1) Diversity as well as abundance of cyprinids in the tributaries vs the Arkansas River mainstem more likely a function of habitat and/or predator density rather than influence of selenium.
2) Several sites on Wildhorse Creek, Fountain Creek, and the St. Charles River, had substantial changes in the populations of some fish species between sample years 2005 and 2006, with fish that were present in one year in high numbers and with a variety of age classes, either

NMED Exhibit 59

absent or present in low numbers the other year. These changes are likely to be linked to higher stream flows present in 2006 and significant habitat changes due to beaver activity at some sites. Variable population compositions and numbers of cyprinids are not uncommon in plains streams with highly variable flow regimes and habitat conditions (Schlosser 1987).

3) Based on an evaluation of age class distribution (indicated by length-frequency distribution data), it was concluded that the following sites had viable and reproducing cyprinid populations (NAMC 2008:

> Arkansas River mainstem: The length-frequency data collected for the fish species at these sites indicates multiple age groups present for most of the species at the sites.
> Fountain Creek - Length-frequency analysis of the flathead chubs indicated that the populations are reproducing, with juvenile and older adult fish present in relatively high numbers at both sites and years.
> St. Charles River - Length-frequency analysis of the fish populations indicated that sites had reproducing populations of central stonerollers, fathead minnows, and sand shiners, with juvenile and adult fish collected during both years (GEI 2007a).
> Wildhorse Creek - the age class distribution of central stonerollers was similar between years, indicating a reproducing population that includes both juvenile and adult fish in both years, despite the extremely high [Se] in water.

Relevance/Surrogacy of Arkansas River Cyprinids to all Cyprinid Species in US

Cyprinids captured from the Arkansas River are representative of cyprinid species occurring throughout the US. This conclusion is based on the following lines of evidence:

- Six of the seven cyprinid species (central stoneroller, fathead minnow, flathead chub, longnose dace, red shiner, and sand shiner) captured from the Arkansas River during this investigation are native to the United States;
- Four of the six cyprinid species found in the Arkansas River basin (central stoneroller, fathead minnow, sand shiner and red shiner) are widely distributed throughout the United States (see species specific distribution maps Attachment 1); and,
- Six of the native species present in the Arkansas River Basin are direct surrogates at the genus level for the 142 native cyprinids in North America (Table E-19).

NMED Exhibit 59

Table E-19. Cyprinid species surrogacy and occurrence in water for native species inhabiting the Arkansas River and select tributaries.

Species	Cyprinid group	# of species represented by genus	[Se] in waterbodies where species occurred	Average tissue concentration or range
Campostoma anomalum Central stoneroller	stonerollers	5 species	3.1-418 ug/L	5-47 mg/kg dw
Pimephales promelas Fathead minnow	Blunthead minnows	4 species	3.1 - 20.3 ug/L	No tissue
Platygabio gracilis Flathead chub	Flathead chub	1 species	3.1 - 20.3 ug/L	No tissue
Rhynichthys cataractae Longnoise dace	dace	9 species	3.1 - 20.3 ug/L	No tissue
Cyprinella lutrensis Red shiner	Satinfin shiners	32 species	3.1 - 20.3 ug/L	23-42 mg/kg dw
Notropis stramineus Sand shiner	Eastern shiners	91 species	3.1 - 20.3 ug/L	10-25 mg/kg dw

Summary cyprinid surrogacy:

Cyprinid species collected from the Arkansas River watershed are representative (at the genus level) of the 142 cyprinid species native to North America. With the exception of one sample location (Whitehorse Creek), the abundance and diversity of cyprinid species present and the occurrence of multiple age classes indicates that cyprinids are successfully surviving and reproducing in the Arkansas River watershed, even with selenium concentrations exceeding 5ug/L in water and 8 mg/kg bw in whole body fish tissue. North American species not represented at the genera level comprise 54 species (mostly chubs – 40 species), many of which are geographically isolated.

