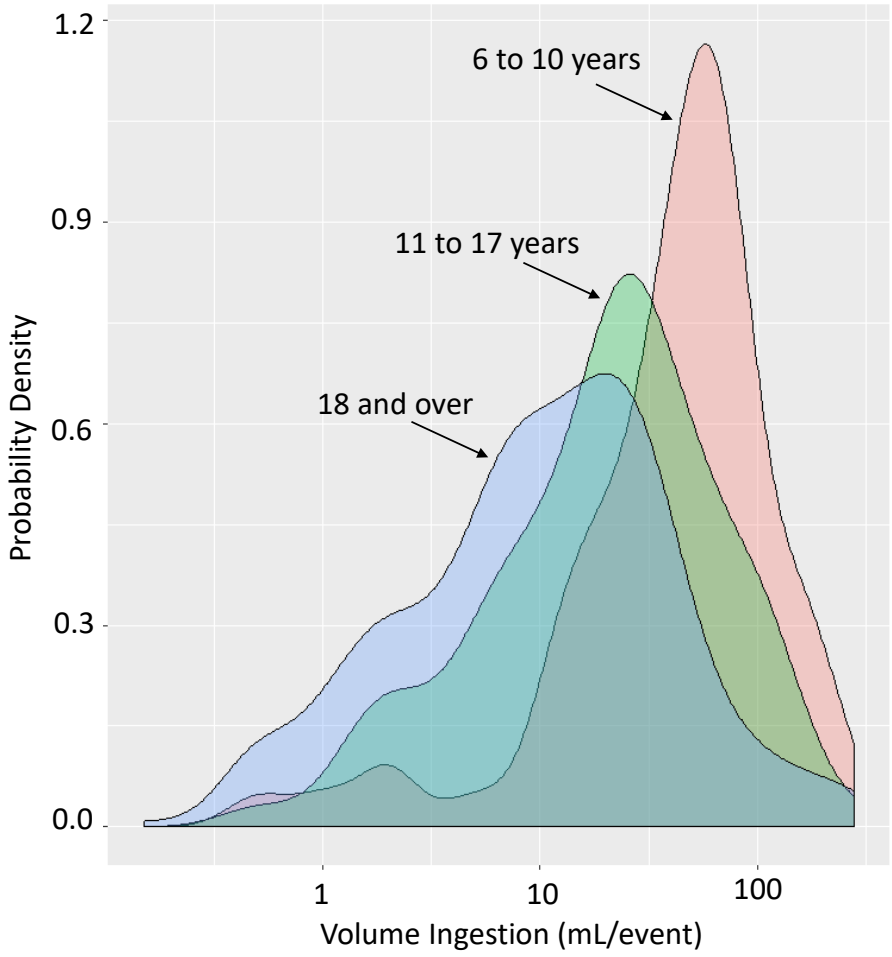
4.2.3.1 Incidental Ingestion

To calculate the recreational incidental ingestion rate in units of volume per day, the EPA combined a distribution of incidental ingestion volumes (volume per event normalized to volume per hour) and a distribution of exposure durations (hours per day). The EPA uses the 90th percentile of the combined

NMED Exhibit 93

distribution of ingestion rate and exposure duration to represent incidental ingestion per day, consistent with the EPA's Human Health Methodology (U.S. EPA 2000). Probability density plots of the combined distributions are shown in Figure 4-2. The ingestion data demonstrate that the mean ingestion rate for children six to 10 years is higher than for older children and adults. These data are discussed in the following sections.

Figure 4-2. Combined Distributions for Age Groups



Ingestion Volume Studies

The EPA evaluated seven studies on ingestion and selected the dataset collected and analyzed by Dufour et al. (2017) for development of these AWQC or swimming advisory recommendations. This study used the same methodology as an earlier study (Dufour et al. 2006) but included 10 times more participants. Both studies used cyanuric acid as an indicator of amount of pool water ingested while swimming in an outdoor pool. Pool water samples were collected before the start of swimming activities, and participants' urine was collected for 24 hours after the swimming event ended; pool water and urine samples were analyzed for cyanuric acid. The dataset collected by Dufour et al. (2017) included age information for each particpant ages six to 81 years, whereas the 2006 study classified individuals as over or under 18 years old. Both studies did not include children younger than six years old. The 2017

study recorded time spent in the water for each participant. The 2017 study results highlighted that younger children tested ingested more than older children or adults. The EPA selected the Dufour et al. (2017) dataset to calculate incidental ingestion volume because of the larger number of particpants, the inclusion of additional age groups, and recording of the duration exposure of each participant. The raw data collected and analyzed by Dufour et al. (2017) was provided by the study authors (U.S. EPA 2018a). The EPA adjusted (i.e., normalized) the volume ingested by each participant to one hour based on the length of time that participant reported being in the water. The summary statistics the EPA calculated using this dataset are shown in Appendix E (Table E-1). Figure 4-3 shows the raw data density plots for the Appendix E Dufour data separately grouped as age groups six to 10, 11 to 17, and 18 years and over. The density plots show the volume of incidental ingestion (mL) per recreational event on a log scale. To develop the distribution, each participant's volume ingested was adjusted to one hour based on the length of time that participant reported being in the water. Incidental ingestion was recorded for 66 individuals in the six- to 10-year category.

Figure 4-3. Incidential Ingestion for Age Groups Based on Appendix E Dufour Data

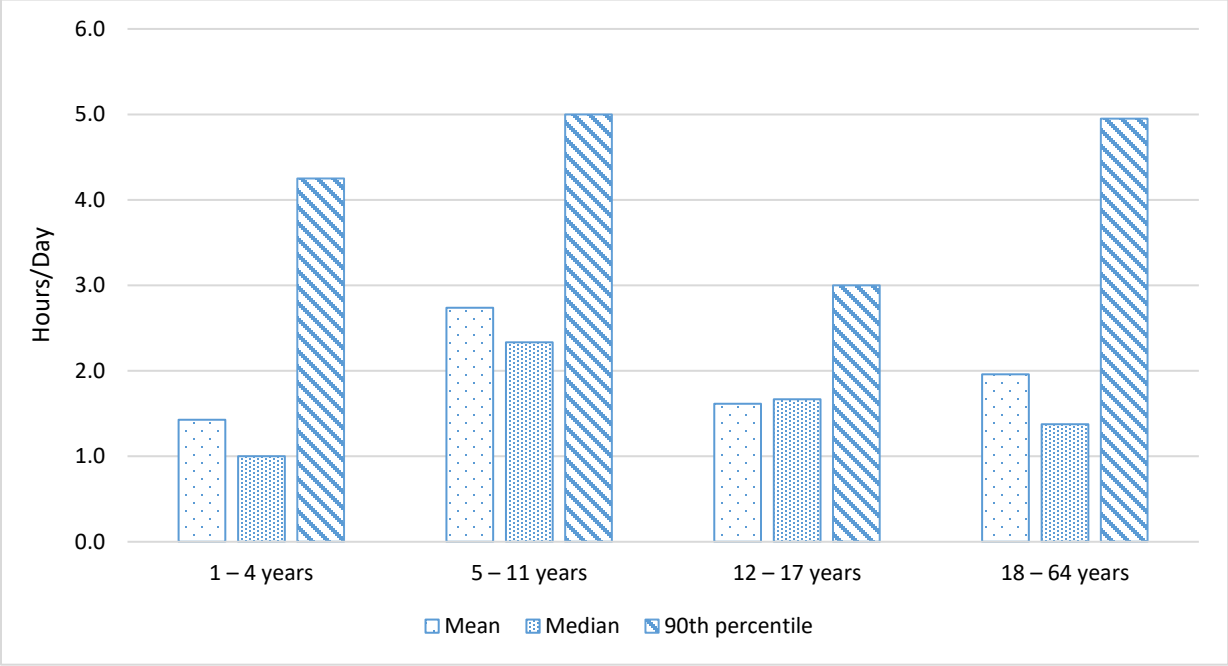
Appendix F describes seven studies that reported incidental ingestion while recreating, but only three others reported ingestion estimates for children (Dufour et al. 2006; Schets et al. 2011; Suppes et al. 2014). These other studies reported children's ingestion volumes similar to Dufour et al. (2017). Although these other studies corroborate the Dufour et al. (2017) findings, they were not selected for deriving the ingestion rate. Dufour et al. (2006) had fewer age groups (i.e., six to 17 and 18+ years), smaller sample size, and did not record time spent in water for each participant, making it a less robust

NMED Exhibit 93

study than Dufour et al. (2017). Schets et al. (2011) collected data in the Netherlands, which may not be representative of the United States due to different behavioral trends in the resident population, including effects of temperature on recreating patterns. In addition, Schets et al. (2011) ingestion volumes are based on self-reported estimates; parents estimated volumes for children five and younger. Self- and parent-reported estimates are more uncertain than the methods used by Dufour et al. (2017). Suppes et al. (2014) used video and urine analysis to estimate ingestion volume. In Suppes et al. (2014) quantitative data were available for 35 participants, which is much lower than the sample size for Dufour et al. (2017). In addition, Suppes et al. (2014) only reported two age groups, children (five to 17 years) and adults (18+ years), which does not allow for the finer discernment of exposure patterns that is possible with the Appendix E and U.S. EPA (2018a) data.

Appendix F also describes the methodology used by the EPA's Office of Pesticide Programs (OPP) to calculate exposures to pool chemicals during swimming to support registration decisions. The Swimmers Exposure Assessment Model (SWIMODEL) (U.S. EPA 2003) uses incidental ingestion values for children that are twice the values used for noncompetitive adult swimmers. The model assumes an incidental ingestion rate of 0.050 L/hour for children ages seven to 10 years and 11 to 14 years while swimming noncompetitively. Incidental ingestion rates among adults while swimming competitively and noncompetitively are 0.0125 L/hour and 0.025 L/hour, respectively.

Duration of Recreational Exposure



Duration of recreational exposure quantifies the length of time people might be exposed to cyanotoxins during their primary contact recreational use. Duration is needed to convert recreational ingestion rates in units of volume per hour to an amount incidentally ingested per day, which is the exposure parameter needed to derive the recommended cyanotoxin values.

The EPA selected recreational exposure data from the EFH (U.S. EPA 2011) for the development of these criteria/swimming advisories. The EPA's EFH (2011) lists time spent per 24 hours in an outdoor spa or pool for different age groups. The data are based on analysis of the National Human Activity Pattern Survey (U.S. EPA 1996). Figure 4-4 compares point estimates for the recreational duration data for different age groups and shows that recreators ages five to 11 years (n = 15) tend to spend more time in the water than other child age groups and adults. A duration was not provided for children younger than age one year.

The EPA investigated available exposure parameters for children younger than six years old, but they have large uncertainties given the lack of measured incidental ingestion data for this age group (see section 7.3.2). See section 7.2 (Recreational Exposure Duration) for further discussion of the available data for recreational exposure duration. The EPA used the distribution of exposure durations for children ages five to 11 years (n = 15; units are hour/day) as described below to calculate incidental ingestion per day.

NMED Exhibit 93

Figure 4-4. Direct Contact Recreational Exposure Duration by Age Group, Based on Table 16-20 in U.S. EPA (2011)[a]

[a] This figure shows a comparison of point estimates. The EPA used the whole distribution for ages five to 11 years in deriving the AWQC and swimming advisory magnitudes.

Determination of Incidental Ingestion per Day

The incidental ingestion volume per day the EPA used to calculate the AWQC or swimming advisories is the product of the distribution of children's incidental ingestion rate for children ages six to 10 years (Appendix E; U.S. EPA 2018a) and the distribution of exposure durations for children ages five to 11 years (U.S. EPA 2011). The lifestage grouping for the duration data include children one year older and one year younger than the lifestage group for the incidental ingestion data.

The individual ingestion rate data points (adjusted to L/hour) were used to calculate a mean and standard deviation of the log-normal transformed dataset. This distribution was combined with the distribution of hours of recreation per day (ages five to 11 years) from the 2011 EFH (Table 16-20 *Time Spent (minutes/day) in Selected Outdoor Locations, Doers Only, At Home in the Outdoor Pool or Spa*). The mathematical relationship between the two variables and the daily incidental ingestion rate is shown in this equation:

$$\text{Ingestion Volume (L/hour)} \times \text{Recreation Duration (hour/day)} = \text{Daily Incidental Ingestion Rate (L/day)}$$

The EPA used probabilistic (Monte Carlo) simulation to develop the combined distribution of these variables as follows:

- Estimated statistical distributions for hourly ingestion rate and recreation duration for different age groups.
- Sampled randomly one value from each of these distributions.

NMED Exhibit 93

- Multiplied the two sampled values.
- Repeated a large number of times (i.e., 100,000 times) to populate the distribution for daily ingestion rate (L/day) or the combined distribution.
- Reported results as summary statistics of the combined distribution.

The distribution shape that best fit the datasets was log-normal for both ingestion volume and exposure duration. Table 4-1 presents summary statistics for different age groups based on the combined distribution analysis. As per the EPA's 2000 Human Health Methodology (U.S. EPA 2000), the 90th percentile of exposure, represented by this combined distribution (0.21 L/day) was used as a point estimate for deriving the AWQC or swimming advisories. Details and the R code for this analysis are shown in Appendix E. Appendix E also includes the mean, median, and standard deviation for the distributions for ages six to 10, 11 to 17, and 18 years and older.

Table 4-1. Results of the Combined Distribution Analysis

Age Group	Summary Statistics for Ingestion Rate (L/day)		
	Median	Mean	90th Percentile
6 to 10 years	0.063	0.094	0.21
11 to 17 years	0.038	0.058	0.13
18+ years	0.015	0.04	0.10

4.2.3.2 Body Weight

Table 8-1 in the EPA's EFH (U.S. EPA 2011) reported body weight statistics based on the National Health and Nutrition Examination Survey, including for a range of age groups. The EPA selected children aged six to 10 years because it reflected the age group with higher ingestion volumes (Appendix E; U.S. EPA 2018a; U.S. EPA 2011) and exposure duration (U.S. EPA 2011).[4] As per the EPA's 2000 Human Health Methodology (U.S. EPA 2000), mean body weight (31.8 kg) was used for deriving the AWQC or swimming advisories. Section 7.3.2 provides a discussion of younger children's exposure factors.

4.2.4 Relative Source Contribution (RSC)

The RSC component of the AWQC calculation allows a percentage of the exposure to a contaminant to include other potential exposure sources. The RSC describes the portion of the RfD available for AWQC-related sources (U.S. EPA 2000); the remainder of the RfD is allocated to other sources of the contaminant. The EPA focused on recreational exposures to microcystins and cylindrospermopsin in ambient freshwaters. To derive recommendations protective of the recreational designated use, the EPA assumes all cyanotoxin exposure is from incidental ingestion of water while recreating; therefore, no RSC term is applied.

[4] The age group six to 10 years includes 10-year-old children. The EPA's *Exposure Factors Handbook* labels this age group as six to < 11 years.

NMED Exhibit 93

5.0 EFFECTS ASSESSMENT

The health effects studies summarized below for microcystins and cylindrospermopsin are described in detail in the EPA's HESDs and Drinking Water Health Advisories for these two cyanotoxins (U.S. EPA 2015a, 2015b, 2015c, 2015d).

5.1 Hazard Identification

5.1.1 Noncancer Health Effects

5.1.1.1 Animal Toxicity Studies

Microcystins

The preponderance of animal toxicity data on the noncancer effects of microcystins is restricted to the microcystin-LR congener. Available data on the RR, YR, and LA congeners do not provide dose-response information sufficient for quantification. The EPA is using data on effects of microcystin-LR to represent other microcystin congeners (U.S. EPA 2015d). Observed effects in animals exposed orally or via intraperitoneal infusion to microcystin-LR include liver, reproductive, developmental, kidney, and GI effects (Chernoff et al. 2002; Falconer et al. 1998; Fawell et al. 1999; Fitzgeorge et al. 1994; Guzman and Solter 1999, 2002; Heinze 1999; Ito et al. 1997a, 1997b; Yoshida et al. 1997). Most oral and injection studies in laboratory animals have demonstrated that the liver is a primary target organ for microcystin toxicity. Liver effects, as well as kidney effects, have been reported in acute, short-term, and subchronic oral studies in laboratory animals exposed to microcystin-LR, in addition to reproductive effects following short-term and subchronic oral exposures. Studies evaluating the chronic toxicity of microcystins have not shown clinical signs of toxicity and are limited by study design and by the lack of quantitative data. For individual study details see the EPA's HESD for microcystins (U.S. EPA 2015d).

Available animal data on the acute oral toxicity of microcystin-LR provide evidence of hepatotoxicity. Liver effects described in the above studies are summarized in Table 5-1. A single oral dose of 500 μg microcystin-LR/kg resulted in diffuse hemorrhage in the liver of mice and rats; more pronounced liver damage occurred at higher doses (Ito et al. 1997a; Fawell et al. 1999; Yoshida et al. 1997). Studies that utilized parenteral administration of microcystin-LR show a steep dose-response with rapid onset of liver damage.

The findings in acute and subchronic studies support the liver as a target organ for microcystin-LR toxicity. The EPA identified a 28-day short-term study by Heinze (1999) as the critical study for derivation of an RfD. Male hybrid rats (10/group) were administered microcystin-LR in drinking water at doses of 0, 50, or 150 μg/kg body weight (Heinze 1999). Liver effects included increased liver weight, and slight to moderate liver necrosis lesions with or without hemorrhages at the low dose and with dose-related increases in necrotic severity. The necrosis was accompanied by changes in serum enzymes indicative of liver damage. All rats in each dose group had liver necrosis. Data were not collected prior to the end of the study so it is not known when during the 28-day study period these effects were manifested.

NMED Exhibit 93

Table 5-1. Liver Effects in Animals Exposed to Microcystins in Selected Acute and Short-term Studies as Discusssed in the EPA's *Health Effects Support Document for the Cyanobacterial Toxin Microcystins* (U.S. EPA 2015d)

Species	Exposure Route	Dosing Regimen	Micro-cystin Congener	Description of Liver Effects	Study
Female BALB/c mice (n = 7)	Gavage	Single dose of 0, 8,000, 10,000, or 12,500 µg/kg Examination at 24 hours after treatment	LR	Centrilobular hemorrhage, hepatocyte degeneration	Yoshida et al. (1997)
Male ICR mice aged (n = 29 age 32 weeks) and young (n = 12 age 5 weeks)	Gavage	Single dose of 500 µg/kg Animals sacrificed at 2, 5, and 19 hours after treatment	LR	Bleeding and disappearance of hepatocytes in the whole liver or in centrilobular region, friable tissue, necrosis, or eosinophilic changes in the centrilobular region	Ito et al. (1997a)
CR1:CD-1(ICR)BR(VAF plus) mice and CR1:CD(SD)BR(VAF plus) rats (5 males and 5 females per group)	Gavage	Single dose of 500, 1,500, or 5,000 µg/kg (no control) Animals sacrificed at day 14 post treatment	LR	Darkly discolored and distended livers; moderate or marked centrilobular hemorrhage of liver; diffuse hemorrhage in the liver	Fawell et al. (1999)
Male ICR mice (n = 5 per group)	Gavage	Repeated doses of 0, 4.6, 23, 46, 93, or 186 µg/kg/day for 7 days Animals sacrificed at day 7	RR	Dose-dependent increase in apoptosis	Huang et al. (2011)
Male hybrid rats (F1 generation of female WELS/Fohm × male BDIX) (10 per group)	Drinking water	Repeated doses of 0, 50, or 150 µg/kg/day for 28 days	LR	Hepatocyte degeneration, hemorrhage, and necrosis; increase in periodic acid-Schiff-positive substances (indicating cell damage), Kupffer cell activation	Heinze (1999)
Male Sprague-Dawley rats (3 per group)	Intraperitoneal infusion	Repeated doses of 0, 16, 32, or 48 µg/kg/day for 28 days	LR	Fibrous tissue, cell death, necrosis, lipid vacuoles, Kupffer cell activation (+2 and +3 severity rating)	Guzman and Solter (1999)

The liver effects in the Heinze (1999) study were supported by additional data from a study by Guzman and Solter (1999). Rats exposed via intraperitoneal infusion displayed histological evidence of liver

NMED Exhibit 93

damage (i.e., inflammation, fibrous tissue, necrosis, and apoptosis). The study authors identified a no-observed-adverse-effect-level (NOAEL) of 16 µg/kg/day and a lowest-observed-adverse-effect-level (LOAEL) of 32 µg/kg/day. Microcystin-LR was delivered directly to the livers of the animals in the study by implanted osmotic pumps and this may account for the liver effects observed at lower doses compared to Heinze (1999). Guzman and Solter (1999) only included three rats per group exposed to doses of 0, 16, 32, or 48 µg/kg/day of microcystin for 28 days, which is a limitation of the study design. Although adverse liver effects were observed, the limited numbers of animals per dose group (n = 3) and the exposure route, which bypassed intestinal barriers to absorption, resulted in greater uncertainty than Heinze (1999). Thus, Guzman and Solter (1999) was not used to derive the RfD.

Some studies observed other kinds of effects following short-term or subchronic oral or intraperitoneal exposures. These studies, including limitations, are discussed in the EPA's HESD for microcystins (U.S. EPA 2015d). Potential effects included reproductive toxicity in males (Chen et al. 2011), maternal mortality (Fawell et al. 1999; Chernoff et al. 2002), and fetal body weight changes (i.e., at 2,000 µg/kg, administered orally during gestational days six to 15, at which significant maternal mortality was observed) (Fawell et al. 1999). Chernoff et al. (2002) did not report adverse effects on fetal or pup weights in two separate intraperitoneal studies.

Cylindrospermopsin

The available acute, short-term, and subchronic studies for cylindrospermopsin (Bazin et al. 2012; Humpage and Falconer 2002; 2003; Reisner et al. 2004; Terao et al. 1994; Shaw et al. 2001) support the liver and kidneys as the primary targets for cylindrospermopsin toxicity (summarized in Table 5-2), with effects on red blood cells also evident. These effects were observed in mice given single or repeated doses of purified cylindrospermopsin via oral administration or intraperitoneal injection (Bazin et al. 2012; Humpage and Falconer 2002, 2003; Reisner et al. 2004; Terao et al. 1994). The EPA did not find health effects information for other cylindrospermopsin congeners or analogs.

No oral reproductive or developmental studies are available for cylindrospermopsin. Developmental toxicity studies following intraperitoneal administration of cylindrospermopsin provide some evidence for maternal toxicity and decreased postnatal pup survival and body weight (Chernoff et al. 2011; Rogers et al. 2007). For individual study details, see the EPA's HESD for cylindrospermopsin (U.S. EPA 2015c).

The RfD for cylindrospermopsin was derived from the 11-week critical study by Humpage and Falconer (2002, 2003). This study was an 11-week study in mice, and the critical effect identified was kidney toxicity. The short-term studies available for cylindrospermopsin (Shaw et al. 2001; Reisner et al. 2004), were also evaluated and are considered supportive of the critical study; however, the EPA concluded that they were not suitable for quantification based on limitations including the use of extract, lack of adequate numbers of animals, monitored endpoints, the limited number of doses tested and endpoints monitored.

Humpage and Falconer (2002, 2003) identified a NOAEL of 30 µg/kg/day and a LOAEL of 60 µg/kg/day for increases in relative kidney weight in mice treated with purified cylindrospermopsin by gavage for 11 weeks. There were indications of reduced renal function effects, decreased urinary protein, and red blood cell effects (including increased bilirubin, spleen weight and polychromasia, indicative of hemolysis) at doses above the LOAEL. Although effects on kidney weight and urine protein levels were observed in male mice, the biological relevance of the latter effect and whether it would also occur in female mice needs further investigation. Mice are known to excrete a group of

NMED Exhibit 93

highly polymorphic, low-molecular-weight urinary proteins that play important roles in social recognition and mate assessment. The relevance of the urinary protein findings in mice to humans is unknown. Humpage and Falconer (2002, 2003) found signs indicative of hemolysis (e.g., increased bilirubin, spleen weight and polychromasia), however these changes were not statistically significant.

Results from Reisner et al. (2004) corroborate Humpage and Falconer (2002, 2003) with comparable effects observed in mice during a three-week study. The kidney and red blood cell effects observed by Reisner et al. (2004) occurred at a LOAEL of 66 μg/kg/day in drinking water. The study authors demonstrated significant increases in hematocrit, acanthocytes (abnormal red blood cells), and liver and testes weights in exposed animals and a duration-related nonsignificant increase in kidney weight. The red blood cell effects were seen as early as the end of the first week of dosing and were present in each of the three weekly blood samples collected. Sukenik et al. (2006) observed similar effects on red blood cells (increases in hematocrit from week 16 to 32 accompanied by increased numbers of acanthocytes up to week 42) in male and female mice exposed to gradually increasing concentrations of cylindrospermopsin (i.e., from 100 to 550 μg/L) in drinking water for 42 weeks. Mice were given cylindrospermopsin in the form of spent medium on which cultures of *Aphanizomenon ovalisporum* had been grown; other medium components were not characterized. The authors proposed a LOAEL of 20 μg/kg/day (equivalent to 200 μg/L) for male and female mice based on changes in hematocrit at 16 weeks (Sukenik et al. 2006). This study was not selected as a critical study because this study used a single dose; however, the kidney and red blood cell effects at that dose after three weeks were comparable to the effects seen in the Humpage and Falconer (2002, 2003) study at a slightly lower 60 mg/kg/day dose after 11 weeks.

The short-term study by Shaw et al. (2001) was also considered in the development of the RfD for cylindrospermopsin. Shaw et al. (2001) reported liver effects (fatty infiltration) in mice given 50 μg/kg purified cylindrospermopsin by gavage for 14 days; this dose is lower than the NOAEL identified in the key study by Humpage and Falconer (2002, 2003). However, the EPA concluded that the Shaw et al. (2001) study was not suitable for quantification based on the limited number of doses tested.

A 90-day oral toxicity study by Chernoff et al. (2018) demonstrated signs of hepatic and renal injury in mice at all dose levels (0, 75, 150, and 300 μg/kg/day). Liver toxicity effects were noted by elevated absolute and relative liver weights, increases in serum alanine aminotransferase activity, reduced serum blood urea nitrogen and cholesterol levels, and increased incidence of hepatocellular hypertrophy and cord disruption. Renal toxicity effects were demonstrated in elevated absolute and relative kidney weights and renal cellular hypertrophy, tubule dilation, and cortical tubule lesions. Males showed more susceptibility to toxic effects; liver and kidney/body weight ratios, reduced cholesterol levels, cellular signs of inflammation, and degree and extent of renal histopathological damage were all observed to be more prominent in males. A NOAEL was not determined for any dose level based on significant liver and kidney effects exhibited in the 75 μg/kg group. The LOAEL of 75 μg/kg observed by Chernoff et al. (2018) is higher than the Humpage and Falconer (2002, 2003) NOAEL of 30 μg/kg.

NMED Exhibit 93

Table 5-2. Kidney and Liver Effects in Animals Exposed to Cylindrospermopsin (Purified) in Acute and Key Short-term Studies in the *Health Effects Support Document for the Cyanobacterial Toxin Cylindrospermopsin* (U.S. EPA 2015c)

Species	Exposure Route	Dosing Regimen	Description of Kidney and Liver Effects	Study
Male Swiss albino mice (10 mice per group, except the highest dose group, which included 6 mice)	Gavage	Repeated doses of 0, 30, 60, 120, or 240 µg/kg/day for 11 weeks	Kidney: dose-related increases in relative kidney weight, proximal renal tubular damage, decreased urinary protein Liver: necrosis, inflammatory foci, and bile duct changes	Humpage and Falconer (2002, 2003)
CD-1 (Swiss-Webster) mice (18 to 20 per group)	Gavage	Repeated doses of 0, 75, 150, or 300 µg/kg/day for 90 days	Kidney: elevated absolute and relative kidney weights, renal cellular hypertrophy, tubule dilation, cortical tubule lesions Liver: elevated absolute and relative liver weights, increases in serum alanine aminotransferase activity, reduced serum blood urea nitrogen and cholesterol levels, increased incidence of hepatocellular hypertrophy and cord disruption	Chernoff et al. (2018)
Male Swiss mice (3 per group)	Gavage	Single dose of 1,000, 2,000, or 4,000 µg/kg Examination at 24 hours after treatment	Liver: dark red liver, apoptosis in the liver and the kidneys	Bazin et al. (2012)
Male ICR mice (n = 24, single group)	Intraperitoneal injection	Single dose of 200 µg/kg Three animals sacrificed at 8 time points, 16–100 hours after treatment	Kidney: proliferation of the endoplasmic reticulum and fat droplet accumulation in cells along the brush borders of the tubules plus limited single cell necrosis Liver: necrosis in the centrilobular region	Terao et al. (1994)
Male ICR mice (4 per group)	Drinking water	Repeated doses of 0 or 0.6 mg/L (estimated at 66 µg/kg/day) for 3 weeks	Kidney: duration-related nonsignificant increase in kidney weight Liver: increases in relative weight	Reisner et al. (2004)
Quackenbush mice (4 per group)	Intraperitoneal injection	Single dose of 200 µg/kg	Liver: fatty infiltration and cell necrosis	Shaw et al. (2001)

NMED Exhibit 93

Species	Exposure Route	Dosing Regimen	Description of Kidney and Liver Effects	Study
Quackenbush mice (4 per group)	Gavage or intraperitoneal injection	0 to 300 μg/kg/day (oral) or 0 to 25 μg/kg/day (intraperitoneal injection) for 14 days	Liver: fatty infiltration (oral), foamy hepatocellular cytoplasm (intraperitoneal injection)	Shaw et al. (2001)

The Humpage and Falconer (2002, 2003) study was determined to be the most appropriate for the quantitative assessment because the LOAEL at 11 weeks would be protective for the effects seen at three weeks in the shorter duration study. For these reasons, this RfD was deemed suitable for development of the short-term drinking water health advisory and for use in recreational exposure scenarios. The EPA's HESD and Health Advisory documents for cylindrospermopsin describe the selection of the critical study and effect in detail and provide the rationale for applicability of the longer-term duration study (U.S. EPA 2015c).

5.1.1.2 Human Studies

Microcystins

The EPA identified the available epidemiological, outbreak, and case study reports on adverse health effects from oral exposures to microcystins. Limited human studies examining microcystin effects on humans exposed via drinking water are available, and no dose response data from oral exposure to microcystins in ambient water were identified. The scant human data on the oral toxicity of microcystin-LR are limited by the potential co-exposure to other pathogens, cyanotoxins, and microorganisms; by the lack of quantitative information; and by the failure to control for confounding factors. Available human studies evidence is supportive of the liver as a target organ for toxicity (Carmichael 2001; Falconer et al. 1983; Giannuzzi et al. 2011; Hilborn et al. 2013; Jochimsen et al. 1998; Li et al. 2011b). The EPA identified four epidemiological studies, three case reports, and two outbreak summaries that evaluated human health effects associated with recreational exposures to cyanobacteria and microcystins. This human health effects information is summarized in the paragraphs that follow.

Backer et al. (2008) characterized microcystin concentrations in blood and reported symptoms in people recreating in a lake with a *Microcystis aeruginosa* bloom to those of people recreating in a nearby bloom-free lake. Low levels of total microcystins (detection limit = 0.08 ng/m^3) were detected in air samples collected above a lake bloom. Phytoplankton counts ranged from 175,000 to 688,000 cells per mL with > 95 percent of those cells being cyanobacteria. Cell densities of potentially toxigenic cyanobacteria ranged from approximately 54,000 to 144,000 cells/mL. Although a visible bloom was present and contained cyanobacterial species capable of producing microcystin, microcystin concentrations in water during the study were low and ranged from 2 to 5 μg/L. Recreational users of the lake at the time of the bloom had no detectable microcystins in their blood and did not report an increase in GI, dermal, respiratory, or neurological symptoms after spending time on the lake. Adenoviruses (level of detection (LOD) = 1,250 gene copy equivalents) and enteroviruses (LOD = 200 plaque forming units/10 L) were not detected in any water sample. This study was limited in the number of participants (n = 104) and included a limited number of exposure days in the analysis (three days). The study demonstrated that people recreating on or in a water body can be exposed to aerosolized microcystins. However, given the limited number of participants and exposure days, and the low levels of microcystins present in the water and as aerosols, there were no reported increases in self-reported symptoms following recreational exposures. Other symptoms consistent with microcystin intoxication (e.g., liver toxicity) were not included in the study.

NMED Exhibit 93

Backer et al. (2010) applied the same experimental approach at three lakes in California. Two of the lakes experienced blooms producing much higher microcystin concentrations compared with the lakes studied in the Backer et al. (2008) study, and the third lake did not contain a toxin-producing bloom. Eighty-one people, aged 12 and older, participated in the study and engaged in waterskiing, using personal watercraft, swimming, or wading. Total microcystins present in the lake containing toxic blooms ranged from < 10 µg/L to > 500 µg/L. Measured microcystin concentrations from personal air samples ranged from the limit of detection (0.1 ng/m^3) to 2.89 ng/m^3; the mean air concentration was 0.4 ng/m^3. Similarly, nasal swabs ranged from below the limit of detection to 5 ng, and all blood samples were below the limit of detection. Recreators had a significantly higher amount of microcystins present in nasal swabs after exposure. No statistically significant differences were noted in the frequency of reported GI, dermal, or respiratory symptoms between participants immediately after they engaged in direct- or indirect-contact recreational activities in the lake with a cyanobacterial bloom and those in a lake without a cyanobacterial bloom. Other symptoms consistent with microcystin intoxication (e.g., liver toxicity) were not included in the study. Adenoviruses or enteroviruses were not detected at the study locations. The authors concluded that it is possible for microcystins to become aerosolized, which in turn represents a potential route of exposure to recreators. They recommended additional research studying larger populations and sensitive subgroups.

Lévesque et al. (2014) conducted a prospective study of residents living in proximity to three lakes in Canada affected by cyanobacteria and microcystins to investigate the relationship between recreational exposure, specifying full contact and limited contact with lake water, and the incidence of GI, dermal, respiratory, and other symptoms (e.g., ear pain, muscle pain). Full contact included swimming, waterskiing, windsurfing, use of watercraft involving launching, accidental falls, and similar activities, and limited contact included fishing, use of watercraft not involving launching, and other activities. The authors reported a dose-effect relationship (p-trend = 0.001) between total cyanobacterial cell counts and severe GI illness with a significant increase in reported symptoms starting at 20,000 cells/mL and above. The study reported a relative risk value of 3.28 (95 percent confidence interval (CI): 1.69–6.37) for the more severe GI symptom index (i.e., GI2, defined as diarrhea or vomiting or (nausea and fever) or (abdominal cramps and fever)) for exposures by full or limited contact to concentrations higher than 100,000 cells/mL (Lévesque et al. 2014). Adjusted relative risks of GI illness were significantly high for limited contact, but no relationship was found between GI symptoms and full contact. The authors explained that study participants avoided full contact with lake waters when high densities of cyanobacteria were visible, but continued to have limited contact. No significant fecal contamination measured by *Escherichia coli* (*E. coli*) was observed with geometric means in the lakes ranging from 8 to 145 colony forming units (CFU)/100 mL.[5] No associations were observed between any symptoms and recreational exposures to microcystins. Overall, the microcystin concentrations were low during the study, and the reported lower bound of the upper tertile was 0.2456 µg/L. The maximum microcystin concentrations for which recreational-related GI symptoms were reported was 7.65 g/L; however, microcystins occurred at much higher concentrations (e.g., maximum reported microcystin concentrations of 108 µg/L and 773 µg/L at two of the study locations), but there was no significant trend of increasing illness symptoms with elevated toxin concentrations. The study did not characterize the primary endpoint of concern for exposure to microcystins (i.e., liver toxicity) and did not conduct the necessary medical testing to determine liver function impairment.

Lévesque et al. (2016) provided additional analysis of the prospective study reported previously. Because GI illness was significantly associated with increasing cyanobacterial cell densities and GI

[5] Current Canadian recreational water guidelines for *E. coli*: geometric mean ≤ 200 *E. coli*/100 mL and single-sample maximum ≤ 400 *E. coli*/100 mL (Health Canada 2012).

NMED Exhibit 93

symptoms can be related to cellular constituents, also termed *endotoxins* in the literature, the authors characterized the relationship between endotoxin exposure and illness in the study participants. Endotoxins include cell wall-associated lipopolysaccharides present in cyanobacteria and Gram negative bacteria. Frozen filters collected during the study were analyzed for endotoxins. The authors found a weak correlation between endotoxin levels and cyanobacteria cell density and reported a significant trend of increasing GI illness with increasing endotoxin concentrations. They also suggest that endotoxin concentrations could be a surrogate for another stressor. They cite other researchers that have suggested the endotoxins could be contributed by other members of the microbial community or the reported symptoms could be related to another stressor (Berg et al. 2008; Blahova et al. 2013; Rapala et al. 2002; Stewart 2006d).

In a recent case report by Vidal et al. (2017), a 20-month-old child and three adults reported GI symptoms several hours after engaging in bathing and other recreational activities at beaches in Montevideo, Uruguay, during January 2015. At that time, a cyanobacterial bloom of mainly *Microcystis* occurred in the River de la Plata. While the GI symptoms in the adults (i.e., diarrhea) rapidly resolved, the child's symptoms (i.e., diarrhea and vomiting) persisted. The child developed fatigue and jaundice, and five days after the exposure, she was admitted to hospital. Tests showed significant increases in bilirubin and serum liver enzymes, and a diagnosis of acute liver failure was given. The child was recommended for, and received, a liver transplant. The city government's beach monitoring program from April 2014 to March 2015 reported mean and maximum microcystin concentrations of 2.9 µg/L of 56 µg/L, respectively. These levels were reported in water samples from the beaches the family used with cyanobacteria presence but without cyanobacterial foam. Mean and maximum microcystin concentrations of 2,900 µg/L and 8,200 µg/L, respectively, were reported in water samples with cyanobacterial foam. The monitoring program also reported geometric means of fecal coliform values below the limit of 1,000 CFU/100 mL. After the child received a liver transplant, histological analysis of the explanted liver revealed liver damage characterized by hemorrhagic necrosis, intracytoplasmic cholestasis, large and multinucleated hepatocytes, proliferation, and nodular regeneration. The pathological findings and detection of microcystin-LR in the liver (2.4 ng microcystin-LR/g and 75.4 ng (D-Leu1) microcystin-LR/g liver) led to a diagnosis of acute liver failure related to exposure to microcystin-LR and cyanobacteria.

In another case report, acute intoxication with microcystin-producing cyanobacterial blooms in recreational water was reported in Argentina in 2007 (Giannuzzi et al. 2011). A male Jet Skier was exposed to a *Microcystis* bloom containing 33,680 and 35,740 cells/mL. A level of 48.6 µg/L of microcystin-LR concentrations was detected in water samples associated with the bloom. The subject was immersed for two hours as a result of an accident that required him to swim to the shoreline towing the Jet Ski. Four hours later the subject reported experiencing nausea and abdominal pain. Three days later the subject sought medical assistance because of respiratory distress requiring his hospitalization. One week after the exposure, the patient developed a hepatotoxicosis with a significant increase of serum alanine aminotransferase, aspartate aminotransferase, and γ-glutamyltransferase. With treatment, the patient recovered within 20 days.

An outbreak among army recruits undergoing canoe exercises who had consumed reservoir water containing a bloom of *Microcystis aeruginosa* reported symptoms of headache, sore throat, vomiting and nausea, stomach pain, dry cough, diarrhea, blistering around the mouth, and pneumonia (Turner et al. 1990). Microcystins, including microcystin-LR, were present in bloom samples. However, high levels of *E. coli* were also found in reservoir water after two weeks. The authors suggested that exposure

NMED Exhibit 93

to microcystins may have had a role in some of the clinical symptoms; however, this case report information is insufficient to establish cause and effect.

Dziuban et al. (2006) and Hilborn et al. (2014) reported 10 outbreaks associated with recreational exposure to cyanobacteria in which microcystins were detected. Hilborn et al. (2014) reported that eight of these investigations evaluated the presence of cyanotoxins; eight detected microcystins; and two detected cylindrospermopsin. In four of the outbreaks, microcystin concentrations ranged from 0.2 µg/L to > 2,000 µg/L. Four outbreaks had microcystin concentrations > 20 µg/L. Cylindrospermopsin and anatoxin-a also were detected in three of the outbreaks. In one outbreak, 20.8 µg/L microcystins was measured, and other cyanotoxins were either not detected or measured. The nine persons reporting illness for this outbreak had symptoms that included abdominal cramps (3 people), diarrhea (3), nausea (3) vomiting (2), fever (2), headache (2), rash (8), eye irritation (1), ear ache (1), neurologic symptoms (2), tingling (2), confusion (1), and respiratory symptoms (1) (Hilborn et al. 2014). Dziuban et al. (2006) reported on two 2004 cyanobacteria-associated outbreaks in which 22 cases of illness were associated with elevated levels of microcystins in Nebraska lakes. The predominant illnesses in both outbreaks included dermatitis and gastroenteritis, and individuals who sought medical care showed a combination of rashes, diarrhea, cramps, nausea, vomiting, and fevers. Walker et al. (2008) also reported about a Nebraska outbreak. Levels of total microcystins at the east swimming beach of Pawnee Lake exceeded 15 ppb on July 12, 2004, and a health alert was issued. However, heavy public use of Pawnee Lake occurred that weekend and more than 50 calls were received from the public, complaining about symptoms such as skin rashes, lesions, blisters, vomiting, headaches, and diarrhea after swimming or water skiing in Pawnee Lake (Walker et al. 2008). The outbreak reports data are not sufficient to establish cause and effects for microcystins because of weaknesses in the nature of the data reported and the many potential confounding variables. The researchers concluded that the disease outbreak data suggest that the time to onset of effects might be rapid, that children might be at higher risk for illness, and that these types of outbreaks occur during the warmer months. Hilborn et al. (2014) noted that HAB-associated illness from recreational exposure might be underreported due to multiple possible exposure routes and the non-specific nature of potential health effects.

Graham et al. (2009) counted 36 states with anecdotal reports of acute cyanotoxin poisonings of animals, humans, or both as reported in journal articles and newspaper articles (Chorus and Bartram 1999; Hilborn et al. 2014; Huisman et al. 2005; Yoo et al. 1995).

Information on the human health effects of microcystins based on epidemiological studies related to drinking water exposures to microcystins are discussed in detail in the EPA's HESD for microcystins (U.S. EPA 2015d). These studies are summarized in the paragraphs that follow.

An epidemiology study done in Australia compared the hepatic enzyme levels from patients served by a public water supply contaminated with a *Microcystis aeruginosa* bloom with enzyme levels from patients living in areas served by water supplies uncontaminated by cyanobacteria (Falconer et al. 1983). Although the authors observed significant variability in enzyme levels between the two groups, the findings were attributed by the authors to the imprecise method of study participant selection and confounding factors such as alcoholism and chronic kidney disease among some of the participants.

A cross-sectional study conducted in China assessed the relationship between the consumption of drinking water and aquatic food (carp and duck) contaminated with microcystins and liver damage in children (Li et al. 2011b). The authors found that mean serum levels of microcystins ranged from below detection to 1.3 µg microcystin-LR equivalents/L. According to the authors, hepatitis B infection was a greater risk for liver damage among these children than the microcystins exposure.

NMED Exhibit 93

An outbreak of acute liver failure occurred in a dialysis clinic in 1996 in Caruaru, Brazil, where dialysis water was contaminated with microcystins, and possibly cylindrospermopsin. Of the 130 patients who received their routine hemodialysis treatment (intravenously) at that time, 116 reported symptoms of headache, eye pain, blurred vision, nausea, and vomiting. Subsequently, 100 of the affected patients developed acute liver failure and, of these, 76 died (Carmichael et al. 2001; Jochimsen et al. 1998). Analyses of blood, sera, and liver samples from the patients revealed microcystins.

In another contamination event at a dialysis center in Rio de Janeiro, Brazil, in 2001, 44 dialysis patients were potentially exposed to microcystin concentrations of 0.32 µg/L, detected in the activated carbon filter used in an intermediate step for treating drinking water to prepare dialysate (Soares et al. 2005). Concentrations of 0.4 µg/L microcystin-LR were detected in the drinking water. Serum samples were collected from 13 dialysis patients 31 to 38 days after the detections in water samples, and patients were monitored for eight weeks. Concentrations of microcystin-LR in the serum ranged from 0.46 to 0.96 ng/mL. Although the biochemical outcomes varied among the patients, markers of hepatic cellular injury and of chlolestasis (elevations of AST, ALT bilirubin, ALP, and GGT) in serum during weeks one to eight after treatment frequently exceeded normal values (Hilborn et al. 2013). Because microcystin-LR was not detected in the dialysate during weekly monitoring after the first detection, the authors suggested that the patients were not continuously exposed to the toxin and that the toxin detected in the serum after eight weeks may have been present in the form of bound toxin in the liver (Soares et al. 2005). Results were consistent with a mild to moderate mixed liver injury (Hilborn et al. 2013). Although the patients in the study had pre-existing diseases, the direct intravenous exposure to dialysate prepared from surface drinking water supplies put them at risk for cyanotoxin exposure and resultant adverse effects (Hilborn et al. 2013).

Cylindrospermopsin

No epidemiological studies were identified for recreational exposure to cylindrospermopsin.

Hilborn et al. (2014) reported two outbreaks associated with recreational exposure to HABs in which cylindrospermopsin was detected between 2009 and 2010. However, cyanobacteria, microcystins, and other cyanotoxins were also present. As mentioned earlier, the results reported from the outbreaks should not be interpreted as cause and effect.

Human data on oral toxicity of cylindrospermopsin are limited, but results indicate that kidney and liver exhibit adverse effects due to cylindrospermopsin exposures. Information on the human health effects of cylindrospermopsin based on epidemiological studies related to drinking water are discussed in detail in the EPA's HESD for cylindrospermopsin (U.S. EPA 2015c). This information is summarized in the paragraphs that follow.

Reports of a hepatoenteritis-like outbreak (mostly in children) in Palm Island, Australia, in 1979 were attributed to consumption of drinking water with a bloom of *Cylindrospermopsis raciborskii*, a cyanobacteria that can produce cylindrospermopsin. No data are available on exposure levels or potential co-exposures to other cyanobacterial toxins and microorganisms. The majority of the cases, mostly children, required hospitalization. The clinical picture included fever, headache, vomiting, bloody diarrhea, hepatomegaly, and kidney damage with loss of water, electrolytes, and protein (Byth 1980; Griffiths and Saker 2003).

Dermal exposure to cylindrospermopsin was evaluated using skin-patch testing in humans (Pilotto et al. 2004; Stewart et al. 2006a). Exposed individuals showed mild irritation, but no statistically significant

NMED Exhibit 93

dose-response relationship or reaction rates were found between skin reactions and increasing cell concentrations for either whole or lysed cells (Pilotto et al. 2004). No detectable skin reactions were observed in individuals exposed to lyophilized *Cylindrospermopsis raciborskii* (Stewart et al. 2006a).

5.1.1.3 Mode of Action for Noncancer Health Effects

Microcystins

Mechanistic studies have shown the importance of membrane transporters for systemic uptake and tissue distribution of microcystins by all exposure routes (Feurstein et al. 2010; Fischer et al. 2005). The importance of the membrane transporters to systemic uptake and tissue access is demonstrated by studies where there was either no liver damage or reduced damage when the hepatic organic anion transporting polypeptide (OATP) receptors were inhibited (Hermansky et al. 1990a, 1990b; Thompson and Pace 1992). OATPs are a transporter family that controls uptake of microcystins by the liver (Fischer et al. 2005).

The uptake of microcystins causes protein phosphatase inhibition and a loss of coordination between cytoskeletal protein phosphorylation by kinases and dephosphorylation by phosphatases. This event initiates altered cell function followed by cellular apoptosis and necrosis (Barford et al. 1998). Both cellular kinases and phosphatases keep the balance between phosphorylation and dephosphorylation of key cellular proteins controlling organization of the cytoskeleton, metabolic processes, gene regulation, cell cycle control, transport and secretory processes, and cell adhesion. Each of the microcystin congeners evaluated (LR, LA, and LL) interacts with catalytic subunits of protein phosphatases PP1 and PP2A, inhibiting their functions (Craig et al. 1996).

As a consequence of the microcystin-induced changes in cytoskeleton proteins, an increase in cellular reactive oxygen species (ROS) leads to cellular apoptosis. In both in vitro and in vivo studies, cellular pro-apoptotic Bax and Bid proteins increased whereas anti-apoptotic Bcl-2 decreased (Fu et al. 2005; Huang et al. 2011; Li et al. 2011a; Takumi et al. 2010; Weng et al. 2007; Xing et al. 2008). Mitochondrial membrane potential and permeability transition pore changes (Ding and Nam Ong 2003; Zhou et al. 2012) lead to membrane loss of cytochrome c, a biomarker for apoptotic events. Wei et al. (2008) identified a time-dependent increase in ROS production and lipid peroxidation in mice after exposure to microcystin-LR. Following intraperitoneal injection of 55 μg/kg of body weight microcystin-LR, the levels of hepatic ROS increased within 0.5 hours of treatment and continued to accumulate for up to 12 hours in a time-dependent manner.

Cylindrospermopsin

Despite the number of studies that have been published, the mechanisms for liver and kidney toxicity by cylindrospermopsin are not completely characterized.

In vitro and in vivo studies showed that cylindrospermopsin can inhibit hepatic protein synthesis (Froscio et al. 2003; Froscio et al. 2008; Terao et al. 1994), which could impact mouse urinary protein production leading to decreased urinary excretion of these proteins. Available evidence indicates that protein synthesis inhibition is not decreased by broad-spectrum CYP450 inhibitors, but they do reduce cytotoxicity (Bazin et al. 2010; Froscio et al. 2003). Hepatotoxicity appears to be CYP450-dependent, which indicates a possible involvement of oxidized or fragmented metabolites and mechanisms other than protein synthesis inhibition (Froscio et al. 2003; Humpage et al. 2005; Norris et al. 2002; Norris et al. 2001).

NMED Exhibit 93

In the Reisner et al. (2004) and Sukenik et al. (2006) reports, microscopic examination of blood samples showed the presence of red blood cells with spiked surfaces rather than their normal biconcave-disc shape. The authors attributed the acanthocyte formation to an increase in the cholesterol to phospholipid ratio of the red blood cell membrane. Phospholipids constitute the matrix material of cell membranes. The authors hypothesized that this change was the consequence of decreased activity of plasma lecithin cholesterol acyl transferase, an enzyme associated with high-density lipoproteins and the esterification of plasma cholesterol. Effects on the cholesterol content of the red blood cell membrane can occur with inhibition of the enzyme increasing membrane fluidity and mean corpuscular volume. Removal of the abnormal blood cells by the spleen increases both spleen weight and serum bilirubin as well as stimulates hematopoiesis. Additional research is needed to examine the lecithin cholesterol acyl transferase enzyme inhibition hypothesis to confirm whether it accounts for the effects on the red blood cell as a result of cylindrospermopsin exposure.

Kidney necrosis and a decreased renal failure index at the high cylindrospermopsin doses in Humpage and Falconer (2002, 2003) are also indicative of an effect on the kidney. Numerous signs of renal damage including proteinuria, glycosuria, and hematuria were also observed in humans after a hepatoenteritis-like outbreak in Palm Island, Australia, in 1979 (Byth 1980). The outbreak was attributed to consumption of drinking water from source waters with a bloom of *Cylindrospermopsis raciborskii*. These effects have been shown to be related to impaired kidney function (Byth 1980); however, no mode of action information for kidney effects was observed in the available animal or human studies of cylindrospermopsin. Because all the studies were conducted in mice, a species that excretes low-molecular-weight proteins in urine, a study is needed of cylindrospermopsin in a laboratory species that does not excrete protein in the urine to determine whether there are comparable effects on kidney weight, protein excretion, and renal cellular damage.