3. Observations of cyprinids in NC Reservoirs (Hyco Reservoir and Belews Lake) – (located at end of NAMC 2008 report).

Crutchfield et al. (2000) evaluated long-term water quality data, selenium chemical concentration data collected for sediment, invertebrate and fish tissues, and invertebrate and fish population data collected from the Hyco Reservoir to document the recovery of the aquatic community following the 1990 installation of a dry fly ash pollution abatement system. Since 1973, data have been collected from six locations in the Hyco Reservoir, with varying fly ash exposure. Gamefish including bluegill sunfish and largemouth bass were reproductively extirpated due to high selenium concentrations prior to installation of the pollution abatement system. The fish community was dominated by green sunfish (*Lepomis cyanellus*), eastern mosquitofish (*Gambusia holbrooki*), gizzard shad (*Dorosoma cepedianum*), and satinfin shiner (*Cyprinella analostana*). Their main observation was that satinfin shiner was a dominant cyprinid in the Se limited fish community prior to selenium reduction.

NMED Exhibit 59

Barwick and Harrell (1997) evaluated fish population monitoring and tissue selenium concentration data to document the recovery of fish populations in Belews Lake for the ten years following installation of a dry fly ash pollution abatement system. Fish diversity and biomass data were collected from 1977 to 1994 (with the exception of 1978-1979 and 1982-1983) at two sites on the lake. In 1980 and 1981, fathead minnows (*Pimephales promelas*) dominated the fish community, representing 62 percent and 81 percent of the biomass, respectively (Barwick and Harrell 1997). By 1984, red shiner (*Cyprinella lutrensis*), common carp (*Cyprinius carpio*), and fathead minnows (*Pimephales promelas*) were the dominant cyprinids in the selenium limited fish community prior to selenium reduction. The authors noted that cyprinid abundance started to decrease as green sunfish, a more Se- tolerant sunfish recovered in 1989-1990, followed by further decreases in 1990-1994, as channel catfish, bluegill, and largemouth bass populations increased (Barwick and Harrell 1997).

Young et al. (2010), reviewing the studies of Belews Lake, NC, note that during the period of maximal selenium inputs, egg and ovary concentrations reached 40-159 mg Se/kg dw. Out of as many as 29 resident species prior to contamination, only catfish and the cyprinids common carp and fathead minnows remained during the period of maximum impact.

4. Presser, T.S., 2013, Selenium in ecosystems within the mountaintop coal mining and valley-fill region of southern West Virginia—assessment and ecosystem-scale modeling: U.S. Geological Survey Professional Paper 1803, 86 p. http://dx.doi.org/10.3133/pp1803.

USGS sampled southern West Virginia ecosystems affected by drainage from mountaintop coal mines and valleys filled with waste rock (valley fills) in the Coal, Gauley, and Lower Guyandotte watersheds during 2010 and 2011. Sampling data from earlier studies in these watersheds (for example, Upper Mud River Reservoir) and other mining-affected watersheds in WV are also are included to assess additional hydrologic settings and food webs for comparison.

1) Site-specific fish abundance and richness data documented the occurrence of various species of chub, shiner, dace, minnow, and central stoneroller (*Campostoma anomalum*) in the sampled watersheds.
2) Model species for streams were limited to creek chub (*Semotilus atromaculatus*) and central stoneroller. Creek chub was present at all sites during USGS sampling in 2010-2011. However, both of these species are considered to have high tolerance for environmental stressors based on results of traditional comparative fish community assessments. Concentrations of Se in water and whole body tissues of creek chub, blacknose dace, and stoneroller are shown in Table E-20.
3) The order of abundance for species with greater than 28 individuals was: creek chub, striped shiner, mottled sculpin, green sunfish, central stoneroller, blacknose dace, bluntnose minnow, and northern hog sucker. Shiners and darters were prevalent, but bluegill sunfish were absent during the 2010 survey.

NMED Exhibit 59

Study Summary:

Samples in various environmental media (water, sediment, algae, macroinvertebrates, fish) were collected by USGS (2010-2011), and others (e.g. WVDEP, Potesta) between 2005 and 2011. The stream segments presented here represent a subset of the stream segments with available data. Only streams with water [Se] > 5.0 ug/L are presented to facilitate comparison with other studies with Se-impacted streams. Overarching observations include:

1) [Se] in water averaged from 5.3 ug/L – 31.4 ug/L with a high of 90 ug/L (Connor Run, 2009).
2) [Se] in fish tissue: creek chub – averaged from 5.8 mg/kg wb to 28 mg/kg wb, with a maximum whole body concentration of 80 mg/kg wb (Little Scary Creek, 2009).
3) [Se] in fish tissue: blacknose dace – averaged from 10.7 mg/kg wb to 66 mg/kg wb, with a maximum whole body concentration of 113 mg/kg wb (Bull push fork w/pond, 2010)
4) [Se] in fish tissue: central stoneroller – averaged from 6.9 mg/kg wb to 12.4 mg/kg wb, with a maximum whole body concentration of 34.5 mg/kg wb (Hughes Fork, 2005). Note also, that central stoneroller, although common through stream segments samples, were not ubiquitous, as was observed in the study conducted by NAMC in the Arkansas River near Pueblo CO.

5. Selenium concentrations in fish tissue collected from the Gunnison River.
http://pubs.usgs.gov/of/2012/1235/of12-1235.pdf

Approach: In sampling conducted in summer 2010, muscle tissue plugs were collected from common carp (*Cyprinus Linnaeus)*, roundtail chub (*Gila robusta; listed*), and whole body tissue samples were collected from speckled dace (*Rhinichthys osculus)* inhabiting critical habitat in the Gunnison River in Western Colorado (Table E-21). Total selenium in fish muscle plugs (mg/kg dw) for roundtail chub, or in whole body (speckled dace) was calculated for all tissues. In follow-up sampling conducted in the summer of 2011, muscle plugs were collected from common carp (*Cyprinus Linnaeus)*, roundtail chub (*Gila robusta; listed*), and bonytail chub (*Gila elegans, listed*) inhabiting critical habitat in the Gunnison River in Western Colorado.

This study was intended to document any changes in selenium concentration in fish over the last 20 years based on remediation efforts that have been completed to date.

Table E-21. Fish tissue concentrations observed in Cyprinids.

Species	**Year**	**Mean (Range) [Se]**	**# > muscle = 11***	**# > whole body = 8**
Roundtail Chub	2010	9.7 mg/kg dw (5.2-32.4)	2/15	
	2011	7.33 mg/kg dw (5.6-11.2)	1/15	
Speckled Dace	2010	7.46 mg/kg dw (5.7-9.7)		6/15

* Muscle plugs were collected since this species is large enough for non-destructive sampling, and b) a listed species.

NMED Exhibit 59

5.0 OTHER DATA – CHRONIC STUDIES WITH INVERTEBRATE SPECIES

A limited number of studies have evaluated the effects of selenite on invertebrate species, an important prey item for fish and birds as summarized by Debruyn and Chapman (2007). The following **studies** with a rotifer, and annelid, and an insect (mayfly) were found suitable for establishing species sensitivity.

5.1 Rotifers

Dobbs et al. (1996) exposed *Brachionus calyciflorus* to selenate in natural creek water for 25 days in a three-trophic level food chain test system. This is one of two laboratory-based experiments (also see Bennett et al. 1986) that involved exposing algae to selenium (in this case as sodium selenate) in water, and subsequently feeding the algae to rotifers which were in turn fed to fish (fathead minnows). In this particular study, the rotifers and fish were exposed to the same concentrations of sodium selenate in the water as the algae, but received additional selenium from their diet (i.e., the algae fed to rotifers and the rotifers fed to fish). The overall exposure lasted for 25 days. Rotifers did not grow well at concentrations exceeding 108.1 µg Se/L in water, and the population survived only 6 days at selenium concentrations equal to or greater than 202.4 µg Se/L in the water (40 µg Se/g dw in the algae). Regression analysis of untransformed growth data (dry weight) determined 4 day post-test initiation resulted in a calculated EC_{10} of 37.84 µg Se/g dw tissue.