5.1.2 Cancer

5.1.2.1 Weight of Evidence Classification

While there is evidence of an association between liver and colorectal cancers in humans and microcystins exposure and some evidence that microcystin-LR is a tumor promoter in mechanistic studies, there is "*inadequate information to assess carcinogenic potential"* of microcystins in humans (U.S. EPA 2005b). The human studies are limited by lack of exposure information and the uncertainty regarding whether these studies adequately controlled for confounding factors such as hepatitis B infection. No chronic cancer bioassays for microcystins in animals are available. The EPA (U.S. EPA 2005a) states that the descriptor of "*inadequate information to assess carcinogenic potential*" is appropriate when available data are judged inadequate for applying one of the other descriptors or for situations where there is little or no pertinent information or conflicting information. The guidelines also state that (p. 2-52) "Descriptors can be selected for an agent that has not been tested in a cancer bioassay if sufficient other information, e.g., toxicokinetic and mode of action information, is available to make a strong, convincing, and logical case through scientific inference." In the case of microcystins, the data suggest that microcystin-LR may be a tumor promoter but not an initiator. Without strong epidemiological data and a chronic bioassay of purified microcystin-LR, the data do not support classifying microcystin-LR as a carcinogen.

No chronic cancer bioassays of cylindrospermopsin were located in the literature. Limited data from an in vivo study showed no indication that the cyanobacterial extract containing cylindrospermopsin in the presence of a tumor promotor indicated preneoplastic changes consistent with its having tumorigenic

NMED Exhibit 93

activity in mice (Falconer and Humpage 2001). Following the EPA guidelines (U.S. EPA 2005a), there is inadequate information to assess carcinogenic potential of cylindrospermopsin.

5.2 Dose-response Assessment

The RfD value for microcystins used to derive this recreational AWQC or swimming advisory is described in the EPA's HESD for microcystins (U.S. EPA 2015d). The EPA identified a 28-day study in male hybrid rats by Heinze (1999) as the critical study (described in section 5.1.1). A LOAEL of 50 µg/kg/day was identified based on increased liver weight, slight to moderate liver necrosis (necrotic severity was dose-related) with hemorrhages, and increased enzyme levels, which was used to derive an RfD of 0.05 µg/kg/day. The EPA selected the study by Heinze (1999) based on the appropriateness of the study duration, the use of multiple doses, dose-related toxicological responses, and histopathological evaluations of toxicity. After 28 days of exposure, rat organ weights (liver, kidneys, adrenals, thymus, and spleen) were measured, and hematology, serum biochemistry, and histopathology of liver and kidneys were evaluated. The critical effect in the Heinze (1999) study was supported by additional acute and subchronic data as described in the EPA's HESD for microcystins and summarized in section 5.1.1.1. The EPA's selection of uncertainty factors and derivation of the RfD are documented in its HESD for microcystins (U.S. EPA 2015d).

The RfD value for cylindrospermopsin used to derive the AWQC and swimming advisory is described in the EPA's HESD for cylindrospermopsin (U.S. EPA 2015c). The EPA identified an 11-week study in mice by Humpage and Falconer (2002, 2003) as the critical study for development of the RfD. The NOAEL was 30 µg/kg/day dose for increases in relative kidney weight seen at the LOAEL of 60 µg/kg/day. Increased relative kidney weights was the critical effect on which to base the point of departure. The EPA's selection of UFs and derivation of the RfD are documented in its HESD for cylindrospermopsin (U.S. EPA 2015c).

NMED Exhibit 93

6.0 RECOMMENDED RECREATIONAL CRITERIA AND SWIMMING ADVISORY DERIVATION

This section summarizes the inputs and shows the calculation for the recommended recreational criteria and swimming advisories for microcystins and cylindrospermopsin.

6.1 Microcystins Magnitude

The magnitude of the recommended recreational criteria and swimming advisory for microcystin toxins is calculated as follows:

$$\text{Recreational value } (\mu g/L) = RfD \times \frac{BW}{IR}$$

Where:

RfD (µg/kg/day)	=	0.05 µg/kg/day (U.S. EPA 2015d)
BW (kg)	=	31.8 kg (mean body weight of children six to 10 years; U.S. EPA 2011)
IR (L/day)	=	0.21 L/day (90th percentile daily recreational water incidental ingestion rate for children age six to 10 years; Appendix E; U.S. EPA 2018a; U.S. EPA 2011; see section 4.2.3.1)

$$\text{Microcystins recommended recreational value} = 0.05\ \mu g/kg/day \times \frac{31.8\ kg}{0.21\ L/day} = 8\ \mu g/L$$

6.2 Cylindrospermopsin Magnitude

The magnitude of the recommended recreational criteria and swimming advisory values for cylindrospermopsin is calculated as follows:

$$\text{Recreational value } (\mu g/L) = RfD \times \frac{BW}{IR}$$

Where:

RfD (µg/kg/day)	=	0.1 µg/kg/day (U.S. EPA 2015c)
BW (kg)	=	31.8 kg (mean body weight of children six to 10 years; U.S. EPA 2011)
IR (L/day)	=	0.21 L/day (90th percentile daily recreational water incidental ingestion rate for children age six to 10 years; Appendix E; U.S. EPA 2018a; U.S. EPA 2011; see section 4.2.3.1)

$$\text{Cylindrospermopsin recommended recreational value} = 0.1\ \mu g/kg/day \times \frac{31.8\ kg}{0.21\ L/day} = 15\ \mu g/L$$

6.3 Frequency and Duration for Recreational Criteria

The frequency and duration components of a criterion describe how often and for how long a water body's conditions can exceed the magnitude and be protective of the designated use (U.S. EPA 2005c). HABs can occur naturally, but can be an uncommon event due to a convergence of climatic and other environmental factors that result in a single short-term bloom lasting days or a couple of weeks. In some cases, multiple HABs can occur in a single year. Alternatively, longer-term HABs can occur regularly in some waters lasting for a few weeks, months, or possibly all year. HABs can occur while conditions conducive to cyanobacterial proliferation exist and limit the use of the water body for primary recreation. Water bodies where a toxic HAB has occurred in the past may experience repeat occurrences of elevated toxins when bloom-promoting conditions reoccur. In some circumstances, anthropogenic inputs are identified and controlled, and the conditions that cause the bloom can be mitigated.

The EPA recognizes that a single sample above the cyanotoxin criteria magnitude does not necessarily indicate that the designated recreational use is not attained. However, when cyanotoxin concentrations exceed the criteria magnitude either in multiple short-term blooms within a year or from a single bloom that persists for an extended period within a year, and when these patterns occur in more than one year, the designated recreational use may not be attained. The frequency and duration components discussed in this section support the identification of a trend or pattern of cyanotoxin excursions that state decision makers can use to inform the evaluation of a water body. The EPA recommends that decisions on whether the designated recreational use is attained should be flexible enough to address both types of exposure patterns when patterns reoccur in more than one year (short-term blooms that occur frequently in a recreational season, or blooms that persist for an extended period during a recreational season). States may want to evaluate the pattern of bloom occurrence and toxin concentrations within and across years to determine if there is a trend toward degradation of the water quality.

The EPA's recommended criteria duration rely on the underlying toxicity data used to derive the criteria. For both toxins, animal toxicological studies consistently demonstrate adverse health effects at various dosages and relevant timeframes. See Tables 5-1 and 5-2. For microcystins, the key study (Heinze 1999) shows adverse liver effects from repeated microcystin exposures (50 and 150 μg/kg body weight) during a study duration of 28 days. Another supporting study showed similar effects (Guzman and Solter 1999). For cylindrospermopsin, the key study (Humpage and Falconer 2002, 2003) had a duration of 11 weeks. The shorter-term studies available for cylindrospermopsin (Shaw et al., 2001; Reisner et al., 2004) were not suitable for quantification due to study limitations; however, effects observed in these studies are the same or similar to the Humpage and Falconer study (2002, 2003) and occur at similar doses. The LOAEL derived from Humpage and Falconer (2002, 2003) was determined to be protective for the adverse effects observed in the shorter duration studies. For both key studies, adverse health effects were noted at the end of the study period and it is not known if those effects occurred earlier.

The criteria are based on the same science used to develop the EPA's Drinking Water Health Advisories for microcystins and cylindrospermopsin, which are 10-day advisories (U.S. EPA 2015a, 2015b). The 10-day drinking water health advisory values represent concentrations of cyanotoxins in finished drinking water below which adverse noncarcinogenic effects are not expected to result from ingestion of drinking water over a 10-day period. Following the detection and confirmation of microcystins or cylindrospermopsin in finished drinking water above the health advisory values, the EPA recommends that drinking water utilities initiate actions to reduce exposure to consumers including determining when to notify drinking water consumers who may be more susceptible to adverse outcomes (U.S. EPA 2015c). If the advisory level continues to be exceeded after 10 days, additional public health measures can be taken, including a do-not-drink and do-not-boil water advisory. Recreational water managers

NMED Exhibit 93

have fewer options to reduce exposure to toxins in recreational waters than do drinking water treatment operators, as recreational water does not go through a treatment process.

The EPA recommends states use 10-day assessment periods over the course of a recreation season to evaluate ambient water body condition and recreational use attainment. The 10-day period links the water body assessment to the adverse health effects from ingestion of the toxins over short-term exposures, consistent with the EPA's Drinking Water Health Advisory (described in greater detail in section 5.1). Also, Cordell (2012) discussed decade-long trends in outdoor recreation activities showing a significant proportion (43 percent) of Americans visited a beach in 2005–2009, up almost 21 percent over the previous decade. Over the same timeframe, participation in swimming in lakes and streams (42 percent of the population) increased by 14 percent (Cordell 2012). Beach visitation surveys have shown that nearly half (47 percent) of the local population are regular beach users with five or more visits in a recreation season (Caldwell et al. 2013). The recommended assessment period is reasonable considering beach visitation rates for recreators living in proximity to a beach or vacationing at a beach for a week or two with daily beach visits expected. Exposure to recreational waters containing microcystins or cylindrospermopsin at or below the recommended magnitude concentrations over the short-term 10-day duration would not be expected to result in the adverse health effects discussed in section 5.

The EPA recommends that if toxin concentrations are higher than the criterion magnitude in a sample collected during a 10-day assessment period, that period should be considered an excursion from the recreational criteria. Elevated toxin concentrations can occur over hours, days, or a couple of weeks and are counted as excursions in a recreational season. A short-term HAB that does not reoccur can result in a small number of excursions of the criteria but is not expected to result in impairment of the recreational use. Such algal blooms may result from conditions that occur naturally (e.g., as a result of unusually hot conditions), but not frequently. Following an excursion (an exceedance during the 10-day assessment period), the EPA recommends increasing the monitoring frequency to better understand the temporal and spatial nature of cyanotoxin occurrence in the affected waterbody.

In some waterbodies, longer-term HABs can persist for many weeks to months with conditions conducive to cyanobacterial proliferation. This can result in many excursions of the recommended toxin values during a recreation season. The EPA recommends that when more than three excursions (an exceedance during the 10-day assessment period) occur within a recreational season and that pattern reoccurs in more than one year, it is an indication the water quality is or is becoming degraded such that the water body no longer supports the recreational use. Recreational freshwaters at lower latitudes can have longer recreational seasons compared with those waters found at higher latitudes. For those waters in more temperate areas with a recreational season of approximately 100 days (i.e., from Memorial Day to Labor Day), three excursions could translate into a maximum of 30 percent of the recreational season not supporting the designated recreational use. Surface waters in areas with longer recreational seasons can also experience conditions that can support HAB proliferation and cyanotoxin occurrence for a longer period of the year. A maximum of three excursions across a recreational season reflects seasonal dynamics and occurrence patterns of HABs within years and the potential for adverse health effects over a short-term duration of exposure (i.e., approximately 30 days).

The EPA recognizes that multiple environmental factors can cause variability in bloom formation and toxin production, and that some years may produce HABs that occur for long periods, or HABs of shorter duration that occur repeatedly throughout a single recreational season, but such events may not occur every year. Therefore, the EPA concludes that it is appropriate to consider a pattern of multiple excursions within a recreational season as well as in multiple years (i.e., more than one year) when

NMED Exhibit 93

determining whether the use is attained. It is important to note that the years with multiple excursions do not have to be consecutive to indicate a water quality problem. The upper-bound frequency (e.g., one year out of three years) is a risk-management decision that states need to determine when developing their water quality standards (WQS). States should include in their WQS the maximum number of years a pattern of cyanotoxin excursions can occur for the recreational use to remain supported.

The EPA does not recommend using a 10-day average concentration or a rolling average to determine an excursion, consistent with available toxicity information. States have flexibility in applying the 10-day assessment period. Some may choose to use pre-defined 10-day assessment periods for water bodies with a documented history of HAB occurrence or detection of elevated levels of cyanotoxins. Another approach is to begin the 10-day assessment period upon observation of a visible bloom. However, only considering the presence of visible blooms can miss episodes of elevated toxins (Raymond 2016). States are encouraged to consider the application of the frequency and duration components to capture elevated toxin concentrations, which may or may not coincide with the general proliferation of total cyanobacteria at high densities. More information on implementation of these values as criteria is provided in technical support materials.

6.4 Frequency and Duration for Swimming Advisory

Local and state governments can use swimming advisories to provide information to recreators on their potential exposure to cyanobacteria and their toxins. Some local and state governments currently post notifications for swimmers, in the form of advisories or warnings, when a cyanobacterial bloom is reported in recreational waters or when cyanotoxin levels exceed advisory thresholds. Table B-2 in Appendix B summarizes currently available information on state cyanotoxin-related guidelines and associated actions, including the issuance of swimming advisories.

The EPA recommends that the magnitude of the swimming advisory value not be exceeded on any single day, to provide timely information for people visiting beaches. The EPA also recommends that any exceedance of the recommended magnitude result in a swimming advisory being issued until the toxin concentration falls below the recommended magnitude. By increasing the monitoring frequency at a site where a swimming advisory is issued, water resources managers may get a clearer understanding of the temporal and spatial nature of water quality that can be useful in making decisions that protect the recreational use. Increased monitoring can also help water managers decide when to remove an advisory. The EPA has published materials for recreational water body managers that describe communicating risk to the public about cyanotoxins in recreational water bodies, monitoring, and responding to HABs (U.S. EPA 2017).

6.5 Recommended Recreational Criteria and Swimming Advisory for Microcystins and Cylindrospermopsin

The magnitude, duration, and frequency are summarized in Table 6-1.

NMED Exhibit 93

Table 6-1. Recreational Criteria or Swimming Advisory Recommendations for Microcystins and Cylindrospermopsin[a]

Application of Recommended Values	Microcystins			Cylindrospermopsin		
	Magnitude (µg/L)	Duration	Frequency	Magnitude (µg/L)	Duration	Frequency
Recreational Water Quality Criteria	8	1 in 10-day assessment period across a recreational season	More than 3 excursions in a recreational season, not to be exceeded in more than one year[b]	15	1 in 10-day assessment period across a recreational season	More than 3 excursions in a recreational season, not to be exceeded in more than one year[b]
Swimming Advisory		One day	Not to be exceeded		One day	Not to be exceeded

[a] These recommendations can apply independently within an advisory program or in WQS. States can choose to apply either or both toxin recommendations when evaluating excursions within and across recreational seasons.

[b] An excursion is defined as a 10-day assessment period with any toxin concentration higher than the criteria magnitude. When more than three excursions occur within a recreational season and that pattern reoccurs in more than one year, it is an indication the water quality has been or is becoming degraded and is not supporting its recreational use. **As a risk-management decision, states should include in their WQS an upper-bound frequency stating the number of years that pattern can reoccur and still support its recreational use.**

The recommended magnitude represents the concentration of microcystins or cylindrospermopsin that is not expected to result in adverse human health effects from short-term recreational exposure to the toxins via incidental ingestion while swimming, based on exposure to young children. The adverse health effects include liver toxicity (for microcystins) and kidney toxicity (for cylindrospermopsin) and could result from exposures to waters containing elevated levels of these toxins.

The **water quality criteria** developed by the EPA describe the magnitude, duration, and the frequency of occurrence of pollutants. HABs may be caused or exacerbated by human activities and elevated nutrient concentrations, but cyanotoxins differ from other pollutants as they are not typically discharged into a water body. The EPA developed recommended criteria for these cyanotoxins that provide a magnitude (8 µg/L microcystins or 15 µg/L cylindrospermopsin) and duration (not to be exceeded in more than three 10-day assessment periods over the course of a recreational season). The EPA expects states to make an explicit risk management decision regarding the frequency (i.e., the number of years this pattern of exceedances can occur in the waterbody) and still support its recreational use.

As a basis for issuing a **swimming advisory**, the EPA recommends a concentration of 8 µg/L microcystins or 15 µg/L cylindrospermopsin not be exceeded on a single day. This is consistent with the goal of a swimming advisory to provide prompt information to people who wish to use the water body for recreation.

NMED Exhibit 93

7.0 EFFECTS CHARACTERIZATION

7.1 Enhanced Susceptibility

Based on the available studies in animals, individuals with liver or kidney disease may be more susceptible to health effects than the general population as the detoxification mechanisms in the liver and impaired excretory mechanisms in the kidney may be compromised. Data from an episode in a dialysis clinic in Caruaru, Brazil, where microcystins (and possibly cylindrospermopsin) were not removed by treatment of dialysis water, identify dialysis patients as a population of potential concern in cases where the drinking water source was contaminated with cyanotoxins.

The data on red blood cell acanthocytes observed in animal studies of cylindrospermopsin suggest that individuals that suffer from anemia (e.g., hemolytic or iron-deficiency) might be a potentially sensitive population. Several rare genetic defects such as abetalipoproteinemia (i.e., a rare autosomal recessive disorder that interferes with the normal absorption of fat and fat-soluble vitamins from food) and hypobetalipoproteinemia are associated with abnormal red blood cell acanthocytes, which appears to result from a defect in expression of hepatic apoprotein B-100, a component of serum low-density lipoprotein complexes (Kane and Havel 1989). Individuals with either condition might be sensitive to exposure to cylindrospermopsin.

Available animal data are not sufficient to determine if there is a definitive difference in the response of males versus females following oral exposure to microcystins. Fawell et al. (1999) observed a slight difference between male and female mice in body weight and serum proteins, but no sex-related differences in liver pathology. Available animal data are not sufficient to determine if there is a definitive difference in the response of males versus females following oral exposure to cylindrospermopsin.

7.2 Recreational Exposure Duration

Recreational exposure data available in the literature are expressed in two primary ways: 1) the volume of water incidentally ingested during recreation (e.g., L/hr), and 2) the duration of the recreational activity (e.g., minutes of recreation per day). A daily incidental ingestion rate distribution was developed by combining these two distributions (for more information see Appendix E). The 90th percentile of the daily incidental ingestion rate distribution for children (see section 7.3) was selected for the derivation of the criteria and swimming advisories, consistent with the 2000 Human Health Methodology.

The EPA identified the following sources of data on the duration of the recreational activity: the EPA's EFH (2011); Schets et al. (2011); and DeFlorio-Barker et al. (2017) (DFB study). See Table 7-1a and Table 7-1b for summary overviews of these studies. One major difference between the studies is in the unit of exposure, reported in minutes per day in one study and minutes per swimming event in the two other studies.

NMED Exhibit 93

Table 7-1a. Durations of Recreational Exposures in Minutes per Day

Reference	Recreational Environment	Age Group (Years Old)	Sample Size	Mean	Units
U.S. EPA *Exposure Factors Handbook* (2011)	In Outdoor Pool or Spa	1 to 4	9	85.6	minutes per day
		5 to 11	15	164.2	
		12 to 17	5	97.0	
		18 to 64	44	117.6	
		> 64	10	78.9	

Table 7-1b. Durations of Recreational Exposures in Minutes per Swimming Event[a]

Reference	Recreational Environment	Age Group (Years Old)	Sample Size	Mean	Units
Schets et al. (2011)	Freshwater	< 15 Years	1,689	79.0	minutes per event
		16+	4,123	54.0	
	Swimming Pool	< 15	1,689	81.0	minutes per event
		16+	4,123	67.5	
DeFlorio-Barker et al. (2017)	Freshwater	< 1	171	56	minutes per event
		1 to 3	1,061	66.7	
		4 to 7	1,738[b]	88.5	
		8 to 12	2,136[c]	92.9	
		13 to 18	1,855	64	
		19 to 34	5,478	45.4	
		35+	8,058	47	
	Marine	< 1	350	60.5	
		1 to 3	2,687	79.1	
		4 to 7	4,260	107.8	
		8 to 12	5,398	121.4	
		13 to 18	4,021	102	
		19 to 34	10,786	68.2	
		35+	19,745	66.9	

[a] Additional information is needed to translate minutes per event to minutes per day.

[b] Number of children ages 4–7 reported to have contact with water: 1,562.

[c] Number of children ages 8–12 reported to have contact with water: 1,901.

The EPA considered these three studies and selected the EFH for use in deriving the criteria and swimming advisories primarily because the EFH dataset represents exposures in minutes per day. Other datasets measured the duration of recreational exposure on an event basis, which require assumptions about how many recreational events occur per day to create the relevant distribution. The EPA conducted analyses comparing these datasets, as described below to evaluate the differences in the distributions given differences in sample size, and evaluated differences given different assumptions of number of events per day.

The EFH (U.S. EPA 2011) lists time spent per 24 hours in an outdoor spa or pool for different age groups (including children five to 11 years old). The EPA acknowledges that the reported sample size

for this study is small (n = 15) for the five-to-11-year-old group. Schets et al. (2011) demonstrate that time spent in swimming pools is similar to time spent in freshwater and therefore EPA concluded that these data are representative of recreational exposure in freshwater. The EFH also presents data for minutes spent "outdoors at a pool/river/lake." The EPA did not select these data as it is uncertain if this is time spent in the water, or total time "at" the location.

Schets et al. (2011) investigated swimming durations in freshwater, marine water, and pools. They surveyed 8,000 adults, 1,924 of whom also provided estimates for their eldest child (< 15 years of age) and found that children spend, on average, 25 minutes longer swimming in freshwater compared to adults. Schets et al. (2011) reported similar mean duration times between swimming pools and freshwater locations for children less than 15 years old (average of 81 and 79 minutes per event, respectively; upper 95 percent CI: 200 and 270 minutes per event, respectively).

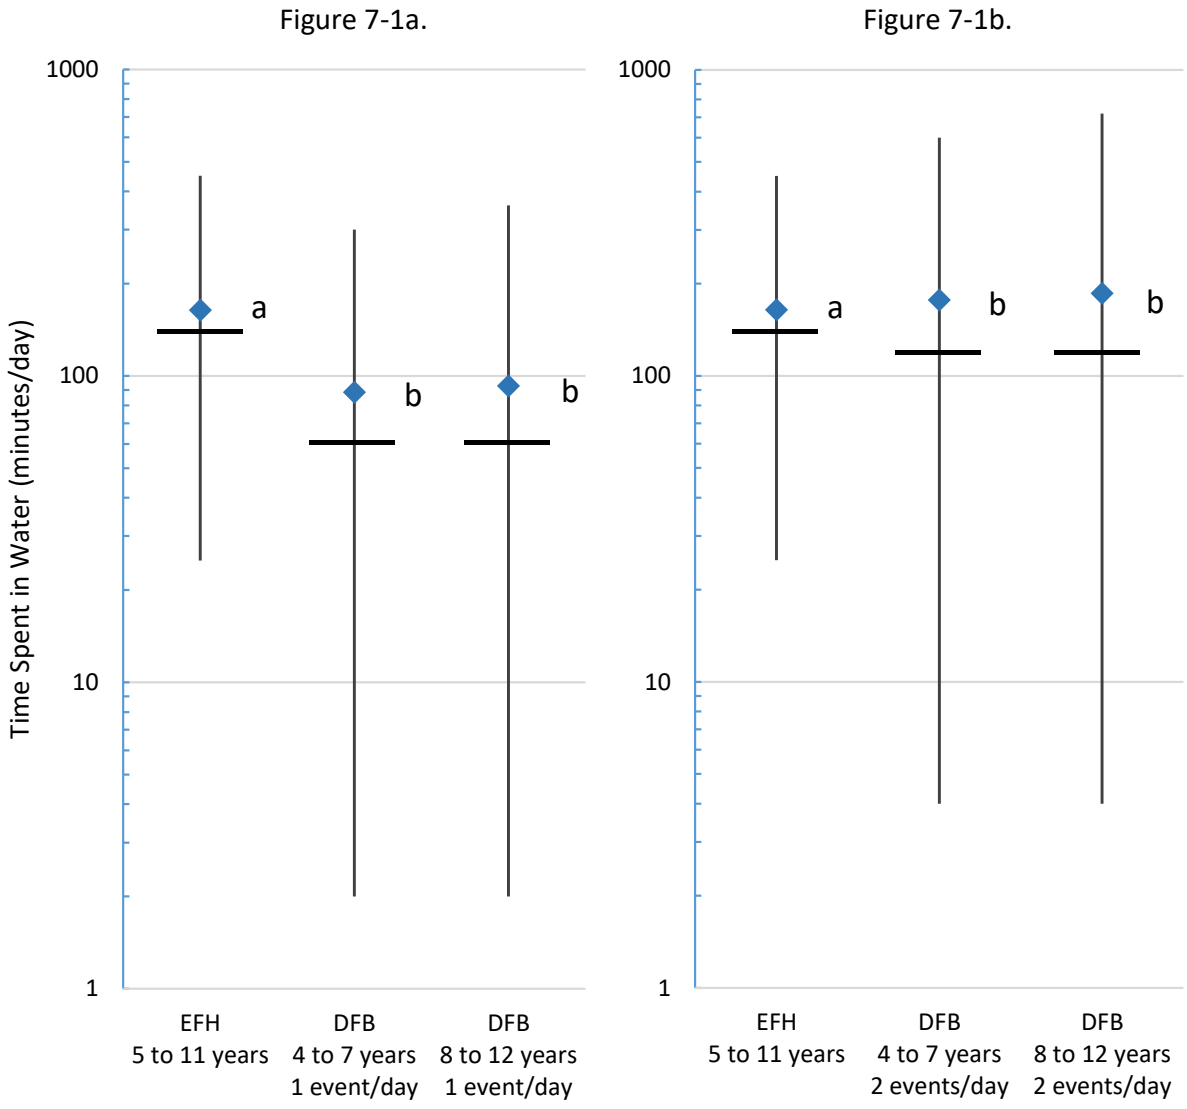
The DFB study (DeFlorio-Barker et al., 2017) compiled self-reported swimming durations from epidemiological study surveys from 12 beaches in which participants were asked to estimate, in minutes, the total time they spent in the water. Parents or guardians were responsible for answering survey questions assessing exposures such as getting water in the mouth or swallowing water, on behalf of their minor children. The study results represent 2,136 children ages eight to 12 years and 1,738 children ages four to seven recreating in freshwater. Marine recreators spent more time in the water compared with freshwater recreators. The authors suggest that behaviors may have been influenced by the warmer water at most of the marine sites (California and Gulf Coast) compared with the freshwater sites in the Great Lakes.

Although not represented in Table 7-1 a or b, the EPA's OPP uses a different approach to estimate chemical exposures for children during pool swimming, for use in its SWIMODEL (U.S. EPA 2003). This model simulates short-term exposure using a high-end estimate of exposure-time per event to represent a maximum, one-time exposure. It also simulates intermediate/long-term exposure using a shorter event duration to represent an average of maximum and minimum exposures over time. Among competitive children swimmers, the short-term exposure duration used by the SWIMODEL is one hour per day for children ages six to 10 and two hours per day for children ages 11 to 15 years based on a survey of swim coaches (U.S. EPA 2003). The competitive swimming scenario (e.g., children swimming laps) is appropriate for conducting risk assessments of exposure to swimming pool chemicals. However, it is less relevant to children's recreational activities in lakes or rivers and therefore was not used in this assessment.

7.2.1 Comparison of Duration of Exposure Distributions

Because the DFB study has a much larger sample size compared to the study results reported in EPA's EFH, the EPA conducted a statistical analysis to compare the distributions of duration of exposure. Because the DFB study age groupings and the EFH age groupings do not exactly align, the EPA compared the four-to-seven and the eight-to-12 age groups from the DFB study with the five-to-11 age group presented in the EFH. Both studies include self-reported data, which are prone to recall bias. Adult recollection of their children's time spent in the water is also uncertain. However, there is no reason to believe there would be differential recall bias between the studies.

Table 7-2 shows the parameters used to create distributions for EFH and DFB studies. The EPA used assumptions of one swimming event per day and two events per day to translate the DFB duration from minutes per event to minutes per day for two different age groups. The EPA assumed the underlying distributions of exposure durations were log-normal. The observed mean and standard deviations in



NMED Exhibit 93

Table 7-2 defined the parameters of the underlying log-normal distributions. The standard deviations take into consideration the numbers of samples, and therefore address differences in numbers of participants in the EFH and DFB studies. A large number (1 million) of samples were drawn from each log-normal distribution defined using these parameters. The distributions were truncated to reflect the observed maximum and minimum values in the EFH and DFB studies for the age groups of interest. Figures 7-1 a and b show the five resulting distributions: the EFH distribution and the DFB distributions assuming one (Figure 7-1a) and two (Figure 7-1b) events per day.

Table 7-2. Parameters Used to Fit Recreation Duration Distributions in Freshwater

Parameter Source	Age Group (sample size)	Mean (min/day)	Standard deviation	Minimum (min/day)	Maximum (min/day)
EPA 2011 EFH (minutes/day)	5 to 11 years (n = 15)	164.2	103.97	25	450
DFB 2017 (minutes/day, assuming one event/day)	4 to 7 years (n = 1,562)	88.5 (1 event)	62.8	2	300
DFB 2017 (minutes/day, assuming two events/day)		177 (2 events)	125.6	4	600
DFB 2017 minutes/day, assuming one event/day)	8 to 12 years (n = 1,901)	92.9 (1 event)	64.7	2	360
DFB 2017 minutes/day, assuming two event/day)		185.8 (2 events)	129.4	4	720

Figure 7-1 a and b. Comparison of Children's Duration of Time Spent Recreating

Comparison of children's time spent in water between EPA's 2011 *Exposure Factors Handbook* (five to 11 years old) (EFH; U.S. EPA 2011) and the DeFlorio-Barker study (DFB) (four to seven and eight to 12 years old) (DeFlorio-Barker et al. 2017) assuming one swimming event per day (Figure 7-1a) or two swimming events per day (Figure 7-1b) for the DFB data. The range of each distribution is represented by the vertical solid line, the short horizontal line indicates the median, and blue diamonds represent the mean. Letters beside the means denote significant differences of the means.

The EPA conducted two statistical tests to compare these distributions; one based on the means of the distributions and the other based on the full distributions. The full duration distribution, not the mean, in combination with the distribution of volume ingested per hour, was used to calculate the daily incidental ingestion rate. The EPA also explored how these comparisons change when one assumes that children engage in one or two swimming events per day (e.g., those who swam, took a break, and then re-entered the water at a later point in the day). The changes in the parameters are shown in Table 7-2.

For the comparison of the means, the EPA used a two-tailed t-test with unequal variances. The mean of the EFH is statistically different from both the DFB age group means (p-value < 0.001) for both one and two events per day. The means of the two DFB age groups are not statistically different from each other

NMED Exhibit 93

(p-value = 0.08) assuming both one event and two events per day. Statistical differences between the means are denoted by letters (a and b) in Figure 7-1. Assuming two events per day for the DFB studies, the means for both DFB study age groups are significantly higher ($p < 0.001$) than the EFH mean. The larger sample size available in the DFB study results in a narrower confidence interval around the mean time spent in water, compared to the 95 percent CI for the mean used in the EFH.

For the comparison of the distributions, the EPA used the Kruskal-Wallis test. Results show that the EFH distribution is not statistically significantly different from either DFB age group distributions (p-value = 0.499, assuming one event per day; p-value = 0.498, assuming two events per day).

The EPA concluded that because the EFH and DFB distributions are not significantly different, the EFH dataset is the most appropriate for deriving criteria and swimming advisory values as it does not require additional assumptions about the number of swimming events that occur per day. The 90th percentile incidental ingestion rates are shown in Table 7-3 below for the EFH distribution and for the DFB distributions. The resulting 90th percentiles of daily incidental ingestion rate are also shown. The 90th percentile of daily ingestion rate based on the EFH distribution most closely corresponds to the 90th percentile of daily ingestion rate using the DFB dataset when two swimming events per day are assumed.

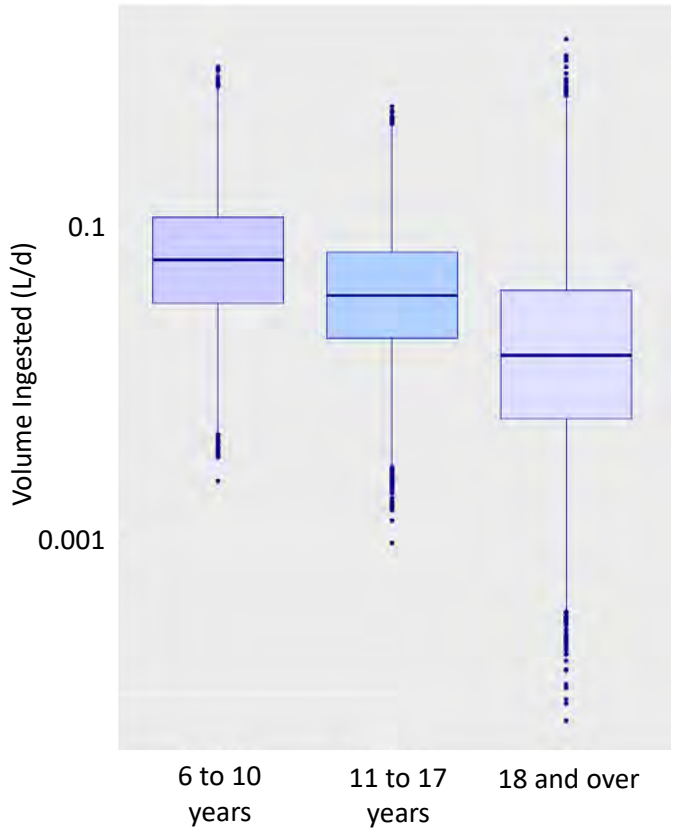
Table 7-3. Calculated Daily Incidental Ingestion Rates Based on EFH and DFB Datasets

Volume per Hour Data Source	Event Duration Data Source	Age Group (years)	Events per Day (if assumed)	90th Percentile Daily Ingestion Rate (L/day)
Recreational AWQC Appendix E full dataset (L/hr)	EPA *Exposure Factors Handbook* (2011)[a] (hr/day)	5 to 11	not needed	0.21
	DeFlorio-Barker et al. (2017) (DFB) (hr/event)	4 to 7	1	0.11
			2	0.23
		8 to 12	1	0.12
			2	0.24

[a] This distribution was used in the derivation of the criteria and recreational swimming advisories.

7.3 Evaluation of Health Protective Values for Different Lifestages

The EPA compiled and evaluated available information for various life stages before selecting children ages six to 10 years as the basis for the recreational criteria values or swimming advisory. This section discusses potential health protective values for children and adults (section 7.3.1) and focuses on exposures of younger children (less than six years) (section 7.3.2).



7.3.1 Consideration of Multiple Lifestages

The EPA used the Appendix E and the Dufour et al. (2017) dataset provided in U.S. EPA (2018a) to generate the box and whisker plots shown in Figure 7-2 for three life stages (children six to 10 years, children 11 to 17 years, and adults 18 years or older). The Appendix E Dufour data for volume ingested per swimming event was normalized to one hour. Each participant's volume ingested was adjusted to one hour based on the length of time that participant reported being in the water. The EPA converted volume of water ingested from L/event to L/hour, then used the swimming duration per day from the EPA's 2011 EFH (hours/day). The distributions were assumed to be log-normal and the plot is

NMED Exhibit 93

visualized in log space. The EPA used the Appendix E Dufour data on ingestion rate (shown in Figure 7-2) and the body weight estimates from the EPA's (2011) EFH (kg) to calculate the ingestion normalized by body weight (L/kg/day) shown in Figure 7-3.

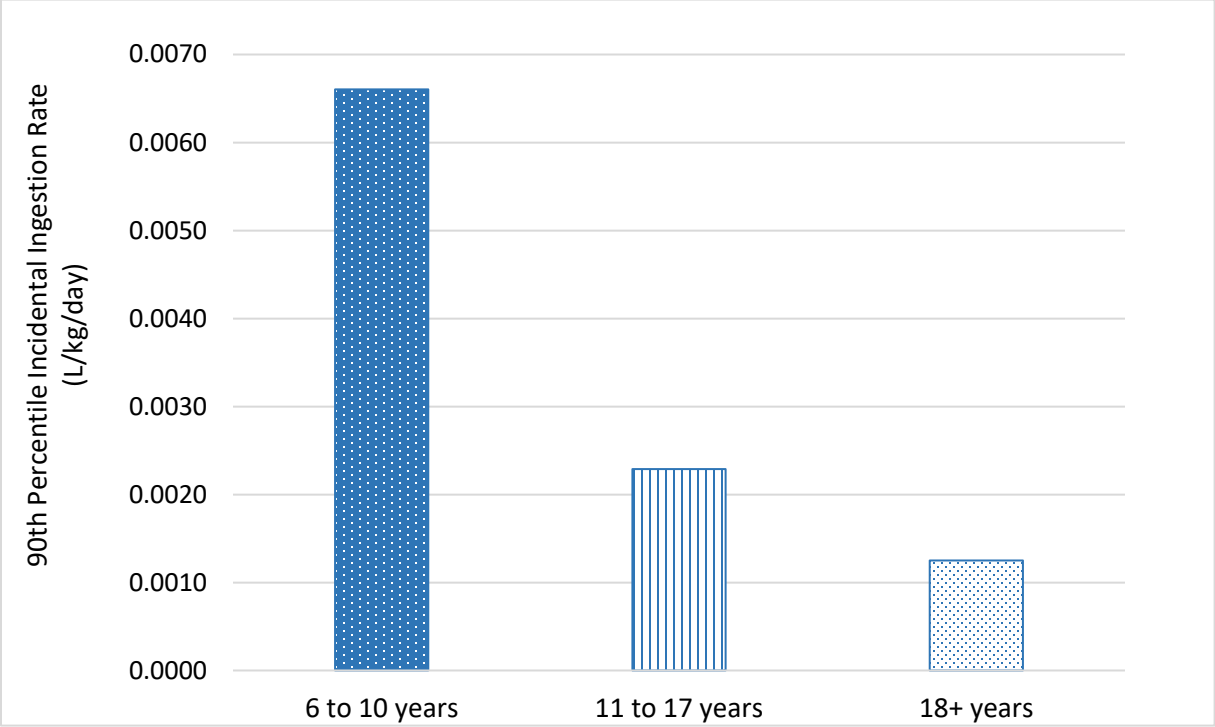


Figure 7-2. Incidental Ingestion During Recreational Activity Based on Age (Appendix E)

In this box plot, the horizontal line the middle of the box is the median (Q2). The length of the box is the interquartile range (IQR) or the 25th percentile to the 50th percentile. The upper whisker vertical line extends to the greatest value less than or equal to Q3+1.5*IQR; the lower whisker extends to the smaller value less than or equal to Q1-1.5*IQR. The dots represent extreme values that are either greater than the upper whisker or lower than the lower whisker.

NMED Exhibit 93

Figure 7-3. Comparison of Children and Adults Incidental Ingestion Rate During Recreational Activity Adjusted for Body Weight

Body weight varies by age. Table 8-1 in the EPA's EFH (U.S. EPA 2011) reported recommended statistics based on the 1999–2006 National Health and Nutrition Examination Survey. Table 7-4 shows the mean body weight for the age groups compared in this section (U.S. EPA 2011).

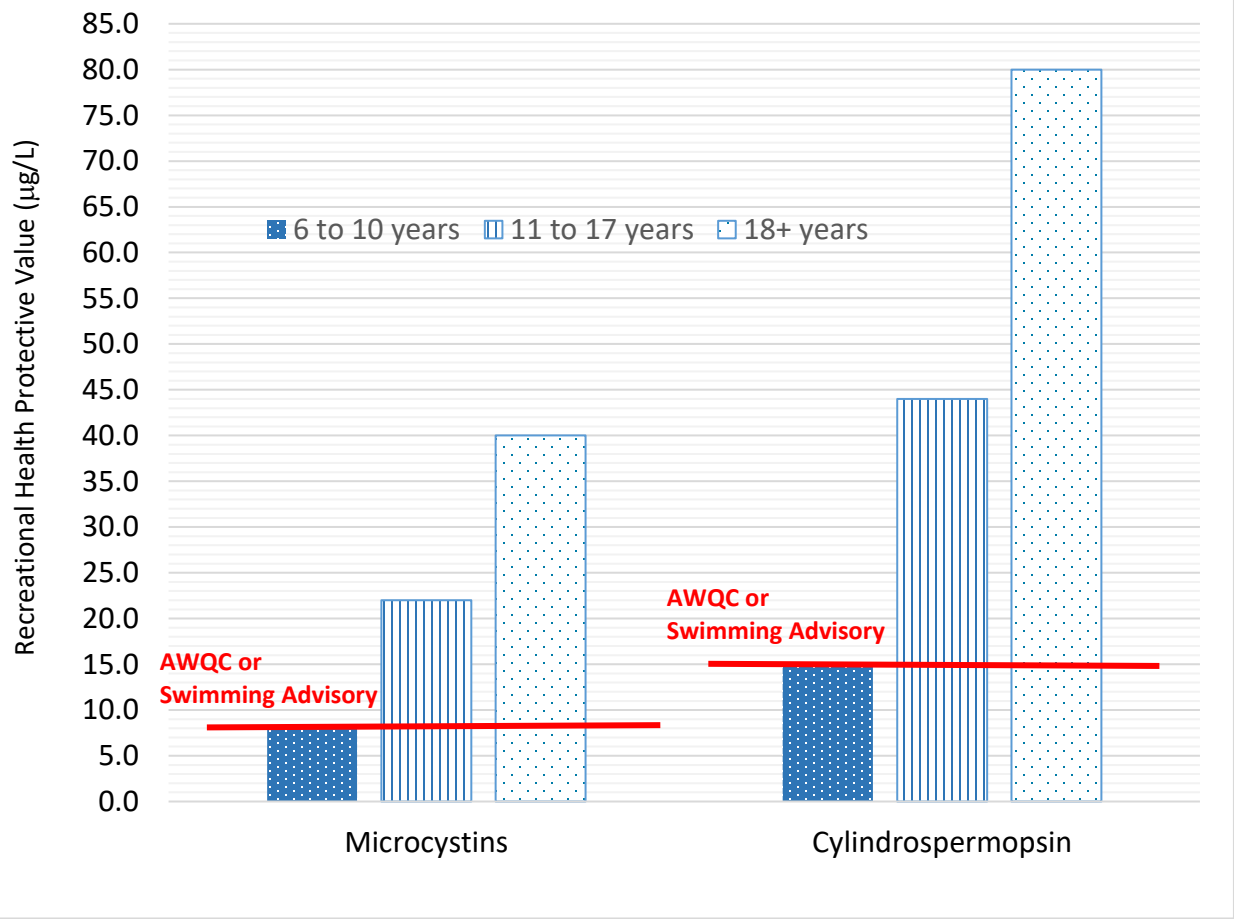
Table 7-4. Mean Body Weight by Age Group Based on U.S. EPA (2011)

Age Group	Body Weight (kg)
Children 6 to 10 years	31.8
Children 11 to 17 years	56.8
Adults 18 to 64	80

The EPA estimated recreational health protective values for these three different age groups for microcystins and cylindrospermopsin to demonstrate the variability due to body weight, recreational

water incidental ingestion, and exposure duration by lifestage. Inputs for these calculations are in Table 7-5.

Table 7-5. Inputs for Calculation of Protective Values for Microcystins and Cylindrospermopsin



Age Group	Ingestion Rate [a] (L/day)	Body Weight [b] (kg)
Children 6 to 10 years	0.21	31.8
Children 11 to 17 years	0.13	56.8
Adults 18+ years	0.10	80.0

[a] Value is 90th percentile of the combined distribution (i.e., ingestion and duration data combined); see Appendix E.

[b] For children age 6 to 10 years, the mean body weight for the 6-to-10-year age group (31.8 kg) was used. For 11 to 17 years, the mean body weight for the 11- to 15-year-old age group (56.8 kg) was used because it was the closest age group available from the EPA's *Exposure Factors Handbook* (U.S. EPA 2011). For adults 18+ the mean body weight for the 21+ year age group (80 kg) was used (U.S. EPA 2011).

As illustrated in Figure 7-4, the AWQC and swimming advisories the EPA calculated to be protective of children ages six to 10 years are also protective of older children and adults.

Figure 7-4. Comparison of Calculated Recreational Health Protective Values for Microcystins and Cylindrospermopsin for Children, Older Children, and Adults

NMED Exhibit 93

7.3.2 Exposure Factors for Children Younger Than Six Years Old

In the calculation of the cyanotoxin values reported in section 6, the EPA utilized exposure parameters reported in the EFH (U.S. EPA 2011) and peer-reviewed study data (study design presented in Dufour et al. 2017; data analyzed in Appendix E; U.S. EPA 2018a). The available incidental ingestion volume and exposure duration values from the Appendix E and the EPA's EFH (U.S. EPA 2011), respectively, were limited to specific age ranges. For incidental ingestion, the data reported were limited to children six years old and older because the Dufour et al. (2017) study design did not include children younger than six years. The EPA's EFH (U.S. EPA 2011) provided a mean recreational exposure duration for children ages one to four years (1.4 hour/day). This duration is shorter than the mean duration for children ages five to less than 11 years (2.7 hour/day). Values for exposure duration were not available for children younger than one year.

The EPA found one other study that characterized incidental ingestion for children. Schets et al. (2011) reported incidental ingestion volumes and durations of recreational events for children ages zero to < 15 years. However, the study did not further divide this cohort into younger children and older children. The incidental ingestion data for children < 15 years represent parental estimates of volumes of freshwater incidentally ingested by their children, which is a different methodological approach compared to the more quantitative approach used by Dufour et al. (2017). The exposure durations were also parental estimates.

The EPA calculated the 90th percentile incidental ingestion rate per day for children younger than six years old in order to compare the daily ingestion rate (L/day) between children six to 10 years and those younger than six years. The daily ingestion rate (0.21 L/day) used to derive the recreational criteria was calculated by combining the distributions for incidental ingestion and exposure duration via a probabilistic (Monte Carlo) analysis (described in section 4.2.3.1). The daily ingestion rate for children younger than six years old (0.11 L/day) was a mixed-age estimate calculated by dividing the 90th percentile for incidental ingestion for children age six to 10 years (0.077 L/hour; see Appendix E) by the mean exposure duration for children one to four years (1.4 hour/day; U.S. EPA 2011). The daily ingestion rate for children younger than six years old is lower than for children six to 10 years old. This calculation was also performed using data from Schets et al. (2011) and resulted in a daily ingestion rate of 0.1 L/day.[6] The EPA evaluated the effect of using parameter values for children younger than six years by including an age-specific body weight and the mixed-age estimate for the daily ingestion rate (L/day) parameters. Table 7-6 shows a comparison of the microcystins magnitude for the two different age groups, children ages six to 10 years and children ages one to less than six years.

The estimates for children younger than six years have large uncertainties given the lack of measured incidental ingestion data specifically for this age group. Information on exposure durations for children less than one-year-old is also lacking. Because exposure durations are greatest for five- to 11-year-olds, the EPA concluded that calculating the ingestion rate using a higher duration was protective of children younger than six years old. Research designed to fill this data gap could be helpful for characterizing the risks to children younger than six years old. Specifically, data to better characterize the volume of water ingested during recreational events would enhance EPA's confidence that the criteria values are protective of children younger than six years old.

[6] This number was calculated as follows: 0.07 L/hour (90th percentile ingestion volume for age zero to less than 15 years from Schets et al. (2011)) divided by 1.4 hr/d (mean for children one to four years from U.S. EPA 2011).

NMED Exhibit 93

Table 7-6. Microcystins Magnitude Comparison Between Children Six to 10 and Children One to Less Than Six Years Old

Age Group	RfD (µg/kg/day)	Body Weight (kg)	Ingestion Rate (L/day)	Magnitude (µg/L)	Magnitude (µg/L) Rounded
6 to 10 years	0.05	31.8	0.21	7.57	8
1 to < 6 years	0.05	15.6 [a]	0.11	7.09	7

[a] This value is the weighted mean of the age groups one to less than two years, two to less than three years, three to less than six years (U.S. EPA 2011).

7.4 Other Recreational Exposure Pathways

The EPA selected primary contact activities and incidental ingestion of water as the primary exposure pathway for derivation of the recreational criteria and swimming advisories. Inhalation and dermal toxicity data were not available; however, there are limited available data to estimate inhalation and dermal exposure. The EPA conducted analyses to compare inhalation and dermal exposure to incidental ingestion of the cyanotoxins while recreating. Section 7.4.1 compares recreational ingestion and inhalation exposures to microcystins. Similarly, section 7.4.2 compares recreational ingestion and dermal exposure. Section 7.7 briefly discusses tribal considerations. Further research is needed to better understand the toxicity from inhalation and dermal exposure to cyanotoxins. The EPA describes the screening analyses in this section because sufficient data to quantify toxicity via these routes were not available.

7.4.1 Inhalation of Cyanotoxins

Volatilization of microcystins and cylindrospermopsin from water to air is not expected due to their size and charges. Both cyanotoxins are rather large molecules compared to volatile chemicals. Microcystin-associated acid groups are charged at the pH of normal surface waters. Cylindrospermopsin features both negative and positive changes and, like other zwitterions, do not volatilize significantly into the air from water (Butler et al. 2012).

According to Wood and Dietrich (2011), waterborne cyanotoxins can be aerosolized through a bubble-bursting process, in which the cyanobacteria and cyanotoxins are ejected and carried into the air where they can bind to particulate matter. Microcystins that are free or bound to particulate matter in air can be deposited into the deepest bronchiolar or alveolar cavities; air borne cyanobacterial cells from aerosolized water droplets would likely be deposited in the upper respiratory tract (Wood and Dietrich 2011).

The EPA identified field studies that measured recreators' exposure levels to aerosols containing microcystins from lakes with blooms containing microcystin-producing *Microcystis aeruginosa*. The studies found low inhalation exposures. In one study, Backer et al. (2008) used personal air samplers in a three-day study of recreational activities in a lake with a cyanobacterial bloom, either carried by the study participant or placed on the participant's boat. The microcystin concentrations in air ranged from below the limit of detection (0.0037 ng/m^3) to 0.456 ng/m^3. Backer et al. (2010) also detected microcystins in ambient air for one day, at one lake, and only from the shoreline sampler. The average air concentration was 0.052 ng/m^3. Backer et al. (2010) also collected 44 personal air samples, which ranged from the limit of detection (0.1 ng/m^3) to 0.4 ng/m^3. The study identified no associations between health effects and microcystin concentrations from inhalation exposure from activities that included swimming, water skiing, Jet Skiing, or boating. The authors noted that the daily mean microcystin

NMED Exhibit 93

concentrations in personal air samples did not correlate with the concentrations of *Microcystis aeruginosa* cells, dissolved microcystins, or total microcystins in the sampled lake water.

In another study by Backer et al. (2010), the lakes had a wider range of concentrations of microcystins (< 10 to > 500 µg/L). The study authors measured microcystins exposure via personal air samplers, nasal swabs, and blood samples for individuals whose activities included swimming, boating, tubing/wakeboarding, riding watercraft, wading, and fishing at the lakes. They found low microcystin levels in personal air samplers below the limit of detection (0.1 ng/m^3) to 2.89 ng/m^3 and also in nasal swabs below the limit of detection (0.1 ng) to 5 ng. The average aerosolized microcystin concentration was approximately 0.3 ng/m^3. Based on the nasal swab data, the investigators estimated on average that the adults inhaled 0.8 ng of microcystins. Microcystin concentration in the water-soluble plasma fraction of the study subjects was also below the limit of detection (1 µg/L). The investigators cautioned that microcystin might be bound to a protein component in the blood or sequestered in liver tissue.