5.2 Aquatic Worms

Although not intended to be a definitive toxicity study for this invertebrate, Besser et al. (2006) evaluated the bioaccumulation and toxicity of selenized yeast to the oligochaete, *Lumbriculus variegatus,* which was intended to be used for dietary exposure in subsequent studies with the endangered desert pupfish, *Cyprinidon macularius*. Oligochaetes fed selenized-yeast yeast diets diluted with nutritional yeast (54 to 210 mg Se/kg) had stable or increasing biomass and accumulated Se concentrations as high as 140 mg/kg dw. The oligochaetes fed the undiluted selenized-yeast (826 µg/g Se dry wt.) showed reduced biomass. The effect level is considered >140 mg Se/kg dw.

5.3 Aquatic Insects (Plecoptera: Mayfly)

Conley, J.M., D.H. Funk and D.B. Buchwalter. 2009. Selenium bioaccumulation and maternal transfer in the mayfly *Centroptilum triangulifer* in a life-cycle, periphyton-biofilm trophic assay. Environ. Sci. Technol. 43:7952-7957.

Conley, J.M., D.H. Funk, N.J. Cariello and D.B. Buchwalter. 2011. Food rationing affects dietary selenium bioaccumulation and life cycle performance in the mayfly *Centroptilum triangulifer*. Ecotoxicol. 20:1840-1851.

Conley, J.M., D.H. Funk, D.H. Hesterberg, L-C. Hsu, J. Kan, Y-T. Liu and D.B. Buchwalter. 2013. Bioconcentration and biotransformation of selenite versus selenite exposed to periphyton and subsequent toxicity to the mayfly *Centroptilum triangulifer*. Environ. Sci. Technol. 47:7965-7973.

NMED Exhibit 59

Conley et al. (2009) exposed mayfly larvae (*Centroptilum triangulifer*) to dietary selenium contained in natural periphyton biofilms to eclosion. The periphyton fed to the mayfly larvae were exposed to dissolved selenite (radiolabeled ^{75}Se) in November 2008 (12.6 and 13.9 µg/L) and in January 2009 (2.4, 2.4, 4.9, 10.3, and 10.7 µg/L). Periphyton bioconcentrated Se an average of 1113-fold over the different aqueous Se concentrations (Table E-22). Twenty 4 to 6-day old mayfly larvae were exposed for 4.5 to 6 weeks to each of the periphyton diets until the larvae eclosed to subimagos. The subimagos were allowed to emerge to the adult imago stage which deposited their egg masses in Petri dishes. Selenium was measured in postpartum adults along with their dry weights and clutch size.

NMED Exhibit 59

Table E-22. Selenium concentrations in water exposed to periphyton, periphyton and mayfly adults.

Treatment	Dissolved [Se] exposed to periphyton, µg/L	[Se] in periphyton, mg/kg dw	[Se] in mayfly adult, mg/kg dw
5A	2.4	2.2	4.2
5B	2.4	2.0	5.7
10A	4.9	4.4	9.7
20C	10.3	8.7	16.2
20D	10.7	11.3	27.5
20A	12.6	25.5	56.7
20B	13.9	17.5	34.8

Selenium increased in concentration from periphyton to the adult mayflies (trophic transfer factor) an average of 2.2-fold (Table E-22). The authors observed a decrease in fecundity as maternal postpartum Se concentrations increased. Fecundity was also related to growth of the mayflies. The authors observed a reduction in fecundity for this mayfly when they were fed diets containing more than 11 mg Se/kg dw. This threshold is considered the effect value for this study. Using the trophic transfer factor of 2.2, the periphyton Se concentration of 11 mg/kg dw translates to an adult mayfly Se concentration of 24.2 mg/kg dw.

Conley et al. (2011) exposed larval *C. triangulifer* similar to Conley et al. (2009) to two different rations of periphyton (1x and 2x) to evaluate the effect of feeding ration on the bioaccumulation and life cycle performance of the mayfly. Periphyton (on plates) was initially exposed to low (1.1 to 3.4 µg/L), medium (5.9 – 8.9 µg/L) and high (19.2 – 23.1 µg/L) selenite. Fifteen 1-2 day-old mayfly larvae were then fed either 1 plate (1x ration) or 2 plates (2x ration) in bottles containing 1.8 L water to eclosion to subimagos (25-29 days). Subimagos were induced to emerge to adults in petri dishes and their clutch size measured through digital imaging. Selenium measurements from this study are given in Table E-23.

Table E-23. Selenium concentrations in water, periphyton and mayfly tissues for two feeding rations.
(Adapted from Table 1 in Conley et al. 2011)

Feeding ration – Se level	Mean dissolved Se exposed to periphyton, µg/L	Mean periphyton, mg Se/kg dw	Mean mayfly tissue, mg Se/kg dw
1x – low	1.1	4.2 ± 0.6 (4)	12.8 ± 3.6 (28)
1x – medium	5.9	11.9 ± 2.1 (4)	31.7 ± 7.5 (15)
1x - high	21.4	27.2 ± 4.2 (4)	68.4 ± 24.0 (9)
2x – low	2.7/3.4[a]	9.5 ± 0.9 (3)	14.1 ± 3.8 (19)
2x – medium	7.1/8.9[a]	19.9 ± 1.6 (3)	21.6 ± 2.8 (22)
2x - high	19.2/23.1[a]	40.9 ± 1.7 (3)	37.3 ± 6.7 (13)

[a] Two values represent two different loading exposures, September and October. The plates were combined for mayfly exposure.

NMED Exhibit 59

Mayflies fed the 1x ration had 54% and 72% reductions in survival relative to controls in the medium and high Se treatment levels, respectively, both significant ($p<0.05$). The mayflies fed the 1x ration also had significant reductions in fecundity in the low (44% reduction), medium (63% reduction) and high (77% reduction) Se treatment levels. However, for the mayflies fed the 2x ration, there were no significant differences between the controls and any of the three Se treatment levels for any of the endpoints measured including survival and fecundity. The 2x ration mayflies had 60% more biomass than the 1x ration mayflies. This growth difference explains why the 1x ration mayflies had higher concentrations of Se in their tissues. The two different rations resulted in vastly different effect levels for Se, <12.8 mg/kg dw in the 1x ration test and >37.3 mg/kg dw in the 2x ration. It is apparent from this study that if the mayflies do not obtain sufficient nutrition, they are more sensitive to selenium. Although reduced feeding levels occur in nature, it is a confounding variable in this study that cannot be used to set a chronic effect level for selenium.

Conley et al. (2013) evaluated the accumulation of selenite and selenate into periphyton with subsequent feeding exposure to mayfly larvae. As in his previous studies, *C. triangulifer* larvae were fed periphyton previously exposed to different concentrations of selenium. In this study, periphyton plates were first exposed to low (10 µg/L) and high (30 µg/L) concentrations of either selenite or selenate and then fed to mayfly larvae to ecolsion to subimagos. The selenite and selenate treatment exposures resulted in similar levels of selenium in the subimagos. Since no differences in selenium accumulation was observed, the selenite and selenate treatments could be pooled for measuring the endpoints, survival and secondary production (total mayfly biomass produced). Mean selenium concentrations fed the mayflies were 2.2, 12.8 and 37 mg/kg Se dw in the control, low and high treatments, respectively. Mayfly tissue (subimago) concentrations (extrapolated from Figure 4a in Conley et al. 2013) were approximately 4-7, 20-35, and 45-75 mg/kg Se dw, in the control, low and high treatments, respectively. The authors reported significant reductions in survival from the control in the high Se treatment (both pooled data and individual selenite and selenate treatments) but no significant differences were observed in the low Se treatments. Secondary production was significantly reduced relative to the control in the high Se treatment for both selenium species. For the low Se exposure treatment, secondary production was not significantly different than the control for the selenite treated periphyton exposure, but was for the selenate and pooled data suggesting an effect level between 20 and 35 mg/kg Se dw. These results as well as those observed in 2x ration exposures in Conley et al. (2011) where no effects were observed at 37.3 mg/kg Se dw generally support the chronic value determined for Conley et al. (2009) of 24.2 mg/kg Se dw.