Wood and Dietrich (2011) studied Lake Rotorua (New Zealand) when it was experiencing a dense bloom of microcystin-producing *Microcystis*. The authors measured a maximum microcystin concentration in the water of 2,140 µg/L and air concentrations from 0.0003 to 0.0018 ng/m^3.

Cheng et al. (2007) used high volume and personal air samplers to measure microcystins in the air at a lake with a cyanobacterial bloom. The authors measured low microcystin concentrations in the water (approximately 1 µg/L) and air concentrations ranging from below the detection limit (0.02 ng/m^3) to 0.08 ng/m^3.

The EPA performed a screening analysis to characterize potential relative exposures. The EPA analyzed the relative potential dose of the cyanotoxins via inhalation exposure compared to oral ingestion to evaluate if recreational criteria values or swimming advisories based on ingestion could be protective of the other exposure routes. Although the recreational use is primary contact recreation, such as swimming, data are available for secondary contact activities such as Jet Skiing or boating and white-capped wave, bubble-bursting action, which can result in cyanotoxins becoming aerosols (microscopic liquid or solid particles suspended in air).

Using the information from Cheng et al. (2007) and inhalation exposure parameters provided in the EPA's EFH (2011), the EPA compared the estimated microcystin ingested dose to the inhaled dose. The first step in this comparative screening analysis was to calculate the incidental ingestion dose using the following equation:

$$\text{Ingestion dose (ng/day)} = \text{Ingestion rate} \times \text{Concentration}_{\text{water}}$$

Where:

Ingestion rate = 90th percentile incidental ingestion rate based on combined distributions of incidental ingestion (Appendix E) and recreational duration (U.S. EPA 2011) (L/day)

$\text{Concentration}_{\text{water}}$ = assumed concentration in water (1,000 ng/L from Cheng et al. (2007)) (ng/L)

The parameters used in the calculation of the estimated ingestion dose for each age group are presented in Table 7-7.

NMED Exhibit 93

Table 7-7. Ingestion Parameters and Estimated Ingestion Dose for Screening-level Comparative Inhalation Exposure Analysis

Age Group	Ingestion Rate (L/day) [a]	Concentration in Water (ng/L) [b]	Ingestion Dose (ng/day)
Children	0.21	1000	210
Adults	0.10	1000	100

[a] Daily recreational incidental ingestion rate calculated in combined distribution analysis for children and adults as described in section 4.2.3.1.

[b] Cheng et al. (2007) measured 0.08 ng/m^3 in air near surface waters with a concentration of 1 µg/L microcystins. This concentration in water was assumed as part of this analysis because Cheng et al. (2007) provided aerosolized levels given a specific concentration in water.

The second step in the comparative screening analysis was to estimate the inhaled dose using the following equation:

$$\text{Inhalation dose (ng/day)} = \text{Inhalation rate} \times \text{Inhalation duration} \times \text{Concentration}_{air}$$

Where:

Inhalation rate = inhalation rate from the EPA's EFH (U.S. EPA 2011; Table 6-2) (m^3/min)

Inhalation duration = inhalation exposure duration from the EPA's EFH (U.S. EPA 2011; Table 16-20) (minutes/day)

$\text{Concentration}_{air}$ = concentration in air (0.08 ng/m^3) assumed from Cheng et al. (2007) (ng/m^3)

The inhalation exposure parameters the EPA used in this equation and the resulting estimated inhaled dose are listed in Table 7-8. The EPA selected inhalation rates for children and adults from the EPA's EFH (U.S. EPA 2011). For this conservative comparative analysis, the EPA selected the highest 95th percentile short-term, moderate intensity activity level inhalation rate—the volume of air inhaled per minute (m^3/minute)—listed for children and adults in EPA's EFH Table 6-2 "Recommended Short-

Table 7-8. Inhalation Exposure Parameters and Estimated Inhaled Dose

Age Group	Inhalation Rate (m^3/min)[a]	Duration of Inhalation Exposure per Day (minutes/day)[b]	Daily Inhalation Rate Adjusted for Duration of Exposure (m^3/day)	Concentration in Air (ng/m^3)[c]	Estimated Inhalation Dose (ng/day)
Children	0.037	560	21	0.08	1.7
Adults	0.04	511	20	0.08	1.6

[a] The EPA's *Exposure Factors Handbook* (EFH; U.S. EPA 2011) did not report recommended short-term, moderate intensity activity level inhalation rate values for children or adults in aggregate; used highest inhalation rate listed for children and adult age groups for this conservative screen. For children, it was the age group 16 to < 21 years, and for adults, it was 51 to < 61 years.

[b] Values are the longest 90th percentile duration reported for child and adult age groups in the EPA's EFH (U.S. EPA 2011) from Table 16-20 "Time Spent (minutes/day) in Selected Outdoor Locations, Doers Only, Outdoors at a Pool/River/Lake." The child and adult age groups with the longest durations spent near or in the water were children 1 to 4 years old and adults 18 to 64 years old.

[c] Cheng et al. (2007) measured 0.08 ng/m^3 in air near surface waters with a concentration of 1 mg/L microcystins.

NMED Exhibit 93

Term Exposure Values for Inhalation (males and females combined)." The child and adult age groups with the highest of these inhalation rates were 16 to < 21 years and 51 to < 61 years, respectively.

To estimate the amount inhaled in a day, the EPA multiplied the inhalation rates for children and adults by an estimated daily inhalation exposure duration for each of these age groups. The EPA estimated daily inhalation exposure duration using a different dataset from the set it used for the incidental ingestion analysis (described in section 4.2.3.1). This was because people do not need to enter the water to be exposed via inhalation, they only need to be *near* or *at* the water. In contrast, recreators who incidentally ingest water while swimming must be *in* the water.

The EPA's EFH (U.S. EPA 2011) provides in Table 16-20 the time spent (in minutes/day) outdoors at a pool/river/lake. The EPA estimated inhalation exposure duration using the number of minutes per day spent outdoors at a pool/river/lake (U.S. EPA 2011). The EPA selected the longest 90th percentile duration values reported for child and adult age groups. The child and adult age groups with the longest times spent outdoors at a pool/river/lake were children one to four years old and adults 18 to 64 years old.

A comparison of the EPA's EFH data provided for time spent outdoors at a pool/river/lake and time spent in the water indicates that all age groups spent more time at a pool/river/lake than they spend in a pool/spa (U.S. EPA 2011). Consistent with the trend that children have longer durations of recreation in water than adults, children's time spent near recreational waters was greater than adults. The children's age group exposure patterns differed between the datasets. The data suggest younger children (one to four years) spend more time at recreational waters compared to school-aged children (five years and older), but children five to 11 years old spend more time in the water compared to other children (U.S. EPA 2011).

It is reasonable that younger children spend more time engaged in activities *at* a pool/river/lake compared to time spent recreating in recreational waters. The EPA selected this dataset to characterize inhalation exposure because younger children can spend more time playing on a beach, where they can be exposed to aerosolized cyanotoxins, than in the water where incidental ingestion can be the primary route of exposure.

The final step for this comparative screening analysis was to compare the ingestion and inhalation doses. The results are presented in Table 7-9. Using conservative assumptions for inhalation rates and inhalation exposure duration and comparing with daily incidental ingestion rates, the ingested dose is estimated to be higher than the estimated inhaled dose for children and adults. This analysis is for screening only and is highly uncertain. Further research is needed to better understand the toxicity from inhalation exposure to cyanotoxins.

Table 7-9. Results of Screening Analysis Comparing Ingestion and Inhalation Doses

Age Group	Ingestion Dose (ng/day)	Inhalation Dose (ng/day)
Children	210	1.7
Adults	100	1.6

[a] Calculations used unrounded parameters; results slightly differ with rounded values.

This analysis supports the conclusion that the inhaled dose can be much less than the incidental ingestion dose while recreating. The studies conducted by Backer et al. (2008, 2010) found low microcystin levels in aerosols above lakes with low or high microcystin concentrations and did not detect microcystin levels in the blood of study participants. In an animal study, no clinical signs or

NMED Exhibit 93

effects on body or organ weights were observed after exposure to microcystin-LR aerosol (Benson et al. 2005). The EPA did not conduct a similar analysis for cylindrospermopsin because published measured air concentration data for this cyanotoxin were not available.

The California Environmental Protection Agency (CalEPA) came to a similar conclusion for water skiers (Butler et al. 2012). They cited Cheng et al. (2007) and noted that their results showed that a liter of water contains 700,000 to 800,000 times the amount of cyanotoxins as in a cubic meter of air. CalEPA calculated that this concentration is equivalent to 1.3 to 1.4 µL aerosolized microcystins/m^3. Compared to the ingestion assumptions used for swimmers in the calculation of their recreational guideline (i.e., 50 mL/hour), CalEPA calculated that a water skier would have to inhale at least 35,000 m^3/hour while skiing to achieve a dose equal to the swimmer, which is 17,000 times the inhalation rate of a marathon runner. CalEPA concluded that a water skier would not inhale enough aerosol to receive a dose similar to what a swimmer gets from ingestion.

Another comparison considers spray exposures from personal watercraft and boat spray. Sinclair et al. (2016) modeled a water-spray exposure scenario and observed much lower exposures than those resulting from swimming or limited contact recreational activities reported in the previous study. Thus, the EPA expects that the comparison above based on exposure from secondary contact recreation is protective of primary contact recreation. Sinclair et al. (2016) also measured urinary concentrations of cyanuric acid after 26 participants' exposure to spray in a simulated 10-minute car wash situation. Subjects wore a protective coverall with hood, vinyl gloves, waterproof footwear, and safety glasses to ensure that only their face and mouths were exposed. The estimated median and 90th percentile ingestion volumes were 0.18 and 1.89 mL, respectively. Converted to a duration of one hour, the amounts would be 1.08 mL and 11.3 mL, which are much lower than the incidental ingestion intakes per hour.

7.4.2 Dermal Absorption

The EPA did not find any peer-reviewed measured data for microcystins or cylindrospermopsin dermal absorption. The EPA's *Dermal Exposure Assessment: A Summary of EPA Approaches* (U.S. EPA 2007) states that to get through the skin, a chemical must dissolve into the stratum corneum, which is a stabilized lipid barrier; therefore, lipid solubility is required initially (U.S. EPA 2007).

The EPA performed a comparative screening analysis to estimate the potential dermal absorbed dose of microcystins and compare it to the incidentally ingested dose. The first step in this comparative screening analysis was to calculate the incidental ingestion dose using the following equation:

$$\text{Ingestion dose} = \text{Ingestion rate} \times \text{Concentration}_{\text{water}}$$

Where:

Ingestion rate = 90th percentile incidental ingestion rate based on combined distributions of incidental ingestion (Appendix E) and recreational duration (EFH; U.S. EPA 2011) (L/day)

$\text{Concentration}_{\text{water}}$ = concentration in water assumed as the health protective value the EPA derived in this document for microcystins (mg/L)

The parameters used in the calculation of the estimated ingestion dose are presented in Table 7-10.

NMED Exhibit 93

Table 7-10. Ingestion Parameters and Estimated Ingestion Dose for Screening-level Comparative Dermal Absorption Exposure Analysis

Ingestion Rate (L/day)[a]	Chemical Concentration in Water (mg/L)[b]	Ingestion Dose (mg/day)
0.21	0.008	0.002

[a] Daily recreational incidental ingestion rate calculated in combined distribution analysis for children and adults as described in section 4.2.3.1.

[b] Concentration in water assumed to be the health protective value for microcystins the EPA derived in this document, converted to mg/L.

To estimate the potential dermal absorbed dose, the EPA used exposure equations in its *Risk Assessment Guidance for Superfund* (U.S. EPA 2004). The first step was to use chemical-specific octanol-water partition coefficient and molecular weight values to estimate dermal permeability, a parameter needed for the equation to estimate dermally absorbed dose. Octanol-water partition coefficients are available for four microcystins, including microcystin-LR. Ward and Codd (1999) estimated the log octanol-water partition coefficients of microcystin-LR, -LY, -LW and -LF using high performance liquid chromatography (HPLC) as 2.16, 2.92, 3.46, and 3.56, respectively. The EPA could not estimate cylindrospermopsin dermal absorption due to the lack of these lipophilicity parameters.

The equation to estimate skin permeability coefficient from U.S. EPA (2004) is:

$$\text{Log } K_p = -2.80 + 0.66 \times \log K_{ow} - 0.0056 \times MW$$

Where:

K_p = dermal permeability coefficient of compound in water (cm/hour)

K_{ow} = octanol-water partition coefficient from Ward and Codd (1999) (dimensionless)

MW = molecular weight (g/mole)

The chemical-specific dermal exposure parameters used to estimate skin permeability are listed in Table 7-11.

Table 7-11. Parameters Used to Estimate Skin Permeability of Microcystins

Microcystin Congener	Log K_{ow}[a]	Molecular Weight (g/mole)	Skin Permeability Coefficient (Log K_p)	Skin Permeability Coefficient (K_p) (cm/hour)
Microcystin-LR	2.16	995.17	-6.95	1.1×10^{-7}
Microcystin-LY	2.92	1002.16	-6.48	3.3×10^{-7}
Microcystin-LW	3.46	1025.2	-6.26	5.5×10^{-7}
Microcystin-LF	3.56	986.16	-5.97	1.1×10^{-6}

[a] Ward and Codd (1999)

NMED Exhibit 93

The equation to estimate dermal absorbed dose for highly ionized organic chemicals from U.S. EPA (2004) is:

$$\text{Dermal absorbed dose} = K_p \times \text{Concentration}_{water} \times t$$

Where:

Dermal absorbed dose	=	dermal absorbed dose per event (mg/cm^2-event)
K_p	=	dermal permeability coefficient of compound in water (cm/hour)
$\text{Concentration}_{water}$	=	chemical concentration in water (mg/cm^3)
t	=	event duration (hour/event)

The exposure parameters and estimated microcystins absorbed dose based on these calculations are presented in Table 7-12.

Table 7-12. Dermal Absorption Exposure Parameters and Estimated Dermal Absorbed Dose

Microcystin Congener	Chemical Conc. in Water (mg/cm^3)[a]	Event Duration[b] (hour/event) (mean for 5- to 11-year-olds)	Dermal Absorbed Dose per Event (mg/cm^2-event)	Total Body Surface Area (cm^2)[c]	Dermal Absorbed Dose per Event (mg/event)
Microcystin-LR	8×10^{-6}	2.7	2.4×10^{-12}	14,800	3.6×10^{-8}
Microcystin-LY			7.1×10^{-12}		1.0×10^{-7}
Microcystin-LW			1.2×10^{-11}		1.8×10^{-7}
Microcystin-LF			2.3×10^{-11}		3.4×10^{-7}

[a] Concentration in water assumed to be the health protective value for microcystins the EPA derived in this document, converted to mg/cm^3.

[b] Event duration is defined as time spent per day in outdoor pool or spa at home as reported in the EPA's EFH (U.S. EPA 2011).

[c] Value is 95th percentile Children 6 to 10 years from U.S. EPA (2011), converted to cm^2.

The final step for this comparative screening analysis was to compare the ingestion and dermal absorbed doses. The results are presented in Table 7-13. The estimated ingested dose is higher than the estimated dermal absorbed dose for children. This assessment is highly uncertain. Further research is needed to better understand the toxicity from dermal exposure to cyanotoxins.

CalEPA also concluded dermal absorption of microcystins and cylindrospermopsin while swimming is not expected to be significant due to the large size and charged nature of these molecules (Butler et al. 2012). CalEPA eliminated the dermal absorption pathway from its risk assessment of microcystins and cylindrospermopsin citing evidence that similarly large molecules such as antibiotics have not been able to be formulated in a way to penetrate the skin (Butler et al. 2012). A U.S. Army-contracted in vitro study by Kemppainen et al. (1990) measured microcystin dermal penetration in 48 hours through excised human abdominal skin and found 0.9 (± 0.3) percent of the total dose in water penetrated through the skin; however, this study has not been peer reviewed.

NMED Exhibit 93

Table 7-13. Results of Screening Analysis Comparing Ingestion and Dermal Absorbed Doses

Microcystin Congener	Ingestion Dose (mg/day)	Dermal Absorbed Dose[a] (mg/event)
Microcystin-LR	0.002	3.6×10^{-8}
Microcystin-LY	0.002	1.0×10^{-7}
Microcystin-LW	0.002	1.8×10^{-7}
Microcystin-LF	0.002	3.4×10^{-7}

[a] Calculations used unrounded parameters; results slightly differ with rounded values.

7.5 Cyanobacterial Cells

Cyanobacteria are associated with two distinct types of stressors, as described in the conceptual model, section 4.1. The first type of stressor are the toxins (microcystins and cylindrospermopsin) produced by the cyanobacteria. Section 3 of this document discusses the nature of these stressors and section 5 discusses related health effects endpoints. These stressors are the basis of the recreational criteria and swimming advisories. The second type of stressor is cyanobacterial cells. At this time, available data are insufficient to develop quantitative recreational values for total cyanobacterial cell density related to inflammatory health endpoints. However, various state and international agencies use total cyanobacterial cell densities in decision-making to determine water quality and to post recreational warnings to the public.

Exposure to cyanobacteria cells in ambient waters is associated with numerous inflammatory health endpoints, including: rashes, respiratory and GI distress, and ear and eye irritation. These effects can be the result of direct contact with bioactive compounds in the cyanobacteria (also referred to as "endotoxins"), or by contact with cyanobacteria-associated microbial commensals via dermal, oral, or inhalation exposure routes (Eiler and Bertilsson 2004; Gademann and Portmann 2008). Section 7.5.1 and Appendix D provide more information about the health effects associated with exposure to cyanobacteria cells based on the scientific literature and related uncertainties. Section 7.5.2 presents information about the use of total cyanobacteria, or other biomass metrics, as an indicator of potential hazard associated with cells or cyanotoxins. Gene-based enumeration methods, satellite remote sensing and uncertainties related to use of cells as indicators are also described. Section 7.5.3 discusses guidelines that use total cyanobacterial cell density as an indicator for toxin presence, quantification of toxigenic cells, and an approach providing cell density estimates related to the recommended 304(a) cyanotoxin criteria.

7.5.1 Health Effects Associated with Cyanobacterial Cells and Uncertainties

Various health studies, described in more detail in Appendix D, relate recreational exposure to increasing densities of cyanobacterial cells with increased incidence of specific health endpoints that can be described as acute inflammatory or allergenic reactions. The EPA identified epidemiological studies, clinical studies, and recreational water outbreak reports in searches of the publicly available and peer-reviewed scientific literature that characterize the human health effects associated with recreating in surface waters where cyanobacteria were present (see Appendix D).

The epidemiological studies provide evidence for statistically significant associations between cyanobacterial cell densities and possible inflammatory or allergenic health endpoints:

NMED Exhibit 93

- Pilotto et al. (1997) reported a significant association with the occurrence of one or more symptoms, such as skin rashes, eye irritation, ear irritation, gastrointestinal distress, fever and respiratory symptoms, and exposure to greater than 5,000 cells/mL for more than one hour. In discussing the significance of the trend of increasing symptom occurrence and with the 5,000 cells/mL cut point, Pilotto et al. (1997) specifically suggested that the 20,000 cell/mL threshold might be too high to be adequately protective of recreators.

- Stewart et al. (2006d) found a significant increase in the inflammatory health effects associated with recreators exposed to > 100,000 total cyanobacteria/mL or a total cyanobacterial surface area > 12 mm^2/mL.

- Lévesque et al. (2014) observed a significant increase in GI symptoms associated with recreational contact. The increase in GI symptoms was significant in the > 20,000-cells/mL and > 100,000-cells/mL categories, and the positive trend for increasing illness with increased total cyanobacterial cell densities also was significant at p-value = 0.001.

- Lin et al. (2015) reported significant associations between respiratory symptoms and exposure to the 25th to 75th percentile range of cyanobacterial cells excluding picocyanobacteria (range 37–237 cells/mL) and between reported respiratory, rash, and earache symptoms and exposure to the highest quartile (range 237–1,461 cells/mL). The 1,461-cells/mL value was the highest cell density observed in that study (Lin et al. 2015).

- Lévesque et al. (2016) reported a significant trend of increasing of GI illness in recreators associated with exposure to the concentration of endotoxins. The authors noted a positive correlation between endotoxin concentrations and total cyanobacterial counts. Relative risks for GI illness were higher for families that also received drinking water from the lakes studied or from wells under the influence of surface water contamination. There was no relationship between GI illness and exposure to *E. coli*. Relative risks also increased for recreators engaged in full (e.g., swimming, water skiing, diving, etc.) or limited (e.g., fishing, use of watercraft) contact recreation and adjustment for the level of exposure did not alter the health relationship.

The variability in the reported epidemiological associations in these studies in both the range of cyanobacterial cell densities reported and specific symptomologies characterized limited identification of a discrete cyanobacterial cell density value associated with a consistent level of effect. Some researchers have suggested that the lack of a described dose-response characterizing cell-related inflammatory health effects could suggest a "threshold" rather than a specific dose-response relationship (Cochrane et al. 2015; Stewart et al. 2006b). Allergy is an example of a threshold mechanism, meaning that there is a level of exposure (i.e., a threshold value) below which the development of sensitization and the elicitation of an allergic reaction will not occur. Defining accurate numerical values for threshold exposure levels is difficult due to lack of validated methods and uncertainties about the mechanism of sensitization (Cochrane et al. 2015).

Scientists investigating the health effects posed by cyanobacteria have pointed out factors that contribute to the epidemiological variability observed and uncertainties in determining what level of cyanobacterial cells result in a specific level of inflammatory responses. For example:

- There are differing cyanobacterial community composition and proportions of the more allergenic, non-cyanotoxin-producing strains relative to the cyanotoxin-producing strains at each

NMED Exhibit 93

site. Researchers have reported non-toxin-producing strains can be more allergenic compared to toxin-producing strains (Torokne et al. 2001).

- There is variability in sensitivity in the study populations.
- There are differences among the specific sites studied.
- The limited size of some studies could have affected the ability to detect significantly increased rates of illness in individual symptom categories (Pilotto et al. 1997; Stewart et al. 2006b). Small sample size diminishes the statistical power of the study and the ability to detect an association if one exists (Rothman et al. 2008).
- The incomplete characterization or consideration of frank or opportunistic pathogens that could co-occur with cyanobacteria in ambient waters also complicates conclusions related to the etiologic agent of the reported symptoms (Lévesque et al. 2014; Lin et al. 2015; Pilotto et al. 1997; Stewart et al. 2006b).

The number of cells in freshwater reported to be statistically-associated with a significant increase in inflammatory endpoints ranged from 5,000 to 100,000 cells per mL. The EPA concluded that, although significant associations with adverse health effects occur across a wide range of cyanobacterial cell densities, the EPA cannot derive the CWA section 304(a) criteria based on total cyanobacterial cell density at this time. There is considerable uncertainty and variability associated with the epidemiological results that did not identify consistent effects at similar cell densities and available data do not support a consistent quantitative dose-response relationship.

Additional research is needed to better describe the health effects associated with exposure to cyanobacteria with more precision using consistent health symptomologies in context with the community of cyanobacteria present (e.g., population of toxigenic versus non-toxin-producing cyanobacteria, shifts in community profile during the study, etc.) and other factors that influence the proliferation of cyanobacteria. Based on currently available science, inflammatory illnesses are significantly increased at values above 100,000 cyanobacterial cells per mL. Guideline values currently in use (see sections 2.1 and 7.5.3) that are within the 5,000 to 100,000 cell density range can find supporting scientific evidence in the peer-reviewed literature described above and in Appendix D.

7.5.2 Cyanobacteria Biomass Measurements as Indicators of Hazard

Under certain conditions, cyanobacteria possessing the toxin synthesis genes, also referred to as toxigenic cyanobacteria, begin producing cyanotoxins. Toxigenic cyanobacteria are a functional subgroup of the total cyanobacterial population that may be present in a water body and the proportion of toxigenic cells present can vary geographically and over time. Numerous biotic and abiotic factors can influence not only the dominance of cyanobacteria within the overall phytoplankton community, but also the proportion of toxigenic cyanobacteria relative to non-toxin-producing cyanobacteria (Davis et al. 2009; Hyenstrand et al. 1998; McCarthy et al. 2009; Neilan et al. 2013; Gobler et al. 2016). Multiple species of cyanobacteria are capable of producing the same toxin, such as the microcystins, which can pose a risk to human and animal health (Crawford et al. 2017). Although scientists have observed a generalized relationship between total cyanobacteria density or chlorophyll *a* and cyanotoxin concentration, these relationships are affected by the dominance of the toxin-producing cyanobacteria within the overall cyanobacterial community (Zhang et al. 2014; Loftin et al. 2016b).

NMED Exhibit 93

Total cyanobacterial cell biomass, described by cell densities or other metrics, such as chlorophyll *a*, can function as a measure of the ecological health of a water body and as an indicator of potential public health hazards, such as inflammatory reactions from exposure to cells and adverse health effects associated with the presence of cyanotoxins. The extent, frequency, persistence, and severity of cyanobacteria proliferation can indicate the eutrophic status of a water body (Yuan and Pollard 2015). Surface water enrichment with nitrogen, notably reduced forms of nitrogen, and phosphorus have been linked to cyanobacteria becoming the dominant phytoplankton (Beaulieu et al. 2013; Glibert et al. 2016; Paerl 2008; Watson et al. 1997). Proliferating cyanobacterial biomass can result in an increased potential for toxins being produced (Pearl et al. 2001; Otten et al. 2012).

Although there can be large variation in the number of toxigenic cyanobacteria present relative to non-toxigenic cyanobacteria in any given body of water, measures of the total cyanobacterial biomass, such as cell counts, chlorophyll, or even visual assessments, can be used effectively in decision-making as early warnings of potential HAB-associated hazards (Loftin et al. 2016b). Pacheco et al. (2016) stated that these measurements can be good indicators of the potential risk of cyanotoxin exposure and useful when access to more sophisticated approaches, resources, or expertise may be limiting. Measurements of total cyanobacteria may also be particularly useful in waters with a history of HAB occurrence and the presence of elevated cyanotoxins.

7.5.2.1 Remote Sensing Techniques for Estimating Cyanotoxins

New and innovative methods, such as remote sensing techniques using satellite imagery, coupled with quantitative analysis to identify cyanobacterial blooms are of increasing interest to states. To date, these techniques cannot yet detect cyanotoxins, but they can quantify cyanobacterial densities in water bodies, an indicator of potential for cyanotoxin presence. Satellite measures of chlorophyll *a*, phycocyanin, or both are used to estimate cyanobacterial cell density based on validated algorithms that quantify relationships between these parameters and in situ measurements of cell density. For example, Stumpf (2014) and Wynne et al. (2010) readily detected by satellite areas of high *Microcystis* densities in larger freshwater bodies, such as Lake Erie.

U.S. EPA has collaborated since 2015 with the National Aeronautics and Space Administration (NASA), NOAA, and the USGS on the Cyanobacteria Assessment Network (CyAN) project. This project is developing the capability to detect and quantify total cyanobacterial blooms and related water quality of U.S. lakes and estuaries using satellite data records (U.S. EPA 2018b). This includes improving interpretation of satellite data and refining algorithms across satellite platforms. CyAN defined an approach for identifying lakes that can be spatially resolved (i.e., visually separated) with satellite imagery given differences in pixel resolutions, a method to quantify frequency of bloom occurrence in recreational freshwater sites, and a method for evaluating changes in the spatial extent of cyanobacterial blooms over time to support state-level assessments (Clark et al. 2017; Urquhart et al. 2017). CyAN has developed a mobile application that makes its processed satellite data more widely available. In 2017, the application was made available to state agencies for beta testing (U.S. EPA 2018b). A CyAN project that compares satellite-based estimations of total cyanobacterial cell density data from monitoring programs in eight states in the eastern United States found that satellite information provided robust estimates for freshwater lakes greater than 100 hectares when the cell densities less than 109,000 cells/mL and above 1 million cells/mL (Lunetta et al. 2015). The estimates were less on target for intermediate densities (i.e., between 110,000 and 1 million cells). The authors attributed this lower performance to the gap in taxonomic information needed to facilitate conversions between cell count and cell volumes (Lunetta et al. 2015).

NMED Exhibit 93

Challenges remain for using remote sensing for cyanotoxin detection and mapping and Stumpf et al. (2016) identify these and a strategy for resolving them. The challenges they note include the lack of a steady relationship between the indicator pigments (i.e., chlorophyll *a* or phycocyanin) and cyanotoxins. These relationships may be valid for several weeks but start to vary over longer time periods due to changes in the amount of cyanotoxin produced as a function of cyanobacterial biomass. Strategic collection of pigment and toxin measurements will improve the application of remote sensing and associated models. The Ocean Land Colour Imager on the Sentinel-3 satellite, launched in 2016, will help address this need and improve data availability for most medium to large lakes around the world.

Given the inherent spatial uncertainty in the distribution of blooms and the potential issues with use of the appropriate satellite product, more attention should be given to the use of field measurements of reflectance to parameterize derivative-based pigment models (Tomlinson et al. 2016). This approach will help standardize processing of the satellite data to consistent reflectance-based products. Standardization is a factor in pigment and cyanotoxin measurement that will also require closer scrutiny. Propagation of known measurement error and uncertainty into the models will establish confidence levels for a variety of applications besides toxin maps. Improving strategies for collecting pigment measurement with toxin measurement will allow a better understanding and use of remote sensing to inform monitoring of toxins in lakes.

7.5.2.2 Molecular Methods for Estimating Cyanotoxins

Scientists have applied newer methods of quantifying microbes in environmental matrices, which increases understanding of bloom dynamics and functional subgroups of cyanobacteria, such as the toxigenic cells (Davis et al. 2009). The use of gene-based enumeration methods allows the quantification of cyanobacteria that contain specific gene sequences for toxin synthesis—without which a cell cannot produce the toxin. When toxigenic cyanobacteria are characterized with these tools, they have been shown to be better predictors of subsequent increases in toxin concentrations than with other traditional enumeration methods.

More recently, the use of gene-based quantification methods has helped to shed light on the community dynamics within a bloom, understand some of the factors that trigger toxic blooms, and provide faster and less expensive measurements of potential bloom toxicity compared to ELISA- and LC/MS/MS-based methodologies. Researchers have shown that microcystins and cylindrospermopsin are produced by non-ribosome-associated peptide synthetases (Dittmann et al. 1997; Moreira et al. 2013). The microcystin synthetase complex is encoded by 10 *mcy* genes (*mcyA* to *mcyJ*) (Neilan et al. 2013). Studies have characterized the abundance of various *mcy* genes in ambient waters (Pacheco et al. 2016; Qiu et al. 2013). The cylindrospermopsin synthetase gene cluster, *cyr*, is not as well characterized, but has been studied in multiple cylindrospermopsin-producing cyanobacteria (Neilan et al. 2013). Other researchers have used qPCR methods to characterize the relative abundance of total cyanobacteria, *Cylindrospermopsis raciborskii* and cylindrospermopsin synthase in lake water (Moreira et al. 2011). Selected examples of monitoring studies using gene-based approaches are described below.

- Davis et al. (2009) characterized toxic and nontoxic strains of *Microcystis* by quantifying the *mcyD* (toxigenic strains) and the 16S rDNA genes (all *Microcystis*) in four lakes in the northeastern United States over a two-year period. At all sites, toxigenic *Microcystis* were a better predictor of microcystin concentrations compared to total cyanobacteria, total *Microcystis*, chlorophyll *a*, or other environmental factors. Gene copies of *mcyD* were significantly correlated with microcystin concentrations in every lake studied (Davis et al. 2009).

NMED Exhibit 93

- HABs in lakes and reservoirs are prevalent in Alberta, Canada, and are affected predominantly by elevated microcystins (Alberta Health 2014). Multiple Canadian governmental departments and public health laboratories in Alberta conducted a monitoring and advisory program for cyanobacteria at beaches. Among the findings were: microcystin-producing cyanobacteria species were dominant in most lakes with blooms peaking in late August to September, microcystin concentrations exceeding Canadian guidelines were not consistently associated with elevated total cyanobacterial cell densities in most cases, and the *mcyE* gene measured by qPCR was a good predictor for cyanobacterial blooms in some lakes (Alberta Health 2014).

- In response to the 2014 Lake Erie HAB event that contaminated the drinking water of Toledo, Ohio, the EPA revised the monitoring requirements for Ohio public water systems. Included in those requirements are testing for the *mycE* gene. If > 5 *myc*E genes/µL are detected in raw water samples, public water systems must monitor for microcystins (Ohio EPA 2017). Ohio is currently testing qPCR methods for total cyanobacteria (16s rDNA) and toxigenic cyanobacteria such as microcystin (*mcy*E gene) and saxitoxin (*sxt*A gene) producers. Ohio's HAB response strategy for recreational waters (Ohio EPA 2017) includes qPCR assessment for cyanotoxin-production genes as an option for cyanobacterial screening. If the qPCR testing indicates an abundance of toxigenic cyanobacteria, additional analysis for the toxin is recommended (Ohio EPA 2017).

- In Lake Champlain, in the northeastern United States, Fortin et al. (2015) applied qPCR-based methods and high-throughput sequencing to evaluate the effect of physico-chemical parameters and nutrients on the dynamics of cyanobacterial community. The researchers observed that total cyanobacteria were correlated with microcystin concentrations (Fortin et al. 2015). They also showed a significant correlation between the microcystin concentrations, the abundance of the *mcyD* gene, and the abundance of *Microcystis* 16S rDNA gene copies. Previous work had shown that *Microcystis* were the predominant microcystin producer present in the same water body (Ngwa et al. 2014).

- Pacheco et al. (2016) reviewed studies examining relationships between the prevalence of microcystin synthetase genes and microcystin concentration, and between chlorophyll *a* or cell density and microcystin concentration. While many studies included in the review did show a correlation for both comparisons, some did not. A lack of correlation between the synthetase genes and microcystin concentration was reported in studies that: (1) extracted the particulate-associated microcystins only; (2) included waters with very low concentrations of total microcystins (e.g., < 0.5 µg/L); or (3) in one study, monitored lakes at a single fixed point in the pelagic zone at the deepest site in each lake using depth-integrated water samples representing the entire photic zone (Beversdorf et al. 2015a; Pacheco et al. 2016). For studies not reporting a correlation between chlorophyll *a* or cell density and toxin concentration, only particulate-associated microcystin was analyzed or a very low concentration (e.g., < 0.05 µg/L) of total microcystins was observed (Pacheco et al. 2016). Zhang et al. (2014), one of the studies included in the Pacheco et al. (2016) review, characterized cylindrospermopsin- and microcystin-producing genotypes in the Macau reservoir, China, and found high cylindrospermopsin concentrations correlated to the prevalence of the *pks* gene ($r^2 = 0.95$, p-value < 0.01) and that *Cylindrospermopsis* dominated the cyanobacterial population in the reservoir studied.

- Crawford et al. (2017) applied an integrated monitoring approach including microscopic cyanobacteria identification, multiplex qPCR for toxin genes, and toxin analysis to assess

NMED Exhibit 93

potential risks and inform bloom management decisions in a HAB event on the Murray River, Australia, in 2016. The qPCR results showed that cylindrospermopsin and saxitoxin genes were present, but were below the level of quantification. No microcystin genes were detected. The qPCR results were corroborated with the lack of detection of any cylindrospermopsin, microcystin, or saxitoxin (Crawford et al. 2017).

7.5.2.3 Uncertainties in Using Cyanobacterial Cells as Indicators

While cell density and pigment measurements can be useful for early detection of cyanobacterial proliferation and informative for bloom monitoring, these approaches may not be sufficiently accurate to predict risk from cyanotoxins (Pacheco et al. 2016). Uncertainties related to the use of total cyanobacteria in decision-making related to toxin concentrations should be considered.

1. Toxigenic cell densities can be a better indicator of the potential of a bloom to produce cyanotoxins compared to measures of total cyanobacterial biomass.

The amount of toxin produced by a toxigenic cyanobacterial cell and the relative abundance of toxigenic strains relative to non-toxigenic ones can vary considerably and be affected by environmental factors (Gobler et al. 2016). Gene-based quantification of toxigenic cyanobacteria can be beneficial for decision-making for HAB management approaches (Lee et al. 2015; Crawford et al. 2017). Davis et al. (2009) observed that quantifying toxigenic *Microcystis* was a better predictor of in situ microcystin levels than other surrogates, such as total cyanobacteria and chlorophyll *a*. The use of qPCR to characterize temporal and spatial variations in the abundance of toxigenic strains can identify the capability of a bloom to produce toxins, and hence the potential for recreator exposure to toxins, including perhaps prior to the hazardous condition occurring (Pacheco et al. 2016).

The importance of the toxigenic cyanobacterial cells has been recognized by the WHO and previously discussed in section 2.1. Based on toxigenic *Microcystis*, approximately 20 µg microcystins per L could be expected, but other species, such as *Planktothrix*, can contain higher microcystin concentrations in a cell compared to *Microcystis* (Fastner et al. 1999). Thus, the WHO commented that microcystin concentrations could be much higher (e.g., 50–100 µg/L) if species with high microcystin content dominate a bloom (WHO 2003a).

2. Total cyanobacteria can be informative as an indicator for the presence of toxins if toxigenic species are abundant or the dominant members of the cyanobacterial community.

Evidence from prior monitoring may demonstrate toxigenic strains tend to dominate blooms in a water body or that a prior bloom had increased densities of toxigenic species occurring in conjunction with elevated toxins. Studies showing good correlation between increased cell densities or other parameters linked to cell proliferation and elevated toxin concentrations can also show the bloom is dominated by toxin-producing species (Rinta-Kanto et al. 2009; Zhang et al. 2014; Pacheco et al. 2016). In one study on Lake Erie over multiple seasons, Rinta-Kanto et al. (2009) observed a positive correlation between the abundance of cyanobacterial and *Microcystis* gene copies and the number of microcystin synthetase genes. *Microcystis* were a strong contributor to the concentration of microcystins in Lake Erie and the relative abundance of *Microcystis* cells was correlated with microcystin concentrations (Rinta-Kanto et al. 2009). Lack of correlation can occur when toxigenic cell density is low or undetectable (Crawford et al. 2017) or low concentrations of toxin are recorded (Rinta-Kanto et al. 2009) and in such cases measures of total cyanobacteria are not good indicators of toxins.

NMED Exhibit 93

3. The proliferation of toxigenic cells and the timing of the presence of elevated toxin concentrations may or may not coincide with the visible proliferation of a HAB.

Decisions to issue recreational water warnings/advisories, or initiate monitoring for cyanotoxins based on total cyanobacteria once a bloom is observed (i.e., green, discolored water, or scum formation/accumulation associated with high densities of cells) may overlook situations where extracellular toxins are present. Cells may accumulate in locations different from where the bloom originated (e.g., by wind or wave action, or both, or be transported downstream). A cell density of 40,000 cells/mL is lower than what might be typically associated with a visible bloom (WHO 2003a). Decision points contingent on visually confirmed blooms may miss or delay the identification of the hazardous condition associated with exposure to elevated cyanotoxins, especially in water bodies with a previous history of HAB events or toxin detections and the downstream waters potentially affected by the HAB.

Davis et al. (2009, 2010) observed bloom dominance shift between toxigenic strains and non-toxigenic strains over the course of a summer. Spatial and temporal dynamics in cyanobacterial population succession is noted in other seasonal studies (Sabart et al. 2010; Otten et al. 2012, Beversdorf et al. 2015b; Fortin et al. 2015; Chen et al. 2017). Ha et al. (2009) observed similar seasonal variations in both the gene copies of microcystin synthetase genes and for total cyanobacteria gene copies, although the cyanobacterial community was consistently dominated by microcystin-producing cells throughout the study.

7.5.3 Use of Cyanobacteria Cell Densities in Guidelines

7.5.3.1 Cyanobacteria Cell Guidelines

A number of states and international agencies include both total cyanobacteria and toxigenic cyanobacteria density guidelines to account for both inflammatory- and toxin-associated health endpoints. Cyanobacterial cell densities used by states and local health departments to provide guidance to recreators on water quality are presented elsewhere in this document (see Table 2-3 for a list of states with cyanobacterial cell density guidelines; see Appendix B for state guidelines and associated actions).

As discussed in section 2.1, the 35 states that currently have HAB-related guidelines include different approaches and guideline levels (see Table 2-3). Seven states have guideline levels that address toxin-producing cyanobacteria as a proportion of the total cyanobacterial population or include a toxin-specific cyanobacteria cell density (California, Idaho, Maryland, New York, New Hampshire, Oregon, and Virginia). The Karuk Tribe, located in California, developed cell-based values for posting cyanotoxin public health warnings for the tribe's recreational waters (Kann 2014).

As described in section 2.1 of this document, the WHO (2003a) guideline value development was informed by results from a review conducted by Chorus and Bartram (1999) and a prospective epidemiology study by Pilotto et al. (1997), which evaluated health effects after recreational exposure to cyanobacteria and reported associations between cyanobacterial cell densities and health. The WHO recommended three tiers of guideline values describing an increasing scale of potential adverse health effects and "between the chiefly irritative symptoms caused by unknown cyanobacterial substances and the potentially more severe hazard of exposure to high concentrations of cyanotoxins, particularly microcystins."

NMED Exhibit 93

- The lowest tier of guideline values (< 20,000 cyanobacterial cells per ml; < 10 µg/L chlorophyll *a*) was mainly associated with a significant increase in irritative or allergenic effects (the inflammatory health endpoints). The WHO, using conservative assumptions, also estimated that microcystin concentrations of 2 to 4 µg/L, and possibly up to 10 µg/L, may be expected at a cell density of 20,000 cells/mL where microcystin producers dominate.

- The second tier (20,000 to 100,000 cyanobacterial cells per ml; 10 to 50 µg/L chlorophyll *a*), describing a moderate probability of adverse health effects from cyanotoxins was informed by (1) modifying the value for the WHO drinking water guideline for microcystin-LR for a recreational exposure scenario and (2) translating microcystin concentrations to cell densities based on the average microcystin content of *Microcystis* cells. The WHO, using conservative assumptions, also estimated that 100,000 cyanobacterial cells/mL could correspond to 20 µg microcystins/L if a bloom consists of *Microcystis* and has an average microcystin content of 0.2 pg/cell.

- At the third tier (> 100,000 cells per mL; > 50 µg/L chlorophyll *a*) "there is the potential for some frequently occurring species (i.e., *Microcystis*) to form scums," which can "increase risks for bathers and others involved in body-contact water sports." The high probability of adverse health effects category is associated with the elevated potential for exposure to cyanotoxins and the potential for severe health outcomes. "The presence of cyanobacterial scum in swimming areas represents the highest risk of adverse health effects due to abundant evidence for potentially severe health outcomes associated with these scums."

- Very high densities of cells occurring in scums (e.g., > 10 million cells/mL or > 5,000 µg/L chlorophyll *a*) can be associated with very high concentrations of toxin.

The Australian National Health and Medical Research Council (NHMRC) published a two-tiered guideline for managing cyanobacteria in recreational water (NHMRC 2008). Tier one includes numeric targets for microcystins based on children's recreational exposures and a toxigenic cell density for *Microcystis aeruginosa*. The NHMRC recommends a secondary guideline for the protection from health hazards associated with high densities of non-toxigenic cyanobacteria consistent with the WHO cyanobacterial cell density recommendations for the moderate probability of health effects. NHMRC used the epidemiological results published by Stewart et al. (2006b) to inform the derivation of the Australian total cyanobacteria guideline number. Stewart et al. (2006b) found a significant increase in the inflammatory health effects associated with recreators exposed to >100,000 total cyanobacteria/mL or a total cyanobacterial surface area > 12 mm^2/mL. Because different cyanobacteria species can have different sizes, the surface area estimate of biomass can take those size differences into account (e.g., 1,000 very big cells versus 1,000 very small cells). NHMRC converted the cell surface reported by Stewart et al. (2006b) to an equivalent biovolume and rounded that value to 10 mm^3/L. This biovolume guideline value applies when toxigenic cyanobacteria are absent in a bloom (NHMRC 2008)

NHMRC calculated a child-based total microcystin concentration of 9.4 µg/L, rounded to 10 µg/L (NHMRC 2008). The authors then converted the toxin concentration to an equivalent toxigenic cell density (50,000 *Microcystis aeruginosa*/mL) using the microcystin cell quota value (0.2 pg/cell). To account for the potential hazard posed by other microcystin-producing cyanobacteria, the cell density was converted into a biovolume equivalent (4 mm^3/L). Other species have different cell sizes, so the biovolume measurement allows comparisons with the other known toxin-producing cyanobacteria that may be present. The biovolume equivalent applies to the total of all cyanobacteria where a known toxin producer is dominant (NHMRC 2008).

NMED Exhibit 93

7.5.3.2 Amount of Toxin per Cell

Toxigenic cyanobacteria produce cyanotoxins that can accumulate inside the cells or be released to the water column. The amounts of toxin produced by a toxigenic cyanobacterium is also referred to as "cell quota." There is variability in the estimate of cyanotoxin concentrations associated with cell density, in part because a bloom can contain both the toxigenic and non-toxin-producing strains of the same species and cyanobacterial community differences between locations could affect the level of cyanotoxin that is present. Thus, it is important to understand the abundance of toxigenic cyanobacteria in a water body. As discussed above, characterizing the abundance of toxin genes can be a better predictor of toxin produced than can calculations based on a toxin cell quota. The WHO's microcystin estimates at the different risk levels were based on converting the recommended total cyanobacterial cell density using a *Microcystis* cell quota value for microcystins (0.2 pg/cell) derived from a laboratory study conducted by Mole et al. (1997) reporting an average microcystin cell quota in laboratory cultures of 0.2 pg/cell (range: 0.07–0.3 pg/cell) (Fitzgerald et al. 1999), but other species and strains of microcystin producers could result in much higher water-column microcystin concentrations given the same cell density (WHO 2003a).

The EPA searched the published peer-reviewed scientific literature for information on the amount of microcystin and cylindrospermopsin produced by or contained in a cell to inform the development of toxigenic cell densities equivalent to the recommended criteria concentrations. Appendix G presents the details related to the search strategy, reference prioritization and search results. The search resulted in the collation of multiple studies reporting cell quotas for microcystin and cylindrospermopsin in multiple genera of cyanobacteria. Laboratory-based culture studies with numerous clones of *Microcystis aeruginosa*, *Cylindrospermopsis raciborskii, Planktothrix agardhii*, and *Planktothrix rubescens* were also found. Many of these references also included either biomass-toxin conversions or graphic data that would support conversion factors from cyanobacterial cell density (expressed in a variety of units including: cells/L, biovolume (μm^3/L), and chlorophyll *a*/L) to toxin concentrations for these species. Aggregated data are presented in Table 7-12. Table G-3 in Appendix G provides additional detail on the studies identified containing cell quota information.

To facilitate a comparison of this information with the value used by the WHO, the EPA organized the reported cell quota information by toxin and by genus (Table 7-14). Within each row, the study type, quantification method, reported means and ranges, and references to the original study are included. Not every study reported a mean, median, maximum, or minimum, so each row represents a collation of the values reported. Ranges of reported cell quotas were large. For example, for all microcystin-producing genera, reported cell quotas ranged from 0 to 4.3 pg/cell and the reported range of the means were 0.015 to 0.58 pg/cell. For *Microcystis*, the mean of the means, for seven studies published between 2008 and 2013, was 0.15 pg/cell. This value is similar to the 0.2 pg/cell value used by the WHO and provides additional evidence that this conversion factor is supported by multiple scientific studies. For the genus *Planktothrix*, the studies identified by the EPA do not suggest that this genus produces much higher amount of microcystin compared to *Microcystis*. However, the EPA's literature search focused on more recently published data and the *Planktothrix* values in the summary table come from only two recent studies that may have not characterized toxin production under optimal conditions. Based on the data presented in Table 7-14, the EPA concluded that the microcystin cell quota used by the WHO is supported. The caveat expressed by the WHO (i.e., cell quota values can be variable within and between species of microcystin-producing cyanobacteria) is also substantiated by the EPA's literature search results. The EPA included the 0.2 pg/cell value in the calculation of a toxigenic cell density for

NMED Exhibit 93

microcystin-producing cyanobacteria equivalent to the recommended toxin magnitude (see section 7.5.3.3).

The EPA also collated similar information for cylindrospermopsin cell quotas. As with other aspects of cylindrospermopsin, less information was available, but multiple field and laboratory studies reporting the mass of toxin per cell were identified. The range of cylindrospermopsin cell quotas (0.0028–14.6 pg/cell in *Cylindrospermopsis*) was larger than for microcystins, as was the range of reported means (0.0028–0.17 pg/cell). The highest value (14.6 pg/cell) was reported from a field study (see Table G-1). The highest value reported in a laboratory study was 0.17 pg/cell. The mean value for all studies was 0.047 pg/cell (n = 10) and for field studies (n = 2) was 0.023 pg/cell. Given the few number of field studies, large uncertainties exist with how representative the mean is of the central tendency of the range. Less information was identified for *Aphanizomenon*, another well-known cylindrospermopsin producer. To have a similar confidence level in the cylindrospermopsin cell quota data compared to microcystins, additional data and an improved sense of the central tendency within the reported ranges is needed. At present, the EPA is not sufficiently confident in the cylindrospermopsin cell quota database to estimate a toxigenic cell density specific for cylindrospermopsin.

NMED Exhibit 93

Table 7-14. Aggregated Cell Quota Summary Data for Selected Microcystin and Cylindrospermopsin-producing Genera

Toxin Genus	Quantification Method[a]; Study Type[b]	Range of Means[c]	Mean[c,d]	Median of Means[c]	Minimum; Maximum[c,e]	References
Microcystins						
All microcystin-producing genera	Mass per cell; Field and lab	0.015 pg/cell – 0.58 pg/cell	0.11 pg/cell	0.091 pg/cell	0 pg/cell – 4.3 pg/cell	Orr and Jones (1998); Jähnichen et al. (2001); Wiedner et al. (2003); Akcaalan et al. (2006); Jähnichen et al. (2007); Briand et al. (2008); Fahnenstiel et al. (2008); Vasconcelos et al. (2011); Sitoki et al. (2012); Tao et al. 	Mass per biovolume; Lab	N/A	N/A	N/A	416 fg/µm^3; 447 fg/µm^3	Pierangelini et al. (2015)

fg = femtogram; pg = picogram; µg = microgram; N/A = not available.

[a] Various methods were used to quantify toxin quotas and quota values were presented in different forms, including toxin mass per cyanobacterial cell and toxin mass per cyanobacterial biomass.

[b] Studies were conducted in two different settings: the field (i.e., environmental) or a laboratory.

[c] Study authors reported data using multiple measurement units. When possible, the EPA converted data to the standard units of pg per cell. The EPA did not identify appropriate conversion factors that would allow genus-specific conversion of quotas described in mass per biomass to mass per cell.

[d] Shows single reported mean if only one study was available or average of reported means.

[e] If reported toxin quota means from one study were the lowest or highest toxin quotas reported within a genus, then these values were listed as the minimum or maximum values, respectively, to better reflect the range of toxin quota values.

[f] *Cylindrospermopsis* is now known as *Raphidiopsis.*

Challenges with collating this information include the variable conditions under which the studies characterized toxin quotas and the various ways the toxin quota data were reported. Conditions under which the toxin quotas were studied include laboratory and field conditions, different environmental and collection-based strains included in the study, and the different environmental conditions existing at the various locations where the field studies were conducted. For the latter, information on some of the external factors affecting toxin production is summarized above to help demonstrate the complex interactions that affect not just if the toxin is produced, but also how much toxin can be produced. The various ways that toxin cell quotas were reported include: toxin mass per cell, toxin mass per unit biomass, and toxin mass per unit biovolume. When possible, the EPA converted the cell quota information into pg per cell to enable a straightforward comparison to the WHO value.

7.5.3.3 Toxigenic Cyanobacteria Value Associated with Recommended Microcystins Criteria/Swimming Advisory

As discussed in section 7.5.3.2 the abundance of toxigenic cells in a water body affects the amount of cyanotoxin produced. The number of toxigenic cyanobacteria relative to the number of total cyanobacteria can vary in time and space. Quantifying the abundance of toxigenic cyanobacteria is a better predictor of potential toxin production compared to total cyanobacteria. Below, the EPA presents a similar approach to that used by the WHO to calculate a cyanobacterial cell density corresponding to recommended criteria/ swimming advisory value for microcystins. Because more data are available for microcystins compared to cylindrospermopsin, this calculation is based on microcystins only.

$$\text{Cyanobacterial cell density (CCD)} = \frac{\text{Ambient cyanotoxin concentration (ACC)}}{\text{Cell toxin amount (CTA)}}$$

Where:

CCD	=	calculated toxigenic cell density associated with a specific toxin concentration
ACC	=	specific toxin concentration target in ambient water (e.g., AWQC value)
CTA	=	amount of toxin produced in a cyanobacterial cell

For the microcystins-producing cyanobacteria (e.g., *Microcystis*):

ACC	=	8 µg/L; recommended recreational criteria value for microcystins
CTA	=	0.2 pg/cell; reported mean concentration of microcystin in a cell of microcystin-producing cyanobacteria

Adding in the conversion factors to convert units, the equation is:

$$\text{CCD} = \frac{\text{ACC (µg/L)} \times 10^6 \text{ pg/µg}}{\text{CTA (0.2 pg/cell)}} \times \frac{\text{L}}{1000 \text{ mL}}$$

NMED Exhibit 93

Adding in the values,

$$\text{CCD} = \frac{8\ \mu\text{g/L} \times 10^6\ \text{pg/}\mu\text{g}}{0.2\ \text{pg/cell}} \times \frac{1\ \text{L}}{1000\ \text{mL}} = 40{,}000\ \text{cells/mL}$$

Thus, a toxigenic microcystin-producing cell density of 40,000 cells/mL has the potential to result in a microcystin concentration of 8 µg/L.

7.6 Other Sources of Microcystins and Cylindrospermopsin

Although the EPA is not including other sources of cyanotoxins in this recreational exposure scenario, the Agency has included summary information on potential sources of cyanotoxins, such as drinking water, ground water, fish, shellfish, dietary supplements, air, soil, and sediments. Exposure to cyanotoxins in finished drinking water is characterized in the Drinking Water Health Advisories (U.S. EPA 2015a, 2015b). States may wish to consider these other sources of cyanotoxins in their public health approach.

7.6.1 Drinking Water

The occurrence of cyanotoxins in drinking water depends on their levels in the raw source water and the effectiveness of treatment methods for removing cyanobacteria and cyanotoxins during the production of drinking water. The EPA has provided *Recommendations for Public Water Systems to Manage Cyanotoxins in Drinking Water* to assist public drinking water systems (PWSs) that choose to develop system-specific plans for evaluating their source waters for vulnerability to contamination by microcystins and cylindrospermopsin (U.S. EPA 2015e). Cyanotoxin management plan templates, water treatment optimization, and a communications tool box are also available on the EPA's Cyanotoxins in Drinking Water website (U.S. EPA 2015e).

The American Water Works Association Research Foundation (AWWARF) conducted a study on the occurrence of cyanobacterial toxins in source and treated drinking waters from 24 public water systems in the United States and Canada in 1996–1998 (AWWARF 2001). Of 677 samples tested, microcystins were found in 80 percent (539) of the waters sampled, including source and treated waters. Only two samples of finished drinking water were above 1 µg/L. A survey conducted in 2000 in Florida (Burns 2008) reported that microcystins were the most commonly found toxin in pre- and post-treated drinking water. Finished water concentrations ranged from below detection levels to 12.5 µg/L.

During the summer of 2003, a survey was conducted to test for microcystins in 33 U.S. drinking water treatment plants in the northeastern and midwestern United States (Haddix et al. 2007). Microcystins were detected at low levels ranging from undetectable (< 0.15 µg/L) to 0.36 µg/L in all 77 finished water samples.

In August 2014, the city of Toledo, Ohio, issued a do-not-drink or -boil advisory to nearly 500,000 customers in response to the presence of total microcystins in the city's finished drinking water at levels up to 2.50 µg/L. The presence of the toxins was due to a cyanobacterial bloom near Toledo's drinking water intake located on Lake Erie. The advisory was lifted two days later, after treatment adjustments led to the reduction of the cyanotoxin concentrations to concentrations below the WHO guideline value of 1 µg/L in all samples from the treatment plant and distribution system.

NMED Exhibit 93

During the late spring and early summer of 2018, both microcystins and cylindrospermopsin were found in the finished drinking water of Salem, Oregon (Novak Consulting Group 2018). Salem's finished drinking water source is the North Santiam River, which is fed by Detroit Lake, a reservoir located southeast of the city. In late May 2018, the State of Oregon issued a recreational advisory for cyanotoxins for Detroit Lake. Less than a week later, the City of Salem issued a do not drink advisory due to the presence of levels of microcystins and cylindrospermopsin in drinking water exceeding health advisories. The drinking water advisory was lifted in the beginning of July based on many consecutive days of finished water results being below health advisory levels.

The EPA has published Drinking Water Health Advisories to address microcystins and cylindrospermopsin in drinking water (U.S. EPA 2015a, 2015b).

7.6.2 Ground Water

Only very limited data are available on microcystins in ground water and no monitoring data were identified for cylindrospermopsin. A study reported microcystins in ground water from a well located near the shore of Lake Chaohu, in China (also known as Chao Lake), which contained high microcystin concentrations (Yang et al. 2016b). Therefore, under certain conditions, ground water hydraulically connected to surface water has the potential to be contaminated by cyanotoxins.

7.6.3 Fish and Shellfish

Fish and shellfish living in waters affected by a cyanobacterial bloom may accumulate cyanotoxins in their muscle tissue and internal organs (Gibble et al. 2016; Kinnear 2010). Some authors have found that microcystins accumulate less in the edible parts of aquatic organisms, such as muscle (Deblois et al. 2011; Gutiérrez-Praena et al. 2013; Song et al. 2009; Vareli et al. 2012; Wilson et al. 2008; Xie et al. 2005; Zimba et al. 2006). Cylindrospermopsin has also been found in fish and shellfish exposed for longer periods of time to a cyanobacterial bloom (Funari and Testai 2008; Ibelings and Chorus 2007; Kinnear 2010; Saker and Eaglesham 1999). For additional information on occurrence of microcystins and cylindrospermopsin in fish and shellfish, please see the Health Advisory document published (U.S. EPA 2015a, 2015b).

7.6.4 Dietary Supplements

Extracts from *Arthrospira* (Spirulina) and *Aphanizomenon flos-aquae* have been used as dietary blue-green algae supplements (BGAS) (Funari and Testai 2008). These supplements are reported to have beneficial health effects including supporting weight loss, and increasing alertness, energy and mood elevation for people suffering from depression (Jensen et al. 2001). A study suggested that BGAS could be contaminated with microcystins ranging from 1 μg/g up to 35 μg/g (Dietrich and Hoeger 2005). In two separate studies, Heussner et al. (2012) and Roy-Lachapelle et al. (2017) both analyzed 18 different commercially available BGAS for the presence of cyanotoxins. Heussner et al. (2012) reported that all products containing *Dolichospermum flos-aquae* (formerly *Aphanizomenon flos-aquae*) tested positive for microcystins at levels ≤ 1 μg microcystin-LR equivalents/g dry weight. Cylindrospermopsin was not found in any of the supplements. Roy-Lachapelle et al. (2017) reported that of the 14 products containing *Spirulina*, three contained total microcystins at levels ≤ 1 μg/g. All four products containing *Dolichospermum flos-aquae* tested positive for total microcystins ranging from 0.8 μg/g to 8.2 μg/g using the Adda oxidation method and from 0.52 μg/g to 5.8 μg/g using the sums of microcystins standards. Cylindrospermopsin was not found in any of the supplements.

NMED Exhibit 93

7.6.5 Ambient Air

Four studies provide air concentration data for cyanotoxins indicating that recreational surface waters with toxigenic cyanobacterial blooms can result in aerosolized cyanotoxins (Backer et al. 2008, 2010; Wood and Dietrich 2011; Cheng et al. 2007). These studies are summarized in section 7.4.1.

7.6.6 Soils and Sediments

Microcystins can adsorb onto naturally suspended solids and dried crusts of cyanobacteria. Cyanotoxins can precipitate out of the water column and reside in sediments for months (Falconer 1998; Han et al. 2012; Wu et al. 2012). In sediments, cylindrospermopsin adsorbs to organic carbon, with little adsorption observed in sandy and silt sediments (Klitzke et al. 2011). The low adsorption of cylindrospermopsin in sediments/silts with low levels of organic carbon reduces the opportunity for microbial degradation.

Maghsoudi et al. (2015) tested adsorption of cyanotoxins onto three fractionated sediment particles, clay-silt (< 75 μm), fine sand (75–315 um) and coarse sand (315–2000 μm) and found that adsorption capacity of coarse sand fraction for all the tested cyanotoxins was less than four percent of the clay-silt fraction. They found that highest adsorption for cylindrospermopsin, microcystin-LW, and microcystin-LF were 73, 57, and 55 percent, respectively, and occurred within two hours. Desorption experiments demonstrated that less than nine percent of cyanotoxins desorbed from sediment within 96 hours.

Song et al. (2015) found that a statistically significant part of the variability of the microcystin concentration in the sediments could be explained by a combination of variables in the water column, such as total microcystins in the water, cyanobacterial biomass in water, pH, and temperature.

7.7 Tribal Considerations

The EPA considered alternative exposure scenarios tribal communities might have, given their cultural practices. Native American food foraging customs or cultural or religious ceremonies can put them into primary or secondary contact with cyanotoxins. Primary contact ceremonial use may include the use of a surface water body for religious or traditional purposes by members of a tribe, involving immersion and intentional or incidental ingestion of water (Eastman 2007).

It is uncertain whether these activities would lead to cyanotoxin exposures higher than the primary recreational contact assumptions for incidental ingestion and exposure duration used in this assessment.

7.8 Livestock and Pet Concerns

The earliest observations of adverse effects of cyanobacterial exposure to animals include the rapid death of stock animals in Australia in 1878 (Francis 1878). Since then, numerous cases of mammal and bird deaths have been documented (Backer et al. 2015; Hilborn and Beasley 2015). These cases were reported throughout the 20th century on all continents except Antarctica (Stewart et al. 2008). The impacts of cyanotoxins on domestic and companion animals are likely under-recognized because many cases are misdiagnosed, few cases are biochemically confirmed, and even fewer are reported in the scientific literature or to animal health systems (Zaias et al. 2010).

Livestock and pets potentially can be exposed to higher concentrations of cyanotoxins, or have increased exposure to cyanotoxins than humans because they are known to consume cyanobacterial scum and mats

NMED Exhibit 93

and drink cyanobacteria-contaminated water (Backer et al. 2013). Dogs are also at risk, as they may lick cyanobacterial cells from their fur after swimming in a water body with an ongoing bloom (CDC 2017a). Mats and scums can represent thousand-fold to million-fold concentrations of cyanobacterial cell populations, and published microcystin concentrations have ranged up to 24 mg microcystins/L from scum material (Chorus and Bartram 1999). Common signs of HAB cyanotoxin poisonings in pets include repeated vomiting, diarrhea, loss of appetite, abdominal swelling, stumbling, seizures, convulsions, disorientation, inactivity, or skin rashes and hives, and in extreme cases collapse and sudden death (CDC 2017a; New York Sea Grant 2014; Trevino-Garrison et al. 2015). Although reports of livestock deaths are uncommon, in extreme cases, death can occur minutes after drinking from a contaminated water source. Acute symptoms of cyanotoxin poisoning can include loss of appetite, weakness, staggering, or inflammation of the muzzle, ear, or udder. Higher levels of cyanotoxins can lead to severe liver damage, the development of jaundice, and severe photosensitization. Often livestock or pets that recover from these ailments can then suffer from chronic failure to thrive (Australia Department of Economic Development Jobs Transport and Resources 2013; Robinson and Alex 1987).

The Centers for Disease Control and Prevention (CDC) provides multiple resources, such as frequently asked questions (FAQs), Veterinarian Cards, and Animal Safety Alerts, to help educate the public of the dangers associated with cyanotoxin exposure to pets (CDC 2017a, 2017b, 2017c). The CDC suggests that pet owners prevent their animals from playing in or drinking scummy water. If a dog has been swimming in scummy water, the CDC recommends rinsing them off immediately to prevent the dog from licking cyanobacteria off their fur (CDC 2017b).

The CDC recommends that pet owners contact a veterinarian if their animal shows the following symptoms of cyanotoxin poisoning: loss of appetite, loss of energy, vomiting, stumbling and falling, foaming at the mouth, diarrhea, convulsions, excessive drooling, tremors and seizures or any other unexplained sickness after being contacted with water (CDC 2017c). While there have been no HAB-associated human deaths in the United States, there have been many pet deaths (especially dogs) due to cyanotoxin exposure via swimming and ingesting contaminated waters. Overall, CDC encourages the public to follow the phrase “when in doubt, its best to keep out” (CDC 2017a).

The One Health Concept acknowledges a connection between human, animal, and environmental health, suggesting that HAB-associated animal illnesses and deaths could serve as predictors of potential HAB-associated risks in humans (CDC 2017d). Following this concept, the CDC created a voluntary reporting system called the One Health Harmful Algal Bloom System (OHHABS) (CDC 2017d). While there are other reporting systems that capture aggregate information on human illnesses or outbreaks, such as the National Outbreak Reporting System (NORS), OHHABS expands reporting to include HAB-associated environmental data, animal case data, and human case data (CDC 2017d). By collecting this information, the goal of OHHABS is to better understand HABs and HAB-associated illnesses. Members of the public can report HABs and cases of HAB-related human or animal illness by contacting local or state public health agencies (CDC 2017d).

The New York State Department of Health (NYSDOH) applied the One Health approach to implement a pilot surveillance system of HAB-related illnesses in 2015. During this pilot period, three dogs were reported to have GI symptoms after exposure to HABs in recreational water; one of these cases was also associated with a human case (Figgatt et al. 2017).

7.8.1 States and Animal HAB Guidelines

A few states have guideline levels specific to the protection of animals from cyanotoxin poisoning (Appendix H). California calculated cattle and dog action levels for the cyanotoxins microcystin and cylindrospermopsin (Butler et al. 2012). California first calculated an RfD (mg/kg body weight/day) for domestic animals for each of the cyanotoxins, based on laboratory studies. For both dogs and cattle, California estimated drinking water ingestion rates (L/kg body weight/day) based on two publications by the National Research Council, *Nutrient Requirements for Beef Cattle and Nutrient Requirements for Dogs and Cats*, and applied an UF of three to account for preferential consumption of cyanobacteria. To determine action levels (acute action level of 100 µg/L for microcystins and 200 µg/L for cylindrospermopsin), California divided the domestic animal RfD for each cyanotoxin by the final water and cyanobacterial biomass intake exposure levels calculated for cattle and dogs, and performed a unit conversion, providing a cyanotoxin concentration that would result in exposure at the RfD level or below. The state performed these calculations for an acute (lethal) and a subchronic scenario.

Oregon followed a similar approach to California's to calculate dog-specific guideline values for the cyanotoxins cylindrospermopsin, microcystin, anatoxin-a, and saxitoxin (Oregon Health Authority 2018). Oregon estimated tolerable daily intake (TDI) values for humans (µg/kg body weight/day) for each of the cyanotoxins, and applied these values to dogs (Farrer et al. 2015). Using California's dog-specific exposure estimate (L/kg body weight/day), Oregon divided the human TDI by the dog-specific ingestion rate to determine its guideline values (0.2 µg/L for microcystin and 0.4 µg/L for cylindrospermopsin).

Grayson County in Texas estimated the quantity of water that would result in a potentially lethal dose of microcystin and cylindrospermopsin for small and large dogs. Using advisory levels of 20 ppb for microcystin and cylindrospermopsin, the county calculated the volume of water that would result in a lethal or near-lethal dose of cyanotoxin by extrapolating the results of mouse studies to 10- and 80-pound dogs. This estimate does not include additional dose amounts that could be ingested by a dog while self-grooming cyanobacteria scum off its fur (Lillis et al. 2012).

At Presque Isle State Park in Pennsylvania, a HABs task force (a partnership of six agencies and organizations) monitors for microcystin and cylindrospermopsin at multiple locations on Lake Erie within the park. Some of the locations monitored include designated dog beaches. Warning signs are posted specifically for dog owners when microcystin levels are detected above 0.2 µg/L (Schnars personal communication 2017; Best personal communication 2017).

Other states mention animal poisoning in their guideline documents but do not give guideline values specific to livestock or companion animals. For example, Utah and Washington report that animal illness or death can be reason to issue or accelerate a HAB advisory warning (Hardy and Washington State Department of Health 2008; Utah Department of Environmental Quality and Department of Health 2017). Ohio includes pets in their public health advisory at threshold levels of 6 µg/L for microcystin and 5 µg/L for cylindrospermopsin; however, Ohio issues the disclaimer that thresholds used are protective of human exposure and may or may not be protective of animals such as dogs or livestock (Ohio EPA 2016). Several other states including Connecticut, Idaho, Kansas, Massachusetts, Nebraska, Vermont, and Virginia provide information via pamphlets and state websites warning about harm to pets or other animals or post about harm to animals in their beach warnings and advisory signage (CDPH 2017; CDEEP 2017; IDEQ 2015; Kansas Department of Health and Environment 2016; Massachusetts Bureau of Environmental Health 2015; Nebraska Department of Environmental Quality and Nebraska Department of Health and Human Services: Division of Public Health 2018; Vermont Department of Health 2015; Virginia Department of Health 2012).

APPENDIX A. INTERNATIONAL RECREATIONAL WATER GUIDELINES FOR CYANOTOXINS AND CYANOBACTERIA

Jurisdiction	Recreational Water Guideline Level	Recommended Action
Australia[a]	Cyanobacteria (total): $\geq$ 10 mm^3/L (where known toxins are not present)	Red level action mode; level 2 guideline: • Immediately notify health authorities for advice on health risk. • Make toxicity assessment or toxin measurement of water if this has not already been done. • Health authorities warn of risk to public health (i.e., the authorities make a health risk assessment considering toxin monitoring data, sample type and variability).
	Cyanobacteria (total): $\geq$ 4 mm^3/L (where a known toxin producer is dominant in the total biovolume)	Red level action mode; level 1 guideline: • Immediately notify health authorities for advice on health risk. • Make toxicity assessment or toxin measurement of water if this has not already been done. • Health authorities warn of risk to public health (i.e., the authorities make a health risk assessment considering toxin monitoring data, sample type and variability).
	Cyanobacteria (total): $\geq$ 0.4 to < 10 mm^3/L (where known toxin producers are not present)	Amber level alert mode: • Increase sampling frequency to twice weekly where toxigenic species are dominant within the alert level definition (i.e., total biovolume). • Monitor weekly or fortnightly where other types are dominant. • Make regular visual inspections of water surface for scums. • Decide on requirement for toxicity assessment or toxin monitoring.
	Cyanobacteria (total): $\geq$ 0.4 to <4 mm^3/L (where a known toxin producer is dominant in the total biovolume)	Amber level alert mode: • Increase sampling frequency to twice weekly where toxigenic species are dominant within the alert level definition (i.e., total biovolume). • Monitor weekly or fortnightly where other types are dominant. • Make regular visual inspections of water surface for scums. • Decide on requirement for toxicity assessment or toxin monitoring.
	Cyanobacteria (total): $\geq$ 0.04 to <0.4 mm^3/L	Green level surveillance mode: • Weekly sampling and cell counts at representative locations in the water body where known toxigenic species are present; or • Fortnightly for other types including regular visual inspection of water surface for scums.
	Cyanobacterial scums consistently present	Red level action mode; level 2 guideline: • Immediately notify health authorities for advice on health risk. • Make toxicity assessment or toxin measurement of water if this has not already been done. • Health authorities warn of risk to public health (i.e., the authorities make a health risk assessment considering toxin monitoring data, sample type and variability).

NMED Exhibit 93

Jurisdiction	Recreational Water Guideline Level	Recommended Action
	Microcystins (total): ≥ 10 µg/L	Red level action mode; level 1 guideline: • Immediately notify health authorities for advice on health risk. • Make toxicity assessment or toxin measurement of water if this has not already been done. • Health authorities warn of risk to public health (i.e., the authorities make a health risk assessment considering toxin monitoring data, sample type and variability).
	Microcystis aeruginosa (total): ≥ 50,000 cells/ml	Red level action mode; level 1 guideline: • Immediately notify health authorities for advice on health risk. • Make toxicity assessment or toxin measurement of water if this has not already been done. • Health authorities warn of risk to public health (i.e., the authorities make a health risk assessment considering toxin monitoring data, sample type and variability).
	Microcystis aeruginosa (total): ≥ 5,000 to < 50,000 cells/ml	Amber level alert mode: • Increase sampling frequency to twice weekly where toxigenic species are dominant within the alert level definition (i.e., total biovolume). • Monitor weekly or fortnightly where other types are dominant. • Make regular visual inspections of water surface for scums. • Decide on requirement for toxicity assessment or toxin monitoring
	Microcystis aeruginosa (total): ≥ 500 to < 5,000 cells/ml	Green level surveillance mode: • Weekly sampling and cell counts at representative locations in the water body where known toxigenic species are present; or • Fortnightly for other types including regular visual inspection of water surface for scums.
Canada[d]	Cyanobacteria (total): ≥ 100,000 cells/ml	Issue swimming advisory.
	Detection of a cyanobacterial bloom	Issue beach closure.
	Microcystins (total): ≥ 20 µg/L (expressed as microcystin-LR)	Issue swimming advisory.
Cuba[c]	Any report of toxic effect in humans or animals	Action (in red): as for "Alert," but with increased actions for public communication.
	Benthic mats: < 40 percent coverage of surfaces with any cyanobacteria; > 20 percent with toxicogenic cyanobacteria; > 50 percent with potentially toxicogenic cyanobacteria	Alert: increased sampling (weekly and more sites); daily inspection; notification to public health unit and local managers; report to local government; warning of the public.

Jurisdiction	Recreational Water Guideline Level	Recommended Action
	(particularly where they are visibly detaching and accumulating in scum)	
	Cyanobacteria: < 500 cells/ml	Monthly visual inspection.
	Cyanobacteria: ≥ 1 of the species known as potentially toxic	Alert: increased sampling (weekly and more sites); daily inspection; notification to public health unit and local managers; report to local government; warning of the public.
	Phytoplankton cells: ≥ 20,000 to < 100,000 cells/ml, > 50 percent of cells cyanobacteria	Alert: increased sampling (weekly and more sites); daily inspection; notification to public health unit and local managers; report to local government; warning of the public.
	Phytoplankton: > 0 to < 1,500 cells/ml	Monthly visual inspection and sampling at least four months per year.
	Scum consistently present; confirmed bloom persistence	Action (in red): as for "Alert," but with increased actions for public communication.
Czech Republic[c]	Cells: > 100,000 cells/ml	Second warning level: closure for public recreation.
	Cells: > 20,000 cells/ml	First warning level (not otherwise specified).
Denmark[c]	Chlorophyll *a*: > 50 µg/L, dominated by cyanobacteria	Relevant authorities are informed and decide when and how the public should be informed; warnings include signs, media, and contact to local user groups such as kindergartens, scouts, water sports clubs.
	Visible surface scum	Relevant authorities are informed and decide when and how the public should be informed; warnings include signs, media, and contact to local user groups such as kindergartens, scouts, water sports clubs.
European Union[f]	Cyanobacterial proliferation (occurrence)	When cyanobacterial proliferation occurs and a health risk has been identified or presumed, adequate management measures shall be taken immediately to prevent exposure, including information to the public.
	Cyanobacterial proliferation (potential for)	Appropriate monitoring shall be carried out to enable timely identification of health risks.
Finland[c]	Algae (includes cyanobacteria): detected	Level 1: Possibly microscopic examination and even toxin analysis if there is a specific cause such as very popular beach or reports of adverse health effects or animal deaths.

Jurisdiction	Recreational Water Guideline Level	Recommended Action
	Algae (includes cyanobacteria): high amount	Level 2: Preferably microscopical examination; toxin analysis; warning of the public is compulsory.
	Algae (includes cyanobacteria): very high amount	Level 3: Preferably microscopical examination; toxin analysis; warning of the public is compulsory.
France[c]	Bloom, scum, change in water color	Microscopy examination. If cyanobacteria are absent: no further action. If present: counting and genus identification.
	Cyanobacteria: < 20,000 cells/ml (± 20 percent)	Active daily monitoring. Counting at least on a weekly basis. Normal recreational activity at the site.
	Cyanobacteria: > 100,000 cells/ml (± 20 percent)	Bathing and recreational activities are restricted. Public is informed.
	Cyanobacteria: ≥ 20,000 to < 100,000 cells/ml (± 20 percent)	Active daily monitoring. Counting on a weekly basis. Recreational activities are still allowed; the public is informed by posters on site.
	Microcystins: 25 µg/L (± 5 percent)	If microcystins < 25 µg/L bathing and recreational activities are restricted. If microcystins > 25 µg/L bathing is banned and recreational activities are restricted. In either case, public is informed.
	Visible scum or foam in recreational or bathing area	All water activities in this area are prohibited. Restrictions do not necessarily apply to the whole recreational site. Other areas without scum may still be open.
Germany[c]	Secchi Disk reading > 1 m AND biovolume: < 1 mm^3/L	Monitor further cyanobacterial development.
	Secchi Disk reading > 1 m AND biovolume: ≥ 1 mm^3/L	Publish warnings, discourage bathing, consider temporary closure.
	Secchi Disk reading > 1 m AND chlorophyll *a* (with dominance by cyanobacteria): < 40 µg/L	Monitor further cyanobacterial development.
	Secchi Disk reading > 1 m AND chlorophyll *a* (with dominance by cyanobacteria): ≥ 40 µg/L	Publish warnings, discourage bathing, consider temporary closure.

Jurisdiction	Recreational Water Guideline Level	Recommended Action
	Secchi Disk reading > 1 m AND microcystins: < 10 µg/L	Monitor further cyanobacterial development.
	Secchi Disk reading > 1 m AND microcystins: ≥ 10 µg/L	Publish warnings, discourage bathing, consider temporary closure.
	Visible heavy scums and/or microcystins: > 100 µg/L	Publish warnings, discourage bathing, temporary closure is recommended.
Hungary[c]	Cell count: ≥ 50,000 to < 100,000 cells/ml	No recommended actions listed, water body classification: Acceptable.
	Cell count: < 20,000 cells/ml	No recommended actions listed, water body classification: Excellent.
	Cell count: ≥ 20,000 to < 50,000 cells/ml	No recommended actions listed, water body classification: Good.
	Cell count: ≥ 100,000 cells/ml	No recommended actions listed, water body classification: Unacceptable.
	Chlorophyll *a* (with dominance by cyanobacteria): < 10 µg/L	No recommended actions listed, water body classification: Excellent.
	Chlorophyll *a* (with dominance by cyanobacteria): ≥ 10 to < 25 µg/L	No recommended actions listed, water body classification: Good.
	Chlorophyll *a* (with dominance by cyanobacteria): ≥ 25 to < 50 µg/L	No recommended actions listed, water body classification: Acceptable.
	Chlorophyll *a* (with dominance by cyanobacteria): ≥ 50 µg/L	No recommended actions listed, water body classification: Unacceptable.
	Microcystins: ≥ 4 to < 10 µg/L	No recommended actions listed, water body classification: Good.
	Microcystins: ≥ 10 to < 20 µg/L	No recommended actions listed, water body classification: Acceptable.
	Microcystins: < 4 µg/L	No recommended actions listed, water body classification: Excellent.
	Microcystins: ≥ 20 µg/L	No recommended actions listed, water body classification: Unacceptable.

Jurisdiction	Recreational Water Guideline Level	Recommended Action
Italy[i]	Cyanobacterial cell count for cyanotoxin-producing species other than microcystins (e.g., cylindrospermopsin, anatoxin-a) > 100,000 cells/ml (± 20 percent)	Emergency phase: weekly sampling and intensified visual inspection; quantification of all identified cyanotoxins; health surveillance; temporary bans on bathing and removal of scums from water and shoreline in addition to alert phase management measure.
	Cylindrospermopsin and anatoxin-a > 20 µg/L	Emergency phase: weekly sampling and intensified visual inspection; quantification of all identified cyanotoxins; health surveillance; temporary bans on bathing and removal of scums from water and shoreline in addition to alert phase management measures.
	Microcystin-LR: > 20 µg/L equivalents	Emergency phase: weekly sampling and intensified visual inspection; quantification of all identified cyanotoxins; health surveillance; temporary bans on bathing and removal of scums from water and shoreline in addition to alert phase management measures.
	Total cyanobacterial cell count > 20,000 cells/ml (± 20 percent) AND microcystin-LR < 20 µg/L equivalents	Alert phase: weekly sampling and visual inspection every 2 days; assessment of bloom extent and stretches of coastline affected; identify presence of cyanotoxins other than microcystins (when relevant); management measures put in place to inform citizens and prevent hazardous exposures using informative and warning panels/signs at waterfront and/or at beach access points, newsletters, brochures, publications on regional and national websites, local information systems, social network, and a Ministry toll-free number.
	Transparency ≥ 1 m AND total phosphorus < 20 µg/L	Routine phase 1: monthly sampling.
	Transparency ≥ 1 m AND total phosphorus > 20 µg/L AND total cyanobacterial cell count ≤ 2,000 cells/ml	Routine phase 2: monthly sampling and weekly visual inspection.
	Transparency ≤ 1 m AND total phosphorus > 20 µg/L AND total cyanobacterial cell count > 2,000 to < 20,000 cells/ml (± 20 percent)	Routine phase 3: fortnightly sampling and weekly visual inspection.
	Visible surface scum	Emergency phase: weekly sampling and intensified visual inspection; quantification of all identified cyanotoxins; health surveillance; temporary bans on bathing and removal of scums from water and shoreline in addition to alert phase management measures.
Netherlands[c]	Biovolume (cyanobacterial cell count): > 0 to < 2.5 mm^3/L	Surveillance level: continue fortnightly monitoring

Jurisdiction	Recreational Water Guideline Level	Recommended Action
	Biovolume (cyanobacterial cell count): > 15 mm^3/L (if 80 percent dominance of microcystin producers and microcystins < 20 µg/L, revert to Alert Level 1).	Alert level 2: weekly monitoring and advice against bathing (by public authority): "You are advised not to bathe in this water;" prohibition by local authority is possible.
	Biovolume (cyanobacterial cell count): ≥ 2.5 to ≤ 15 mm^3/L	Alert level 1: weekly monitoring and issue warning (by site operator) for duration of that week: "Toxic blue-green algae. Risk of skin irritation or intestinal problems." In case of daily site inspection, reevaluate the warning on a daily basis.
	Chlorophyll *a*: > 0 to < 12.5 µg/L	Surveillance level: continue fortnightly monitoring.
	Chlorophyll *a*: > 75 µg/L	Alert level 2: weekly monitoring and advice against bathing (by public authority): "You are advised not to bathe in this water;" prohibition by local authority is possible.
	Chlorophyll *a*: ≥ 12.5 to ≤ 75 µg/L	Alert level 1: weekly monitoring and issue warning (by site operator) for duration of that week: "Toxic blue-green algae. Risk of skin irritation or intestinal problems." In case of daily site inspection, reevaluate the warning on a daily basis.
	Surface scum: category 1	Surveillance level: continue fortnightly monitoring.
	Surface scum: category 2	Alert level 1: weekly monitoring and issue warning (by site operator) for duration of that week: "Toxic blue-green algae. Risk of skin irritation or intestinal problems." In case of daily site inspection, reevaluate the warning on a daily basis.
	Surface scum: category 3	Alert level 2: weekly monitoring and advice against bathing (by public authority): "You are advised not to bathe in this water"; prohibition by local authority is possible.
New Zealand[h]	Cyanobacteria (benthic): 20−50 percent coverage of potentially toxigenic cyanobacteria attached to substrate	Alert (amber mode): • Notify the public health unit. • Increase sampling to weekly. • Recommend erecting an information sign. • Consider increasing the number of survey sites. • If toxigenic cyanobacteria dominate the samples, testing for cyanotoxins is advised. If cyanotoxins are detected in mats or water samples, consult the testing laboratory to determine if levels are hazardous.
	Cyanobacteria (benthic): greater than 50 percent coverage of potentially toxigenic cyanobacteria attached to substrate	Action (red mode) situation 1: • Immediately notify the public health unit. • If potentially toxic taxa are present (see Table 2) then consider testing samples for cyanotoxins. • Notify the public of the potential risk to health.

Jurisdiction	Recreational Water Guideline Level	Recommended Action
	Cyanobacteria (benthic): Up to 20 percent coverage of potentially toxigenic cyanobacteria attached to substrate	Surveillance (green mode): • Undertake fortnightly surveys between spring and autumn at representative locations in the water body where known mat proliferations occur and where there is recreational use.
	Cyanobacteria (benthic): up to 50 percent where potentially toxigenic cyanobacteria are visibly detaching from the substrate, accumulating as scums along the river's edge or becoming exposed on the river's edge as the river level drops.	Action (red mode) situation 2: • Immediately notify the public health unit. • If potentially toxic taxa are present (see Table 2) then consider testing samples for cyanotoxins. • Notify the public of the potential risk to health.
	Cyanobacteria (total): < 0.5 mm^3/L (biovolume equivalent of the combined total of all cyanobacteria)	Surveillance (green mode): • Undertake weekly or fortnightly visual inspection and sampling of water bodies where cyanobacteria are known to proliferate between spring and autumn.
	Cyanobacteria (total): $\leq$ 500 cells/ml	Surveillance (green mode): • Undertake weekly or fortnightly visual inspection and sampling of water bodies where cyanobacteria are known to proliferate between spring and autumn.
	Cyanobacteria (total): $\geq$ 1.8 mm^3/L (biovolume equivalent of potentially toxic cyanobacteria)	Action (red mode) situation 1: • Continue monitoring as for alert (amber mode). • If potentially toxic taxa are present (see Table 1), then consider testing samples for cyanotoxins • Notify the public of a potential risk to health.
	Cyanobacteria (total): $\geq$ 0.5 to < 1.8 mm^3/L (biovolume equivalent of potentially toxic cyanobacteria)	Alert (amber mode): • Increase sampling frequency to at least weekly. • Notify the public health unit. • Multiple sites should be inspected and sampled.
	Cyanobacteria (total): $\geq$ 0.5 to < 10 mm^3/L (total biovolume of all cyanobacterial material where the cyanobacterial population has been tested and shown not to contain known toxins)	Alert (amber mode): • Increase sampling frequency to at least weekly. • Notify the public health unit. • Multiple sites should be inspected and sampled.
	Cyanobacteria (total): $\geq$ 10 mm^3/L (total biovolume of all cyanobacterial material	Action (red mode) situation 2:

Jurisdiction	Recreational Water Guideline Level	Recommended Action
	where the cyanobacterial population has been tested and shown not to contain known toxins)	• Continue monitoring as for alert (amber mode). • If potentially toxic taxa are present (see Table 1), then consider testing samples for cyanotoxins. • Notify the public of a potential risk to health.
	Cyanobacterial scums consistently present for more than several days in a row	Action (red mode) situation 3: • Continue monitoring as for alert (amber mode). • If potentially toxic taxa are present (see Table 1), then consider testing samples for cyanotoxins. • Notify the public of a potential risk to health.
	Microcystins (total): ≥ 12 µg/L	Action (red mode) situation 1: • Continue monitoring as for alert (amber mode). • If potentially toxic taxa are present (see Table 1), then consider testing samples for cyanotoxins. • Notify the public of a potential risk to health.
Poland[c]	Visible blooms	Sampling of bathing sites not less than 4 times per season (the interval between sampling does not exceed one month), including responses to cyanobacteria if blooms are observed.
Scotland[e]	Chlorophyll *a*: ≥ 10 µg/L with dominance of cyanobacteria	1. Watch for scum or conditions conducive to scums. 2. Discourage bathing and further investigate hazard. 3. Post on-site risk advisory signs. 4. Inform relevant authorities.
	Cyanobacteria: ≥ 20,000 cells /ml	1. Watch for scum or conditions conducive to scums. 2. Discourage bathing and further investigate hazard. 3. Post on-site risk advisory signs. 4. Inform relevant authorities.
	Cyanobacterial scum formation in bathing areas	1. Immediate action to control contact with scums; possible prohibition of swimming and other water contact activities. 2. Public health follow-up investigation. 3. Inform public and relevant authorities.
Singapore[c]	Chlorophyll *a*: ≤ 50 µg/L (of 95 percent of a 3-year rolling period)	Status of the sites reviewed annually. If the assessment is that the water body is unsuitable for primary water contact activities, the public is notified.
Spain[c]	Cyanobacteria proliferation potential (High, Medium, Low)	Criteria for assessment of health risk and response are set locally; some health authorities use WHO scheme, others include further risk parameters (such as number of users, type of use); temporary closure has occasionally occurred based on the abundance of cyanobacteria.

Jurisdiction	Recreational Water Guideline Level	Recommended Action
Turkey[c]	Cells: < 20,000 cells/ml	Level 1: recreational activities are allowed to continue and users are informed by posters on site. Monitoring (sampling, counting and species identification) should be done fortnightly.
	Cells: 20,000–100,000 cells/ml	Level 2: At > 20 000 cells/mL, microcystins are analyzed. If microcystin-LR equivalents >25 µg/L, immediate action to inform relevant authorities and public. Discourage users from swimming and other water contact activities by advisory signs on site.
	Chlorophyll *a* (if dominated by cyanobacteria): < 10 µg/L	Level 1: recreational activities are allowed to continue and users are informed by posters on site. Monitoring (sampling, counting and species identification) should be done fortnightly.
	Microcystin-LR: < 10 µg/L equivalents	Level 1: recreational activities are allowed to continue and users are informed by posters on site. Monitoring (sampling, counting and species identification) should be done fortnightly.
	Microcystin-LR: > 25 µg/L equivalents	Level 2: At > 20,000 cells/mL, microcystins are analyzed. If microcystin-LR equivalents >25 µg/L, immediate action to inform relevant authorities and public. Discourage users from swimming and other water contact activities by advisory signs on site.
	Visible scum in bathing area	Level 3: all activities in the water may be prohibited.
World Health Organization (WHO)[b,g]	Chlorophyll *a*: 10 µg/L with dominance of cyanobacteria	Low risk: post on-site advisory signs, inform relevant authorities.
	Chlorophyll *a*: 50 µg/L with dominance of cyanobacteria	Moderate risk: watch for scums or conditions conducive to scums, discourages swimming and further investigate hazard, post on-site risk advisory signs, inform relevant authorities.
	Cyanobacteria: 100,000 cells/ml	Moderate risk: watch for scums or conditions conducive to scums, discourages swimming and further investigate hazard, post on-site risk advisory signs, inform relevant authorities.
	Cyanobacteria: 20,000 cells/ml	Low risk: post on-site advisory signs, inform relevant authorities.
	Cyanobacterial scum formation in areas where whole-body contact and/or risk of ingestions/aspiration occur	High risk: immediate action to control contact with scums, possible prohibition of swimming and other water contact activities, public health follow-up investigation, inform public and relevant authorities.

APPENDIX B. STATE RECREATIONAL WATER GUIDELINES FOR CYANOTOXINS AND CYANOBACTERIA

EPA compiled the information presented in this appendix based on searches of state websites for publicly available information regarding guidelines or action levels for cyanotoxins and cyanobacteria. Online searches for state guidance were conducted in 2015, 2016, and 2018. Direct personal communication of state guidelines and state public comments on the draft AWQC revealed some updated information.

Table B-1. Summary Counts of State Recreational Water Guidelines for Cyanotoxins and Cyanobacteria by Type and Scope of Guidelines

Recreational Water Guideline Type and Scope	Number of States and List of States	Additional Information
Quantitative guidelines for cyanobacteria only	5 states: Arizona, Idaho, Maine, New Hampshire, Wisconsin	Measurements for these criteria include cyanobacterial cell densities, proportion of toxigenic cyanobacteria, chlorophyll concentration, and Secchi disk depth measurements.
Quantitative guidelines for cyanotoxins only	4 states: Illinois, Iowa, Nebraska, Ohio	State guidelines address four cyanotoxins in order from most to least common: microcystins (24 states) anatoxin-a (11 states) cylindrospermopsin (9 states) saxitoxin (5 states)
Quantitative guidelines for cyanotoxins and either quantitative or qualitative guidelines for cyanobacteria	20 states: California, Colorado, Connecticut, Indiana, Kansas, Kentucky, Maryland, Massachusetts, Michigan, New Jersey, New York, North Dakota, Oklahoma, Oregon, Pennsylvania, Rhode Island, Utah, Vermont, Virginia, Washington	
Qualitative guidelines only	6 states: Delaware, Florida, Missouri, Montana, North Carolina, West Virginia	Examples include: presence of surface scum visible discoloration presence of potentially toxic algae presence/absence test for microcystins
Guidelines under development	4 states: Arkansas, Georgia, Minnesota, Wyoming	

Note: The EPA found that Texas and North Carolina published guidelines in the past, but the guidelines are no longer found on their websites. Missouri is in the process of developing quantitative thresholds.

Table B-2. State Recreational Water Quality Guideline for Cyanotoxins and Cyanobacteria Sorted by Type

State	Recreational Water Guideline Level	Recommended Action	Reference
States with Guidelines Based on Cyanobacteria Only			
Arizona	Blue-green algae (mean value based on a minimum of two sample events within one peak season): 20,000 cells/ml and Chlorophyll *a* result (mean value based on a minimum of two sample events within one peak season) in target range	Violation of the Narrative Nutrient Standard.	Arizona Department of Environmental Quality (2008). Narrative Nutrient Standard Implementation Procedures for Lakes and Reservoirs. http://www.azdeq.gov/environ/water/standards/download/draft_nutrient.pdf. Last Accessed: 11/27/2018.
Idaho	*Microcystis* or *Planktothrix*: >40,000 cells/ml	Public health advisory posting by Public Health District in conjunction with water body operator.	IDEQ (Idaho Department of Environmental Quality) (2015). Blue-Green Algae Bloom Response Plan: Final. http://www.healthandwelfare.idaho.gov/Portals/0/Health/EnvironmentalHealth/Idaho%20Blue-Green%20Algae%20Response%20PlanFinal.pdf. Last Accessed: 11/27/2018.
	Sum of all potentially toxigenic taxa: ≥ 100,000 cells/ml	Public health advisory posting by Public Health District in conjunction with water body operator.	
	Visible surface scum that is associated with toxigenic species	Public health advisory posting by Public Health District in conjunction with water body management agency.

APPENDIX C. LITERATURE SEARCH DOCUMENTATION

The recreational ambient water quality criteria (AWQC) or swimming advisories document for microcystins and cylindrospermopsin relied significantly on information identified, reviewed, and synthesized in the EPA's *Health Effects Support Document for the Cyanobacterial Toxin Microcystins*, *Heath Effects Support Document for the Cyanobacterial Toxin Cylindrospermopsin*, *Drinking Water Health Advisory for the Cyanobacterial Microcystin Toxins*, and *Drinking Water Health Advisory for the Cyanobacterial Toxin Cylindrospermopsin* (U.S. EPA 2015c, 2015d, 2015a, 2015b). The EPA conducted supplemental literature searches to answer additional questions related to recreational exposures, exposure factors, and to identify new health data.

For the Health Effects Support Documents (HESDs), the EPA conducted a comprehensive literature search from January 2013 to May 2014 using Toxicology Literature Online (TOXLINE), PubMed, and Google Scholar. The EPA assembled available information on occurrence; environmental fate; mechanisms of toxicity; acute, short-term, subchronic, and chronic toxicity and cancer in humans and animals; and toxicokinetics and exposure. For a detailed description of the literature review search and strategy, see the HESDs for microcystins and cylindrospermopsin (U.S. EPA 2015c, 2015d).

The EPA conducted supplemental literature searches in September 2015 to capture references published since the completion of the HESDs' literature searches and to account for the recreational exposure scenario. The specific questions investigated include:

1. What levels of anatoxin-a, cylindrospermopsin, or microcystins are humans—of all ages, including children—exposed to through recreational use (activities) in freshwaters or marine waters from incidental ingestion, inhalation, and dermal exposure routes?
2 What health effects information for humans or animals exposed to cylindrospermopsin or microcystins (through ingestion, inhalation, and dermal exposure routes) has been published since the health effects literature searches were conducted for the EPA's 2015 HESDs for cylindrospermopsin and microcystins?
3. What recreational water use safety levels or criteria have been set for microcystins or cylindrospermopsin by states or international governments, and how did they derive them?
4. What new information, if any, is available regarding how aquatic recreational exposure ingestion rates in children differ among age groups between zero and 18 years?
5. What incidents of companion animal (e.g., dogs, horses) or livestock poisonings, including mortality or adverse health effects, due to exposure to cyanotoxins in freshwaters, marine waters, or beaches have occurred in the past 15 years? Specifically, when and where did these incidents occur, to which cyanotoxin were the animals exposed, how were they exposed, and what were the weights and breeds of the affected animal(s)?

The EPA implemented a unique literature search strategy to address each research question. Trial searches were conducted, and results were evaluated to refine the search strategies (e.g., to reduce retrieval of citations unrelated to the research questions). The search strings were refined to improve the relevancy of the results. The literature search strategies implemented for each research question are subsequently detailed.

NMED Exhibit 93

Research Question 1: What levels of anatoxin-a, cylindrospermopsin, or microcystins are humans—of all ages, including children—exposed to through recreational use (activities) in freshwaters or marine waters, from incidental ingestion, inhalation, and dermal exposure routes?

The EPA searched the bibliographic databases, PubMed and Web of Science (WoS), to identify candidate journal article literature relevant to human exposure to anatoxin-a, cylindrospermopsin, or microcystins through recreational activities. PubMed and WoS contain peer-reviewed journal abstracts and articles on various biological, medical, public health, and chemical topics. The WoS search string differs slightly from the PubMed search string due to how the search engines treat search terms with more than one word. Both search strings are presented below.

Results

The searches returned 321 journal articles after removing duplicates between PubMed and WoS results. Based on a screening review of each article's title and abstract, the EPA retrieved nine articles that appeared to be studies that measured, reviewed, or estimated human recreational exposure to cyanotoxins.

C.1 Research Question 2: What health effects information for humans or animals exposed to microcystins, cylindrospermopsin, or anatoxin-a (through ingestion, inhalation, and dermal exposure routes) has been published since the health effects literature searches were conducted for the EPA's 2015 HESDs for Cylindrospermopsin and Microcystins?

The EPA searched PubMed and WoS to identify candidate journal article literature relevant to health effects associated with exposure to anatoxin-a, cylindrospermopsin, or microcystins. The WoS search string differs slightly from the PubMed search string due to how the search engines treat search terms with more than one word. Both search strings are presented below.

Results

The searches returned 1,000 journal articles after removing duplicates between PubMed and WoS results. Based on a screening review of each article's title and abstract, the EPA retrieved 40 articles that appeared to be prospective human epidemiological studies (n = 1), ecological human epidemiologic studies (n = 2), reviews of human health effects (n = 4), in vivo animal studies (n = 30), or reviews of in vivo animal studies (n = 3).

C.2 Research Question 3: What recreational water use safety levels or criteria have been set for microcystins or cylindrospermopsin by states or international governments and how did they derive them?

To identify state-level recreational guidelines for cyanobacteria and cyanotoxins, the EPA searched the websites of state-level departments of public health, environmental health, and natural resources for all 50 U.S. states. If relevant recreational guidelines were not found by searching state-level websites, the EPA conducted Google searches of the internet using state names, key terms for cyanobacteria and cyanotoxins (e.g., harmful algal bloom, blue-green algae, microcystin, cylindrospermopsin), and key terms for guidelines (e.g., advisory, guidance, guideline, standard, regulation). For international governments, the EPA used the 2012 report, *Current Approaches to Cyanotoxin Risk Assessment, Risk Management and Regulations in Different Countries*, by Dr. Ingrid Chorus, Federal Environment Agency, Germany, to identify international government recreational safety levels for cyanobacteria and cyanotoxins. In addition, the EPA implemented the same search strategy as used for U.S. states to identify updated international recreational guidelines or guideline levels not featured in the 2012 report by Dr. Ingrid Chorus.

C.3 Research Question 4: What new information, if any, is available regarding how aquatic recreational exposure ingestion rates in children differ among age groups between zero and 18 years?

Search of Bibliographic Databases

The EPA searched PubMed, WoS, and Google Scholar to identify literature that has cited, or is similar (based on terms identified in the titles and abstracts) to, the studies that provide water ingestion data for swimmers or during water recreational activities in the EPA's (2011) *Exposure Factors Handbook* (EFH) (i.e., Dorevitch et al. 2011; Dufour et al. (2006); Schets et al. 2011). The PubMed and WoS searches were conducted on 10/9/2015, the publication dates searched were 1/1/2011 to 10/9/2015, and an English filter was applied. The Google Scholar search was conducted on 10/9/2015 and could not be limited by year or language.

NMED Exhibit 93

Results

Together all three searches returned 341 journal articles. Duplicates were removed between PubMed and WoS, but this total might include duplicates between Google Scholar results and WoS/PubMed results. Based on a screening review of each article's title and abstract, the EPA retrieved five articles, four of which were published between 2013 and 2015 and appeared to measure or estimate incidental water ingestion. The EPA also retrieved one 2012 study that assessed duration of non-swimming recreational water exposure by using novel time lapse photography technology.

Google Search of Internet

In addition, the EPA conducted a Google search of the internet focused on specified URL domains (listed in Table C-1) to identify candidate gray literature (e.g., state, federal, or international government reports or guidance). The Google search string is presented below. The Google search of the internet could not be limited by year or language.

Table C-1. Internet URL Domains Searched for Research Question 4

Organization	URL Domain
U.S. Government	.gov .us
All U.S. States	Google Custom Search Engine
Centers for Disease Control and Prevention, including Agency for Toxic Substances and Disease Registry	cdc.gov
Australia, including Australian Department of Health	gov.au
Canada, including Health Canada	gc.ca
European Union, including • European Chemicals Agency • European Commissions on Environment, Public Health, Food, and Health and Consumers	europa.eu
Public Health England	hpa.org.uk
United Kingdom	gov.uk
Germany	.de
Education websites	.edu
HERA (Human and Environmental Risk Assessment) Project	heraproject.com
World Health Organization	who.int

Results

The Google search returned 390 results after removing duplicates. Based on a preliminary screen of each result, the EPA retrieved two documents which appeared to either derive or cited an incidental ingestion rate while recreating which had not previously been identified during the literature search process.

C.4 Research Question 5: What incidents of companion animal (e.g., dogs, horses) or livestock poisonings, including mortality or adverse health effects, due to exposure to cyanotoxins in freshwaters, marine water, or beaches have occurred in the past 15 years? Specifically, when and where did these incidents occur, to which cyanotoxin were the animals exposed, how were they exposed, and what were the weights and breeds of the affected animal(s)?

The EPA searched PubMed, WoS, and Agricola to identify candidate journal article literature relevant to companion animal or livestock poisoning due to exposures to cyanobacterial cells, anatoxin-a, cylindrospermopsin, or microcystins. The EPA first searched PubMed and WoS with a focus on dogs. The EPA conducted two additional searches in PubMed, WoS, and Agricola focused on livestock, and on cats and birds. The search strings for each search iteration are presented below.

Results

The number of journal articles returned by the three searches is provided in Table C-2. Based on a screening review of the article's title and abstract, the EPA retrieved five of the 35 journal articles retrieved during the search focused on dogs. These five articles appeared to provide information about an incident of cyanotoxin exposure to an animal where the authors confirm that the animal was exposed to a cyanotoxin by either measuring the concentration of cyanotoxin found in the animal or by sampling the body of water to which the animal had contact.

Table C-2. Number of Journal Articles Returned by Three Search Strategies for Research Question 5

Search Strategy Focus	Number of Results Returned from PubMed, WoS, and Agricola Searches
Dogs	35[a]
Livestock	100
Cats and birds	169[b]

[a] Search conducted in PubMed and WoS only.