The following invertebrate studies were inconclusive for establishing species sensitivity because of limitations in the experimental designs, as explained for each.

NMED Exhibit 59

5.4 Aquatic Insect (Midge: Chironimids)

Malchow et al. (1995) fed fourth instar *Chironomus decorus* midge larvae a diet of seleniferous algae under laboratory conditions for 96 hours. For algae cultured with selenite, a larval tissue concentration of 4.05 µg Se/g dry weight resulted in a 46% reduction in growth relative to the controls. At a larval tissue concentration of 8.6 µg Se/g dry weight, larval growth was reduced by only 39%. Since the study only reported two exposure concentrations, it is unclear if the tissue effect concentration at 4.05 µg Se/g dry weight is real or an anomaly. Additional exposure concentrations and subsequent effect levels are needed to resolve this issue.

Malchow et al. (1995) also fed fourth instar *Chrionomus decorus* midge larvae a diet of algae cultured with selenate, and the midge larvae were exposed under laboratory conditions for 96 hours. A dietary exposure of 2.11 µg Se/g dry weight significantly reduced larval growth (15% reduction) at tissue concentrations of 2.55 µg Se/g dry weight. At a larval tissue concentration of 6.62 µg Se/g dry weight, growth was reduced 20% relative to the controls. The 15-20% reduced growth at larval tissue concentrations 2.55 µg Se/g dry weight may be statistically significant, but not biologically meaningful. In addition, exposure to only two selenium concentrations precludes confirmation of a dose-response.

Alaimo et al. (1994) also exposed *2010* midge larvae to selenite diet, but the selenium source was from field contaminated widgeongrass (*Ruppia maritima*). *Ruppia* stems and leaves were collected from four selenium contaminated evaporation ponds located in the San Joaquin Valley of California. Three-day old larvae were exposed to each of the four treatment diets (*Ruppia* from each pond) plus a Cerophyll control for 14 days (egg to pupation), with the moderately hard reconstituted water renewed at day 7 and every three days thereafter. The growth (weight) of exposed larvae was significantly reduced in all of the selenium treatments when compared to the controls. The lowest effect level was observed for the Westlake pond (primarily selenite), where growth was reduced 40 percent relative to the controls at a larval tissue concentration below the detection level (1.0 ppm dry weight, or 1.0 µg Se/g dry weight). These results are suspect because the field collected *Ruppia* likely contained contaminants other than selenium, the control organisms were fed a different diet (Cerophyll), and the single concentration exposure is difficult to defend.

6.0 OTHER DATA – FIELD STUDY WEST VIRGINIA IMPOUNDMENTS

In response to the USEPA (2004) draft whole fish tissue criterion for selenium, the West Virginia Department of Environmental Protection (2010) initiated a study to assess selenium bioaccumulation among fishes residing in the State's lakes and streams. A focus of the study was the collection and evaluation of bluegill, *Lepomis macrochirus*, larvae (ichthyoplankton) from selected waterbodies since

NMED Exhibit 59

2007, based on concerns regarding fish population health at locations subjected to elevated selenium inputs, particularly during the more sensitive developmental life stages of fishes (e.g. yolk-sac larvae). Also, in 2009, WVDEP began acquiring data about selenium concentrations within fish eggs of various species within reference and selenium-impacted waters. WVDEP also conducted deformity surveys of adult fishes in selenium enriched waters as well as at reference locations in 2008-2009.