[b] Duplicates between PubMed/WoS results and Agricola results were not removed. Therefore, the cats and birds search might include duplicates between Agricola results and PubMed/WoS results.

APPENDIX D. REVIEW OF THE STATE OF THE SCIENCE ON CYANOBACTERIAL CELLS HEALTH EFFECTS

D.1 Introduction

This appendix provides information gathered and reviewed to determine the state of the science on health effects from cyanobacterial cells. The EPA conducted literature searches to identify studies relevant to the health effects from cyanobacterial cells. Detailed information on the design and implementation of these searchers is provided in Appendix C. Results from these literature searches were reviewed for relevance to cyanobacterial cell exposures and health effects.

D.1.1 Animal Studies

Cyanobacterial cells cause allergenicity and irritation in animals, independent of whether the cyanobacterial cells produce toxin. Three animal studies (Shirai et al. 1986; Stewart et al. 2006c; Torokne et al. 2001) demonstrated hypersensitivity reactions and dermal and eye irritation in several species that did not correlate with microcystin content. Although the number of studies is limited and different species were evaluated in each study, these studies provide evidence to support hypersensitivity reactions in animals from exposure to cyanobacteria when cyanotoxins are not present (Shirai et al. 1986; Torokne et al. 2001) and when they are (Stewart et al. 2006c).

Cyanobacteria bloom samples collected from five different lakes or ponds were tested for allergenic and irritative effects in guinea pigs and rabbits, respectively (Torokne et al. 2001). The microcystin content (presumed to be total LR, RR, and YR) ranged from not detected to 2.21 mg/g. To determine sensitization, guinea pigs were initiated with an intradermal injection of freeze-dried cyanobacteria followed seven days later by topical application at the injection site. Sensitization was moderate to strong in 30–67 percent of guinea pigs and did not correlate with microcystin content. The *Aphanizomenon ovalisporum* sample (a non-toxin-producing strain) sensitized 91 percent of the animals and was the strongest allergen. Skin irritation tests in albino rabbits showed slight or negligible irritation, except for *Aphanizomenon ovalisporum*, which showed moderate irritation. The eye irritation evaluation in rabbits was positive for four of the five samples containing *Microcystis*.

Shirai et al. (1986) reported that C3H/HeJ mice, immunized intraperitoneal with either sonicated or live cells from a *Microcystis* water bloom, developed delayed-type hypersensitivity when challenged two weeks later with a subcutaneous injection sonicated *Microcystis* cells. A positive reaction, as assessed by footpad swelling, was seen in mice immunized with either live cells or sonicated cells. Both toxic and nontoxic *Microcystis* cells induced delayed-type hypersensitivity in this mouse study. Because this strain of mouse is unresponsive to lipopolysaccharide (LPS), the footpad delayed-type hypersensitivity was not related to LPS, thus, the antigenic component of the sonicated cyanobacterial cells is not known.

Stewart et al. (2006c) conducted a mouse ear swelling test in which cylindrospermopsin and *Cylindrospermopsis raciborskii* solutions generated irritation of the abdominal skin exposed during induction (two percent w/v lysed cell solution containing 73 µg/mL cylindrospermopsin). Subsequent dermal exposures to the *Cylindrospermopsis raciborskii* solution produced hypersensitivity reactions ($p = 0.001$). The cyanobacteria *Microcystis aeruginosa* and *Anabaena circinalis* elicited no responses in this test.

NMED Exhibit 93

Two of the cyanobacterial cell studies in animals found that rodents became sensitized after exposure and subsequent challenge to non-toxin strains (Shirai et al. 1986; Torokne et al. 2001). Torokne et al. (2001) found that a nontoxic strain was more sensitizing and irritating than the toxic strains evaluated. These experiments support the conclusion that there is no relationship between the cyanotoxin content and the allergenic effect of cyanobacteria.

D.1.2 Clinical and Laboratory Human Studies

Several types of studies and reports provide information on associations between cyanobacteria exposure and health effects. Clinical and in vitro studies (Bernstein et al. 2011; Geh et al. 2015; Pilotto et al. 2004; Stewart et al. 2006a) have been able to assess associations between cyanobacteria exposure and human health effects including dermal and allergenic reactions. Three clinical studies assessed dermal exposure to cyanobacterial cells using skin-patch or skin-prick testing in humans (Bernstein et al. 2011; Pilotto et al. 2004; Stewart et al. 2006a). Some of the exposed individuals showed mild irritation or allergenicity. No statistically significant dose-response relationships were found between skin irritation and increasing cyanobacterial cell concentrations. The allergenicity study suggests that cyanobacteria are allergenic, particularly among people with chronic rhinitis (Bernstein et al. 2011).

Skin-patch testing in humans was performed by Pilotto et al. (2004) with laboratory-grown cylindrospermopsin-producing *Cylindrospermopsis raciborskii* cells, both whole and lysed, which were applied using adhesive patches at concentrations ranging from < 5,000 to 200,000 cells/mL to the skin of 50 adult volunteers. After 24 hours, patches were removed and evaluation of the erythematous reactions were graded. Analysis of participants' reactions to patches treated with whole cells showed an odds ratio (OR) of 2.13 and a 95 percent confidence interval (CI) of 1.79–4.21 ($p < 0.001$). Lysed cells patch analysis showed an OR of 3.41 and a 95 percent CI of 2.00–5.84 ($p < 0.001$). No statistically significant increase or dose-response between skin reactions and increasing cell concentrations for either patches (whole or lysed) was observed. Subjects had skin reactions to the cylindrospermopsin, and positive control patches more frequently than to the negative control patches. The mean percentage of subjects with a reaction was 20 percent (95 percent CI: 15–31 percent). When subjects reacting to negative controls (39) were excluded, the mean percentage was 11 percent (95 percent CI: 6–18 percent). Evaluation of erythematous reactions showed that mild irritations (grade 2) were resolved in all cases within 24 to 72 hours.

Stewart et al. (2006a) conducted a skin-patch test with 39 volunteers (20 dermatology outpatients; 19 controls) who were exposed to six cyanobacterial suspensions, including toxigenic species, nontoxigenic species, mixed suspensions, and two cyanobacterial LPS extracts. All cyanobacterial suspensions of lyophilized cells were tested at three concentrations, 0.25 percent w/v, 0.05 percent w/v, 0.005 percent w/v, and the estimated doses of cyanotoxins were 2.4 ng/kg cylindrospermopsin and 2.6 ng/kg microcystins. Only one subject showed significant responses to cyanobacterial suspensions, specifically to two suspensions of cyanobacterial cells: *Cylindrospermopsis raciborskii* and mixed *Microcystis aeruginosa* and *Cylindrospermopsis raciborskii*, both of which contained one or more cyanotoxins. This subject showed no evidence of any dose-response effect in the dermal reactions. None of the participants reacted to the cyanobacterial LPS extracts, which ranged from 260 ppb to 31 ppm. This small clinical study demonstrated that dermal hypersensitivity reactions to cyanobacteria exposure occur infrequently, and further research into risk factors for predisposition to this type reaction could be beneficial.

Bernstein et al. (2011) studied skin sensitization to nontoxic extracts of *Microcystis aeruginosa* in 259 patients with chronic rhinitis over two years. Patients were evaluated with aeroallergen skin testing and

skin-prick testing. The authors found that 86 percent of the subjects had positive skin-prick tests to *Microcystis aeruginosa*, and that patients with existing allergic rhinitis were more likely to have reactions and sensitization to cyanobacteria than the controls (non-atopic health subjects). This study indicated that cyanobacterial allergenicity is associated with the nontoxic portion of the cyanobacteria.

Geh et al. (2015) studied the immunogenicity of extracts of toxic and nontoxic strains of *Microcystis aeruginosa* in patient sera (18 patients with chronic rhinitis and three non-atopic healthy subjects as documented in Bernstein et al. 2011). Enzyme Linked Immunosorbent Assay (ELISA) test was used to test IgE-specific reactivity, and gel electrophoresis, followed by immunoblot and mass spectrometry, was done to identify the relevant sensitizing peptides. The authors found an increase in specific IgE in those patients tested with the nontoxic *Microcystis aeruginosa* extract than the extract from the toxic strain. After pre-incubation of the nontoxic extract with various concentrations of microcystin, the authors found that phycocyanin and the core-membrane linker peptide were responsible for the release of β-hexosaminidase in rat basophil leukemia cells. The authors concluded that non-toxin-producing strains of cyanobacteria are more allergenic than toxin-producing strains in allergic patients, and that the toxin may have an inhibitory effect on the allergenicity of the cyanobacterial cells.

Facciponte et al. (2018) used polymerase chain reaction (PCR) to detect aerosolized cyanobacteria inhaled into the human respiratory tract. They found cyanobacteria at high frequencies in the upper respiratory tract (92.2 percent) and central airway (79.3 percent) of the study subjects (n = 77). The findings suggests that humans inhale aerosolized cyanobacteria, which can remain in the nostrils and the lungs.

D.1.3 Epidemiological Studies, Case Reports, and Outbreaks

Among the epidemiological studies discussed here, some identified significant associations between cyanobacteria exposure and a range of health outcomes including dermal, eye/ear, gastrointestinal (GI), and respiratory effects. Several of these studies also measured one or more cyanotoxins and found no association between cyanotoxin occurrence or exposure and health effects. Additional evidence from outbreak and case reports provides support for health effects associated with cyanobacteria exposure. The studies vary in study design, methods used, size of study population, cyanobacterial species evaluated, health effects identified, and cyanobacterial cell densities associated with human health effects. Therefore, substantial uncertainty remains regarding the associations between cyanobacterial cell exposure and human health effects. Overall, these studies provide evidence of statistically significant associations between cyanobacterial cell exposure and human health effects even in the absence of cyanotoxins. However, the reported associations between cyanobacterial cell densities and health outcomes are not consistent.

Eight epidemiological studies evaluated short-term health effects associated with recreational exposure to cyanobacterial blooms (El Saadi et al. 1995; Lévesque et al. 2014; Lin et al. 2015; Philipp 1992; Philipp and Bates 1992; Philipp et al. 1992; Pilotto et al. 1997; Stewart et al. 2006d). See Table D-1 for a summary list of these studies. The health outcomes evaluated included dermal, GI, respiratory, and other acute effects, such as eye or ear symptoms. Seven studies evaluated recreational exposure to freshwater cyanobacteria, and one evaluated exposure to marine water cyanobacteria (Lin et al. 2015). Two studies included field sites in the continental United States or Canada (Lévesque et al. 2014; Stewart et al. 2006d), three occurred in the United Kingdom (Philipp 1992; Philipp and Bates 1992; Philipp et al. 1992), and three were conducted in subtropical and tropical regions in Australia (El Saadi

NMED Exhibit 93

et al. 1995; Pilotto et al. 1997) and Puerto Rico (Lin et al. 2015). These epidemiological studies are discussed below in chronological order.

Table D-1. Cyanobacteria Epidemiological Studies Summary

Reference	Study Design, n, and Location	Cyanobacteria Identified	Cyanotoxins Measured	Health Association[a]	Lowest Significant Cyanobacterial Cell Density (cells/mL)
Philipp (1992)	Cross-sectional n = 246 United Kingdom (Hampshire)	*Microcystis* sp., *Gleotrichia* sp.	–	No statistically significant health associations	No quantitative cyanobacterial cell densities provided
Philipp and Bates (1992)	Cross-sectional n = 382 United Kingdom (Somerset)	*Microcystis* sp., *Gleotrichia* sp.	–	No statistically significant health associations	No quantitative cyanobacterial cell densities provided
Philipp et al. (1992)	Cross-sectional n = 246 United Kingdom (Lincolnshire, South Yorkshire)	*Oscillatoria* sp., *Aphanizomenon* sp., *Aphanothece* sp., *Merismopedia* sp.	–	No statistically significant health associations	No quantitative cyanobacterial cell densities provided
El Saadi et al. (1995)	Case-control n cases = 102 GI, 86 dermatological n controls = 132 Australia (South Australia)	*Anabaena* sp., *Aphanizomenon* sp., *Planktothrix* sp., *Anabaena circinalis*, *Microcystis aeruginosa*	–	No statistically significant health associations	No quantitative cyanobacterial cell densities provided
Pilotto et al. (1997)	Cross-sectional n = 295 exposed n = 43 unexposed Australia (South Australia, New South Wales, Victoria)	*Microcystis aeruginosa*, *Microcystis* sp., *Anabaena* sp., *Aphanizormenon* sp., *Nodularia spumigena*	Hepatotoxins detected by mouse bioassay	Significant positive association between combined symptoms (GI, dermal, respiratory, fever, eye or ear irritation) and cyanobacteria	> 5,000
Stewart et al. (2006d)	Cohort (prospective) n = 1,331 Australia (Queensland, New South Wales) and Florida	Cyanobacteria identified, species not specified	Microcystins detected by HPLC with photodiode array detection or ELISA; cylindro-spermopsin and anatoxin-a detected by HPLC-MS/MS; saxitoxins not detected by HPLC with fluorescence detection	Significant positive association between respiratory symptoms and cyanobacteria Significant positive association between combined symptoms (GI, dermal, respiratory, fever, eye or ear irritation) and cyanobacteria	> 100,000[b]

Reference	Study Design, n, and Location	Cyanobacteria Identified	Cyanotoxins Measured	Health Association[a]	Lowest Significant Cyanobacterial Cell Density (cells/mL)
Lévesque et al. (2014)	Cohort (prospective) n = 466 Canada (Quebec)	Cyanobacteria identified, species not specified	Microcystins detected by ELISA	Significant positive association between GI symptoms with fever and cyanobacteria	20,000–100,000
Lin et al. (2015)[c]	Cohort (prospective) n = 15,726 Puerto Rico (Boquerón)	Cyanophyte filament, *Pseudanabaena* sp., Picocyanophyte, *Synechococcus* sp., *Synechocystis* sp., Cyanophyte cell pair, *Phormidium* sp., *Lyngbya* sp., *Trichodesmium* sp., *Aphanothece* sp., *Johannesbaptistia* sp., *Komvophoron* sp., Cyanophyte colony, Cyanophyte unicell sphere	Lyngbyatoxin-a and debromo-aplysiatoxin measured but not detected by HPLC-MS	Significant positive association between respiratory illness and cyanobacteria other than picocyanobacteria	36.7–237.4
				significant positive association between rash and cyanobacteria other than picocyanobacteria	> 237.4

sp. = unspecified species of the genus; HPLC = high performance liquid chromatography; MS = mass spectrometry; MS/MS = tandem mass spectroscopy

[a] Includes only significant associations between recreational cyanobacteria exposure and health effects.

[b] Values were converted from cyanobacterial cell surface area (> 12.0 mm^2/mL) to cyanobacterial cell density (> 100,000 cells/mL) using conversions in NHMRC (2008). Relationship between biomass and cyanobacterial cell density can vary by species and cell size (Lawton et al. 1999; Stewart et al. 2006d).

[c] Lin et al. (2015) evaluated picocyanobacteria and cyanobacteria other than picocyanobacteria separately.

Three cross-sectional studies were conducted by Philipp et al. (Philipp 1992; Philipp and Bates 1992; Philipp et al. 1992) to evaluate health effects related to exposure to cyanobacteria from recreational activities including sailing, windsurfing, and fishing in water bodies in the United Kingdom. Questionnaires were administered to participants who visited one of six inland lakes to evaluate exposure and morbidity (including dermal, eye/ear, GI, and respiratory symptoms). Several species of cyanobacteria were identified and, in some cases, cyanobacterial levels exceeded the National Rivers Authority threshold for "potential to cause harm." Only minor morbidity was identified among recreators, and no statistically significant associations between cyanobacteria exposure and morbidity were identified.

El Saadi et al. (1995) conducted a case-control study in Australia to evaluate exposure to river water with detectable levels of cyanobacteria and GI and dermatological symptoms evaluated by a medical practitioner. This river was used as a source for drinking water, domestic water, and recreational water. The authors found no significant association between recreational exposure to river water with cyanobacteria and GI or dermatological symptoms. Cyanotoxins were not measured, but species of cyanobacteria were present that were capable of producing cyanotoxins.

These four studies (El Saadi et al. 1995; Philipp 1992; Philipp and Bates 1992; Philipp et al. 1992) provided no quantitative data on cyanobacterial cell densities. Therefore, they could not help inform determination of a quantitative level associated (or not associated) with health effects.

Four more recent epidemiological studies assessed the association between exposure to recreational waters containing cyanobacteria and human health and provide quantitative density data for cyanobacterial cells (Lévesque et al. 2014; Lin et al. 2015; Pilotto et al. 1997; Stewart et al. 2006d). These studies reported at least one statistically significant association between exposure to cyanobacteria and human health outcomes, including GI illness (Lévesque et al. 2014), respiratory symptoms (Lin et al. 2015; Stewart et al. 2006d), dermal symptoms (Lin et al. 2015), or combined symptomology (GI, dermal, respiratory, and other symptoms) (Pilotto et al. 1997; Stewart et al. 2006d). These associations were linked to a range of densities of cyanobacterial cells from as low as > 5,000 cells/mL (Pilotto et al. 1997) to as high as 100,000 cells/mL (analogous to ≥ 12 mm^2/mL (NHMRC 2008; Stewart et al. 2006d). In contrast to the studies that examined all cyanobacteria, Lin et al. (2015) evaluated picocyanobacteria, larger cyanobacterial cells, and total phytoplankton, and reported health effects associated with 37–1,461 cells/mL for cyanobacteria other than picocyanobacteria.

Pilotto et al. (1997) investigated the health effects from recreational exposures (including jet-skiing, water skiing, swimming, and windsurfing) to cyanobacteria in Australia. The study included 852 participants, 777 who had water contact and were considered exposed, and 75 not exposed. There were 338 recreators (295 exposed, 43 not exposed) after exclusion of those who experienced symptoms or had recreational exposure in the five days prior to the initial interview at the water recreation site (the *after exclusion* study group). Health outcomes evaluated included diarrhea, vomiting, flu-like symptoms (e.g., cough), skin rashes, mouth ulcers, fevers, or eye or ear infections. Water samples were collected for evaluation of cyanobacterial cell counts, hepatotoxins, and neurotoxins.

In the *after exclusion* study group, when all symptoms were combined, the authors found a significant trend of increasing symptom occurrence with duration of exposure at seven days post-exposure (p-value for trend =0.03). Similarly, in the *after exclusion* study group there was a significant trend of increasing symptom occurrence with increasing cyanobacterial cell count (p-value for trend = 0.04). To account for the combined effect of duration of exposure and cyanobacterial cell density, unexposed participants were compared with those exposed for up to 60 minutes and for more than 60 minutes to water with up to 5,000 cells/mL and to water with more than 5,000 cells/mL. For the *after exclusion* study group, a significant trend of increasing symptom occurrence with increasing levels of exposure was identified (p-value for trend = 0.004). In addition, participants with recreational exposure for more than 60 minutes to cyanobacterial densities above 5,000 cells/mL had a significantly higher symptom occurrence rate at seven days post-exposure than unexposed participants (OR = 3.44, CI: 1.09–10.82). In this study, the significant trends observed in the *after exclusion* study group were not observed when all participants were included.

Pilotto et al. (1997) reported toxicity data collected by the Australia Water Quality Center. Presence or absence of particulate (intracellular) hepatotoxins in concentrated surface water phytoplankton samples was measured by mouse bioassay. The authors reported that hepatotoxins were identified at one site on two separate interview days and at three sites for one day each. No evidence of neurotoxins was detected. They reported that no significant association was found between the presence of hepatotoxins and symptom occurrence at two and seven days after exposure. Data and analysis methods were not provided. The authors point out that trends were observed at seven days and not at two days after exposure and this might suggest a delayed rather than an immediate allergic response. The authors also stated they could not rule out other causative factors, such as other microorganisms, that could co-occur with cyanobacteria. The results from this study informed the recommendations made by WHO in *Guidelines for Safe Recreational Water Environments* (WHO 2003).

Stewart et al. (2006d) conducted a prospective cohort study to investigate the incidence of acute symptoms in individuals exposed to cyanobacteria via recreational activities in lakes and rivers in Australia and Florida. This study included 1311 recreators with any water contact-related activity (e.g., swimming, boat entry/egress). Cyanobacterial cell densities were characterized in terms of cell surface area rather than cell counts (to normalize for cell size differences among different species). Authors evaluated incidence of acute symptoms in recreators exposed to low, medium and high levels of cyanobacteria.

Study subjects were asked to complete a self-administered questionnaire before leaving for the day after enrollment and to submit to a telephone follow-up interview. The questionnaire and follow-up interview forms gathered information on various acute illnesses, their onset and severity. Respiratory symptoms among study participants in the high recreational exposure group (total cyanobacterial cell surface area > 12 mm^2/mL on day of recreation) were significantly greater compared to participants in the low recreational exposure group (< 2.4 mm^2/mL) (adjusted OR = 2.1, 95 percent CI: 1.1–4.0). Respiratory symptoms were defined as difficulty breathing, dry cough, productive cough, runny nose, unusual sneezing, sore throat, or wheezy breathing. Reports of any symptom among study participants in the high exposure group were significantly greater compared to reports among study participants in the low recreational exposure group (adjusted OR = 1.7, 95 percent CI: 1.0–2.9). However, when subjects with recent prior recreational water exposure were excluded the result remained positive but not significant (adjusted OR = 1.6, 95 percent CI: 0.8–3.2). A dose-response relationship between increased cyanobacterial biomass and increased symptom reporting was not identified. The authors speculated that the pattern in their data could be due to a threshold effect. No other significant associations with health effects were identified.

For water samples that contained potentially toxic cyanobacteria, Stewart et al. (2006d) measured cyanotoxins including microcystins, saxitoxins, cylindrospermopsin and anatoxin-a by HPLC or HPLC-MS/MS methods. Cyanotoxins were infrequently identified and only at low levels. Microcystins were detected on two occasions (1 and 12 μg/L). Cylindrospermopsin was found on seven occasions (ranging from 1 to 2 μg/L). Anatoxin-a was identified on a single recruitment day at a concentration of 1 μg/L. A statistically significant increase in symptom reporting was found to be associated with anatoxin-a exposure, but the number of exposed subjects was very low (n =18). No relationship between fecal indicator bacteria (fecal coliforms) and symptoms was identified.

Lévesque et al. (2014) conducted a prospective study of health effects including GI, respiratory, dermal, eye/ear, and other symptoms associated with cyanobacteria and microcystin exposure at three lakes in Canada (Quebec), one of which was a local supply of drinking water. The study evaluated acute symptoms in humans (466 subjects included in analysis) living in proximity to lakes affected by blooms and analyzed recreational exposure (full and limited contact) and drinking water exposure scenarios for both cyanobacterial cells and microcystins.

More severe GI symptoms, defined as diarrhea, vomiting, nausea and fever, or abdominal cramps and fever, were associated with recreational contact (full and limited) and cyanobacteria. For the more severe GI symptoms, the adjusted relative risk (RR) increased with cyanobacterial cell counts providing evidence of a dose-response relationship (p-value for trend = 0.001, < 20,000 cells/mL: RR = 1.52, 95 percent CI: 0.65–3.51; 20,000–100,000 cells/mL: RR = 2.71, 95 percent CI: 1.02–7.16; > 100,000 cells/mL: RR = 3.28, 95 percent CI: 1.69–6.37). No evidence of a dose-response relationship for cyanobacterial cell counts and the less severe GI symptoms was found. No relationship was observed between duration of contact or head immersion and risk of GI symptoms. A significant increase for both

the less and the more severe GI symptoms was found with contact in the more highly impacted lakes (median cell densities 20,001–21,485 cells/mL), but not in the less impacted lake (median 1,032 cells/mL). No relationship was observed between microcystin concentrations and risk of GI symptoms. No significant associations between recreational exposures to cyanobacteria and health effects other than GI effects were identified.

To evaluate possible co-exposures, authors measured microcystin concentrations and *E. coli* as a fecal indicator. Lévesque et al. (2014) measured particulate (intracellular) and dissolved microcystins by ELISA and found that microcystin concentrations varied by lake and by sample location (littoral versus limnetic). Microcystins were detected in all three lakes. At Lake William the median values were below the limit of detection at littoral and limnetic stations, with maximum values of 0.63 µg/L and 0.02 µg/L, respectively. At Lake Roxton littoral stations, the median concentration was 0.23 µg/L (range: 0.008 µg/L–108.8 µg/L) and at limnetic stations the median was 0.12 µg/L (range: 0.04 µg/L–1.12 µg/L). The Mallets Bay littoral stations had a median of 0.70 µg/L (range: under limit of detection – 773 µg/L) and the limnetic stations had a median of 0.35 µg/L (range: 0.001 µg/L–125 µg/L).

Lévesque et al. (2014) reported that as a whole the microcystin concentrations during contact were relatively low (first tertile: < 0.0012 µg/L; second tertile: 0.0012–0.2456 µg/L; third tertile: > 0.2456 µg/L). Symptoms were examined in relation to recreational and drinking water exposure to cyanobacteria and microcystins. Only GI symptoms were associated with recreational contact. The highest microcystin concentration at which an episode of GI symptoms was reported was 7.65 µg/L. There was no significant increase in adjusted RR of GI symptoms with recreational exposure to more than 1 µg/L microcystins. Adjusted RR (adjusted for gender, gastrointestinal (GI) symptoms reported in the two weeks prior to data collection, residence's source of drinking water) for GI illness without fever and GI illness with fever were 1.06 (95 percent CI=0.32–3.52) and 1.48 (95 percent CI = 0.41–5.23), respectively. There were significant increases in adjusted RR of several symptoms in participants who received their drinking water from a source contaminated by cyanobacteria (muscle pain, GI illness, skin, and ear symptoms).

Lévesque et al. (2014) found that the geometric mean of *E. coli* at the three lakes ranged from 0 to 145 CFU per 100 mL, and there was no association between GI illness and *E. coli* levels. The authors noted that GI symptoms could have other causes, such as *Aeromonas* infections; however, the symptoms were not related to fecal contamination as measured by culturable *E. coli.* They also noted that people avoided full recreational contact during blooms and more people engaged in limited contact recreation at higher cell counts. This observation explains the counterintuitive finding that participants with limited contact exposure (fishing, watercraft without direct water contact) had higher likelihood of symptom reporting compared to participants with full contact.

A follow-up analysis (Lévesque et al. 2016) characterized the same health data as Lévesque et al. (2014) to evaluate the relationship of bacterial endotoxin (e.g., LPS) concentration to GI symptoms. Endotoxin concentrations were slightly correlated with cyanobacterial counts (polychoric correlation coefficient = 0.57). The highest tertile of endotoxin concentration (> 48 endotoxin units/mL) was significantly associated with GI illness both with and without fever (GI illness without fever RR = 2.87, CI: 1.62–5.08; GI illness with fever RR = 3.11, CI: 1.56–6.22). Adjustment to the level of cyanobacteria did not alter the relationship between endotoxin and GI illness and authors hypothesize that other Gram negative bacteria might play a role in the relationship between endotoxin levels and GI illness as has been suggested in a previous study (Berg et al. 2011). Authors note that they stored filtered water samples at −80 ºC for several months prior to conducting endotoxin testing and that another study

(O'Toole et al. 2009) showed a 44 percent mean decline in the concentration of endotoxins in samples stored at -80 ºC for several weeks compared to samples stored at 4 ºC for 24 hours. Lévesque et al. (2016) caution that concentrations reported could be underestimated and should be interpreted on an ordinal basis. Two other studies conducting endotoxin testing on frozen samples found concentrations of a similar magnitude as this study (Berg et al. 2011; Rapala et al. (2002).

Lin et al. (2015) conducted a prospective study based on data collected in 2009 at Boquerón, Puerto Rico for 26 study days involving 15,726 enrollees to examine the association between phytoplankton cell counts and illness among beachgoers. Three categories of phytoplankton were evaluated: picocyanobacteria, cyanobacteria other than picocyanobacteria, and total phytoplankton. The analysis compared people exposed at phytoplankton cell count levels > 25th percentile (e.g., 25th to 75th percentile, > 75th percentile) to people exposed at levels < 25th percentile (range of cyanobacteria other than picocyanobacteria: < 37 to 1461 cells/mL).

The Lin et al. (2015) study reported significant associations between recreational exposure to cyanobacteria other than picocyanobacteria and respiratory symptoms, rash, and earache. For the other symptoms measured, including eye irritation, no significant associations were observed. More specifically, cyanobacterial (other than picocyanobacterial) densities of 37 to 237 cells/mL (> 25th to < 75th percentile) and densities ≥ 237 cells/mL (≥ 75th percentile) were associated with increased respiratory symptoms (> 25th to < 75th percentile, OR = 1.30, 95 percent CI: 1.08–1.56; ≥ 75th percentile, OR = 1.37, 95 percent CI: 1.12–1.67) in study participants who reported body immersion. Respiratory symptom occurrence was defined as any two of the following: sore throat, cough, runny nose, cold, or fever. Cyanobacterial (other than picocyanobacterial) densities >237 cells/mL were associated with rash (OR = 1.32, 95 percent CI = 1.05–1.66) and earache (OR = 1.75, 95 percent CI: 1.09–2.82). Study participants who reported head submersion or swallowing of water showed no relationship between recreational exposures to cyanobacteria (other than picocyanobacteria) and respiratory symptoms. There was no association between recreational exposures to cyanobacteria (other than picocyanobacteria) and respiratory symptoms in study participants who reported head submersion or swallowing of water. A statistically significant association between cyanobacterial cell exposure (other than picocyanobacterial cell exposure) and all health effects combined was also observed.

Lin et al. (2015) measured the dermatoxins, debromoaplysiatoxin, and lyngbyatoxin, using HPLC-mass spectrometry and did not detect levels above the limit of detection of 1.0 ppb. Authors reported that debromoaplysiatoxin and lyngbyatoxin-a are photolabile and are unlikely to persist in the water column (Moikeha and Chu 1971). They noted that the health effects identified in this study were consistent with previous blooms of *Lyngbya majuscula*, which can produce these toxins, though *Lyngbya* only comprised three percent of total planktonic cyanobacteria (other than picocyanobacteria). It is also possible that the cyanobacterial cells or associated contaminants could be having direct health effects as cyanotoxins levels were below the limit of detection.

To evaluate possible co-exposures, some studies measured cyanotoxins and fecal indicators. Lin et al. (2015), Lévesque et al. (2014), Pilotto et al. (1997), and Stewart et al. (2006d) measured one or more cyanotoxins or total hepatotoxins. In some cases, cyanotoxin levels were below the limit of detection. To determine if study participants possibly were exposed to fecal contamination, three of the studies (Lévesque et al. 2014; Lin et al. 2015; Stewart et al. 2006d) measured bacterial fecal indicators at some study locations and times. Of the studies that measured bacterial fecal indicators, none found an association between bacterial fecal indicators and health effects. Of these studies, the only one with data

available for viral fecal indicators or concentrations of waterborne pathogens was Lin et al. (2015) provided in Wade et al. (2010) and Soller et al. (2016).

In summary, although four studies identified significant associations between cyanobacteria exposure and health effects, the type of health effect identified varied. One study reported a significant association between GI illness and exposure to cyanobacteria (Lévesque et al. 2014). Stewart et al. (2006d) and Lin et al. (2015) identified statistically significant associations between cyanobacterial cell exposure and respiratory effects. Lin et al. (2015) also found a statistically significant association between earache and cyanobacterial densities. Both Pilotto et al. (1997) and Stewart et al. (2006d) found statistically significant associations between cyanobacterial cell exposure and all symptoms combined. The three cross-sectional studies conducted in the United Kingdom in 1990 found no statistically significant associations, although some minor elevated morbidity was observed in exposed individuals (Philipp 1992; Philipp and Bates 1992; Philipp et al. 1992). Another 1992 case-control epidemiological study in Australia found no statistically significant symptoms for exposed recreators (El Saadi et al. 1995).

The Centers for Disease Control and Prevention (CDC) has collected information on illness outbreaks associated with HABs, which commonly involve cyanobacteria. This information includes human health effects and water-sampling results voluntarily reported to the Waterborne Disease Outbreak Surveillance System via the National Outbreak Reporting System and the Harmful Algal Bloom-related Illness Surveillance System. CDC published summary information on HAB-associated outbreaks from recreational exposures focusing on 2009–2010 with limited additional information available for outbreaks that occurred in 2001, 2004, and 2011–2012 (Dziuban et al. 2006; Hilborn et al. 2014; Hlavsa et al. 2014; Yoder et al. 2004). CDC defines a recreational water-associated outbreak as the occurrence of similar illnesses in two or more persons, epidemiologically linked by location and time of exposure to recreational water or recreational water-associated chemicals volatilized into the air surrounding the water.

The 2009–2010 reporting cycle was notable, as almost half (46 percent) the recreational water outbreaks reported to CDC were associated with HABs (Hilborn et al. 2014). Three of the outbreaks confirmed the presence of cyanobacteria, and four confirmed the presence of microcystins at levels greater than 20 μg/L. GI and dermatologic symptoms were the most commonly reported symptom categories associated with HAB-related outbreaks in freshwater (Dziuban et al. 2006; Hilborn et al. 2014; Hlavsa et al. 2014; Yoder et al. 2004). For the cyanobacteria-associated outbreaks with reported symptom counts, the most common symptoms reported were GI related, including vomiting, diarrhea, and nausea (estimated to be > 40 percent). The second most frequent outbreak symptom reported was skin rash (> 27 percent cases reported). Fever, earache, skin irritation, and headache were the next most frequently reported symptoms (11 percent, nine percent, and nine percent of cases reported, respectively).

During 2009 and 2010 in the United States, 11 outbreaks of illness associated with HABs were reported to CDC, all occurring in freshwater lakes and reported via the National Outbreak Reporting System (NORS) and the Harmful Algal Bloom-related Illness Surveillance System (HABISS). Hilborn et al. (2014) analyzed the HAB outbreak data from 2009–2010 and found the 11 outbreaks affected at least 61 persons, resulting in two hospitalizations, and included GI, dermatologic, respiratory, neurologic, and other symptoms. Sixty-six percent of case patients were individuals aged one to 19 years (n = 38 of 58 total) and 35 percent were aged nine years or younger (n = 20). In addition, in a cyanobacteria-associated outbreak in 2001, 42 children were affected. Outbreak data are typically limited in scope and thought to represent an underreporting of the "true" occurrence of illness in a population, but available

information suggests that children may share a disproportional share of the health burden associated with recreational exposures to cyanobacterial HABs.

Dziuban et al. (2006) and Walker et al. (2008) reported on outbreaks in Nebraska. Dziuban et al. (2006) described two 2004 cyanobacteria-associated outbreaks in which 22 cases of illness were reported from exposure to Nebraska lakes. The predominant illnesses in both outbreaks included dermatitis and gastroenteritis, and individuals who sought medical care showed a combination of rashes, diarrhea, cramps, nausea, vomiting, and fevers. Walker et al. (2008) also reported about a Nebraska outbreak. Levels of total microcystins at the east swimming beach of Pawnee Lake exceeded 15 ppb on July 12, 2004, and a health alert was issued. However, heavy public use of Pawnee Lake occurred that weekend and more than 50 calls were received from the public, complaining about symptoms such as skin rashes, lesions, blisters, vomiting, headaches, and diarrhea after swimming or water skiing in Pawnee Lake (Walker et al., 2008).

D.2 Mode of Action

Few mechanistic investigations have been completed on how exposure to cyanobacterial cells might lead to inflammatory response. Torokne et al. (2001) evaluated the sensitization and irritation potential of *Microcystis*, *Anabaena*, *Cylindrospermopsis*, and *Aphanizomenon* bloom and strain samples and found no correlation between the cyanotoxin content and allergenicity. For example, the nontoxic *Aphanizomenon* was the most allergenic sample, more allergenic than the most toxic cyanobacterial cells they studied, *Microcystis aeruginosa*. Stewart et al. (2006e) concluded that cutaneous effects strongly suggest allergic reactions, and symptoms such as rhinitis, conjunctivitis, asthma, and urticaria (or hives) also indicate immediate hypersensitivity responses, which are probably explained by a cascade action of pro-inflammatory cytokines.

Bernstein et al. (2011) suggested that the allergenic structure of cyanobacteria might be associated with a non-toxin-producing part of the organism. Building on this conclusion, Geh et al. (2015) conducted a series of experiments to identify the cyanobacteria allergen(s) responsible for sensitization. Study participants were given skin-prick tests with extracts from nontoxic *Microcystis aeruginosa* strains. Serum from these individuals was collected from a subset of 15 patients who elicited strong skin test responses to *Microcystis aeruginosa* and from three healthy control subjects. The lysate from nontoxic *Microcystis aeruginosa* strains was significantly ($p < 0.01$) more immunoreactive than the lysate from the toxin-producing strains, which suggests that the nontoxic strain was more allergenic than the toxic strain. They found, however, that IgE binds to *Microcystis aeruginosa* peptides present in lysates of both the toxic and nontoxic strains. Geh et al. (2015) also performed a β-hexosaminidase release assay, as a surrogate assay for measuring histamine release, to identify functional activity of the *Microcystis aeruginosa* extracts using rat basophil leukemia cells. The authors concluded that the same allergen is present in toxic and nontoxic *Microcystis aeruginosa* lysates, but suggest the toxic *Microcystis aeruginosa* lysate might contain an endogenous inhibitor that prevents IgE from effectively binding to the specific allergen. The further analysis by Geh et al. (2015) of the sera of individuals exposed to nontoxic *Microcystis aeruginosa* lysate indicated that either linker core-membrane peptide or phycocyanin, or both, are potentially responsible for *Microcystis aeruginosa* allergenicity.

Epidemiological studies and case reports suggest respiratory effects that could be consistent with an allergic or hay fever type reaction (Giannuzzi et al. 2011; Stewart et al. 2006e). Inhalation exposure to bacterial endotoxins (i.e., a toxin that is part of the cyanobacterial cell as opposed to exotoxins such as microcystins and cylindrospermopsin) has been found to be associated with pulmonary disease,

including asthma, chronic obstructive airway disease, and emphysema (Stewart et al. 2006b). A recent review of the structure and effects of cyanobacterial LPS suggested that it could act as an antagonist of the TLR4 receptor and inhibit the inflammatory-response pathway (Durai et al. 2015).

Stewart et al. (2006e) also noted that, although symptoms and time to onset can be disparate, several reports described:

> "a collective group of symptoms resembling immediate or Type-I hypersensitivity reactions. Immediate hypersensitivity reactions are commonly associated with atopy, which is the familial tendency to react to naturally occurring antigens, mostly proteins, through an IgE-mediated process. Atopy frequently manifests as a spectrum of diseases, e.g., seasonal rhinitis, conjunctivitis, asthma, and urticaria."

Documentation of this type of respiratory response is consistent with results from Geh et al. (2015) and further supports that immune system response follows exposure to cyanobacteria.

In older literature, cyanobacterial LPS was suspected as being a cause of inflammatory response because this cell structure, also found in many Gram negative bacterial species, has been observed to initiate acute inflammatory responses in mammals that are typical of a host reaction to tissue injury or infection (Stewart et al. 2006b). The Stewart et al. (2006e) review, however, found evidence to support this mechanism lacking. Although all cyanobacteria contain the pigment phycocyanin, not all species of cyanobacteria have shown dermal reactions. Also, some species of cyanobacteria produce toxins that are known dermal irritants (e.g., lyngbyatoxin-a). Pilotto et al. (2004), however, found that 20–24 percent of the study participants exposed to cyanobacterial cells via skin patches for 24 hours showed dermal reactions to cyanobacteria species, both whole and lysed cells.

Stewart et al. (2006b) noted that the effects of microcystin- and cylindrospermopsin-producing bacteria on the GI tract could suggest that cyanotoxins and LPS from the cyanobacteria or other bacteria residing in the gut might cross a gut mucosal barrier that has been disrupted and enhance the adverse effects of cyanotoxins.

An aquatic invertebrate study using brine shrimp (*Artemia salina, Daphnia magna*, and *Daphnia galeata*) to determine the toxicity of microcystin and cylindrospermopsin in combination with cyanobacterial LPS found that pre-exposure to LPS increased the lethal concentration (LC_{50}) of cylindrospermopsin eight-fold (Lindsay et al. 2006). The authors concluded that the decrease in susceptibility to cylindrospermopsin was due to the effects of LPS on detoxification enzyme pathways; LPS decreased toxic metabolites of cylindrospermopsin by suppressing the invertebrate cytochrome P450 system, thus decreasing toxicity.

NMED Exhibit 93

APPENDIX E. INCIDENTAL INGESTION EXPOSURE FACTOR COMBINED DISTRIBUTION ANALYSIS

This appendix describes in detail the approach used to derive the value for ingestion rate in units of liters per day. The ingestion rate is used in the derivation of the recommended cyanotoxin values in this document.

To arrive at liters of ingestion per day, the EPA combined data on liters of ingestion per hour and the number of hours spent in the water per day. Both of these parameters were represented as log-normal distributions. The sources of the data were:

- Recreational water ingestion per hour – The lead author of Dufour et al. (2017) provided the EPA's Office of Water, Health and Ecological Criteria Division with the raw data collected and analyzed in the study, which included mL of water ingested during a swimming event. Each participant in the study also reported the length of time they spent in the water. The ingestion per event was normalized to one hour for each participant and converted to liters to arrive at liters ingested per hour. The mean and standard deviation were calculated for different age groups (6 to 10, 11 to 17, 18 years and up, and all ages). See Table E-1 below for summary statistics for this parameter. Subsequent to the EPA's analysis, Dufour et al. posted their raw dataset on data.gov (U.S. EPA 2018). There are few minor variations in the dataset analyzed here and the posted dataset (i.e., the posted dataset included an additional adult participant's results, specified time spent in the water as 45 minutes for two participants, rounded ingestion volumes of 0.5 up to 1, and indicated a higher ingestion volume for one adult woman). The EPA performed a sensitivity analysis to see if these differences impacted the results and found no significant effect. The very slight differences were within the rounding to the third decimal. No differences were observed between the datasets for the results of the combined distribution analysis for the six- to 10-year age group.

- Duration of swimming per day – the EPA's 2011 *Exposure Factors Handbook* (EFH; Table 16-20). Time Spent (minutes/day) in Selected Outdoor Locations, Doers Only, At Home in the Outdoor Pool or Spa). Table E-2 below shows the summary statistics provided by the EPA's EFH.

Table E-1. Parameters Used to Fit Ingestion Distributions

Ingestion Rate (L/hour)				
Age Group (sample size)	**Mean[a]**	**Standard deviation**	**Minimum**	**Maximum**
6 to 10 (child) (n = 66)	0.03745	0.03355	0.00033	0.20000
11 to 17 (child) (n = 170)	0.03996	0.04377	0.00067	0.26800
18+ (adult) (n = 312)	0.02811	0.04960	0.00012	0.36800
All (6 to 50+) (n = 549)	0.03290	0.04643	0.00012	0.36800

[a] Arithmetic mean based on raw data provided by the Dufour et al. (2017) study authors. The ingestion rates for age groups children (6 to 10), teens (11 to 15), and adults (16 and over) were reported as geometric means in Dufour et al. (2017).

NMED Exhibit 93

Table E-2. Parameters Used to Fit Recreation Duration Distributions

EPA 2011 EFH (Excerpt from Table 16-20) (minutes/day)					
Age Group (sample size)	**Mean**	**Standard deviation**	**Median (50th percentile)**	**Minimum**	**Maximum**
1 to 4 (n = 9)	85.6	86.3	60	15	255
5 to 11 (n = 15)	164.2	103.97	140	25	450
12 to 17 (n = 5)	97	53.8	100	40	180
18 to 64 (n = 44)	117.6	112.7	83	4	450
> 64 (n = 10)	78.9	85.3	53	1	258

R (open source programming language) was used to perform the calculations described in this appendix. The annotated R code is shown below, following a summary of what calculations were performed and assumptions.

The water ingestion rate per hour data from Dufour were used to compute an arithmetic mean and standard deviation, which are in turn used to compute the log geometric mean (GM) and log geometric standard deviation (GSD) using a mathematical conversion formula. The log GM and log GSD are used as distributional parameters to generate 10,000 random samples representing water ingestion rates per hour of recreational activity (L/hour).

The mean and standard deviation of the number of recreational hours spent in the water per day are reported as summary statistics in the EFH 2011, and are used to compute the log GM and log GSD using a mathematical conversion formula. The log GM and log GSD are used as distributional parameters to generate 10,000 random samples representing water ingestion rates per hour of recreational activity (hour/day).

The two component distributions are assumed to be statistically independent of each other and are multiplied to generate a combined distribution with 10,000 values for the ingestion rate of water per day of recreational activity in L/day. Summary statistics, including the mean, standard deviation, and point estimates of various percentiles, are then computed from the combined distribution. The EPA chose the 90th percentile point estimate for children six to 10 (0.21 L/day) to calculate the recommended cyanotoxin values.

NMED Exhibit 93

APPENDIX F. INGESTION STUDIES

The EPA reviewed seven studies to evaluate recreation-associated incidental ingestion (DeFlorio-Barker et al. 2017; Dorevitch et al. 2011; Dufour et al. 2006, 2017; Schets et al. 2011; Schijven and de Roda Husman 2006; Suppes et al. 2014). Evans et al. 2006 was also reviewed, but is the same dataset as Dufour et al. (2017), so it is not included in the table. The EPA's approach for estimating incidental exposure while swimming used by the EPA's Office of Pesticide Programs (OPP) is also summarized below.

F.1 DeFlorio-Barker et al. (2017)

DeFlorio-Barker et al. (2017) combined ingestion data from Dufour et al. (2017) and time spent in the water data from 12 cohorts of epidemiological studies to estimate the volume of water ingested per swimming event. They calculated the ingested volume per minute (mL/minute) for each Dufour et al. (2017) study participant, using the mL ingested and the self-reported time spent in the water for each participant. The National Epidemiological and Environmental Assessment of Recreational Water Study and Southern California Coastal Water Research Project epidemiological studies included 68,685 recreators at four freshwater and eight marine beaches. The participants in these studies estimated how much time they spent in the water. DeFlorio-Barker et al. (2017) combined the mL/minute ingestion rate from Dufour et al. (2017) and the self-reported time spent in the water for the epidemiological study participants to calculate the volume of water ingested per event. The results of this study corroborate other studies that demonstrate that, on average, children have higher incidental ingestion than adults when recreating.

F.2 Dorevitch et al. (2011)

Dorevitch et al. (2011) evaluated incidental ingestion associated with multiple types of water contact activities in both surface water (canoeing, fishing, kayaking, motor boating, and rowing) and in pools (canoeing, fishing, kayaking, swimming, wading/splashing, and walking around the pool as a control). The surface water activities did not include swimming because the water body was designated for secondary contact recreation only. Volume of ingestion was self-reported via interviews (3,367 participants: 2,705 individuals recreating in the Chicago Area Waterway System (CAWS, surface water) and 662 individuals recreating at a public outdoor swimming pool). At the end of their exposure, participants self-reported whether they ingested water, and how much, during their recreational experience. The authors used a subset of the pool exposures to assess cyanuric acid in urine to determine the accuracy of the self-reported ingestion volumes. There was strong agreement between self-reported results and cyanuric acid measurement (none = 0.0014±0.008 L; drop to teaspoon = 0.0094±0.011 L; mouthful = 0.026±0.037 L).

The results indicate that the odds of ingesting a teaspoon or more of water are significantly higher among swimmers than among those who just immersed their head in a swimming pool or those who participated in the other, more limited contact activities on surface waters. More specifically, rowing, motor boating, fishing, wading/splashing, and non-capsizing kayaking and canoeing were found to be low-ingestion activities, resulting in 95 percent upper confidence limit ingestion volumes between 0.01 and 0.012 L/hour. Less than five percent of limited contact recreators on surface waters reported swallowing any water. The study authors considered those who capsized during canoeing or kayaking a "middle ingestion category," with mean incidental ingestions of 0.006 to 0.005 L/hour. Swimmers were the highest ingestion category, with a mean of 0.01 L/hour. Swimmers in a pool were more than

NMED Exhibit 93

50 times as likely to report swallowing a teaspoon of water compared to people who canoed or kayaked in surface waters.

In surface water, participants ages six years and above incidentally ingested the most water while canoeing and capsizing compared to any other activity assessed (median = 0.0036 L; mean = 0.006 L; Upper 95 percent CI: 0.0199 L). Kayaking and capsizing in surface water resulted in nearly as high incidental ingestion (mean = 0.005 L; Upper 95 percent CI: 0.0165). In swimming pool water, participants ages six and above incidentally ingested the most water while swimming compared to any other activity assessed (median = 0.006 L; mean = 0.01 L; Upper 95 percent CI: 0.0348 L). Duration of activities was not reported, so the ingestion volumes are on a per event basis.

F.3 Dufour et al. (2006)

The EPA's *Exposure Factors Handbook* (EFH) (2011) presents values for incidental ingestion while recreating values citing Dufour et al. (2006). Dufour et al. (2006) measured the incidental ingestion of water while participants were swimming in a pool and found that children under the age of 18 ingested higher volumes of water while swimming than adults. The 2006 study design instructed participants to swim for at least 45 minutes, so the time the participants spent in the water is probably not representative of preferred or regular patterns for recreation duration and the actual duration was not recorded. Both studies reported higher ingestion among children compared to adults. The values presented in the EFH adjusted the Dufour et al. (2006) data from a per event basis to an hourly ingestion rate. The EFH recommends using the 97th percentile ingestion rate for children and the maximum reported value for adults because the dataset is limited (U.S. EPA 2011).

F.4 Evans et al. (2006)

Evans et al. (2006) presented results from an observational study of incidental water ingestion during recreational swimming activities using the same methodology as the Dufour et al. (2006) pilot study. This study characterized ingestion volumes for younger children verses older children and adults. Evans et al. (2006) reported higher ingestion volumes for younger children. Although study results were presented at a conference, they were not published, so the EPA did not cite this publication in the derivation of the recommended cyanotoxin values. However, Dufour et al. (2017) includes the data reported by Evans et al. (2006).

F.5 Schets et al. (2011)

A study in the Netherlands by Schets et al. (2011) used questionnaires to collect estimates of water swallowed while swimming/bathing in freshwater, marine water, and swimming pools. Of the 8,000 adults who completed the questionnaire, 1,924 also provided estimates for their eldest child (< 15 years of age). The participants estimated the amount of water they or their children swallowed while swimming. Participants chose between four categories of water volumes: (1) no water or only a few drops; (2) one to two mouthfuls (a shot glass); (3) three to five mouthfuls (coffee cup); and (4) six to eight mouthfuls (soda glass). Schets et al. (2011) also conducted a series of experiments to measure the amount of water that corresponded to a mouthful of water and converted the data in the four response categories to volumes of water ingested per event. Adult men swallowed, on average 0.030 L/hour and women swallowed 0.020 L/hour, with somewhat greater ingestion in marine waters than in freshwater or a swimming pool. In fresh and marine waters children swallowed about the same as adults, and in swimming pools they ingested more than adults, on average, 0.038 L/hour compared with 0.030 and 0.021 for males and females, respectively (Schets et al. 2011). The EPA made the assumption that

NMED Exhibit 93

exposure in a swimming pool is roughly equivalent to exposure in fresh and marine waters. Schets (2011) supports that assumption, although it is a somewhat more conservative assumption for children. However, when bodyweight is taken into account the greater exposure to children versus adults becomes clear. Additional research would be helpful to clarify uncertainty in differences in ingestion from different types of waters.

F.6 Schijven and de Roda Husman (2006)

Schijven and de Roda Husman (2006) studied sport and occupational diver incidental ingestion. The types of water studied for occupational divers (n = 37 divers) were open sea and coastal marine water, and freshwater. For sport divers (n = 483 divers), the types of water considered were open sea and coastal marine water, fresh recreational water, canals and rivers, city canals, and swimming pools. The divers were asked to estimate how much water they swallowed in terms of: none, few drops, shot glass, coffee cup, or soda glass. The authors translated the description of volumes from the questionnaires into average volumes. Occupational divers reported incidentally ingesting more water per dive in marine water (mean: 0.0098 L/dive; maximum: 0.1 L/dive) compared to freshwater (mean: 0.0057 L/dive; maximum: 0.025 L/dive). Sports divers wearing an ordinary diving mask reported incidentally ingesting the most water per dive in swimming pools (mean: 0.02 L/dive; maximum: 0.19 L/dive), followed by recreational freshwater (mean: 0.013 L/dive; maximum: 0.19 L/dive) and coastal marine water (mean: 0.0099 L/dive; maximum: 0.19 L/dive). Sports divers wearing a full face mask reported incidentally ingesting less water than sports divers wearing an ordinary diving mask. The mean ingestion rates in freshwater ranged from 0.0015 to 0.019 L/hour, with the highest mean being for adult recreational divers wearing an ordinary diving mask and the lowest mean for adult recreational divers wearing a full face mask. The mean ingestion rates in marine water ranged from 0.0005 to 0.014 L/hour, with the highest mean being for adult recreational divers wearing an ordinary diving mask and the lowest mean for adult recreational divers wearing a full face mask. The age of the divers was not included in the study report. Occupational divers dived on average 60–95 minutes and sport divers dived on average 42–52 minutes per dive.

F.7 Suppes et al. (2014)

Suppes et al. (2014) used a similar measurement method as Dufour et al. (2006, 2017), (i.e., using cyanuric acid as an indicator of pool water ingestion) to evaluate the rate of water ingested by 16 children ages five to 17 years. They and found that children on average ingested pool water at a higher rate than adult participants. Total time in water, quantified by viewing videos, was used to adjust pool water ingestion volumes to obtain rates. After adjustments for false-positive measurements were applied, the mean rate at which adults ingested water was 0.0035 L/hour with range 0–0.051 L. The mean rate at which children ingested water was 0.026 L/hour with range 0.0009–0.106 L/hour.

F.8 U.S. EPA (2003)

Additional estimates of incidental water ingestion rates while swimming in pools have been identified by the EPA's OPP. OPP calculated people's exposures to pool chemicals while they swim using its Swimmers Exposure Assessment Model (SWIMODEL) (U.S. EPA 2003). SWIMODEL uses incidental ingestion values for children that are twice the values used for adults. Incidental ingestion rates among adults while swimming competitively and noncompetitively are 0.0125 L/hour and 0.025 L/hour, respectively. The model assumes an incidental ingestion rate of 0.050 L/hour for children ages seven to 10 years and 11 to 14 years while swimming noncompetitively. The 0.050 L/hour value is the value used

NMED Exhibit 93

in the EPA OPP's Standard Operating Procedures (U.S. EPA 2000) and is based on recommendations from EPA's Risk Assessment Guidance for Superfund, Part A (U.S. EPA 1989, 2000, 2003).

F.9 Summary

Although these studies used different methodologies and have limitations with respect to reporting information for different age group categories, their results show a similar pattern compared to Dufour et al. (2006, 2017): children ingest water at a higher rate while swimming than adults. Dufour et al. (2017) and Dufour et al. (2006) identified mean ingestion rates for children of 0.037–0.040 and 0.049 L/hour, respectively, and adult rates of 0.028 and 0.021 L/hour, respectively. Depending on water type, Schets et al. (2011) found a mean ingestion volume for children aged zero to 14 years of 0.028–0.038L/hour for children and 0.020–0.036 L/hr for males and females. The most pronounced differences were for swimming pools, where children ingested at a higher rate (0.038 L/hour) than adults (males: 0.030 L/hour; females: 0.021 L/hour). Dorevitch et al. (2011) reported ingestion rates while swimming for all ages of 0.010L/hour. Suppes et al. (2014) reported an adjusted mean ingestion rate of 0.026 L/hour for children and a rate of 0.0035 L/hour for adults.

Table F-1 includes: sample size, measurement methodology, the maximum values or the upper confidence intervals (CI) for the mean ingestion per event, time spent in the water (mean or range), and the mean ingestion volume normalized to one hour (or range if a range of durations were reported). This information supports comparison of the studies and help with understanding the range of different recreational exposures from activities.

The column with normalized ingestion (mL/hour) was populated using the following methods:

- Dufour et al. (2017) – The EPA used the individual data points from this dataset. Each participant's volume ingested was adjusted to one hour based on the length of time that participant reported being in the water.

- Dufour et al. (2006) – The EPA assumed that all swimming events were 45 minutes in duration. The values reported in Table F-1 are the same as the values in EPA's EFH (2011).

- DeFlorio-Barker et al. (2017) – Normalized data are not included in Table F-1 because the authors used the Dufour et al. (2017) rate in their modeling, so including the normalized data would be duplicative of Dufour et al. (2017).

- Dorevitch et al. (2011) – Study authors included normalized values in the study publication.

- Schets et al. (2011) – The EPA used the mean duration values provided in the publication to calculate the normalized value for each age and activity category.

- Suppes et al. (2014) – Study authors reported volume per hour.

- Schijven and de Roda Husman (2006) – The EPA used the range of duration values provided in the publication to calculate the normalized value for each activity category.

			Swimming pool, Recreational diving w/full face mask	Adults	13 (190)	42 to 52	15 to 19

[a] Age group ranges reflect the age groupings reported in the study. In some cases the authors did not separate data by different age groups among children or between adults and children.

[b] The values shown are arithmetic means calculated from the Dufour dataset. The Dufour et al. (2017) publication reported ingestion volumes as geometric means for children (6 to 10 years), teens (11 to 15 years), and adults (16 years and over).

[c] Each participant's volume ingested was adjusted to one hour based on the length of time that participant reported being in the water.

[d] No maximum values are reported in the study; 90th provided percentile in parentheses.

[e] No maximum values are reported in the study; upper limit of the CI is provided.

[f] Swimming duration was reported as ≥ 45 minutes, however authors derived and reported only hourly ingestion per event.

APPENDIX G. INFORMATION ON CELLULAR CYANOTOXIN AMOUNTS

The information in the tables in this appendix was generated from a brief survey of the peer-reviewed and published scientific literature. This survey was not a formal systematic literature search and was conducted to evaluate the availability of data needed to calculate a cyanobacterial cell density potentially associated with a specific cyanotoxin concentration.

The information in Tables G-3 and G-4 was generated from both a brief survey and a standardized search of the peer-reviewed and published scientific literature. The purpose of these searches was to evaluate the availability of cyanotoxin quota data (i.e., cyanotoxin content per cyanobacterial cell or per unit biomass, for microcystins and cylindrospermopsin) needed to calculate a cyanobacterial cell density potentially associated with a specific cyanotoxin concentration.

The EPA conducted a brief initial survey of the available peer-reviewed and published scientific literature in December 2016 and identified 29 studies with data on cellular toxin amounts. After reviewing the available data, a formal literature search was conducted. The purpose of this literature search and screening was to identify literature relevant to answering the following research question: What cyanotoxin cell quota data (i.e., cyanotoxin content per cyanobacterial cell or per unit biomass, for microcystins and cylindrospermopsin) are available in the peer-reviewed literature?

Search terms were identified with support from a subject matter expert and library science professionals and included genera of known microcystins or cylindrospermopsin producers, names of the toxins of interest, and keywords that could indicate that quota data were reported. The search was conducted in PubMed and results were limited to articles published in English from 1987 to March 2017. A summary of the literature search results is provided in Table G-1.

Table G-1. Summary of Cyanotoxin Cell Quota Data Literature Search Results

Database	Results	Notes/Limits
PubMed	253	1987 to present; English
Web of Science	472	1987 to present; English
Total Unique	**485**	

The EPA developed search strategies for each database. Both search strategies included the same set of keywords but varied in how these keywords were strung together. The Web of Science search strategy also included limits, a feature not characteristic of a search strategy conducted using PubMed. The search strategies are provided below.

The EPA conducted title and abstract screening of the 253 search results (generated from both database searches) and classified them as "relevant," "maybe relevant," or "not relevant." Titles were considered "relevant" if the title or abstract included mention of cell quota data for microcystins or

NMED Exhibit 93

cylindrospermopsin or if the title or abstract indicated that the study had quantitative information on cyanobacterial cell density and microcystins or cylindrospermopsin concentration and therefore may contain sufficient data to calculate a quota. Titles were considered "maybe relevant" if the title or abstract indicated the article might have information relevant to the research question. Title and abstract did not specifically include the term "quota" but indicated that it may have had quantitative information on cyanobacterial cell density and microcystins or cylindrospermopsin concentration or if cyanobacterial cells were only quantified by molecular methods such as PCR and toxin concentrations were measured. Titles were considered "not relevant" if the title/abstract did not appear to have information about microcystins or cylindrospermopsin quotas or densities/concentrations, if the study was a spiked cyanotoxin experiment (meaning cyanotoxins were added, not produced by cyanobacteria present), or if the study was not a peer-reviewed article, book, or government document.

The EPA prioritized the studies to facilitate the review. Prioritization yielded a high number of studies classified as "relevant" or "maybe relevant." Relevant studies were further prioritized for each cyanotoxin of interest based on date of publication. The approach for prioritization is presented in Table G-2. A full text review was conducted on Priority 1 studies only.

Table G-2. Summary of Study Prioritization

Toxin	Priority 1 Classification Criteria	Priority 2 Classification Criteria	Priority 3 Classification Criteria
Microcystins	Classified as relevant based on title/abstract screening; Did not use PCR quantification or evaluate benthic cyanobacteria; Identified predominant species without statistical analysis; Published in last 5 years; and Field study or study with both field and laboratory component.	Studies that use only PCR for quantification of cyanobacteria; and All laboratory studies (internal or external forcing, mitigation studies, studies evaluating non-nutrient pollutants).	Methods studies; and Studies on benthic cyanobacteria.
Cylindrospermopsin	Classified as relevant based on title/abstract screening; Did not use PCR quantification or evaluate benthic cyanobacteria; Identified predominant species without statistical analysis; Published in last 10 years; and Field study or laboratory study.	Studies that use only PCR for quantification of cyanobacteria.	Methods studies; and Studies on benthic cyanobacteria.

Extracted data from studies meeting the criteria for "Priority 1" are presented below in Table G-3 and are further summarized in Table G-4. Relevant quota data were extracted from both the text and figures in "Priority 1" studies. All figures were digitized using GraphPad Digitizer software, as appropriate. All extracted data from text and figures underwent primary and secondary review for quality assurance purposes.

The EPA's primary interest when reviewing the data was to identify the amount of toxin per cyanobacterial cell when toxin was present in a sample. In the environment, it is possible for cyanobacterial cells to be present with no toxin being produced (e.g., the cyanobacteria are a non-toxin-producing strain or environmental conditions do not support toxin production). The EPA only included quota data where toxin was detected.

The studies included in Table G-3 vary in methods used, conditions evaluated, and presentation of data. Typically, complete, raw data were unavailable. The EPA made choices regarding selection, presentation, aggregation, and conversion of data to develop the necessary standardization required for comparing and analyzing these data. Specifically, if quota values were from the same sample at a single location, the average and range were recorded; results from different sampling locations were recorded separately; and multiple mean quota values within the same study were recorded separately (note that separate mean values could be reported for different sampling sites or species within the same genera).

NMED Exhibit 93

The EPA found that study authors report toxin quota data in various forms, including but not limited to toxin mass per cyanobacterial cell, toxin mass per cyanobacterial biomass, and toxin mass per cyanobacterial biovolume. Scientific measurement units vary among studies. The EPA presents the cell quota data in Table G-3 in the units reported by the study authors (i.e., without conversion to standard units). However, when possible, the EPA converted data to a standard set of units, picograms (pg) per cell, in Table G-4 so that data could be summarized and compared. The EPA did not identify appropriate conversion factors that would allow genus-specific conversion of quotas described in mass per biovolume to mass per cell or mass per biomass to mass per cell. The EPA considered converting biovolume quotas using methods cited in the Australian national guidelines (Australian Government National Health and Medical Research Council, 2008) and Ackaalan (2006), but ultimately decided that the number of uncertainties associated with these methods were too great. Thus, data with unique units are summarized separately in Table G-3, Table G-4, and Table 7-14.

Within Table G-3 and Table G-4, the EPA categorized studies as either "field" or "lab." Field studies include studies where environmental samples were collected and analyzed for cell quota data without additional manipulation of growing conditions. In some studies, environmental samples were taken to a laboratory where growing conditions were optimized or manipulated to determine cyanotoxin cell quota. These studies were categorized as laboratory studies. Other laboratory studies analyzed cell quota in laboratory strains that were not collected in the environment for the purpose of the analysis. For laboratory studies, only control data were extracted. In laboratory studies where there was no true control the conditions closest to ambient conditions were selected (e.g., multiple conditions were tested and none was the clear control, all data were included).

While the traditional definition of toxin quota refers to the intracellular amount of toxin, some studies presented the total toxin present normalized by the cell density or the extracellular toxin normalized by cell density as a quota. In other cases, methods for calculation of the quota were not very clear. If a quota value was presented (i.e., intracellular toxin per cell) this was recorded. If this value was not available or was not clearly described, was recorded as presented by the study authors and assumed to be intracellular or the total amount of toxin per cell. Extracellular toxin per cell was not recorded. The EPA recognizes that the exclusion of extracellular toxin data could lead to an underestimation of the amount of toxin per cell, in particular for cylindrospermopsin as *Cylindrospermopsis* has been shown to constitutively produce the toxin, which can stay inside the cells during log phase growth and accumulate externally upon entering the stationary phase (Davis et al. 2014; Burford et al. 2016). Researchers have also demonstrated that cylindrospermopsin production can be excreted in response to phosphorus limitation and induce other cells to excrete alkaline phosphatase to the water body resulting in a phosphorus scavenging effect (Bar-Yosef et al. 2010).

Some field studies identified the presence of cyanotoxins and multiple cyanobacterial genera including more than one potential toxin producer with no clear predominant toxin-producing species. Table G-3 only includes cell quota values from field studies where there was a clear predominant toxin-producing genera. In these instances, the study was grouped with the predominant toxin-producing genera. In mixed samples with multiple cyanobacteria and no predominant toxin-producing species, quota data were not included. The EPA recognizes that this approach presents a possible limitation to conclusions on toxin quota as studies conducted under non-bloom conditions were excluded. Predominant species are easier to identify when there is a bloom, however, traditional microscopic identification of cyanobacteria does not distinguish between toxigenic and non-toxigenic strains. The proportion of toxigenic cells within a cyanobacterial community and the copy number of the *mcyD* gene per cell can vary significantly, both affected by environmental parameters (Davis et al. 2009).

NMED Exhibit 93

Table G-3 includes cell quota data for microcystin and cylindrospermopsin-producing genera. For each study, data are provided, where available, on the genus and species of the cyanobacteria, the site where the sample was collected or the clone used to estimate cellular toxin for, the type of study (i.e., field or laboratory), and the reported toxin quota data. Notes relevant to each study are reported in the final column of the table, when appropriate.

Relevant toxin data include the mean toxin quota per cell, the median toxin quota per cell, the minimum toxin quota per cell, or the maximum toxin quota per cell. These data are reported where available and not all data points were reported in each study. Data are presented using the units of measure reported by the study authors.

Table G-3. Cell Quota Data for Microcystin and Cylindrospermopsin-Producing Genera

Toxin	Genus/Species[a]	Site/Clone	Study Type[b]	Toxin Quota Data[c]	Reference	Notes
Microcystin	*Microcystis* spp.	Grangent Reservoir, France	Field	Mean: 0.576 pg/cell Min: 0.042 pg/cell Max: 4.19 pg/cell	Sabart et al. (2013)	Data digitized from Figure 6b; The authors report cell quotas for different size ranges of *Microcystis aeruginosa* cells and these values represent the minimum and maximum for all sizes; Mean calculated using all cell quota data reported at all time points for all sizes; Study provides highest reported mean for *Microcystis* spp. mass per cell, field and field and lab combined
	Microcystis spp.	Lake Victoria, Kenya	Field	Mean: 17 fg/cell Median: 553 fg/cell	Sitoki et al. (2012)	Sixteen *Microcystis* strains identified
	Microcystis spp.	Lake Taihu, China	Field	Mean: 0.015 pg/cell Min: 0 pg/cell Max: 0.159 pg/cell	Wang et al. (2013)	Data digitized from Figure 4a,b; Mean calculated using all cell quota data reported at all time points for all colony sizes; Study provides minimum cell quota value and lowest reported mean for *Microcystis* spp. mass per cell, field, and field and lab combined
	Microcystis spp.	Dapugang River, Lake Taihu, China	Field	Cell quota data not presented	Xue et al. (2016)	
	Microcystis spp.	Umia River, Galicia, Spain	Field	Max: 570 µg/g biomass	Alvarez et al. (2016)	Mixed bloom: *Microcystis aeruginosa*, *Scenedesmus* spp., *Kirchneriella* spp.; unclear which is predominant
	Microcystis spp.	Lake Taihu, China	Field	Mean: 640.59 µg/g biomass	Wei et al. (2016)	Data digitized from Figure 4a,b; Only microcystin-L-R

Toxin	Genus/Species[a]	Site/Clone	Study Type[b]	Toxin Quota Data[c]	Reference	Notes
				Min: 13.21 µg/g biomass Max: 1389.13 µg/g biomass		congener reported; Mean calculated using cell quota data for all time points; Study provides mean, minimum, and maximum cell quota values for *Microcystis* spp. mass per biomass, field
	Microcystis spp.	FACHB-905	Lab	Mean: 20.25 fg/cell Min: 17.05 fg/cell Max: 28.47 fg/cell	Wei et al. (2016)	Data digitized from Figure 1D and Figure 2D; Mean calculated using cell quota data for all time points
	Microcystis aeruginosa	Lake Huron, United States	Field	Mean: 140 fg/cell Mix: 10 fg/cell Max: 350 fg/cell	Fahnenstiel et al. (2008)	Study provides highest reported mean, maximum, and minimum cell quota values for *Microcystis aeruginosa* mass per cell, field, and field and lab combined
	Microcystis aeruginosa	Aguieira reservoir, Portugal	Field	Mean: 0.12 fg/cell Mix: 0.07 fg/cell Max: 0.22 fg/cell	Vasconcelos et al. (2011)	Data digitized from Figure 5; *Microcystis aeruginosa* was dominant microcystins producer; Mean calculated using all cell quota data for all yearly time points
	Microcystis aeruginosa	Lake Erie, United States	Field	Mean: 3.34 µg/mg biomass Min: 1.37 µg/mg biomass	Horst et al. (2014)	Data digitized from Figure 3 and Figure 6; Study provides mean and maximum cell quota value for *Microcystis aeruginosa* mass per biomass, field
	Microcystis aeruginosa	Hartbeespoort Dam, South Africa	Field	Min: 0.14 µg/g biomass Max: 268 µg/g biomass	Mbukwa and Mamba (2012)	Study provides minimum cell quota value for *Microcystis aeruginosa* mass per biomass, field
	Microcystis aeruginosa	BCCUSP232	Lab	Mean: 18.84 fg/cell Min: 15.07 fg/cell	Chia et al. (2016)	Data digitized from Figure 4b; Study provides lowest reported mean for

	Multiple genera including *Aphanizomenon*	Langer See, Germany	Field		Wiedner et al. (2008)	Data available but were not digitized

Abbreviations: *M.* = *Microcystis*; spp. = multiple species in the genus

[a] Both the genus and species are reported where available. In some studies, the genus was reported but the species was not reported. In other studies, multiple species were analyzed within a specific genus but the specific species were not identified. In both instances, studies were categorized as the genus name (e.g., *Microcystis*) spp. Separately, in some studies multiple genera were considered. In these studies, available toxin quota data were not digitized as they could not be used for comparison purposes. Only information about the studies are presented in this table with a note that data are available but were not digitized.

[b] Studies were conducted in two different settings: the field (i.e., environmental) or a laboratory. In some instances, field samples were subjected to optimized growth conditions in the laboratory. These studies were classified as laboratory; not as field studies.

[c] Toxin cell quota data were not converted and are reported in the measurement units used by the study authors. Significant figures were not normalized among the data points.

[d] The genus *Cylindrospermopsis* has been renamed to *Raphidiopsis*.

Table G-4 provides the first step in summarizing and grouping cell quota data for microcystin and cylindrospermopsin-producing genera. Studies presented in Table G-3 were grouped by genus and species when possible. Studies that looked at more than one species within a specific genus or that did not specify which species were considered within that genus were placed in a single group (e.g., *Microcystis* spp., *Planktothrix* spp.). Within each genus/species group, studies were further grouped based on their study type and the quantification method used in that study. For each study type and quantification method group, data were aggregated on the mean, minimum, and maximum cell quota values presented in each study included in that group. In Table G-4, the range of the means, arithmetic mean (of the means), median of the means, minimum cell quota value, and maximum cell quota value are reported for the studies included in that group. Note that studies were not identified in the literature search for all quantification methods and study types for all genus/species groups. The EPA converted data to a standard set of units, pg per cell, when possible. No other conversions were attempted. Additional information about the approach used to summarize the available cell quota data is provided in the footnotes accompanying the table.

Table G-4. Cell Quota Appendix Summary Data for Microcystin and Cylindrospermopsin-producing Genera

Toxin	Genus, Species	Quantification Method[a]; Study Type[b]	Range of Means[c,d]	Mean[c,d]	Median of Means[c,e]	Minimum; Maximum[c,f]	References

Acronyms and Abbreviations: fg = femtogram; pg = picogram; µg = microgram; N/A = not applicable.

[a] Various methods were used to quantify toxin quotas and quota values were presented in different forms, including toxin mass per cyanobacterial cell and toxin mass per cyanobacterial biomass.

[b] Studies were conducted in two different settings: the field (i.e., environmental) or a laboratory. In some instances, field samples were subjected to optimized growth conditions in the laboratory. These studies were classified as laboratory; not field.

[c] Study authors reported data using multiple measurement units. When possible, the EPA converted data to the standard units of pg per cell. The EPA did not identify appropriate conversion factors that would allow genus-specific conversion of quotas described in mass per biomass to mass per cell.

[d] Shows single reported mean if only one study was available or average of reported means.

[e] Median of means not calculated if only one mean value was available or if only minimum and/or maximum cell quota values were available.

[f] If reported toxin quota means from one study were the lowest or highest toxin quotas reported within a genus, then these values were listed as the minimum or maximum values, respectively, to better reflect the range of toxin quota values.

[g] The genus *Cylindrospermopsis* has recently been renamed to *Raphidiopsis*.

APPENDIX H. TABLES OF STATE-ISSUED GUIDELINES SPECIFIC TO ANIMAL CYANOTOXIN POISONING

H.1 California

Table H-1. California Environmental Protection Agency (2012) Action levels for Selected Pet and Livestock Scenarios

	Microcystins[a]	Cylindrospermopsin	Media (units)
Subchronic water intake, dog[b]	2	10	water (µg/L)
Subchronic crust and mat intake, dog	0.01	0.04	crusts and mats (mg/kg dw)[c]
Acute water intake, dog[d]	100	200	water (µg/L)
Acute crust and mat intake, dog	0.5	0.5	crusts and mats (mg/kg dw)[c]
Subchronic water intake, cattle[e]	0.9	5	water (µg/L)
Subchronic crust and mat intake, cattle[e]	0.1	0.4	crusts and mats (mg/kg dw)[c]
Acute water intake, cattle[e]	50	60	water (µg/L)
Acute crust and mat intake, cattle[e]	5	5	crusts and mats (mg/kg dw)[c]

[a] Microcystins LA, LR, RR, and YR all had the same RfD so the action levels are the same.
[b] Subchronic refers to exposures over multiple days.
[c] Based on sample dry weight (dw).
[d] Acute refers to exposures in a single day.
[e] Based on small breed dairy cows because their potential exposure to cyanotoxins is greatest.

Table H-2. California Environmental Protection Agency (2012) Reference Doses and Acute and Subchronic Action Levels for Canine Exposure to Cyanotoxins in Drinking Water

	Microcystin	Cylindrospermopsin
Water consumption L/kg-day	0.085	0.085
Uncertainty factor (unitless)	3	3
Acute RfD[a] mg/kg/day	0.037	0.04
Acute action level µg/L	100	200
Subchronic RfD mg/kg/day	0.00064	0.0033
Subchronic action level µg/L	2	10

NMED Exhibit 93

H.2 Indiana

Indiana has adopted guidance for cyanotoxins for dog exposures:

"A warning to dog owners using the Fort Harrison State Park Dog Park Lake will occur whenever any cyanotoxins are detected, and dogs will be prohibited from swimming at the values of 0.8 µg/L microcystin, any anatoxin-a detection, and 1.0 µg/L of cylindrospermopsin."

Indiana Department of Environmental Management (2018). Blue-Green Algae: Indiana Reservoir and Lake Update.http://www.in.gov/idem/algae/. Last Accessed: 02/27/2018.

H.3 Oregon

Table H-3. Oregon Dog-specific Guideline Values for Cyanotoxins in Recreational Waters (µg/L)

	Microcystin	Cylindrospermopsin
Dog Guidance Value	0.2	0.4

Note: All dog-specific guideline values have been changed in this revision because California EPA's estimate of the amount of water an exercising dog consumes per kilogram body weight was updated in 2012 (from 0.168 to 0.255 L/kg-day). Current dog-specific guideline values are now consistent with the California EPA update. The dog-specific value for saxitoxins was further modified by application of an uncertainty factor to the dog-specific TDI for interspecies differences in sensitivity between humans (the species in the critical study) and dogs.

H.4 Grayson County, Texas

Table H-4. Grayson County, Texas Microcystin Guidelines for Dogs

Quantity of Lake Water Ingested to Receive a Potentially Lethal Dose of Microcystin, Assuming that Mouse and Dog Toxic Responses are Equivalent

	Gallons of Water	Pounds of Water
10-pound dog	2.70	22.50
80-pound dog	21.57	180.00

Quantity of Lake Water Ingested to Receive a Potentially Lethal Dose of Microcystin, Assuming that Mouse and Dog Toxic Responses are Equivalent (at actual concentrations found in Grand Lake, Oklahoma, in June 2011) Highest measured microcystin concentration was 358 ppb.

	Gallons of Water	Pounds of Water
10-pound dog	0.15 (19.3 ounces)	1.26
80-pound dog	1.21	10.06

*This is not including additional dose amounts that could be ingested from a dog self-grooming algae scum off its fur.
**LD_{50} for microcystin-mouse used in calculations = 45 µg/kg
***20 ppb microcystin is algal toxin threshold for BGA Warning (condition red)

Quantity of Lake Water Ingested to Receive a Potentially Lethal Dose of Cylindrospermopsin, Assuming that Mouse and Dog Toxic Responses are Equivalent 20 ppb Cylindrospermopsin in Lake Water

	Gallons of Water	Pounds of Water
10-pound dog	263	2,200
80-pound dog	2,109	17,601

*This is not including additional dose amounts that could be ingested from a dog self-grooming algae scum off its fur.
**LD_{50} for cylindrospermopsin-mouse used in calculations = 4400 µg/kg
***20 ppb cylindrospermopsin is algal toxin threshold for BGA Warning (condition red)

United States Environmental Protection Agency

Office of Water
EPA **823-D-19-002**
December 2019

Draft Technical Support Document:

Implementing the 2019 Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin

NMED Exhibit 94

Notice: This technical support document contains several questions and answers relating to the Environmental Protection Agency's (EPA) *Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin*.[1] Microcystins and cylindrospermopsin are two types of cyanotoxins that are produced from photosynthetic bacteria, called cyanobacteria. Exposure to the microcystins and cylindrospermopsin can pose health risks to humans and animals. Symptoms reported after recreational exposure to cyanobacterial blooms included skin irritations, gastrointestinal illnesses, hepatomegaly and kidney damage.

The information in this document is primarily intended to support states, authorized tribes, and territories (collectively referred to as "states and authorized tribes") interested in adopting the recommended criteria into their state or tribal water quality standards (WQS) or using the recommended values as the basis for swimming advisories and related public notification purposes.[2] EPA envisions that if states or authorized tribes decide to use the values for issuing swimming advisories they might do so in a manner similar to their current recreational water advisory programs.

Chemical and physical factors in a waterbody can play a role in the composition and production of cyanotoxins associated with a toxigenic cyanobacterial bloom (such factors include, but are not limited to, levels of nitrogen and phosphorus, the availability of organic matter, turbidity, turbulence or flushing of a waterbody, light attenuation, water temperature and pH). The recommended criteria and swimming advisory values were derived based on data related to exposure factors, including the rate of incidental consumption of water while swimming and the duration of time spent recreating in water, and are recommended for waters designated for primary contact recreation. Some states and authorized tribes may experience other hazards associated with cyanobacterial blooms that are not addressed in this document (e.g., with respect to cytokines or other cyanotoxins), therefore a more holistic approach to monitoring waterbodies may be necessary to ensure public health protection.

Exposure to cyanobacteria and their toxins can also occur through non-recreational pathways such as consumption of cyanotoxin-contaminated drinking water and food (including fish), and during bathing or showering. This document does not address or provide recommendations for non-recreational exposures. Although there are no national level recommended criteria for cyanotoxins in public water supply designated uses, in 2015, EPA published health advisories for the cyanotoxins, microcystins and cylindrospermopsin in finished drinking water. For information related to the drinking water health advisories for microcystins and cylindrospermopsin, see https://www.epa.gov/ground-water-and-drinking-water/drinking-water-health-advisory-documents-cyanobacterial-toxins.

This document provides background information on the factors that contribute to cyanobacterial growth and toxin production; recommendations on how to monitor for cyanobacteria and two of their known cyanotoxins (microcystins and cylindrospermopsin) in waterbodies; and information on how to complete assessments, list impaired or threatened waters, and develop Total Maximum Daily Load (TMDLs), based

[1] USEPA (U.S. Environmental Protection Agency). 2019. *Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin 2019.* EPA 822-R-18-004. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/wqc/recommended-human-health-recreational-ambient-water-quality-criteria-or-swimming-advisories.

[2] When a bloom or the presence of cyanotoxins is confirmed, the recreational waterbody manager usually issues a public notification (either a swimming advisory or a closure of swimming areas) to raise awareness of the potential risks associated with contact with the cyanobacterial bloom or its toxins in recreational waters. Swimming advisories are recommendations to limit swimming or other recreational water-contact activities, due to an increased health risk from contact with or ingestion of the cyanobacteria or cyanotoxins; whereas, a closure notification or posting typically means that the waterbody is officially closed to the public. Decisions to post an advisory or closure for a waterbody or a beach are local decisions. Information about communicating swimming advisories or closures to the public, including sample templates, is available at Communicating about Cyanobacterial Blooms and Toxins in Recreational Waters (webpage).

on WQS that adhere to EPA's 2019 recommended criteria for total microcystins and cylindrospermopsin. While this document cites statutes and regulations that contain requirements applicable to these programs, it does not impose legally binding requirements on EPA, states, authorized tribes, other regulatory authorities, or the regulated community. EPA, states, authorized tribes and other decision makers may adopt approaches on a case-by-case basis that differ from those provided in this document, as appropriate and consistent with statutory and regulatory requirements. Also, EPA may update this document as new scientific and technical information becomes available. In addition to this document, EPA has prepared the following information to support states and authorized tribes in their efforts to monitor and respond to cyanobacterial blooms and cyanotoxins in recreational waters:

- Cyanobacterial Harmful Algal Blooms in Water (website): https://www.epa.gov/cyanohabs
- Monitoring and Responding to Cyanobacteria and Cyanotoxins in Recreational Waters
- Recommendations for Cyanobacteria and Cyanotoxin Monitoring in Recreational Waters

6. What information should states and authorized tribes consider when prioritizing which waterbodies to monitor based on risk of elevated levels of cyanotoxins? 12

7. How frequently and over what time period should states and authorized tribes collect data on cyanotoxin levels? 14

8. How should states and authorized tribes analyze and interpret cyanotoxin monitoring data and information to evaluate ambient conditions and recreational use support 15

9. What should states and authorized tribes consider when selecting an analytical method and sampling locations? 17

10. What data and information should states and authorized tribes assemble and evaluate to complete CWA water quality assessments with EPA's recommended cyanotoxin criteria? 19

11. Should states and authorized tribes update their assessment methodology to include the evaluation of cyanotoxin data and information? If so, what should be considered in these updates? 19

12. What happens if a state or authorized tribe does not have sufficient data to make an assessment determination? 20

13. What factors should be considered in defining waterbody segmentation (e.g., if dividing a waterbody into smaller assessment units for advisories and 303(d) listings)? 20

14. How should states and authorized tribes approach waterbody assessments for a waterbody that is already on the CWA section 303(d) list? 20

Implementation Questions about Water Quality Management Plans (e.g., TMDLs) 21

15. How should states and authorized tribes complete TMDLs for waterbodies that are listed under CWA section 303(d) as impaired or threatened due to cyanotoxins? 21

General Questions about Cyanotoxin Water Quality Criteria

1. What are EPA's recommended recreational water quality criteria for total microcystins and cylindrospermopsin?

In 2019, EPA issued its recreational water quality criteria recommendations for the cyanotoxins, microcystins and cylindrospermopsin, reflecting the latest scientific knowledge, public comments, and external scientific peer review. The criteria are designed to protect the public from incidental exposure to harmful levels of these cyanotoxins while participating in water-contact activities where immersion and incidental ingestion of water are likely. Such activities include but are not limited to swimming, water skiing, tubing, skin diving, water play by children, or similar water-contact activities in all waterbodies designated for such recreational uses.[3] EPA issues such recommendations under the statutory authority of the Clean Water Act (CWA), Section 304(a).

EPA's recommended recreational water quality criteria for total microcystins and cylindrospermopsin consist of three components:

- *Magnitude* — The numeric expression of the maximum amount of a pollutant that may be present in a waterbody while also protecting the designated use(s) of the waterbody. In this case, the magnitude represents the concentration of total microcystins (8 µg/L) or cylindrospermopsin (15 µg/L) in the water column that is not expected to result in adverse human health effects from short-term recreational exposure to the cyanotoxins via incidental ingestion while recreating (e.g., swimming), based on children's exposure parameters.
- *Duration* — Duration is the period of time over which the magnitude is calculated. Exposure to recreational waters containing microcystins or cylindrospermopsin at or below the recommended magnitude concentrations over the short-term ten-day duration would not be expected to result in the adverse health effects discussed in health effects assessment (Section 5) of the criteria document.
- *Frequency* of excursion — The number of times the contaminant may be present above the recommended criteria concentration (magnitude) over the specified period (duration). For these criteria, the frequency corresponds to how often (within a single recreational season, *and across* multiple recreational seasons) the concentration of total microcystins or cylindrospermopsin in a waterbody may exceed the magnitude concentration and be protective of the designated use. The recommended frequency within a single recreational season is no more than three excursions. The number of years that a pattern of more than three excursions can occur *across* recreational seasons and still deemed to be protective of the designated use—referred to in Question 3 as the *recurrence frequency*—is a risk management decision, to be made by a state or authorized tribe. If a state or authorized tribe chooses to adopt the recommended criteria into its state or tribal WQS, EPA recommends that the state or authorized tribe include this recurrence frequency number in its WQS (see Table 1, note b).

EPA developed the following criteria values for total microcystins and cylindrospermopsin concentrations for states and authorized tribes to consider as the basis for human health protection in primary contact recreational waters (see Table 1 for a summary of the magnitude, duration and frequency).

[3] For information about the scope and applicability of recreational criteria, see EPA's 2012 *Recreational Water Quality Criteria*, (Section 2.0 Applicability and Scope). Office of Water 820-F-12-058. https://www.epa.gov/sites/production/files/2015-10/documents/rwqc2012.pdf

Table 1. Recreational Water Quality Criteria Recommendations for Microcystins and Cylindrospermopsin [a]

Total Microcystins Magnitude (µg/L)	Cylindrospermopsin Magnitude (µg/L)	Duration	Frequency
8	15	1 in 10-day assessment period across a recreational season	Not more than 3 excursions in a recreational season in more than one year [b]

[a] States and authorized tribes can choose to adopt one or both criteria recommendations.

[b] An excursion is defined as a 10-day assessment period with any toxin concentration higher than the criteria magnitude. When more than three excursions occur within a recreational season and that pattern reoccurs in more than one year, it is an indication the water quality has been or is becoming degraded and is not supporting its recreational use. As a risk management decision, states and authorized tribes should include in their WQS an upper-bound frequency stating the number of years that pattern can reoccur and still support its recreational use.

Cyanobacterial blooms can occur naturally but can be an uncommon event due to a convergence of climatic and other environmental factors that result in a single short-term bloom lasting days or a couple of weeks. In some cases, multiple blooms can occur in a single year. Alternatively, longer-term cyanobacterial blooms can occur regularly in some waters lasting for a few weeks, months, or possibly all year. Cyanobacterial blooms can occur while conditions conducive to cyanobacterial proliferation exist and limit the use of the waterbody for primary recreation. The criteria components listed in Table 1, above, can help to identify a short- or long-term temporal trend or a spatial distribution pattern of cyanotoxin excursions that can be used to evaluate a waterbody.

EPA recognizes there are multiple environmental factors that can cause variability in bloom formation and toxin production, and that some years may produce HABs that occur for long periods, or HABs of shorter duration that occur repeatedly throughout a single recreational season, but such events may not occur every year. Therefore, EPA concludes that it is appropriate to consider a pattern of multiple excursions within a recreational season as well as a pattern of excursions in multiple years (i.e., more than one year) when determining whether the use is attained. It is important to note that the years with multiple excursions do not have to be consecutive to indicate a water-quality problem. The upper bound frequency (e.g., one year out of three years) is a risk management decision that states and authorized tribes need to determine when developing their WQS. States and authorized tribes should include the number of years a pattern of cyanotoxin excursions can occur for the recreational use to be supported.

EPA recommends that if toxin concentrations are higher than the criterion magnitude in a sample collected during a ten-day assessment period, then that period should be considered an excursion from the recreational criteria. A short-term cyanobacterial bloom that does not reoccur can result in a small number of excursions of the criteria but is not expected to result in impairment of the recreational use. Such cyanobacterial blooms may result from conditions that occur naturally (e.g., as a result of unusually hot conditions), but not frequently. EPA recommends that when more than three excursions (an exceedance during the ten-day assessment period) occur within a recreational season *and* that pattern reoccurs in more than one year, it is an indication that the water quality is or may be becoming degraded such that the waterbody may no longer support the recreational use. Multiple excursions over a single recreation season indicates that a waterbody may not support a recreational use for a significant proportion of the season. EPA recommends that a concentration of 8 µg/L total microcystins or 15 µg/L cylindrospermopsin not be exceeded in more than three ten-day assessment periods over the course of a recreation season in more than one year. EPA does not recommend averaging sampling data to determine an excursion, because averaging does not give a clear picture of the pattern of cyanobacterial bloom formation and cyanotoxin exposure to the population using the waterbody for recreational purposes.

The number of years over which time an observed pattern (of three or more ten-day excursions during a recreational season) can occur across recreational seasons is a risk management decision that states and

authorized tribes should consider when developing their criteria. States and authorized tribes should include the number of years a pattern of cyanotoxin excursions can occur for the use to be supported in their WQS. Furthermore, states and authorized tribes may make different risk management decisions for different types of waterbodies. EPA recommends states and authorized tribes clarify these differences in their WQS. For more information about how the criteria were developed, see: https://www.epa.gov/wqc/recommended-human-health-recreational-ambient-water-quality-criteria-or-swimming-advisories.

2. How can EPA's recommended recreational water quality criteria values for total microcystins and cylindrospermopsin be used for swimming advisories?

State, tribal or local governments can use swimming advisories to provide information to recreators on their potential exposure to cyanobacteria and their toxins. EPA envisions that if states or authorized tribes decide to use the values as swimming advisory values, they can manage a cyanotoxin monitoring and advisory program in the same way as they manage any already existing recreational water advisory programs (i.e., those for *E. coli* or enterococci). States and authorized tribes may choose to apply either or both recommended magnitude values as the basis for swimming advisories (i.e., public notifications) for recreational waterbodies. For this purpose, EPA recommends that the magnitude (i.e., 8 µg/L total microcystins or 15 µg/L cylindrospermopsin) not be exceeded on any given day.

Table 2. Swimming Advisory Recommendations for Microcystins and Cylindrospermopsin[a]

Total Microcystins Magnitude (µg/L)	Cylindrospermopsin Magnitude (µg/L)	Duration	Frequency
8	15	One day	Not to be exceeded

EPA recognizes that some states and authorized tribes may handle swimming advisories through their health departments and not through their environmental quality departments. As a result, inter-departmental coordination may be helpful to implement an advisory program which can also serve to inform drinking water providers and water quality practitioners. EPA has provided an example Cyanobacteria Bloom Response Contact List on its website to help state or tribal employees consider who to contact in the event of a cyanobacterial bloom.

Swimming advisories can be used to provide information to recreators on their potential exposure to cyanobacteria and their toxins. Some local and state governments currently post notifications for swimmers, in the form of advisories or warnings, when a cyanobacterial bloom is reported in recreational waters or when cyanotoxin levels exceed swimming advisory thresholds.

If using the recommended values for public notification purposes (swimming advisory or beach closure), EPA recommends that the relevant authority (typically a local health department official or environmental protection agency) notify the public whenever a sample exceeds the recommended criteria concentration value. EPA also recommends that an exceedance of the recommended criteria concentration result in a swimming advisory being issued until subsequent sampling results show that the toxin concentration has fallen below the recommended magnitude value of the criteria. By increasing the monitoring frequency at a site where a swimming advisory is issued, recreational waterbody managers will get a clearer understanding of the temporal and spatial nature of toxins that can be useful in making management decisions to protect the recreational use, including when to remove an advisory.

EPA also recognizes that environmental conditions may change rapidly from one sample period to the next, depending on the frequency of samples taken. For an example of how the state of Ohio uses toxin concentration results to make swimming advisory decisions, see the Example 1 text box below. Appendix B of the criteria document summarizes available information on state recreational water guidelines for

cyanotoxins and cyanobacteria (see: https://www.epa.gov/wqc/recommended-human-health-recreational-ambient-water-quality-criteria-or-swimming-advisories.

Example 1: State of Ohio example of a tiered approach to public notifications

The Ohio Environmental Protection Agency collaborated with the Department of Natural Resources and the Department of Health to develop a tiered notification system which takes different actions based on different numeric thresholds for cyanotoxin concentrations in recreational waters. That is, the state takes various actions—such as posting information about harmful algal blooms (HABs), issuing a recreational public health advisory, or temporarily closing recreational waters through a no contact advisory—depending on the severity of the bloom event.

Toxin of concern	Informational sign postings about HABs at recreational waters	Recreational public health advisory	Elevated recreational public health advisory (e.g. no contact)
Microcystin-LR	< 6 µg/L	6 µg/L	20 µg/L
Cylindrospermopsin	< 5 µg/L	5 µg/L	20 µg/L

Once an advisory is posted, Ohio conducts a standard sampling protocol for cyanotoxins and lifts the advisory once two consecutive samples taken at least one week apart show cyanotoxins have decreased below the advisory threshold. For more information, see the *State of Ohio Harmful Algal Bloom Response Strategy for Recreational Waters* (Ohio EPA, 2016).

EPA has published materials for recreational waterbody managers responsible for monitoring and responding to cyanobacterial blooms. These materials include a communication toolbox with examples of public messages, press releases, and warning and posting signage that recreational waterbody managers may use to inform the public of increased health risks associated with exposure to cyanobacteria and their toxins. In addition, EPA has provided recommendations for public health officials or waterbody managers (or relevant state, local or tribal officials) to consider various water monitoring, sampling and testing methods to determine whether a cyanobacterial bloom is producing toxins, whether the bloom presents an increased risk to water-contact recreators and human health, and whether immediate actions should be taken to notify the public if a closure is recommended based on waterbody test results.

3. What flexibilities do states and authorized tribes have when they choose to adopt recreational water quality criteria for total microcystins and cylindrospermopsin?

When states or authorized tribes choose to adopt EPA's *Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin*, states and authorized tribes have flexibility to accommodate specific water quality-related circumstances while meeting the requirements of the CWA and the WQS regulation. In addition to considering the Agency's national recommended water quality criteria when revising their WQS, states and authorized tribes may adopt, where appropriate, other scientifically defensible criteria that differ from EPA's recommendations. For example, states and authorized tribes can:

- *Define the length of the recreational season.* States and authorized tribes can adopt seasonal designated uses of a waterbody with respect to various 304(a) recommended criteria, including the recommended criteria for total microcystins and cylindrospermopsin. Therefore, for states

and authorized tribes that have adopted seasonal uses, the recommended cyanotoxin criteria would apply only to the primary contact recreation season. 40 CFR 131.10(f) specifies that states and authorized tribes "may adopt seasonal uses as an alternative to reclassifying a waterbody or segment thereof to uses requiring less stringent water quality criteria. If seasonal uses are adopted, water quality criteria should be adjusted to reflect the seasonal uses, however, such criteria shall not preclude the attainment and maintenance of a more protective use in another season." The length of a "recreational season" is an important consideration because states and authorized tribes would likely monitor the quality of their highest-priority recreational waters throughout the recreational season (for more on prioritizing waterbodies for assessments, see Question 6). For purposes of establishing seasonal WQS, a change to the recreational season constitutes a change to the state's or authorized tribe's designated use in their WQS under 40 CFR 131.10(f) and would need to be reviewed and approved by EPA pursuant to section 303(c) of the CWA. Because local health departments or departments of parks and recreation may define the recreational seasons for inland waterbodies, it is important for states and authorized tribes to coordinate with these local authorities when identifying the length of the state's or tribe's recreational season in WQS.

- *Define a recurrence frequency.* The criteria for total microcystins and cylindrospermopsin recommend that the magnitude values should not be exceeded in *more than three ten-day periods per recreational season in more than one year*, but the criteria do not specify an upper-bound number of years that pattern can occur across recreational seasons (i.e., a recurrence frequency). This provides states and authorized tribes the flexibility to define a recurrence frequency. For example, some states or authorized tribes might count the recurrence frequency over a rolling 5-year period while others choose to count over a rolling 10-year period.

  If a state or authorized tribe chooses to adopt the recommended criteria, EPA expects the state or tribe to also include this recurrence frequency in its WQS. A state or authorized tribe may achieve this with a written statement in its standards. An example written statement could say, *"The concentration of total microcystins shall not exceed 8 µg/L in more than three ten-day periods per recreational season, for more than one recreational season, over a 5-year period."*

- *Derive site-specific criteria elements*. States and authorized tribes may adopt EPA recommended criteria or may modify the criteria to fit their unique situation based on site-specific data and information. For example, a state or tribe may derive site-specific criteria based, in part, on information about the exposure variables among the population that uses the waterbody (e.g., age and incidental ingestion rates) or to allow for specific cultural or land use practices at or near the site. The site-specific criteria must be scientifically defensible and protective of the designated use of the state's or tribe's waterbodies and approved by EPA pursuant to section 303(c) of the CWA.

- *Revise the designated uses of waterbodies within their state*. If a state or authorized tribe finds that attaining one of the designated CWA section 101(a)(2) uses[4] in its standards is not feasible, the state or authorized tribe may remove or modify the designated use based on appropriate use attainability analysis and documentation subject to EPA's review and approval. Therefore, if the recreational criteria for total microcystins or cylindrospermopsin cannot be attained, the state or authorized tribe can consider whether to modify or remove the designated use.

[4] Uses that provide for the protection and propagation of fish, shellfish, and wildlife, and recreation in and on the water, as well as for the protection of human health when consuming fish, shellfish, and other aquatic life (e.g. recreation use, aquatic life use).

4. What is the relationship between cyanobacterial blooms and the recommended criteria?

Cyanobacteria, commonly referred to as blue-green algae, are photosynthetic bacteria that occur naturally in waters, including waters used for primary contact recreation. Under certain conditions, cyanobacteria may grow rapidly to form accumulations known as cyanobacterial blooms. When the proliferation of cells making up the bloom also contains toxin-producing strains of cyanobacteria, there is the potential to have elevated concentrations of the cyanotoxins, microcystins and cylindrospermopsin, present. Generally referred to as a harmful algal blooms (HABs), these toxin-producing cyanobacterial blooms can cause harm to animals, people, or the environment. Accumulations of cyanobacteria have been associated with outbreaks of inflammatory illness (e.g., rashes) unrelated to the production of cyanotoxins.

Some states have chosen to adopt a value based on cell density as a screening tool, with further tests for specific toxins after confirming that a bloom is present. EPA did not develop recommended criteria or swimming advisories based on cyanobacterial cell density; however, the Agency summarized available information on adverse effects that may result from exposure to cyanobacterial cells and estimated a cell density value corresponding to the toxin-based criteria magnitude. For more information on the health effects from exposure to cyanobacterial cells, go to:

- Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin (see section 7.5 Cyanobacterial Cells)

Exposure to the toxins, microcystins and cylindrospermopsin, can pose additional health risks to humans and animals. Symptoms reported after recreational exposure to cyanobacterial blooms (including microcystin-producing genera) included skin irritations, allergic reactions or gastrointestinal illnesses. Symptoms of exposure to cylindrospermopsin have been reported to include fever, headache, vomiting, bloody diarrhea, hepatomegaly and kidney damage with the loss of water, electrolytes and protein.

For more information on the health effects from exposure to microcystins and cylindrospermopsin, go to:

- Health Effects Support Document for the Cyanobacterial Toxin Microcystins
- Health Effects Support Document for the Cyanobacterial Toxin Cylindrospermopsin

The presence of cyanobacteria does not necessarily mean that cyanotoxins are being produced, and conversely, cyanotoxins can be present at levels above the criteria magnitude when accumulations of cyanobacteria were not observed.[5] Benthic cyanobacteria, occurring at the bottom of the waterbody, may not be visible from the surface, but may still produce toxins.

For information on identifying blooms and specific cyanobacteria, go to:

- USGS Field and Laboratory Guide to Freshwater Cyanobacteria Harmful Algal Blooms for Native American and Alaska Native Communities.

5. Why should I consider nutrient pollution if I am implementing criteria for cyanotoxins?

Nitrogen and phosphorus loadings, or nutrient pollution input into recreational waterbodies from agricultural, industrial, and urban sources can provide optimal conditions for cyanobacterial blooms and cyanotoxin production. Preventing nutrient input and reducing nitrogen and phosphorus levels in a waterbody can help to reduce the occurrence of cyanobacterial blooms or the levels of cyanotoxins in blooms containing toxin-producing strains of cyanobacteria.[6]

The relationships between nutrients and other physical, chemical or environmental conditions is complex and can present an added challenge to recreational waterbody managers responsible for monitoring and responding to cyanobacterial blooms. In addition to nutrient concentrations, factors such as the availability of organic matter, turbidity, turbulence or flushing of a waterbody, light attenuation, temperature and pH can play a role in the composition and cyanotoxin production associated with a cyanobacterial bloom.

The sources of nutrients present in waterbodies are both natural and anthropogenic. Soil and erosion of phosphorus-containing rocks are the most significant natural sources of the phosphorus in surface waters, while bed sediment resuspension can be the major source of phosphorus to the lower water column. Significant natural sources of nitrogen include fixation of nitrogen gas, N_2, and dry and wet deposition of nitrogen compounds from the atmosphere. Human-induced nutrient pollution comes from several sources:

1. Stormwater runoff (e.g., urban and rural) contains nitrogen and phosphorus from fertilizers (especially those applied in excess or before a rain storm), yard clippings, leaves, and pet wastes that are washed away to local waterbodies or conveyed through storm sewer systems.
2. Municipal wastewater discharges (including septic systems) process billions of gallons of wastewater every day. Municipal wastewater contains nitrogen and phosphorus from human waste, food, and certain soaps and detergents.
3. Industrial wastewater discharges from industrial facilities, such as food processing and fertilizer manufacturing facilities, are sources of nitrogen and phosphorus.
4. Agricultural practices, including concentrated animal feeding operations and row crops, are sources of nitrogen and phosphorus. Other sources include: animal waste, gaseous nitrogen-based compounds like ammonia and nitrogen oxides released to the atmosphere from ventilated production houses, manure storage structures, or fields where manure (or other fertilizers) is applied and re-deposited onto land and eventually washes into surface waters.

Reductions in nutrient pollution help to reduce the occurrence of cyanobacterial blooms and waterbody eutrophication. Studies have shown that excess nitrogen can stimulate the growth of the cyanobacteria, *Microcystis*.[7] Elevated concentrations of total and dissolved phosphorus and soluble phosphates and nitrates provide optimal conditions for the increased production of microcystins. Controlling phosphorus and nitrogen inputs could reduce the biomass of cyanobacteria in the system, and the frequency and concentration of microcystins produced.

The World Health Organization: Guidelines for Safe Recreational Water Environments (PDF) contains a

chapter on algae and cyanobacteria in fresh water, which includes short- and long-term management options—including nutrient management and implementation of control and abatement technologies, among other practices—with the goal of preventing or reducing the occurrence of cyanobacterial blooms in recreational waters.

As a long-term strategy to address eutrophication and cyanobacteria blooms, states and authorized tribes may consider adopting numeric nutrient criteria into their WQS or, alternatively, develop a numeric target to implement a narrative nutrient criterion that has already been adopted into their WQS. Numeric nutrient criteria or targets are useful as efficient and effective tools to support water quality assessments, watershed protection or restoration, TMDL development and permitting programs, where applicable. Specifically, numeric nutrient criteria or targets sets the foundation for states and authorized tribes to develop environmental baselines, manage water quality more effectively, measure progress, and support broader implementation initiatives (such as water quality trading, best management practices (BMPs), land stewardship, wetlands protection, voluntary collaboration, and stormwater runoff control strategies). EPA stands ready to provide technical assistance to states and authorized tribes who are developing numeric nutrient criteria or targets for different waterbody types through EPA's N-STEPS program.[8]

EPA continues to provide scientific and technical assistance to states and authorized tribes who are working to reduce nutrient pollution as a means of reducing the occurrence of cyanobacterial blooms. Implementation Questions about Monitoring, Assessment and Listing

6. What information should states and authorized tribes consider when prioritizing which waterbodies to monitor based on risk of elevated levels of cyanotoxins?

Recognizing the potential risks of exposure to cyanotoxins, states and authorized tribes across the country are monitoring for cyanobacteria (as a potential precursor to blooms), microcystins, cylindrospermopsin, or other algal toxins. Some states and authorized tribes have reported microcystins data through the Water Quality Portal, an interagency website that provides public access to water quality data.[9] Reporting data on cyanobacterial blooms and toxin levels can improve transparency with the public and help to provide a regional or national understanding of where blooms are taking place.

[8] https://www.epa.gov/nutrient-policy-data/n-steps
[9] https://www.waterqualitydata.us/

States and authorized tribes are encouraged to upload microcystins data to the Water Quality Portal (see: https://www.waterqualitydata.us/).

EPA recommends that states and authorized tribes prioritize their waterbodies, for monitoring purposes, based on risk factors relevant to the likelihood of a cyanotoxin or HABs event and its relative impact to recreational users of each waterbody. Prioritizing which waterbodies to monitor can help to direct often limited resources where they will be most effective.

States and authorized tribes may also consider their capacity to include cyanobacterial indicators as part of a robust monitoring and assessment program necessary to evaluate the condition of their waterbodies. Some states and authorized tribes consider existing phytoplankton data or use satellite imagery as a screening tool to identify waters that may need additional sampling.[10] States and authorized tribes may also use field test kits to screen for waters with elevated toxins before collecting a sample. States and authorized tribes are encouraged to collaborate with a range of state, tribal and local agencies, waterbody managers and citizen science/volunteer monitoring organizations to monitor local waterbodies, leveraging the presence of local resources to collect and analyze samples in a timely and appropriate manner for risk management and response activities.

CWA practitioners, public health officials, and other waterbody managers may consider a variety of information when prioritizing which waterbodies to monitor for potential cyanotoxins. Some of the factors listed below may help state, tribal and local officials to identify which waterbodies are most vulnerable:

- the type of waterbody, and types and numbers of recreational users;
- past/historical occurrence of HABs and cyanotoxin production;
- seasonal patterns of cyanobacterial blooms (influenced by temperature and precipitation, among other factors);
- point and nonpoint sources of contamination (especially nutrients) in the waterbody and in the watershed;
- physical and hydrologic factors (e.g., depth, fetch,[11] light attenuation, availability of organic matter, turbidity, pH and nutrients);
- chlorophyll-a and phycocyanin[12] levels (e.g., cell densities);
- other water quality limitations or impairments; and,
- any other information gathered as part of source water assessments or sanitary surveys.

EPA has developed materials to assist recreational waterbody managers interested in monitoring for and responding to cyanobacteria and cyanotoxins in recreational waters. In addition, EPA has provided recommendations for various water sampling and testing methods to determine whether a cyanobacterial bloom is producing cyanotoxins, whether the bloom presents a risk to human health, and whether actions should be taken to notify the public and reduce public health risks from various recreational uses of a waterbody, including if a closure is recommended.

- Monitoring and Responding to Cyanobacteria and Cyanotoxins in Recreational Waters.

[10] For a list of state recreational water guidelines relating to cyanobacteria or cyanotoxins, see Appendix B of the criteria document, https://www.epa.gov/wqc/recommended-human-health-recreational-ambient-water-quality-criteria-or-swimming-advisories.

[11] Fetch refers to the area of a lake surface over which the wind blows in an essentially constant direction, thus generating waves. The term also is used as a synonym for fetch length, which is the horizontal distance over which wave-generating winds blow.

[12] Phycocyanin is a pigment present in cyanobacteria.

- Recommendations for Cyanobacteria and Cyanotoxin Monitoring in Recreational Waters (PDF).

The following additional sources of information may inform states and authorized tribes when taking a risk-based approach to prioritizing recreational waterbodies.

- Cyanobacteria Assessment Network, CyAN: EPA's Office of Research and Development, the National Aeronautics and Space Administration (NASA), the National Oceanic and Atmospheric Administration (NOAA) and United States Geological Survey (USGS) are collaborating to provide interactive maps based on satellite imagery and data on chlorophyll-a levels in large waterbodies nationwide.[13]
- Field and Laboratory Guide to Freshwater Cyanobacteria Harmful Algal Blooms for Native American and Alaska Native Communities: This 2015 guide, produced by the USGS, provides field images to help differentiate between cyanobacterial blooms (some of which produce toxins), non-toxic algal blooms, and floating plants that might be confused with algae.
- Water Quality Portal: The National Water Quality Monitoring Council, USGS and EPA sponsor the Water Quality Portal, an interagency website that provides public access to water quality data collected by over 400 federal, state, tribal, and local agencies.
- Other resources may be found in pages 5 through 7 of EPA's document, Recommendations for Cyanobacteria and Cyanotoxin Monitoring in Recreational Waters (PDF).

7. How frequently and over what time period should states and authorized tribes collect data on cyanotoxin levels?

States and authorized tribes have discretion and flexibility when establishing a monitoring program for cyanotoxins. For example, states and authorized tribes may prioritize which waterbodies they monitor and how frequently they monitor those waterbodies (for information on prioritization, see Question 6). Baseline monitoring could include routine monitoring (e.g., weekly monitoring over the course of a recreation season), responsive/episodic monitoring (e.g., initiating sampling in response to a physical bloom or reported potential negative health impact to animals or humans), or a combination of the two. EPA recommends that states and authorized tribes use their monitoring strategy or annual workplans to identify the monitoring approach that will be implemented for the recreational season, considering available resources and the potential use of tools, such as remote sensing and citizens' volunteer monitoring.

[13] Algorithms to assess bloom frequency and severity have been developed; however, current satellite resolution and sensing capabilities limit the ability to apply the CyAN assessment methods on a national scale. Satellites with the highest resolution, such as Landsat, can capture 62% of lakes greater than 1 ha (2.47 acres) and 95% of the lakes with public drinking water intake locations. Unfortunately, these satellites make less frequent flyovers and are not equipped with sensors capable of distinguishing CyanoHABs from other types of HABs. Lower resolution satellites capture less than 1% of waterbodies and only 33% of drinking water intakes but make more frequent flyovers and can identify CyanoHABs. For more information, see:

Urquhart et al. *A method for examining temporal changes in cyanobacterial harmful algal bloom spatial extent using satellite remote sensing*. Harmful Algae, 67 (2017), pp. 144-152. https://doi.org/10.1016/j.hal.2017.06.001

Clark et al. *Satellite monitoring of cyanobacterial harmful algal bloom frequency in recreational waters and drinking water sources*. Ecological Indicators, 80 (2017), pp. 84-95. https://doi.org/10.1016/j.ecolind.2017.04.046

Stumpf et al. Challenges for mapping cyanotoxin patterns from remote sensing of cyanobacteria. Harmful Algae, 54 (2016), pp. 160-173. https://doi.org/10.1016/j.hal.2016.01.005

Following initial detection and confirmation of microcystins or cylindrospermopsin in waterbodies designated for primary contact recreation, EPA recommends more frequent monitoring until the bloom subsides or the cyanotoxin levels no longer exceed the cyanotoxin criteria magnitude level. Once the cyanotoxins have subsided, EPA suggests that regular monitoring of prioritized waterbodies continue for the duration of the recreation season.

For more information about monitoring for cyanotoxins, see EPA document:

- Recommendations for Cyanobacteria and Cyanotoxin Monitoring in Recreational Waters

8. How should states and authorized tribes analyze and interpret cyanotoxin monitoring data and information to evaluate ambient conditions and recreational use support?

The recommended ten-day duration component of the criteria naturally translates into use of ten-day assessment periods over the course of a recreation season to evaluate ambient waterbody condition and recreational use attainment. EPA recognizes that some states and authorized tribes have routine daily, weekly, biweekly, or monthly sampling schedules in place for different water bodies and recreational areas. Monitoring at other waterbodies may be event driven in response to a bloom. EPA recommends more frequent sampling if a bloom is detected, particularly if it is documented to have toxin levels that exceed the criteria magnitude.

Weekly monitoring may provide two samples within the ten-day assessment period, or weekly monitoring may provide data for two consecutive ten-day assessment periods (depending on how the weeks and ten-day periods align). If one or more samples are collected within the ten-day assessment period that exceed the criteria magnitude, these are counted as a single excursion. Biweekly or monthly sampling schedules can also be considered with respect to ten-day assessment periods, recognizing that some states and authorized tribes may choose to use fixed, *a priori* intervals while others may begin a ten-day period with the first sample that exceeded the criteria magnitude.

States and authorized tribes have flexibility delineating the ten-day assessment periods within their recreational season. The Example 2 text box is provided to illustrate how exceedances can count towards excursions when assessing use attainment. For the application of these criteria, an exceedance is defined as an instance when the monitoring data indicates a concentration of microcystins or cylindrospermopsin that is higher than the recommended magnitude value, and an excursion is defined as an instance of one or more exceedances within a ten-day assessment period that corresponds to the duration. The calendar figures in Example 2 illustrate two ways states and authorized tribes could set up their ten-day assessment periods, either by blocking out ten-day periods before the start of the recreation season (Example 2A) or by marking ten-day assessment periods from the date a bloom is detected and an exceedance is confirmed (Example 2B).

Example 2: Examples of How a State or Tribe Might Count Exceedances and Excursions

The following examples illustrate two hypothetical scenarios describing the evaluation of exceedances and determination of excursions for the ten-day duration period. These scenarios are intended to demonstrate how the number of excursions can be counted within a given recreation season. The red X shown on the example calendars denote days where cyanotoxin monitoring results were above the recommended cyanotoxin magnitude (exceedances). The shaded boxes represent ten-day assessment periods. An assessment period with one or more exceedances is counted as an excursion.

Example 2A: Predetermined Monitoring Schedule

June

Sunday	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday
1	2	3	4	5	6	7
8 X	9 X	10 X	11 X	12	13	14
15	16	17	18	19	20	21 X
22 X	23 X	24	25	26	27 X	28 X
29	30					

Example 2A. In this example, the state or authorized tribe establishes regularly-scheduled monitoring to begin on June 1, and on June 8 monitoring results showed an exceedance of the cyanotoxin magnitude. Subsequent monitoring showed exceedances June 9, 10 and 11, and later in the month on June 21, 22 and 23, and June 27 and 28. In this case, the nine exceedances equate to three excursions because the exceedances were detected across three separate ten-day assessment periods.

Example 2B: Responsive Ten-Day Periods

June

Sunday	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday
1	2	3	4	5	6	7
8 X	9 X	10 X	11 X	12	13	14
15	16	17	18	19	20	21 X
22 X	23 X	24	25	26	27 X	28 X
29	30					

Example 2B. In this example, the state or authorized tribe monitors for cyanotoxins in response to a suspected bloom, once the monitoring data indicates a concentration of microcystins or cylindrospermopsin that is higher than the recommended magnitude. On June 8 a suspected bloom was confirmed and monitoring results showed an exceedance of the cyanotoxin magnitude. Subsequent monitoring showed exceedances June 9, 10 and 11. A second bloom was suspected later in the month and confirmed through additional monitoring showed exceedances on June 21, 22, 23, 27 and 28. In this case, the nine exceedances equate to two excursions because the exceedances were detected across two separate ten-day periods.

9. What should states and authorized tribes consider when selecting an analytical method and sampling locations?

When selecting a method to monitor for cyanotoxins, states and authorized tribes should consider cost and practicality of various monitoring methods, and reliability and comparability of results, among other factors. More than 100 microcystin congeners are known to exist, although the majority of toxicological data on the effects of microcystins are available for microcystin-LR (a frequently monitored congener). Therefore, EPA established its recommended criterion for microcystins based on microcystin-LR and used it as a surrogate for other microcystin congeners. Two congeners of cylindrospermopsin have been identified. Analytical methods must be sufficiently sensitive to detect the cyanotoxins in question at concentrations below the criteria magnitude. Analytical results may vary depending on the analytical methods used.

Methods vary widely in sensitivity, rapidity, cost, and ease of use. As described below, there are both rapid screening tests and laboratory methods used to detect and identify cyanobacterial cells; determine the presence, absence, or count of individual congeners; or measure the concentration of total cyanotoxins in a water sample. In waterbodies that have been prioritized for monitoring, it may be cost effective to use field test kits at several locations throughout the waterbody prior to selecting samples for lab-based analysis (see below for description of field test kits). Some analytical methods measure the sum of all congeners while other methods measure specific congeners of interest. Each method has specific requirements for sample preparation/processing and analytical standards. These should also be considered when planning monitoring programs. EPA does not recommend any single method to monitor

for cyanotoxins and refers readers to the National Environmental Methods Index (https://www.nemi.gov/home/) for information on analytical methods.

Methods for quantifying cyanotoxins (total or individual congener concentrations) include:

- Lab-based enzyme–linked immunosorbent assay (ELISA) methods, to measure cyanotoxins in question. The ELISA method is typically run with only a microcystin-LR standard for comparison but can quantify a broad range of microcystin congeners (especially if using an ADDA-based antibody) and other compounds that are similar to microcystin congeners (e.g., nodularin).
- Field test kits (e.g., Abraxis test strip, Envirologix QualiTube). These field-based methods do not require laboratory instrumentation and can produce semi-quantitative results within about an hour; however, their relatively high limit of quantification (approximately 1-10 µg/L) may better suit these methods for screening purposes.
- Protein phosphatase inhibition assay (PPIA). This method has varying degrees of specificity depending on its substrate composition and may react to compounds in the sample, other than microcystins.
- High performance liquid chromatography (HPLC) combined with ultraviolet/photodiode array detectors (UV/PDA). This method requires known toxin standards to be run alongside the water sample(s) to quantify the toxin concentration(s) and its results are limited to only those congeners for which standards are available and analyzed. LC-UV methods are based on a non-selective detector and co-eluting interferents can prevent accurate identification of components and quantitation. It is less sensitive than mass spectrometry methods (see below).
- Liquid chromatography/tandem mass spectrometry (LC/MS/MS).[14] Like HPLC-PDA, this method typically requires known toxin standards to be run alongside the water sample(s) to quantify the toxin concentration(s) and its results are limited to only those congeners for which standards are available and analyzed. It is, however, the most precise method for quantitation of analytes (such as specific microcystin variants) if standards are available. May require use of solid phase extraction for analytes with weak product ion abundance (microcystins). The LC-MS/MS MMPB (2-methyl-3(methoxy)-4-phenylbutyic acid) method, however, analyzes the chemically cleaved ADDA group common to all microcystin variants and provides an alternative LC-based approach for analyzing total microcystins. The MMPB method may also detect microcystins break-down products and could potentially overestimate total microcystins concentrations in some settings.

EPA recognizes that several states or authorized tribes may monitor for cyanobacterial cell densities in addition to, or in lieu of, monitoring for cyanotoxins. Two methods for quantifying cyanobacterial cells include microscopy and quantitative polymerase chain reaction (qPCR) and microarrays/DNA chips.

Like other aspects of monitoring programs, decisions on sample location are guided by the management questions being addressed. For example, when monitoring recreational waters for public health protection, it's reasonable to target sample collection toward capturing the highest potential exposure risks; therefore, EPA recommends that states and authorized tribes collect single grab samples from designated swimming areas, near the shoreline, or composite samples from points within the splash zones where children play. Monitoring for other objectives may result in sampling at other areas of a waterbody (e.g., if sampling for source water protection, rather than the protection of recreational

[14] For more information on single laboratory validated methods for detecting cyanotoxins in freshwaters by LC/MS/MS, see (1) https://www.epa.gov/water-research/single-laboratory-validated-method-determination-cylindrospermopsin-and-anatoxin to detect cylindrospermopsin and anatoxin-a, and (2) https://www.epa.gov/water-research/single-laboratory-validated-method-determination-microcystins-and-nodularin-ambient to detect microsystins and nodularin (combined intracellular and extracellular).

uses).

EPA has produced technical materials to aid in the development of cyanobacteria and cyanotoxin monitoring programs, including information on available testing methods and sampling logistics. See materials at:

- For recommendations related to establishing a sampling and monitoring program, see: https://www.epa.gov/cyanohabs/recommendations-cyanobacteria-and-cyanotoxin-monitoring-recreational-waters;
- For a summary of methods used to detect cyanobacteria and cyanotoxins in water, see: Determination of Cyanotoxins in Drinking and Ambient Freshwaters; and,
- For a set of frequently asked questions related to laboratory analysis for microcystins in drinking water, see: Frequently Asked Questions: Laboratory Analysis for Microcystins in Drinking Water.

10. What data and information should states and authorized tribes assemble and evaluate to complete CWA water quality assessments with EPA's recommended cyanotoxin criteria?

States and authorized tribes are required under 40 CFR 130.7(b)(5) to assemble and evaluate all existing and readily available water quality-related data and information when determining which waterbodies belong on the state's or authorized tribe's CWA section 303(d) list of impaired and threatened waters. For states and authorized tribes that have adopted the recommended recreational criteria for total microcystins and cylindrospermopsin and are interested in assessing against the criteria, "readily available data and information" would include observed concentration levels for microcystins and cylindrospermopsin collected by the state, authorized tribe, or other stakeholders (e.g., citizen science water monitoring groups).

In addition to observed concentration levels of microcystins and cylindrospermopsin, EPA considers advisories to be existing and readily available data and information. Hence, for states and authorized tribes that implement the recommended swimming advisory levels but do not adopt the recommended criteria, advisories can be used to support water quality assessments using other applicable WQS (e.g., designated uses and narrative criteria). EPA recommends that states and authorized tribes include within their assessment methodologies information about how the state or tribe will use advisories to evaluate attainment of narrative water quality criteria and associated designated uses.

11. Should states and authorized tribes update their assessment methodology to include the evaluation of cyanotoxin data and information? If so, what should be considered in these updates?

States and authorized tribes should consider updating their water quality assessment methodology to address any water quality standard adopted by the state or authorized tribe. An assessment methodology constitutes the decision process that a state or authorized tribe employs to determine the water quality attainment status of waters in the state or on tribal lands. Under 40 CFR 130.7(b)(6), states and authorized tribes are required to provide documentation to EPA to support their determination to include or not include waters on its impaired and threatened waters list. States and authorized tribes are required to include a description of the methodology used to develop the list; a description of the data and information used to identify waters for the list, including a description of the data and information used by the jurisdiction; and, a rational for any decisions to not use existing and readily available data and information to develop the list.

EPA encourages states and authorized tribes to make the assessment methodology available to the public for review and comment prior to, or along with, solicitations for data and information. Such engagement helps facilitate stakeholder input to the state's or authorized tribe's assessment of water quality status, including recreational use assessments. If states and authorized tribes choose to adopt the recommended cyanotoxin recreational criteria, EPA recommends that they update their assessment methodologies to account for any criteria-specific considerations. For states and authorized tribes that use the swimming advisory recommendation, EPA also encourages them to describe in their assessment methodology how, if at all, the advisory information will be used to support water quality assessments using other applicable WQS (e.g., designated uses and narrative criteria).

12. What happens if a state or authorized tribe does not have sufficient data to make an assessment determination?

EPA recommends that states and authorized tribes submit an integrated water quality report that uses a five-category approach for classifying the WQS attainment status for each waterbody in their jurisdiction. Consistent with this approach, EPA recommends that waterbody segments be placed in waterbody assessment Category 3 of the Integrated Report when there is insufficient available data and/or information to make a use-support determination. Information on the appropriate use of Category 3 can be found in EPA's 2009 memo to assist states and authorized tribes in the preparation of the 2010 Integrated Water Quality Reports.[15]

13. What factors should be considered in defining waterbody segmentation (e.g., if dividing a waterbody into smaller assessment units for advisories and 303(d) listings)?

States and authorized tribes have flexibility to define the segmentation for waterbodies within their jurisdiction. Information on segmenting waters can be found in EPA's 2005 memo to assist states and authorized tribes in the preparation of the 2006 Integrated Water Quality Reports.[16]

14. How should states and authorized tribes approach waterbody assessments for a waterbody that is already on the CWA section 303(d) list?

Consistent with any applicable water quality standard, states and authorized tribes make future assessment decisions based on an evaluation of existing and readily available water quality-related data and information against the water quality standard and accompanying assessment method. The assessment decision informs whether a waterbody should be identified as impaired or threatened on the jurisdiction's Section 303(d) list.

States and authorized tribes can decide not to include a waterbody/pollutant combination that was previously identified as impaired or threatened on a state's or tribe's 303(d) list (also known as, "delist") for several reasons, including: (a) the water quality standard is now being met, (b) there were flaws in the

original listing, (c) a TMDL was developed and approved by EPA, or (d) other point sources or nonpoint source controls are expected to meet WQS as described in 40 CFR 130.7(a)(b)(1).

Implementation Questions about Water Quality Management Plans (e.g., TMDLs)

15. How should states and authorized tribes complete TMDLs for waterbodies that are listed under CWA section 303(d) as impaired or threatened due to cyanotoxins?

States and authorized tribes can develop TMDLs for the pollutant(s) that promote development of cyanobacterial blooms and elevated levels of microcystins and cylindrospermopsin above EPA's recommended criteria. As previously discussed in this document, nitrogen and phosphorus loadings can provide optimal conditions for the formation of cyanobacterial blooms and cyanotoxin production. Although accurately deriving the quantity of nutrient pollution reduction necessary to meet WQS for cyanotoxins (or cyanobacteria) is a complex process, states and authorized tribes can use tools EPA is currently developing to better understand the relationship between the causal variables—pollutant loads of nitrogen and phosphorus—and the response variables of the cyanotoxin microcystins.[17] States and authorized tribes may also want to conduct site-specific studies to help refine these relationships and should consider the state of the science as they prioritize and schedule TMDLs to address cyanotoxins.

[17] Additional research is currently being conducted by EPA and others to improve the understanding between cyanotoxins and nutrient pollution. For example, see:

1. Lester L. Yuan and Amina I. Pollard, Managing microcystin: identifying national-scale thresholds for total nitrogen and chlorophyll-*a*, *Freshwater Biology*, 59, 9, (1970-1981), (2014).

Final Technical Support Document:

Implementing the 2019 National Clean Water Act Section 304(a) Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin

NMED Exhibit 95

Notice: This technical support document is primarily intended to support states, authorized tribes,[1] and territories (collectively referred to as "states and authorized tribes") in implementing the Environmental Protection Agency's (EPA) national Clean Water Act (CWA) Section 304(a) *Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins*[2] *and Cylindrospermopsin*.[3] States and authorized tribes may adopt one or both of the national CWA Section 304(a) recommended criteria into their state or tribal water quality standards (WQS) or may use the recommended criteria magnitude values as the basis for swimming advisories and related public notification purposes.

This document provides general information about the recommended criteria and flexibilities states and authorized tribes have, if implementing the criteria. The document also provides recommendations on how to assemble and interpret monitoring data, how to use monitoring data and other available information to make CWA Section 303(d) assessment determinations, and how to develop water quality management plans, including Total Maximum Daily Loads (TMDLs) and National Pollutant Discharge Elimination System (NPDES) permits, aimed at addressing nutrients as a precursor to cyanotoxin production.

While this document cites statutes and regulations that contain requirements applicable to these programs, it does not impose legally binding requirements on EPA, states, authorized tribes, other regulatory authorities, or the regulated community. EPA, states, authorized tribes, and other decision makers may adopt approaches on a case-by-case basis that differ from those provided in this document, as appropriate and consistent with statutory and regulatory requirements. Also, EPA may update this document as new scientific and technical information becomes available. In addition to this document, EPA has prepared the following information to support states and authorized tribes in their efforts to monitor and respond to cyanobacterial blooms and cyanotoxins in recreational waters:

- Cyanobacterial Harmful Algal Blooms in Water (website): https://www.epa.gov/cyanohabs
- Monitoring and Responding to Cyanobacteria and Cyanotoxins in Recreational Waters (website): https://www.epa.gov/cyanohabs/monitoring-and-responding-cyanobacteria-and-cyanotoxins-recreational-waters
- Recommendations for Cyanobacteria and Cyanotoxin Monitoring in Recreational Waters (PDF): https://www.epa.gov/cyanohabs/recommendations-cyanobacteria-and-cyanotoxin-monitoring-recreational-waters

---

[1] "Authorized tribes" in this document generally refers to those federally recognized Indian tribes with authority to administer a CWA Section 303(c) WQS program. (Under EPA's regulations, a tribe that is eligible to administer WQS is likewise eligible to administer CWA Section 401 water quality certifications). When this document discusses CWA Section 402 implementation authority, "authorized tribes" refers to federally recognized Indian tribes with authority to administer a CWA Section 402 program. When this document discusses CWA Section 303(d) implementation authority, "authorized tribe" refers to federally recognized Indian tribes with authority to administer a CWA Section 303(d) program.

[2] Microcystins comprise a class of over 100 congeners and unless specified otherwise, "microcystins" refers to *total* microcystins.

NMED Exhibit 95

General Questions about Recommended Cyanotoxin Water Quality Criteria

1. What are EPA's national CWA Section 304(a) recommended recreational water quality criteria for microcystins and cylindrospermopsin?

In 2019, EPA issued its national Clean Water Act (CWA) Section 304(a) recreational water quality criteria recommendations for two cyanotoxins, microcystins and cylindrospermopsin, reflecting the latest peer-reviewed scientific knowledge. The criteria are designed to protect the public from incidental exposure to harmful levels of these cyanotoxins while participating in water-contact activities in freshwater where immersion and incidental ingestion of water are likely. Such activities include, but are not limited to, swimming, water skiing, tubing, skin diving, water play by children, or similar water-contact activities in waterbodies designated for such recreational uses.[4] EPA issued its 2019 recommended criteria under the statutory authority of CWA Section 304(a).

EPA's 2019 recommended criteria for microcystins and cylindrospermopsin are summarized in Table 1, below. For more information on the magnitude, duration and frequency components of the criteria, see *Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin 2019* (Section 6).

Table 1. National CWA Section 304(a) Recommendations for Recreational Water Quality Criteria for Microcystins and Cylindrospermopsin[a]

Microcystins Magnitude (µg/L)	**Cylindrospermopsin Magnitude** (µg/L)	**Duration**	**Frequency**
8	15	1 in 10-day assessment period across a recreational season	Not more than 3 excursions in a recreational season in more than one year[b]

[a] States and authorized tribes can choose to adopt one or both criteria recommendations.

[b] An excursion is defined as a 10-day assessment period with any toxin concentration higher than the recommended criteria magnitude. When more than three excursions occur within a recreational season and that pattern reoccurs in more than one year, it is an indication the water quality has been or is becoming degraded and is not supporting its recreational use. As a risk management decision, states and authorized tribes should include in their WQS an upper-bound recurrence frequency stating the number of years that pattern can reoccur and still support its recreational use.

[4] For information about the scope and applicability of recommended recreational water quality criteria, see EPA's 2012 *Recreational Water Quality Criteria*, (Section 2.0 Applicability and Scope). Office of Water 820-F-12-058. https://www.epa.gov/sites/production/files/2015-10/documents/rwqc2012.pdf.

NMED Exhibit 95

States and authorized tribes may adopt one or both of the national CWA Section 304(a) recommended criteria into their state or tribal water quality standards (WQS). Per WQS regulations at 40 CFR 131.20(a)[5], if a state or tribe chooses not to adopt water quality criteria for one or both of these cyanotoxins based either on EPA's recommendations or other scientifically defensible methods,[6] the state or authorized tribe must provide an explanation for not adopting such criteria as part of its triennial review.

EPA recognizes that multiple environmental factors can cause variability in algal bloom formation and toxin production, and that some years may produce blooms that occur for long periods, or blooms of shorter duration that occur repeatedly throughout a single recreational season, but such events may not occur every year. Therefore, EPA recommends that states and authorized tribes consider the pattern of excursions within a recreational season *and* across multiple years when determining whether the recreational use is attained.

The duration and frequency of cyanobacterial blooms can vary, with short-term blooms lasting days or weeks and long-term blooms lasting several months, or possibly all year. As a result, the frequency of excursions—defined as ten-day assessment periods during which time toxin concentrations have been measured above the recommended criteria magnitude—can also vary. States and authorized tribes that choose to adopt the national CWA Section 304(a) recommended criteria would analyze the pattern of excursions throughout the duration of each recreational season, and from one season to the next, as specified in state or tribal standards (see Question 3 for more on defining the length of a recreational season). For example, a 90-day recreational season with one ten-day excursion each month is a different pattern than a 90-day recreational season with three consecutive ten-day excursions in the final month of the recreational season. An understanding of the patterns of blooms can help waterbody managers respond effectively to protect public health. The recommended criteria components listed in Table 1, above, can help to identify a short- or long-term temporal trend or a spatial distribution pattern of cyanotoxin excursions that can be used to evaluate a waterbody (see Question 8, which provides detail on how to count excursions within a recreational season).

EPA recommends that when more than three excursions occur within a recreational season *and* a pattern (of more than three excursions per recreational season) reoccurs in more than one year, it is an indication that the water quality is or may be becoming degraded such that the waterbody no longer supports its recreational use. It is important to note that a pattern of more than three excursions per recreational season would not need to be *the same* pattern each year (e.g., the pattern of multiple excursions may resemble a long-term bloom of back-to-back excursions one year and several discrete, short-term excursions another year). A determination of whether the waterbody supports its recreational use would depend on the number of years when multiple cyanotoxin excursions are observed with respect to the *recurrence frequency*, which is specified by the state or authorized tribe that adopts the criteria. It is also important to note that the years with multiple excursions do not have to be consecutive to indicate a water quality problem. The recurrence frequency is a risk management decision that states and authorized tribes need to determine when developing their WQS. States and authorized tribes may make different risk management decisions for different types of waterbodies but should specify in their

[5] 40 CFR 131.20(a): "… if a State does not adopt new or revised criteria for parameters for which EPA has published new or updated CWA section 304(a) criteria recommendations, then the State shall provide an explanation when it submits the results of its triennial review to the Regional Administrator consistent with CWA section 303(c)(1) and the requirements of paragraph (c) of this section."

[6] 40 CFR 131.11(b)(iii)

NMED Exhibit 95

adopted criteria the number of years a pattern of multiple (i.e. more than three) cyanotoxin excursions per recreational season can occur for the recreational use to be supported (see Example 1 text box in Question 3).

2. How can EPA's recommended recreational water quality criteria values for microcystins and cylindrospermopsin be used for swimming advisories?

When a bloom or the presence of cyanotoxins is confirmed, the recreational waterbody manager typically issues a public notification (either a swimming advisory or a closure of swimming areas) to raise awareness of the potential risks associated with contact with the cyanobacterial bloom or its toxins in recreational waters. Swimming advisories are recommendations to limit swimming or other recreational water-contact activities, due to an increased health risk from contact with or ingestion of the cyanobacteria or cyanotoxins; whereas, a closure notification or posting typically means that the waterbody is officially closed to the public.

EPA envisions that if states or authorized tribes decide to use the recommended criteria magnitude values for swimming advisory purposes, they can manage a cyanotoxin monitoring and advisory program in the same way as they manage any existing recreational water advisory program (e.g., those for pathogen indicators, like *E. coli* or enterococci).[7] States and authorized tribes may choose to apply either or both recommended criteria magnitude values as the basis for public notifications (i.e., swimming advisories or closures) at recreational waterbodies. EPA's swimming advisory recommendations for microcystins and cylindrospermopsin are summarized in Table 2, below.

Table 2. Swimming Advisory Recommendations for Microcystins and Cylindrospermopsin[a]

Microcystins Magnitude (µg/L)	Cylindrospermopsin Magnitude (µg/L)	Duration	Frequency
8	15	One day	Not to be exceeded

[a] States and authorized tribes can choose to apply one or both recommended magnitude values as the basis for swimming advisories.

The guidelines for posting an advisory or closure for a waterbody are typically set at the state, tribal, or local level.[8] EPA recognizes that some states and authorized tribes may handle swimming advisories through their health departments and not through their environmental quality departments. As a result, inter-departmental coordination may be helpful to implement an advisory program which can also serve to inform drinking water providers and water quality practitioners. EPA has provided an example Cyanobacteria Bloom Response Contact List on its website to help state or tribal employees consider who to contact in the event of a cyanobacterial bloom (see: https://www.epa.gov/sites/production/files/2017-07/contact-list-rec-water.docx).

[7] Note, however, that monitoring, reporting and notification of potential exposure to cyanobacteria and their toxins in coastal recreation waters cannot be funded under the BEACH Act Grant program.

[8] We use the term, "jurisdictional level" to include state or tribal. See *Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin 2019* (Appendix B), which summarizes available information on state recreational water guidelines for cyanotoxins and cyanobacteria.

NMED Exhibit 95

If using EPA's swimming advisory recommendations for a swimming advisory or a closure, EPA recommends that the relevant authority (typically a local health department official or water quality management official) notify the public whenever the concentration of microcystins or cylindrospermopsin in a sample is higher than the recommended criteria magnitude value. EPA also recommends that a swimming advisory not be lifted until at least two subsequent samples, taken at least 24 hours apart, show that the toxin concentration has fallen below the recommended magnitude value of the criteria. States and authorized tribes may choose to extend the re-sampling period after issuing a swimming advisory over several days, to allow for additional photodegradation of the cyanotoxin.[9] The important point is to wait until the concentration of microcystins or cylindrospermopsin subsides below the recommended swimming advisory magnitude values before the swimming advisory is lifted. By increasing the monitoring frequency at a site where a swimming advisory is issued, recreational waterbody managers will get a clearer understanding of the temporal nature of toxins which can be useful in making management decisions to protect the recreational use, including when to remove an advisory.

EPA has published materials to help recreational waterbody managers responsible for monitoring and responding to cyanobacterial blooms. These materials include customizable infographics and a communication toolbox with examples of public messages, press releases, and signage that recreational waterbody managers may use to inform the public of increased health risks associated with exposure to harmful algal blooms (HABs), or cyanobacteria, and their toxins. In addition, EPA has provided recommendations for waterbody managers (or relevant state, local or tribal officials) regarding various water monitoring, sampling, and testing methods. These recommendations can help waterbody managers determine whether a cyanobacterial bloom is producing toxins, whether the bloom presents an increased health risk to water-contact recreators, and whether immediate actions should be taken to notify the public if a closure is recommended based on waterbody test results. For more information, follow these links:

NMED Exhibit 95

3. What flexibilities do states and authorized tribes have if they adopt the recommended recreational water quality criteria for microcystins and cylindrospermopsin?

If states or authorized tribes choose to adopt EPA's national CWA Section 304(a) *Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin*, several flexibilities are available to accommodate specific water quality-related circumstances while meeting the requirements of the CWA and EPA's WQS regulation.[10] In addition to considering the Agency's national recommended water quality criteria when revising their WQS, states and authorized tribes may adopt, where appropriate, other scientifically defensible criteria that differ from EPA's recommendations. For example, states and authorized tribes can:

- *Define the length of the recreational season.* States and authorized tribes can adopt seasonal designated uses of a waterbody with respect to various CWA Section 304(a) recommended criteria, including the recommended criteria for microcystins and cylindrospermopsin. For states and authorized tribes that have adopted seasonal uses, the recommended cyanotoxin criteria would apply only to the primary contact recreational season.[11] The length of a "recreational season" is an important consideration because states and authorized tribes would likely monitor the quality of their highest-priority recreational waters throughout the recreational season. For purposes of establishing seasonal WQS, a change to the recreational season constitutes a change to the state's or authorized tribe's designated use in their WQS and would need to be reviewed and approved by EPA pursuant to CWA Section 303(c). Because local health departments or departments of parks and recreation may define the recreational seasons for inland waterbodies, it is important for states and authorized tribes to coordinate with these local authorities when identifying the length of the state's or tribe's recreational season in WQS.
- *Prioritize waterbodies for monitoring.* EPA recommends that states and authorized tribes prioritize their waterbodies, for monitoring purposes, based on risk factors relevant to the likelihood of a cyanotoxin or HAB event and its relative impact to recreational users of each waterbody. Prioritizing which waterbodies to monitor can help to direct limited resources where they will be most effective (for more on prioritizing waterbodies for monitoring, see Question 6). For all recreational waterbodies—especially for those that are lower priority for monitoring—EPA also recommends that states and tribes communicate with their constituents about how to identify and report a potential cyanobacterial bloom (for templates and other communication tools, see Question 2).
- *Define a recurrence frequency.* The recommended criteria for microcystins and cylindrospermopsin recommend that the toxin concentrations should not be above the recommended criteria magnitude values in more than three 10-day periods per recreational season *in more than one year*, but the recommended criteria do not specify an upper-bound number of years that pattern can occur across recreational seasons (i.e., a recurrence frequency). This provides states and authorized tribes the flexibility to define what the recurrence frequency should be for their state or tribe. The recurrence frequency can be thought of as a sliding window of time during which patterns of excursions should be considered. For example, some states or authorized tribes might assess the pattern of excursions over a rolling 3-year period while others may choose to count over a rolling 5-year period, or longer. EPA recommends that each state or

[10] 40 CFR Part 131 – Water Quality Standards.

[11] 40 CFR 131.10(f) specifies that states and authorized tribes "may adopt seasonal uses as an alternative to reclassifying a waterbody or segment thereof to uses requiring less stringent water quality criteria."

NMED Exhibit 95

authorized tribe documents the recurrence frequency in the state or tribal water quality standards or supporting documents. Example 1, below, provides sample text that a state or authorized tribe could include in its adopted criteria to specify the recurrence frequency. EPA encourages states and authorized tribes to explain their selection of recurrence frequency to their constituents when they put their draft standards out for public comment.

Example 1: Written Statement to Specify Recurrence Frequency

> If a state or authorized tribe chooses to adopt the recommended criteria, EPA expects the state or tribe to also include the recurrence frequency in its WQS. A state or authorized tribe may achieve this with a written statement in its standards. An example written statement could say, *"The concentration of microcystins shall not exceed 8 µg/L in more than three 10-day periods per recreational season, for more than one recreational season, over a rolling 5-year period."*

- *Determine how to delineate the 10-day assessment period.* States and authorized tribes have flexibility in applying the 10-day assessment period. Some may choose to use predetermined 10-day assessment periods for waterbodies with a documented history of cyanobacterial blooms or cyanotoxin production (e.g., the month of June could have three 10-day assessment periods). Another approach is to begin the 10-day assessment period in response to a visible bloom that has been confirmed as toxin-producing. States and authorized tribes are encouraged to consider the application of the frequency and duration components to capture elevated toxin concentrations (which may or may not coincide with the general proliferation of total cyanobacteria at high densities). More information on delineating assessment periods throughout a recreational season is provided in Question 8.
- *Derive site-specific criteria elements*. States and authorized tribes may modify EPA-recommended criteria to fit their unique situation, based on site-specific data and information, pursuant to 40 CFR 131.11(b)(ii). For example, a state or tribe may derive site-specific criteria based, in part, on information about the exposure variables among the population that uses the waterbody (e.g., age and incidental ingestion rates) or to take into account specific cultural or land use practices at or near the site. The site-specific criteria must be based on sound scientific rationale and protective of the designated use of the state's or tribe's waterbodies pursuant to 40 CFR 131.11(a) and approved by EPA pursuant to Section 303(c) of the CWA.
- *Revise the designated uses of waterbodies within their state*. Pursuant to 40 CFR 131.10(g), states and authorized tribes may remove a designated CWA Section 101(a)(2) use,[12] which is not an existing use, if the state can demonstrate that attaining the designated use is not feasible because one of the attainability factors listed in 40 CFR 131.10(g) is met. The decision to remove a designated CWA Section 101(a)(2) use (e.g., primary contact recreation use) or a sub-category of such a use, or to designate a subcategory of such a use that requires less stringent criteria, must be based on an appropriate use attainability analysis, pursuant to 40 CFR 131.10(j). Additionally, revisions to designated uses are considered a change to water quality standards that must include documentation to support the use revision pursuant to 131.10 and 131.20 and are subject to

[12] CWA Section 101(a)(2) uses are those that provide for the protection and propagation of fish, shellfish, and wildlife, and recreation in and on the water, as well as for the protection of human health when consuming fish, shellfish, and other aquatic life (e.g. recreation use, aquatic life use).

NMED Exhibit 95

public participation requirements of 40 CFR 131.20(b) and to EPA's review and approval under CWA Section 303(c).[13]

- *Adopt a WQS variance.* A state or authorized tribe could adopt, and EPA could approve, a WQS variance in cases where the recreational use and associated criterion (microcystins or cylindrospermopsin, as translated to nutrients) are unattainable in the near-term, but it is possible to make feasible progress toward attaining that designated use and criterion.[14] For information on the connection between cyanotoxins and nutrients, see Question 16. For information on translating between microcystins and nutrient loads in lakes, see Question 17 and Question 18.

4. What is the relationship between cyanobacterial cell density and the recommended criteria?

EPA recognizes that some states and authorized tribes have included total cyanobacterial cell density values as an important part of their HAB management strategy. EPA did not recommend criteria based on cyanobacterial cell density because of the uncertainties quantifying the relationship between cell densities and observed health effects. Available information on cell density, health endpoints, and guidelines developed by other authorities on total cyanobacteria cells is described in the Effects Characterization section (Section 7.5) and in Appendix D of the national CWA Section 304(a) recreational water quality criteria recommendations for microcystins and cylindrospermopsin. EPA presents a toxigenic cell number based on the number of toxigenic cells that could produce microcystins equivalent to the recommended criteria magnitude. The Effects Characterization section also describes gene-based detection methods (i.e., quantitative polymerase chain reaction (qPCR)) that can target and quantify the toxigenic subpopulation of cyanobacteria that are present in a waterbody and used in some states or authorized tribes (see Section 7 of the national CWA Section 304(a) recreational water quality criteria recommendations for microcystins and cylindrospermopsin).

The presence of cyanobacteria does not necessarily mean that cyanotoxins are being produced, and conversely, cyanotoxins can be present at levels above the recommended criteria magnitude when accumulations of cyanobacteria were not observed.[15] Additionally, benthic cyanobacteria, occurring at the bottom of the waterbody, may not be visible from the surface, but may still produce toxins.

NMED Exhibit 95

5. What are the potential health effects of cyanotoxin exposure to humans, pets and livestock?

EPA's national CWA Section 304(a) recommended criteria for microcystins and cylindrospermopsin reflect the latest scientific knowledge on the potential human health effects from recreational exposure to these two cyanotoxins.[16] Potential human health effects from recreational exposure to cyanobacteria and these two cyanotoxins could range from gastrointestinal illnesses to liver and kidney damage. For information on the health effects of exposure to microcystins and cylindrospermopsin to humans, go to:

- Health Effects Support Document for the Cyanobacterial Toxin Microcystins
- Health Effects Support Document for the Cyanobacterial Toxin Cylindrospermopsin

Although the recommended recreational criteria values are for the protection of human health (not pets and livestock), common signs of cyanotoxin poisonings in pets and livestock may include repeated vomiting, diarrhea, loss of appetite, abdominal swelling, stumbling, seizures, convulsions, disorientation, inactivity, or skin rashes and hives, and in extreme cases collapse and sudden death. For more information on concerns relating to pet or livestock exposure to microcystins and cylindrospermopsin, including a summary of guidelines that several states or authorized tribes have developed, go to:

- Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin (Section 7.8 Livestock and Pet Concerns)
- Learn more about how to protect your dog (Protect Your Pooch: How to keep your dog safe from toxic algae)

In addition to the EPA resources listed above, the Centers for Disease Control and Prevention (CDC) provides multiple resources, such as frequently asked questions (FAQs), Veterinarian Cards and Animal Safety Alerts, to help educate the public of the dangers associated with cyanotoxin exposure to pets. The CDC suggests that pet owners prevent their animals from playing in—or drinking—scummy water. If a dog has been swimming in scummy water, the CDC recommends rinsing them off immediately to prevent the dog from licking cyanobacteria off their fur. The CDC also collects voluntarily reported data on individual human and animal cases of illnesses from HAB-associated exposures through its One Health Harmful Algal Bloom System.[17]

[16] Although accumulations of cyanobacterial cells have been associated with outbreaks of inflammatory illness (e.g., rashes) unrelated to the production of cyanotoxins, available data are insufficient to develop recreational values for a total cyanobacterial cell density related to inflammatory health endpoints among humans.

NMED Exhibit 95

Implementation Questions about Monitoring, Assessment and Listing

6. What information should states and authorized tribes consider when prioritizing which waterbodies to monitor based on risk of elevated levels of cyanotoxins?

EPA recommends that states and authorized tribes prioritize their waterbodies, for monitoring purposes, based on an objective set of risk factors relevant to the likelihood of a cyanotoxin or HAB event and its relative impact to recreational users of each waterbody. Prioritizing which waterbodies to monitor can help to direct often limited resources where they will be most effective. It is important that a prioritization process is transparent, does not create inequities to vulnerable populations, and works to ensure that waterbodies with high recreational use and likelihood of having algal blooms are prioritized.

States and authorized tribes are encouraged to collaborate with a range of state, tribal and local agencies, waterbody managers and citizen science/volunteer monitoring organizations to monitor local waterbodies. By leveraging the presence of local resources to monitor, states and authorized tribes can more effectively coordinate risk management and response activities. For example, a local recreational waterbody manager who is collecting weekly samples for other indicators may be able to collect an additional sample for cyanotoxins. CWA practitioners, public health officials, and other waterbody managers may consider a variety of information when prioritizing which waterbodies to monitor for potential cyanotoxins. Some of the risk factors listed below may help state, tribal and local officials to identify which waterbodies are most vulnerable:

- the type of waterbody and numbers of recreational users (e.g., is it a public swimming area?);
- past/historical occurrence of cyanotoxin producing blooms;
- seasonal patterns of cyanobacterial blooms (influenced by temperature and precipitation, among other factors);
- point and nonpoint sources of nutrients in the waterbody and in the watershed;
- physical and hydrologic factors (e.g., depth, fetch[18], light attenuation, availability of organic matter, turbidity, temperature, pH);
- chlorophyll-a and phycocyanin[19] levels (i.e., cell densities);
- other water quality limitations or impairments; and,
- any other information gathered as part of source water assessments or sanitary surveys.

Some states and authorized tribes use screening tools to determine which waterbodies to prioritize for cyanotoxin sampling. They may look at related data such as cyanobacteria or phytoplankton data collected as part of their monitoring program. States and authorized tribes may consider using field test kits to screen for waters with elevated toxins before collecting a sample for laboratory analysis. Another screening tool based on satellite imagery is the Cyanobacteria Assessment Network (CyAN). EPA's Office of Research and Development developed the CyAN Mobile Application for the early detection of select algal blooms (those containing phycocyanin) in U.S waterbodies and freshwater lakes over one sq km in size to help local and state water quality managers make faster and better-informed management

[18] Fetch refers to the area of a lake surface over which the wind blows in an essentially constant direction, thus generating waves. The term also is used as a synonym for fetch length, which is the horizontal distance over which wave-generating winds blow.

[19] Phycocyanin is a pigment present in cyanobacteria. Sensors are available which measure the presence of this pigment and report relative cyanobacteria concentrations in cells/mL.

NMED Exhibit 95

decisions related to cyanobacterial blooms. It provides an easy-to-use, customizable interface for accessing algal bloom satellite data for over 2,000 of the largest lakes and reservoirs in the United States. The CyAN app is free and available for download in the Google Play™ store for Android™ devices, and a web-based version of the app is currently being developed. [20]

Reporting data on cyanobacterial blooms and toxin levels can improve transparency with the public and help to provide a regional or national understanding of where blooms are taking place. Some states and authorized tribes have reported microcystins data through the Water Quality Portal, an interagency website that provides public access to water quality data collected by over 400 federal, state, tribal and local agencies .[21] Anytime states are monitoring water quality and whenever authorized tribes or other organizations are using EPA grant money to perform water quality monitoring, they are required, as part of their grant terms and conditions, to upload their data to the Water Quality Portal. The Portal is one of many sources of information which may inform states and authorized tribes when taking a risk-based approach to prioritizing recreational waterbodies for monitoring.

Additional materials to assist recreational waterbody managers interested in monitoring for and responding to cyanobacteria and cyanotoxins in recreational waters are listed below:

- Monitoring and Responding to Cyanobacteria and Cyanotoxins in Recreational Waters.
- Recommendations for Cyanobacteria and Cyanotoxin Monitoring in Recreational Waters (PDF).
- Field and Laboratory Guide to Freshwater Cyanobacteria Harmful Algal Blooms for Native American and Alaska Native Communities: This 2015 guide, produced by the USGS, provides field images to help differentiate between cyanobacterial blooms (some of which produce toxins), non-toxic algal blooms, and floating plants that might be confused with algae.
- EPA Sanitary Survey App for Marine and Fresh Waters: EPA has updated its recreational sanitary survey app, *EPA Sanitary Survey App for Marine and Fresh Waters*, to help waterbody managers evaluate all contributing waterbody and watershed information including water quality data, pollution source data, and land use data. The updated app enables jurisdictions to easily gather

[20] Methods to assess bloom temporal frequency, spatial extent, magnitude, and lake occurrence with satellite data have been developed. The 300-meter resolution Sentinel-3 satellites capture less than 1% of waterbodies and approximately 33% of drinking water intakes but provide frequent monitoring and can readily identify cyanobacterial HABs. Therefore, CyAN assessment methods can be applied at a national scale but are limited to the largest lakes. Satellites with 10 to 30 m resolution, such as Landsat and Sentinel-2, can capture 62% of lakes greater than 1 ha (2.47 acres) and 95% of the lakes with public drinking water intake locations. These satellites make less frequent flyovers and are not as well equipped with sensors to easily distinguishing cyanobacterial HABs from other types phytoplankton. For more information, see:

information on possible existence of harmful algal blooms, in addition to likely sources of bacterial pollution.

7. How frequently and over what time period should states and authorized tribes monitor cyanotoxin levels?

States and authorized tribes have discretion and flexibility when establishing a monitoring program for cyanotoxins. For example, baseline monitoring could include routine monitoring (e.g., weekly monitoring over the course of a recreational season), responsive/episodic monitoring (e.g., initiating sampling in response to a physical bloom or reported potential negative health impact to animals or humans), or a combination of the two. EPA recommends that states and authorized tribes use their monitoring strategy or annual workplans to identify the monitoring approach that will be implemented for the recreational season, considering available resources and the potential use of tools, such as remote sensing and citizens' volunteer monitoring.

EPA recommends more frequent sampling if a bloom is detected, particularly if it is documented to have toxin levels above the recommended criterion magnitude. That is, once a concentration higher than the criterion magnitude is detected, a state or authorized tribe with a biweekly or responsive sampling program should switch to more frequent sampling (e.g., weekly or daily) until the bloom subsides or the cyanotoxin concentrations are no longer above their respective cyanotoxin criteria magnitude levels. Once the cyanotoxins have subsided, EPA recommends that regular monitoring of prioritized waterbodies continue for the duration of the recreational season. EPA also recommends that states and authorized tribes consider doing follow up monitoring at these sites in subsequent years to capture the recurrence frequency.

For more information about monitoring for cyanotoxins, see EPA document, Recommendations for Cyanobacteria and Cyanotoxin Monitoring in Recreational Waters.

8. How should states and authorized tribes analyze and interpret cyanotoxin monitoring data and information to evaluate ambient conditions and recreational use support?

The recommended 10-day duration component of the criteria naturally translates into the use of 10-day assessment periods over the course of a recreational season to evaluate ambient waterbody conditions and recreational use attainment.

The sampling frequency (daily, weekly, biweekly, etc.) is a risk-management decision made at the state, tribal, or local level. Weekly monitoring may provide two samples within the 10-day assessment period, or weekly monitoring may provide data for two consecutive 10-day assessment periods (depending on how the weeks and 10-day periods align). If one or more samples are collected within the 10-day assessment period that are above the criteria magnitude, these should be counted as a single excursion. EPA recognizes other sampling schedules may be used as long as they take into consideration the need to be protective of recreational use of the given waterbody.

States and authorized tribes have flexibility delineating the 10-day assessment periods within their recreational season. Example 2 text box, below, is provided to illustrate how samples with concentrations

NMED Exhibit 95

above the criterion magnitude can count towards excursions when assessing use attainment. For the application of these criteria, an excursion is defined as a 10-day assessment period during which time monitoring data shows a concentration of microcystins or cylindrospermopsin that is higher than the recommended magnitude value. When more than three excursions occur within a recreational season and a pattern of excursions reoccurs for more than one year within the recurrence frequency (described in Question 3), the criterion is exceeded (i.e., the waterbody would be considered impaired).

The calendar figures in Example 2 illustrate two ways states and authorized tribes could set up their 10-day assessment periods, either by blocking out 10-day periods before the start of the recreational season (Example 2A) or by marking 10-day assessment periods from the date a bloom is detected and an excursion is confirmed (Example 2B). Once an approach to delineating 10-day assessment periods is selected, the same approach should be used each year.

NMED Exhibit 95

Example 2: Examples of How a State or Tribe Might Delineate Assessment Periods

The following examples are intended to demonstrate how the number of excursions can be counted within a given recreational season. The red X shown on the example calendars denotes days when cyanotoxin monitoring results were *above* the recommended cyanotoxin criteria magnitude, and the blue check denotes days when monitoring results that were *below* the recommended cyanotoxin criteria magnitude. The shaded boxes represent 10-day assessment periods. A 10-day assessment period with one or more measured cyanotoxin concentrations above the criteria magnitude is counted as an excursion. Boxes without any shading, in Example 2B, represent days that are not included in a 10-day assessment period (because no recent bloom was observed).

Example 2A: Predetermined 10-Day Assessment Periods

June/July

Sunday	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday
✓ 1	2	3	4	5	6	7
✓ 8	9	10	11	12	13	14
X 15	16	17	18	19	20	21
✓ 22	23	24	25	26	27	28
X 29	30	1	2	3	4	5
✓ 6	7	8	9	10	11	12

Example 2A. In this example, the state or authorized tribe establishes a predetermined weekly monitoring schedule to begin on June 1 and has delineated consecutive 10-day assessment periods throughout the recreational season. On June 1, June 8, June 22, and July 6, weekly monitoring results showed a cyanotoxin concentration below the recommended criteria magnitude. However, monitoring results from June 15 and June 29 showed concentrations above the recommended criteria magnitude, resulting in two excursions in the month of June because the cyanotoxin concentrations were detected above the recommended criteria magnitude during two separate 10-day assessment periods.

NMED Exhibit 95

Example 2B: Responsive 10-day Assessment Periods

June/July

Sunday	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday
1	2	3	4	5	6	7
8	9	10	11	12 X	13	14
15	16	17	18	19 ✓	20	21
22	23	24	25	26	27	28
29 X	30	1	2	3	4	5
6 ✓	7	8	9	10	11	12

Example 2B. In this example, the state or authorized tribe monitors for cyanotoxins *in response to* a suspected bloom, once the monitoring data indicates a concentration of microcystins or cylindrospermopsin that is higher than the recommended criteria magnitude. On June 12, the first suspected bloom of the season was sampled and confirmed when monitoring results showed a cyanotoxin concentration above the recommended criteria magnitude. This started the 10-day assessment period and a sample taken one week later, on June 19th, showed that the cyanotoxin levels had subsided. Again, on June 29th, a suspected bloom was sampled and confirmed, triggering the start of a new 10-day assessment period (through July 8th). Once again, a sample taken one week later, on July 6th, showed that the cyanotoxin levels had subsided. (Note: If the sample on July 6th showed toxin concentrations above the recommended criteria magnitude, a new 10-day assessment period would begin on July 9th.) The measures above the recommended criteria magnitude equate to two 10-day excursions because the elevated cyanotoxin concentrations were detected across two separate 10-day periods. Response-based monitoring may be a better option for local jurisdictions with limited monitoring resources.

9. What should states and authorized tribes consider when selecting an analytical method?

States and authorized tribes may choose an analytical method that they deem appropriate for monitoring and assessment purposes. When selecting a method to monitor for microcystins or cylindrospermopsin, states and authorized tribes should consider cost and practicality of various monitoring methods, and reliability and comparability of results, among other factors. Well over 100 microcystin congeners are known to exist; however, the majority of toxicological data on the effects of microcystins are available for microcystin-LR (a frequently monitored congener). Therefore, EPA established its recommended criterion for microcystins based on microcystin-LR and used it as a surrogate for other microcystin congeners.

NMED Exhibit 95

Analytical methods should be sufficiently sensitive to detect the cyanotoxins in question at concentrations below the recommended criteria magnitude; however, analytical results may vary depending on the analytical methods used.

Methods vary widely in sensitivity, rapidity, cost, and ease of use. As described below, there are both rapid screening tests and laboratory methods used to detect and identify cyanobacterial cells; determine the presence, absence, or count of individual congeners; or measure the concentration of total cyanotoxins in a water sample. It may be cost effective to use field test kits at several locations throughout a waterbody prior to selecting samples for lab-based analysis (see below for description of field test kits). Some analytical methods measure the sum of all congeners while other methods measure specific congeners of interest. Methods that measure more congeners provide a more complete assessment of potential public health risk, while methods that identify specific congeners can be helpful to understand specific characteristics of the bloom. Each method has specific requirements for sample preparation/processing and analytical standards. These should also be considered when planning a monitoring program.

EPA does not require any single method to monitor for cyanotoxins. Analytical methods should be sufficiently sensitive with minimum detection levels lower than the recommended criteria magnitude of microcystins and cylindrospermopsin. In addition to the list below, EPA refers readers to the National Environmental Methods Index (https://www.nemi.gov/home/) for information on analytical methods. Also, the Interstate Technology and Regulatory Council Harmful Cyanobacterial Blooms project team has included a comprehensive summary of analytical methods and a method selection tool on its website (https://www.itrcweb.org/Team/Public?teamID=82).

Methods for quantifying cyanotoxins (total or individual congener concentrations) include, but are not limited to:

- EPA developed standardized methods for analyzing cyanotoxins in ambient and drinking water:
    - EPA Method 544, a standardized, single laboratory validated liquid chromatography/tandem mass spectrometry (LC/MS/MS) method for the detection of microcystins and nodularin in drinking water;
    - EPA Method 545, a standardized, single laboratory validated LC/MS/MS method for the detection of cylindrospermopsin and anatoxin-a in drinking water; and
    - EPA Method 546, a standardized, single laboratory validated method using an Adda enzyme-linked immunosorbent assay for the detection of microcystins and nodularin in ambient and drinking water.
- Lab-based Enzyme-Linked Immunosorbent Assay (ELISA) method. The ELISA method is typically run with only a microcystin-LR standard for comparison but can quantify a broad range of microcystin congeners (especially if using an ADDA-based antibody).
- Field test kits (e.g., Eurofins Technologies (formerly Abraxis) test strip, Envirologix QualiTube). These field-based methods do not require laboratory instrumentation and can produce semi-quantitative results within about an hour; however, these methods may be better suited for screening purposes, given their limited range of quantification.
- High performance liquid chromatography (HPLC) combined with ultraviolet/photodiode array detectors (UV/PDA). This method requires known toxin standards to be run alongside the water sample(s) to quantify the toxin concentration(s), and its results are limited to only those congeners for which standards are available and analyzed. HPLC-UV/PDA methods are based on a non-selective detector and co-eluting interferents can prevent accurate identification of components and quantitation. It is less sensitive than mass spectrometry methods (see below).

NMED Exhibit 95

- Liquid chromatography/tandem mass spectrometry (LC/MS/MS).[22] Like HPLC-UV/PDA, this method requires known toxin standards to be run alongside the water sample(s) to quantify the toxin concentration(s) and its results are limited to only those congeners for which standards are available and analyzed. It is, however, the most precise method for quantitation of analytes (such as specific microcystin congeners) if standards are available. This method may also require the use of solid phase extraction for analytes with weak product ion abundance (microcystins). The LC-MS/MS MMPB (2-methyl-3(methoxy)-4-phenylbutyic acid) method analyzes the chemically cleaved ADDA group common to all microcystin congeners and therefore provides an alternative LC-based approach for analyzing a broad range of microcystin congeners. The MMPB method may also detect microcystins break-down products and could potentially overestimate microcystin concentrations in some settings.
- Protein phosphatase inhibition assay (PPIA). This method has varying degrees of specificity depending on its substrate composition and may react to compounds in the sample other than microcystins.[23]

EPA recognizes that several states or authorized tribes may monitor for cyanobacterial cell densities in addition to, or in lieu of, monitoring for cyanotoxins. Laboratory-based methods for quantifying cyanobacterial cells include microscopy and quantitative polymerase chain reaction (qPCR) and microarrays/DNA chips. Field-based methods include, but are not limited to, remote sensing based on satellite imagery, FlowCam (imaging particle analysis), flow cytometry, and derivative spectrophotometry. For more on the relationship between cell densities and the recommended criteria, see Question 4.

10. What should states and authorized tribes consider when selecting sampling locations?

Like other aspects of a monitoring program, decisions on sample location are guided by the management questions being addressed. For example, when monitoring recreational waters for public health protection, it's reasonable to target sample collection toward capturing the highest potential exposure risks; therefore, EPA recommends that states and authorized tribes collect single grab samples from designated swimming areas, near the shoreline, or a composite of samples taken at the same time from points within the splash zones where children play (e.g., ankle-, knee- and chest-deep). EPA does not recommend averaging sampling data taken at different times because averaging data over time does not give a clear picture of the pattern of cyanobacterial bloom formation and cyanotoxin exposure to the population using the waterbody for recreational purposes. For example, states should not average data collected over different days in a ten-day assessment period.

---

[22] For more information on single laboratory validated methods for detecting cyanotoxins in freshwaters by LC/MS/MS, see (1) https://www.epa.gov/water-research/single-laboratory-validated-method-determination-cylindrospermopsin-and-anatoxin to detect cylindrospermopsin and anatoxin-a, and (2) https://www.epa.gov/water-research/single-laboratory-validated-method-determination-microcystins-and-nodularin-ambient to detect microcystins and nodularin (combined intracellular and extracellular).

NMED Exhibit 95

When collecting samples, it is essential to establish and follow quality assurance (QA) and quality control (QC) procedures. EPA has created guidance for producing quality assurance project plans (QAPP) to aid in documenting quality assurance/quality control (QA/QC) procedures.[24] It is recommended that a QAPP be in place for monitoring programs to assure the quality of the resulting data and the appropriateness of their use. Detailed procedures for collecting, handling, and analyzing samples are typically specified in the field standard operating procedures (SOPs) and analytical methods SOPs.[25]

SOPs may also be informed by sample collection and handling procedures established by the laboratory performing sample analysis. For example, a laboratory may require a specific type of bottle in which to collect a sample or may provide instructions for chilling a sample after collection. Laboratories establishing sample collection and handling procedures should adhere to protocols defined by the chosen analytical method but may also consult the USGS guidelines for design and sampling for cyanobacterial toxin and taste-and-odor studies in lakes and reservoirs.[26]

EPA has produced technical materials to aid in the development of cyanobacteria and cyanotoxin monitoring programs, including information on available testing methods and sampling logistics.

11. What data and information should states and authorized tribes assemble and evaluate to complete CWA water quality assessments with EPA's recommended cyanotoxin criteria?

States and authorized tribes are required under 40 CFR 130.7(b)(5) to assemble and evaluate all existing and readily available water quality-related data and information when determining which waterbodies belong on the state's or authorized tribe's CWA Section 303(d) list of impaired and threatened waters. "Readily available data and information" relevant to assessment against the recommended recreational criteria for microcystins or cylindrospermopsin would include observed concentration levels for

[24] For more information on how to create a Quality Assurance Project Plan, see https://www.epa.gov/quality/guidance-quality-assurance-project-plans-epa-qag-5.

[25] The National Aquatic Resource Surveys (NARS) collaborative programs between EPA, states, and tribes designed to assess the quality of the nation's waters include field and laboratory procedures for collecting algal toxin samples in the program QAPP, field operation manual and lab operation manual. Additionally, for examples of a state SOPs for collecting and analyzing algal toxin samples, see (1) https://www.kdheks.gov/algae-illness/Response_Plan/Appendix_J.pdf and (2) https://www.dec.ny.gov/docs/water_pdf/habsprogramguide.pdf.

[26] Graham, J.L., Loftin, K.A., Ziegler, A.C., and Meyer, M.T., 2008, Guidelines for design and sampling for cyanobacterial toxin and taste-and-odor studies in lakes and reservoirs: U.S. Geological Survey Scientific Investigations Report 2008–5038. Reston, VA. https://pubs.usgs.gov/sir/2008/5038/.

NMED Exhibit 95

microcystins and cylindrospermopsin collected by the state, authorized tribe, or other stakeholders (e.g., local health departments, federal agencies, or citizen science water monitoring groups).

EPA also considers swimming advisories to be existing and readily available data and information for completing water quality assessments. Hence, for states and authorized tribes that implement the recommended swimming advisory levels—regardless of whether or not they adopted the recommended criteria—advisories would support water quality assessments using other applicable WQS (e.g., designated uses and narrative criteria).

12. Should states and authorized tribes update their assessment methodology to include the evaluation of cyanotoxin data and information? If so, what should be considered in these updates?

States and authorized tribes should consider updating their water quality assessment methodology, if needed, to address any water quality standard adopted by the state or authorized tribe. An assessment methodology constitutes the decision process that a state or authorized tribe employs to determine the water quality standards attainment status of waters on the state or on tribal lands. Under 40 CFR 130.7(b)(6), states and authorized tribes are required to provide documentation to EPA to support their determination whether to include or not include waters on their impaired and threatened waters lists. States and authorized tribes are required to include a description of the methodology used to develop the list; a description of the data and information used to identify waters for the list, including a description of the data and information used by the jurisdiction; and a rationale for any decisions to not use existing and readily available data and information to develop the list. When updating their methodologies, states and authorized tribes should describe any expectations regarding data and information associated with their cyanotoxin criteria, including any data quality, quantity and representativeness considerations needed to evaluate the recurrence frequency aspect of the criteria. In addition, states and authorized tribes should update their methodologies to describe how they will identify the pollutants (e.g., nutrients) causing or expected to cause violations of the cyanotoxin criteria, consistent with 40 CFR 130.7(b)(4).

EPA encourages states and authorized tribes to make the assessment methodology available to the public for review and comment. Such engagement helps facilitate stakeholder input to the state's or authorized tribe's assessment of water quality status, including recreational use assessments. If states and authorized tribes choose to adopt the recommended cyanotoxin recreational criteria, EPA recommends that they update their assessment methodologies to account for any criteria-specific considerations. For states and authorized tribes that use the swimming advisory recommendation to inform attainment with a narrative water quality standard, EPA also recommends that they describe in their assessment methodology how the advisory information will be evaluated and used to determine attainment of applicable narrative water quality criteria and associated uses.

13. What happens if a state or authorized tribe does not have sufficient data to make an assessment determination?

NMED Exhibit 95

EPA regulations require that states and authorized tribes assemble and evaluate all existing and readily available water quality-related data and information to develop their CWA Section 303(d) list (40 CFR 130.7(b)(5)). As such, states and authorized tribes must be inclusive in the types of water quality data and information they collect and evaluate. However, EPA recognizes that there may be circumstances when it is not possible to make an attainment decision because the state or authorized tribe has determined that the readily available data and information are insufficient. With regard to EPA's 304(a) recommendation, examples of these circumstances may include, but are not limited to, determining that the cyanotoxin data and information were collected using insufficient QA/QC measures or are not representative of the conditions of the waterbody.

If a state or authorized tribe decides not to rely on certain available information and data in making listing decisions, it must provide a technical, science-based rationale. 40 CFR 130.7(b)(6)(iii). Waters identified as impaired and listed on the Section 303(d) list in the previous reporting cycle should not be removed in the subsequent listing cycle unless the state or authorized tribe can provide a rationale for doing so.

14. What factors should be considered in defining waterbody segmentation (e.g., if dividing a waterbody into smaller assessment units for advisories and CWA Section 303(d) listings)?

States and authorized tribes have flexibility to define the segmentation of waterbodies within their jurisdiction; there is no single approach to the development of a segmentation scheme. Assessment decisions can reflect the broader ecological system (e.g. an entire lake) or be partitioned to smaller components (e.g. smaller assessment units). Whatever approach a state or authorized tribe selects, waterbody segmentation should be consistent with water quality standards and capable of providing a spatial scale that is adequate to characterize attainment status. States and authorized tribes generally segment waters to represent homogeneity in physical, biological or chemical conditions.

15. How should states and authorized tribes approach waterbody assessments for a waterbody that is already on the CWA Section 303(d) list?

Consistent with any applicable water quality standard, states and authorized tribes make future assessment decisions based on an evaluation of existing and readily available water quality-related data and information against the water quality standard using the accompanying assessment method. The assessment decision informs whether a waterbody should be identified as impaired or threatened for microcystins or cylindrospermopsin on the jurisdiction's CWA Section 303(d) list. Waterbodies can be listed as impaired for multiple waterbody/pollutant combinations. When data and information indicate non-attainment for a waterbody that is already on the CWA Section 303(d) list (e.g., waterbodies having impaired recreation use due to *E. coli*, Enterococci or another pollutant), the state or authorized tribe should add microcystins and cylindrospermopsin to the list of impairments for the waterbody already listed as impaired.

For cyanotoxins, states and authorized tribes can decide not to include a waterbody/pollutant combination that was previously identified as impaired or threatened on a state's or tribe's 303(d) list (also known as "delist") for several reasons, including: (a) the water quality standard is now being met, (b) there were flaws in the original listing, (c) a TMDL was developed and approved by EPA, or (d) other point

NMED Exhibit 95

sources or nonpoint source controls are expected to meet WQS as described in 40 CFR 130.7(b)(1). Note that for microcystins and cylindrospermopsin, the number of years of data that would be needed to demonstrate that the water quality criteria are being met would tie back to the recurrence frequency that a state or tribe would have established in its WQS. In addition, for these cyanotoxins, states and authorized tribes could use swimming advisories to inform listing and delisting waters from their CWA Section 303(d) lists based on narrative criteria, as mentioned in Question 12.

NMED Exhibit 95

Implementation Questions about Water Quality Management Plans (e.g., TMDLs and NPDES permitting)

16. Why should I consider nutrient pollution if I am implementing the recommended criteria for cyanotoxins?

Loading of excess nutrients, including nitrogen and phosphorus, into recreational waterbodies from urban, industrial, and agricultural sources can contribute to cyanobacterial blooms and cyanotoxin production, as nitrogen and phosphorus are required for cyanobacterial growth. Reducing excess nitrogen and phosphorus in a waterbody can help to reduce the occurrence of cyanobacterial blooms or the levels of cyanotoxins in blooms containing toxin-producing strains of cyanobacteria.[27]

The relationships between nutrients and other physical, chemical, or environmental conditions are complex and can present added challenges to recreational waterbody managers responsible for monitoring and responding to cyanobacterial blooms. In addition to nitrogen and phosphorus concentrations, factors such as the availability of organic matter, turbidity, turbulence or flushing of a waterbody, light attenuation, temperature, and pH can play a role in the composition and cyanotoxin production associated with a cyanobacterial bloom. For more information on the factors influencing the occurrence of cyanobacterial blooms and toxin production, see Section 3.1.1 of the recommended criteria document.

The sources of nutrients present in waterbodies are both natural and anthropogenic. Soil and erosion of phosphorus-containing rocks are the most significant natural sources of the phosphorus in surface waters, while resuspension of bed sediment can be the major source of phosphorus to the lower water column. Significant natural sources of nitrogen include fixation of nitrogen gas, N_2, by diazotrophic organisms, as well as dry and wet deposition of naturally derived nitrogen compounds from the atmosphere. Human-caused nutrient pollution comes from several sources, for example:

1. Stormwater runoff in rural and urban areas contains nitrogen and phosphorus from fertilizers (especially those applied in excess or before a rainstorm), yard clippings, leaves, and pet wastes that are washed away to local waterbodies or conveyed through storm sewer systems. Land-based disturbances neighboring a waterbody (such as deforestation, soil compaction, reduced riparian buffers, erosion, or added impermeable surfaces) can increase stormwater runoff and can result in more nutrient pollution and sedimentation.
2. Discharges from municipal wastewater systems contain nitrogen and phosphorus from human waste, food, and certain soaps and detergents.
3. Discharges from industrial facilities, such as fertilizer manufacturers or food processing facilities, are sources of nitrogen and phosphorus.
4. Nonpoint source runoff from agriculture practices, such as the application of fertilizer to row crops and manure management can also be a source of nutrients.

Controlling excess phosphorus and nitrogen inputs could reduce the biomass of cyanobacteria in the system, and the frequency and concentration of microcystins and cylindrospermopsin produced. For

[27] For the results of a study on how the experimental limitation of nutrient supplies aided in the diminishing of a cyanobacterial bloom, see: Pace, M. et al. Reversal of a cyanobacterial bloom in response to early warnings. *Proceedings of the National Academy of Science. USA* 114, 352–357; DOI:10.1073/pnas.1612424114 (2017).

NMED Exhibit 95

more information on the impact of stressors, including elevated concentrations of total and dissolved phosphorus and nitrogen (e.g., soluble phosphates and nitrates), on the increased production of microcystins and cylindrospermopsin, see Section 3.0 of the national CWA Section 304(a) recommended criteria document.

As a long-term strategy to address eutrophication and cyanobacteria blooms, EPA recommends that states and authorized tribes consider adopting numeric nutrient criteria into their WQS or, alternatively, develop a numeric target to implement a narrative nutrient criterion that has already been adopted into their WQS. Numeric nutrient criteria or targets are useful tools to support water quality assessments, watershed protection or restoration, TMDL development, and permitting programs, where applicable. For information on translating between microcystins and nutrient loads in lakes, see Question 17 and Question 18. EPA stands ready to provide technical assistance to states and authorized tribes who are developing numeric nutrient criteria or targets for different waterbody types through EPA's Nutrient Scientific Technical Exchange Partnership and Support (N-STEPS) program.[28]

EPA continues to provide scientific and technical assistance to states and authorized tribes who are working to reduce excess nutrients as a means of reducing the occurrence of cyanobacterial blooms. For more information on what EPA is doing to help reduce excess nutrients and for tools to assist states and authorized tribes, refer to:

- A Compilation of Cost Data Associated with the Impacts and Control of Nutrient Pollution (PDF)

In addition to the EPA resources listed above, the document, World Health Organization: Guidelines for Safe Recreational Water Environments (PDF), contains a chapter on algae and cyanobacteria in freshwater, which includes short- and long-term management options—including nutrient management and implementation of control and abatement technologies, among other practices—with the goal of preventing or reducing the occurrence of cyanobacterial blooms in recreational waters.

17. How should states and authorized tribes complete TMDLs for waterbodies that are listed under CWA Section 303(d) as impaired or threatened due to cyanotoxins?

To address an impairment due to microcystins or cylindrospermopsin, states and authorized tribes would develop TMDLs for the pollutant(s) that promote development of cyanobacterial blooms capable of producing microcystins and cylindrospermopsin at levels above EPA's recommended criteria. As

[28] https://www.epa.gov/nutrient-policy-data/n-steps

previously discussed in this document, excess nutrients (nitrogen and/or phosphorus) and other factors (e.g., temperature) can provide optimal conditions for the formation of cyanobacterial blooms and cyanotoxin production. Accurately deriving the quantity, timing, and geographic distribution of pollutant reductions necessary to meet WQS for cyanotoxins (or cyanobacteria) is a complex process; however, states and authorized tribes can use technical tools to better understand the relationship between the pollutants and the biological and chemical responses associated with cyanobacterial blooms and the production of cyanotoxins such as microcystins. Technical tools that improve the understanding between nutrient pollution and adverse water quality effects associated with both non-toxic and toxic harmful algal blooms include empirical models developed for nutrient water quality criteria development,[29] as well as empirical and mechanistic models used for nutrient TMDLs that address impairments related to dissolved oxygen or elevated algal biomass (which can co-occur with toxic harmful algal blooms). States and authorized tribes may also want to conduct site-specific studies to help refine these relationships and should consider the state of the science as they prioritize and schedule TMDLs to address cyanotoxins.

18. Where a state or authorized tribe has adopted water quality criteria for microcystins and/or cylindrospermopsin, are National Pollutant Discharge Elimination System (NPDES) permits expected to include effluent limits for cyanotoxins?

In general, EPA does not anticipate NPDES permit limits for microcystins or cylindrospermopsin because most facilities subject to NPDES permit requirements do not typically discharge cyanotoxins directly. However, as previously discussed in this document, excess nitrogen and phosphorus loadings can provide optimal conditions for the formation of cyanobacterial blooms and cyanotoxin production. To better inform decisions around how best to control cyanotoxins and meet water quality standards, it may be helpful for NPDES permitting authorities to consider the risk of elevated levels of cyanotoxins in the receiving water when evaluating nutrient requirements in NPDES permits. States and authorized tribes can use technical tools to better understand the relationship between the pollutants—nitrogen and phosphorus—and the biological and chemical responses associated with toxic harmful algal blooms, including cyanotoxins. Technical tools that improve the understanding between nutrient pollution and adverse water quality effects associated with algal blooms, both non-toxic and toxic harmful algal blooms, include empirical models developed for nutrient water quality criteria development,[30] nutrient models

NMED Exhibit 95

that target dissolved oxygen or elevated algal biomass (which can co-occur with toxic harmful algal blooms), and state and federal technical guidance specific to the development of NPDES permit requirements. The document, *Ambient Water Quality Criteria to Address Nutrient Pollution in Lakes and Reservoirs,* summarizes the latest scientific information on nutrient pollution in lakes and reservoirs.[31] This document was published in July 2021 and contains a valuable summary of the current science on the issue of nutrients and bloom formation.

States and authorized tribes may also want to conduct site-specific studies to help refine these relationships and consider the state of the science as they evaluate the need for nutrient requirements in NPDES permits where there are applicable water quality criteria for cyanotoxins. For waterbodies where TMDLs have been developed to meet applicable water quality criteria for cyanotoxins, and the TMDL includes a waste load allocation for nitrogen and phosphorus, based on translations from microcystin concentrations, the waste load allocation is used to establish permit limits for nitrogen and phosphorus to meet the water quality criteria per 40 CFR 122.44(d)(1)(vii)(B). Conversely, where there are applicable water quality criteria for cyanotoxins but no TMDL for nutrients based on a microcystin translation, NPDES permitting authorities should consider the available science in determining whether nutrient discharges cause, have reasonable potential to cause, or contribute to impairments of applicable water quality criteria for cyanotoxins. Where the Director of the permitting authority determines that nutrient discharges cause, have reasonable potential to cause, or contribute to such impairments, the permit must include nutrient limits that are derived from and comply with the applicable water quality criteria per 40 CFR 122.44(d)(1)(vii)(A).

Introduction

Purpose

The New Mexico Environment Department (NMED) Surface Water Quality Bureau (SWQB) in collaboration with the New Mexico Department of Health (NMDOH), resource management agencies, and other stakeholders have developed a Harmful Algal Blooms (HABs) Advisory Program for New Mexico to inform collaborators and the public when HAB are present in New Mexico surface waters so they can make informed decisions to protect public and animal health. This HAB Advisory Guidance provides NMED, NMDOH, resource management agencies, and other cooperators with procedural guidelines should a HAB be suspected in surface waters in New Mexico. The plan also outlines the process should an HAB be identified in a public drinking water supply and information on reporting potential HAB-related illnesses. Publicly accessible lakes and reservoirs used for recreation are the primary focus of this plan and NM's HAB Advisory Program at this time because these waterbodies are the most likely to be associated with exposure of people or animals to cyanotoxins or other cyanobacteria-related irritants via water contact, accidental ingestion, or inhalation. Information in this plan can also be used for other surface waters where HABs occur. The plan will be reviewed at least annually by NMED SWQB and will be updated as new information on this emerging contaminant is determined and becomes available. When changes affect the scope, implementation, or outcome of HAB advisories, this guidance document will be revised accordingly.

Background and HAB Ecology

Cyanobacteria are naturally occurring important components of the aquatic environment. Cyanobacteria is commonly referred to as blue-green algae since cyanobacteria appear and function similarly to algae; however, cyanobacteria are not true algae. Under normal conditions, cyanobacteria are present in the water column or attached to surfaces at low levels.

HABs occur when dense concentrations of certain cyanobacteria capable of producing cyanotoxins that can have serious health consequences for humans, pets, and livestock quickly form, and can rapidly become toxic when these cyanotoxins are released into the water column when cells rupture or die. Other consequences of HABs include but are not limited to food web alterations and ecological dead zones (e.g., fish kills); ecotourism and property value losses; and negative impacts on drinking water supplies, agriculture, and wildlife (Carmichael 1992, Fawell et al. 1993, WHO 1999, WHO 2021).

When HABs occur, cyanobacteria typically become visibly abundant and form dense brown, tan, green, red, pink, or blue-green colonies. Blooms on or in the water may look like spilled paint,

NMED Exhibit 96

grass clippings, scums, or turbid water. Mat-forming HABs may occur on rocks, sediment, wood, aquatic vegetation, or artificial material, along with algae, microbes, and inorganic material.

Cyanotoxins can be produced by both planktonic (e.g., drifting or moving along in the water column) and mat-forming HABs (connected to the substrate). Many factors, including excess nutrients, sunlight, wind, flow, and temperature contribute to the formation of planktonic HABs. Although HABs can occur at any time, they are more likely to occur in late summer and early fall when temperatures are warm, water levels have stabilized, nutrients have been assimilated, and primary productivity increases. HABs may occur in some lakes and reservoirs following turn-over when nutrients are released from the bottom as cooler water is brought toward the surface. Shallow lakes and reservoirs with long residence times or elevated concentrations of nutrients have an increased likelihood of blooms. Mat-forming blooms are most common in wadable streams and rivers, but can also be found in lakes, reservoirs, and hot springs (CA NCRWCB 2022).

Exposure Routes and Health Effects

General health effects caused by exposure to toxic algae vary according to the type of toxin, the level of exposure, and the type of exposure (dermal, inhalation, and incidental ingestion).

Human symptoms include:

- skin irritation
- stomach cramps
- rashes
- kidney / liver damage
- fever
- sore throat
- headaches
- muscle / joint pain
- diarrhea
- neurotoxic effects
- hives
- nausea / vomiting
- increased asthma symptoms
- allergic reactions such as rhinitis (stuffy / runny nose)

Animals, especially dogs, may experience poisoning. Symptoms of pet poisoning include swelling of mouth, ear, or udder, vomiting, seizures, rashes, disorientation, staggering, inactivity, etc. and in extreme cases, sudden collapse and death (EPA 2019). See Appendix A for more information on pets and livestock.

There is inadequate evidence at this time to determine whether these toxins from algae cause cancer or other long term illness in humans or pets. See Appendix A for how thresholds were determined.

Advisory Guidance Thresholds

One objective of this plan is to identify cyanobacteria and cyanotoxin thresholds that will be used to inform the public and cooperators when human health risks may be present based on the presence of a HAB and the presence of cyanotoxin concentrations that exceed recreational thresholds (see Appendix A for additional details regarding how these thresholds were determined). This information can then be used by the public and cooperators to take appropriate precautions to protect the health of people and animals. Such actions may include, but are not limited to, avoiding areas with blooms, limiting access to waterbodies, cleaning fish properly, and conducting additional monitoring of public water supplies.

Table 1 details advisory guidance thresholds for recreational waters affected by HABs for three advisory levels – HAB WATCH, HAB WARNING, and HAB DANGER

Table 1. Advisory Status and Thresholds

	HAB WATCH	HAB WARNING	HAB DANGER
Toxigenic cyanobacteria cell density (cells/mL)[1,2,3]	Visual indication of HAB Presence (Determination by NMED based on photo and/or laboratory analysis)	>100,000 (determined by laboratory analysis)	none
Microcystins (µg/L) [1,2,3,4]	≥0.1	>8	>2,000
Cylindrospermopsin (µg/L) [3,4]	≥0.04	>15	none
Anatoxin-a (µg/L)[3,4,5,6]	≥0.1	>15	>90
Saxitoxins (µg/L) [3,5,7]	≥0.02	>8	>75

[1] WHO 2003
[2] WHO 2021
[3] USEPA 2019a
[4] Based on contract laboratory Reporting Limits used by NMED
[5] OHA 2021
[6] CWQMC 2016
[7] EFSA 2009

	HAB WATCH	HAB WARNING	HAB DANGER
Health risks	Low Risk, but Potential for risk level to quickly increase	Potential for long-term illness	Potential for acute poisoning Potential for long-term illness
		Short-term effects (e.g., skin and eye irritation, nausea, vomiting, diarrhea)	Short-term effects (e.g., skin and eye irritation, nausea, vomiting, diarrhea)
Recommended actions (NMED and resource managers)	Issue WATCH advisory to avoid primary contact recreation where HABs are observed	Issue WARNING advisory to avoid primary contact recreation	Issue DANGER advisory to avoid primary contact recreation
	Post WATCH signs	Post WARNING signs	Post DANGER signs
	Sampling recommended at least once every 2 weeks	Sampling recommended at least once every two weeks	Consider CLOSURE Sampling recommended at least once every two weeks

Table 2. Advisory Status and Recommendations for Recreationists

HAB WATCH
A **HAB WATCH** advisory means there is evidence that a harmful algal bloom is developing.
• As always, do not drink untreated surface water or get it in your mouth. • Avoid algae blooms while swimming and wading. Swimming is not recommended near visible blooms. • Supervise and keep pets away from both water and shoreline algae and rinse them with clean water if contact occurs. • Rinse fish with clean water prior to cooking thoroughly and eat only the fillet portion.

Table 2. Advisory Status and Recommendations for Recreationists (cont.)

HABWARNING
A **HAB WARNING** advisory usually means measured values exceed thresholds established by the NMED in a waterbody or portion of a waterbody. This is a strong indication that a harmful algal bloom is present.
• Do not drink the water or get it in your mouth • Do not swim or water ski. • Adults should avoid algae blooms while wading. • Supervise children and prevent them from entering the lake or playing near algae deposited on the shoreline. • Keep dogs or other animals away. • Avoid areas of algae when boating or paddleboarding. • Use caution when fishing because the effects of HAB toxins on fish are not well understood. If you choose to fish, rinse fish with clean water prior to cooking thoroughly and eat only the fillet portion.

HAB DANGER
A **HAB DANGER** advisory means measured values greatly exceed thresholds established by the NMED in a waterbody or portion of a waterbody. This usually means the bloom has become very large and/or high levels of dangerous toxins have been measured. A portion or the entire waterbody may be temporarily closed by the resource manager as part of the HAB DANGER Advisory.
• Do not drink water or get it in your mouth • Do not swim, wade, paddleboard, boat, or water ski • Keep dogs or other animals away. • Eating fish at these toxin levels is not recommended because the effects of HAB toxins in fish are not well understood. If you choose to fish, rinse fish with clean water prior to cooking thoroughly and eat only the fillet portion.

Advisory Guidance Process

The following procedures have been developed for notifying the resource managers and the public of recreation risks in surface waters associated with HABs. New Mexico's HAB response strategy is based on four steps: 1) Surveillance, Reporting and Preliminary Screening; 2) Data Collection; 3) Determining Advisories and Updating the HAB Advisory Map; and 4) Lifting Advisories

Step 1: Surveillance, Reporting and Preliminary Screening

One of the most important aspects of HAB surveillance is the recreating public. To maximize public participation in the advisory program as well as HABs reporting, NMED and cooperators should inform and educate the public about HABs and the advisory program. NMED may issue a press release at the beginning of the HABs season to remind the public of the upcoming season, the health risks associated with HABs, and how to identify and report HABs and HAB-related illnesses. NMED, DOH and cooperating agencies should work to inform the public of the adverse health effects associated with HABs and how to identify and report a suspected bloom and any cases of human or animal illness or death. Useful information about HABs, how to identify them, and what to do in the event of a HAB can be found on the NMED HAB Advisory webpage. In the event of a public health notification or closure, NMED, DOH and cooperating agencies should coordinate to ensure that information is disseminated via signs, press releases, videos, websites, social media, and other public forums.

NMED, DOH and all cooperators encourage anyone experiencing symptoms possibly related to a HAB event to call the New Mexico Poison and Drug Information Center at 1-800-222-1222. The Poison Information Center coordinates reported HAB cases with DOH to be reported to the EPA One Health Harmful Algal Blooms System (OHHABS). OHHABS is a collaborative network between state and federal partners and provides electronic reporting by state and local health departments via the National Outbreak Reporting System (NORS), case studies of HAB-related illness surveillance, and support from the Great Lakes Restoration Initiative that uses OHHABS data to inform their restoration objectives. More information and resources can be found on the OHHABS website. DOH will review the information and relay illness reports to NMED so follow-up monitoring can occur.

> To report a bloom, the public and resource managers should use EPA's bloomWatch app. BloomWatch is a participatory science app that allows users to find and report potential cyanobacteria blooms in water bodies. The data users provide help NMED and EPA track and manage water quality to protect public health and the environment from harmful blooms. NMED encourages everyone to download and review how to use the bloomWatch app to report suspected harmful algal blooms.

Waterbodies with heavy recreational use, particularly those with swimming beaches or those that are frequently used for swimming and similar water contact activities, should be visually inspected by management agencies weekly during periods of high recreational use (approximately May through November). Some priority lakes identified by NMED are routinely monitored, generally monthly, during the HAB season (approximately mid-July through November). Visual inspection should generally occur through observations by resource management agencies (e.g., New Mexico State Parks, National Park Service, New Mexico Wildlife Department, United States Forest Service, Bureau of Land Management, US Army Corps of Engineers, Bureau of Reclamation, United States Fish and Wildlife Service) as well as NMED, municipalities, and other cooperators.

Field tests are optional but may provide preliminary information on the potential health risks of a suspected HAB as well as the type of laboratory analysis that should be conducted. Once reported to NMED, suspected HABs can be evaluated by NMED or a cooperator using jar and/or stick tests to determine whether cyanobacteria are present (see procedures as well as safety protocols in NMED's HABs SOP 13.2 for procedure). Cooperators can also use field test strips (e.g., Abraxis Strip Test®) to test for cyanotoxins. Samplers should follow test strip protocols provided in their purchased test kit. Field test strips, jar and/or stick test will be used to prioritize sampling by NMED SWQB and cannot be used to determine exceedances of HAB WARNING and HAB DANGER thresholds.

Resource constraints may limit the number of lakes and reservoirs that can be inspected on a routine basis by resource management agencies, and the public may not consistently report suspected blooms. Therefore, NMED will use Cyanobacteria Assessment Network (CyAN) and EPA's HAB Forecasts satellite imagery can detect HABs due to the unique spectral signature of cyanobacteria. Although EPA is actively working to improve resolution, for lakes and reservoirs to be considered resolvable by CyAN, they currently must meet a minimum size requirement (300 by 300 meters) at this time. According to EPA, this size threshold results in approximately 14 New Mexico waterbodies that can be monitored remotely by NMED. NMED will analyze imagery for these waterbodies using screening metrics that determine the areal extent of blooms and bloom persistence over time. NMED may also use CyAN imagery to determine if smaller lakes and reservoirs should be investigated.

Step 2: Water Quality Data Collection

NMED SWQB will schedule a sampling event ASAP as resources allow as detailed in respective HABs and priority lake Sampling and Analysis Plans (SAPs) and SWQB's HABs Standard Operating Procedure (SOP) 13.2. NMED will take photos and collect water samples for cyanotoxin analysis as well as cyanobacteria identification and enumeration as resources allow. Total microcystins,

will generally be evaluated during all sampling events. Cylindrospermopsin and other cyanotoxins will be evaluated when they may be elevated and as resources allow.

NMED does not provide analytical support for private waterbodies unless there is a public health concern associated with the waterbody. If other entities or landowners are interested in having samples analyzed, a list of common laboratories that analyze cyanobacteria and cyanotoxins can be found on EPA's website: https://www.epa.gov/cyanohabs/laboratories-analyze-cyanobacteria-and-cyanotoxins.

Step 3: Determining Advisories and Public Notification Steps

NMED will utilize available data that meets the NMED SWQB quality assurance requirements to determine where to issue advisories based on exceedances of advisory thresholds. The public health notification process includes (1) updating New Mexico's HABs Advisory Map, (2) posting signs at the waterbody, and (3) optional additional public outreach via press releases or social media.

All current advisories will be available on the HABs Advisory Map. Additional information related to extent of the current advisory will be identified on the map. NMED encourages cooperators and recreationists to visit the webpage for the most up-to-date information.

When NMED Issues HAB Advisories, NMED will work with the resource managers on a public information campaign including signage at the waterbody. NMED will not always be able to post signage in a timely manner. It is expected for resource managers and cooperators to post the necessary signage whenever possible. NMED will share signage files for agencies to print and post. NMED will also work with resource managers to procure and distribute more durable signage where necessary.

Once an advisory has been issued for a waterbody, NMED and resource management agencies will continue to monitor the location, extent, and severity of HABs to provide the most up-to-date information to recreationists. NMED will discontinue routine monthly monitoring at the end of November. In circumstances where data indicates that an advisory should be changed (such as elevating a **HAB WATCH** to a **HAB WARNING** or lifting an advisory), the public health notification (e.g., map, listserv notice, etc.) will be updated accordingly. Resource management agencies should also ensure that any human illnesses or animal deaths have been reported to DOH.

Step 4: Lifting and Discontinuing Advisories

HAB WATCH will be lifted if there is evidence that a bloom has fully dissipated at a waterbody, as indicated laboratory cyanobacteria toxin analyses and/or cyanobacteria identification**. HAB WARNING** and **HAB DANGER** will be downgraded to the appropriate status if cyanotoxin concentrations from two consecutive sampling events at the site, separated by at least 1 week (i.e., 7 days, 168 hours), are below the applicable **HAB Advisory** thresholds. Any advisories that have not yet lifted will be lifted on November 30th due to winter conditions unless current toxin levels indicate otherwise. HABs can pop up anytime and anywhere, therefore it is best to always exercise caution; when in doubt stay out.

Once confirmed, NMED will change the waterbody status, or it will be removed from the Current Advisory tab on the NMED's HABs advisory Map. Cooperators and the public are encouraged to check the New Mexico HABs Advisory Map for information on sampling results and advisory status. Resource management agencies should continue to observe the waterbody and report new cyanobacterial blooms if they appear.

Appendix A: Rationale for Selected Thresholds

Cyanotoxin Thresholds

In May 2019, the US Environmental Protection Agency (EPA) released *Recommended Human Health Recreational Ambient Water Quality Criteria or Swimming Advisories for Microcystins and Cylindrospermopsin* that states and authorized tribes can consider for inclusion as water quality criteria for the protection of primary contact recreation and/or for issuing public health advisories (USEPA 2019a). The recommended cyanotoxin thresholds are 8 µg/L total microcystins and 15 µg/L cylindrospermopsin**.** These recommendations are based on incidental ingestion by children while swimming since children represent the most vulnerable age group due to their extended periods of water play as well as the quantity of water they typically ingest during water play. The recommendations were derived from peer-reviewed scientific literature and criteria methodologies in EPA's Exposure Factors Handbook (2011). Thresholds were only developed for microcystin and cylindrospermopsin since these toxins have sufficient toxicological data. Sampling in New Mexico primarily targets microcystins and cylindrospermopsin as these are the two cyanotoxins that EPA has established recommended recreational criteria that are also in New Mexico's Water Quality Standards (20.6.4.900.D New Mexico Administrative Code, USEPA, 2019b).

EPA has not released recommended criteria for any other cyanotoxins. The program may expand to include other cyanotoxins as additional guidance, data, and understanding of the impacts of varying levels of these cyanotoxins become available. NMED will use the EPA recommended thresholds of **8 µg/L total microcystins and 15 µg/L cylindrospermopsin for the HAB WARNING** advisory; NMED will also use the same thresholds for anatoxin and saxitoxin established in Colorado by the Colorado Department of Public Health and Environment: **15 µg/L anatoxin** and **8 µg/L saxitoxin**. NMED will use Utah Department of Environmental Quality's established "Danger Advisory" threshold for New Mexico's **HAB DANGER** thresholds: **2000 µg/L total microcystins**, **90 µg/L anatoxin**, and **75 µg/L saxitoxin**. New Mexico's **HAB WATCH**

thresholds are based off of MDLs for analytical methods utilized by NMED; these are : **0.1 µg/L total microcystins,** 0**.04 µg/L cylindrospermospin**, 0**.1 µg/L anatoxin**, and 0**.02 µg/L saxitoxin**.

Thresholds included in this plan will be updated as additional cyanobacteria and cyanotoxin data are collected in New Mexico surface waters and new scientific information becomes available.

Cyanobacteria Thresholds

This plan also identifies potentially harmful levels of cyanobacteria because there may be risks associated with direct contact with cyanobacteria cells themselves, regardless of whether they can produce known cyanotoxins (USEPA 2019a). In addition, cyanobacteria may quickly transition from not producing cyanotoxins to producing cyanotoxins, and some genera of cyanobacteria can produce different toxins at different times, some of which may not be documented (Otten and Paerl 2015).

The type of cyanotoxins present in a waterbody depend on the species/genera of cyanobacteria, though some species/genera can produce multiple types of toxins. Moreover, toxigenic cyanobacteria, or those cyanobacteria with genes that allow for cyanotoxin production, may only produce cyanotoxins under certain environmental conditions. A list of toxigenic cyanobacteria and the cyanotoxins they can produce are listed in Table 3.

These cyanotoxins are categorized by their primary mode of action: dermatoxins (i.e., skin irritants), hepatotoxins (i.e., affect liver function), and neurotoxins (i.e., affect central nervous system).

Toxin abbreviations are as follows: APL, aplysiatoxins; LPS, lipopolysaccharides; LYN, lyngbyatoxin-a; CYL, cylindrospermopsins; MC, microcystins; NOD, nodularins; ATX, anatoxins; BMAA, β-N-methylamino-L-alanine; GTX, guanitoxin; NEO, neosaxitoxins; SAX, saxitoxins.

When released from cyanobacteria cells, cyanotoxins are colorless and may remain in the water column after a bloom has dissipated. Studies have shown cyanotoxins persist anywhere from five days to several months in water and up to six months in dry scum (USEPA 2019a). The rate at which cyanotoxins are removed depends on environmental factors such as water pH and temperature, ultraviolet degradation, the presence of particulate matter, water depth, and bacterial breakdown (USGS 2008 USEPA 2019a). Studies have also shown that certain strains of

microcystin can remain in sediments for months or, conversely, bypass sediments and enter groundwater. Cyanotoxins and cyanobacteria can also flow downstream from lakes and reservoirs for indeterminate distances (Yang et al. 2016, USEPA 2019a).

Planktonic Blooms

Planktonic blooms, most often found in lakes and reservoirs in New Mexico, are characterized by cyanobacteria cells suspended in the water column, floating on the water surface, or aggregated on shorelines. Since planktonic blooms pose the greatest health risk to recreators exposed through direct contact with cyanobacteria dispersed in the water column or floating on the water surface, planktonic blooms are most commonly sampled via surface grab samples.

For planktonic blooms, **HAB WARNING** advisories are issued when cyanobacteria cell densities exceed **100,000 cells/mL**. This cell density was selected after reviewing scientific studies utilized by other state agencies and health organizations (Graham et al. 2009, Farrer et al. 2015). The cell density threshold was chosen after reviewing World Health Organization (WHO 1999) guidelines and represents the level at which acute health effects transition from low to moderate risk (Table 4). Any combination of cyanobacteria taxa found in a planktonic bloom can trigger a bloom advisory due to the high risk of dermal contact and inhalation presented by these types of blooms. **HAB WATCH** advisories will be issued on a case-by-case basis by NMED after evaluating all available evidence including photos, satellite data, preliminary testing, and laboratory analysis that indicate the presence of a developing HAB.

Table 2. World Health Organization guidelines for cyanobacterial bloom characterization (Graham et al. 2009)

Relative Probability of Acute Health Effects	Cyanobacteria[1] (cells/mL)	Microcystin-LR[2] (μg/L)	Chlorophyll-*a*[3] (μg/L)
Low	< 20,000	< 10	< 10
Moderate	20,000-100,000	10-20	10-50
High	100,000-10,000,000	20-2,000	50-5,000
Very High	>10,000,000	>2,000	>5,000

Cyanotoxins are emerging contaminants and while the advisory plan aims to protect public health, more research is needed to understand all of the risks posed by HABs. Specific areas of research include fish consumption, inhalation of aerosolized particles, and health effects on animals.

NMED Exhibit 96

Mat-Forming Blooms

Not enough data has been collected on Mat-Forming Blooms in New Mexico to currently include these in the response plan. The public is encouraged to visit the NMED HABs webpage for resources to help identify these and avoid them whenever possible. NMED SWQB is currently exploring adding Benthic HABs to the HABs Advisory Program and will be modeled after Utah DEQ's methodology.

Other Health Risks

Cyanotoxins are emerging contaminants and while the advisory plan aims to protect public health, more research is needed to understand all the risks posed by HABs. Specific areas of research include fish consumption, inhalation of aerosolized particles, and health effects on animals.

Fish Consumption

At this time, there is insufficient information to determine the risk of consuming fish caught in waters with a HAB. Studies have shown that toxins mainly accumulate in the liver and viscera of fish, and small amounts of microcystin has been detected in the fillet (Vasconcelos 1999, de Magalhaes et al. 2001, Kann 2008, WA DOE 2010, Kann et al. 2011). At a minimum, organs and skin should be removed and discarded, and fillets rinsed with clean water prior to cooking or freezing fillets. Caution should be taken with shellfish as cyanotoxins have been shown to accumulate in edible tissue (Vasconcelos 1999).

Pets and Livestock

Currently, there is insufficient information to determine the risk HABs pose to animals. It is suspected but not confirmed that dog deaths due to cyanotoxins have occurred in New Mexico. Oregon has established recreational use values for cyanotoxins and dogs that are much lower than the EPA recommended criteria for humans. NMED recommends never letting animals near water that is suspected of a HAB as they are likely to ingest the water or cyanobacteria causing the bloom. Please see the NMDOH HABs and Animals Fact Sheet for more information.

Aerosols

Currently, there is insufficient information to determine the risk aerosolized HABs pose to the public. It is suspected that cyanotoxins can become aerosolized especially with churning wave action and boating or waterskiing and it is possible that the aerosols could be transported for miles. Please see the Great Lakes HABs Collaborative fact sheet about HAB toxins in air for more information.