WVDEP scientists found that larval deformity rates were variable throughout the study duration but were nonetheless correlated with waterborne selenium exposure. Reference locations produced age-based larval bluegill subsamples (24-168 hours) with low deformity rates (0 - 1.27%); whereas, locations with seleniferous inputs exhibited bluegill deformity rates ranging from 0% to 47.56% in developmental stages up to 312 hours. Maximum deformity rates among staged bluegill subsamples as determined through these evaluations were 19.28%, representing specimens collected from selenium-enriched waters. Concentrations of selenium within fish eggs also varied according to study location and ranged from <0.8 mg/kg dry weight among bluegill eggs at the control site to 64.62 mg/kg dry weight among largemouth bass, *Micropterus salmoides,* eggs collected from selenium-enriched waters. Searches for more mature, yet developmentally-deformed fishes revealed increased deformity rates (14%) among largemouth bass residing in a selenium impacted reservoir as compared to deformity rates among largemouth bass found in the reference lake (0%). The data on egg selenium concentrations are not adequate for constructing a concentration-response curve. Nevertheless, the overall deformity rate in the contaminated Upper Mud River Reservoir was 5% among 10,000 individual fish, average egg selenium concentration 9.8 mg/kg dw. The overall deformity rate in the reference Plum Orchard Lake was 0.5% among 13,000 individuals, average egg selenium concentration nondetectable or <0.8 mg/kg dw.

NMED Exhibit 59

7.0 OTHER DATA - NUTRITIONAL DEFICIENCY/SUFFICIENCY STUDIES CONTAINING MEASURED SELENIUM IN THE DIET AND WHOLE BODY FISH TISSUE

Ingested dietary dose studies in fish designed to identify nutritionally deficient and/or nutritionally sufficient selenium doses in fish food or prey primarily describe selenium effects on growth, with survival reductions and effects on antioxidant enzyme activity also occasionally reported. A number of the dietary studies have measured a range of dietary doses that maximize fish growth, as opposed to a single dietary dose associated with nutritional sufficiency for growth. Regardless of whether nutritionally sufficient dietary doses are reported as a single concentration or as a range of concentrations, reduced growth or survival is observed at both lower dietary doses (nutritional deficiency) and at higher dietary doses (toxicity).

Although dietary doses are normally presented as selenium concentrations in food, expressed in terms of mg/kg Se in the diet, several studies have also concurrently presented nutritionally deficient/sufficient Se levels in terms of the whole body Se concentration in the fish. These studies permit a comparison of nutritionally deficient/sufficient whole body Se residues in fish to the national criterion for Se in whole bodies of fish. When combined with measured whole body fish tissue residues associated with toxicity, a complete picture of the range of Se residues in whole body fish tissue associated with nutritional deficiency, nutritional sufficiency and toxicity emerges.

Eight fish species have information on both nutritionally deficient dietary doses and whole body concentrations of selenium measured in the same study (Table E-24). Six of the eight species are native to North America. Nutritionally deficient dietary doses of Se range between 0.03 mg/kg dw in Atlantic salmon (*Salmo salar*, Poston et al. 1976) associated with reduced survival to 1.4 mg/kg dw in Atlantic cod (*Gadus morhua,* Hamre et al. 2008), also associated with reduced survival. Whole body Se residues identified as nutritionally deficient range between 0.64 mg/kg dw in Malabar grouper (*Epinephelus malabaricus*) associated with suboptimal weight gain and feed efficiency (Lin and Shiau 2005) and 4.72 mg/kg dw in North African catfish (*Clarias gariepinus*), also associated with suboptimal weight gain (Abdel-Tawwab et al. 2007). The whole body Se residues associated with growth and/or survival reductions due to nutritional deficiency of the six North American species (Prussian carp, Han et al. 2011; common carp, Gaber 2007; Atlantic cod, Hamre et al. 2008; Coho salmon, Felton et al. 1990; cobia, Lin et al. 2010; Atlantic salmon, Poston et al. 1976) all range between 1.0 and 2.7 mg/kg dw.

Ten fish species have information on both nutritionally sufficient dietary doses and whole body concentrations of selenium measured in the same study (Table D-23). Eight of the 10 species are native to North America. Nutritionally sufficient dietary doses of Se for the North American resident species, all but one of which are based on maximum growth of fish, range between 0.1 mg/kg dw in hybrid striped

NMED Exhibit 59

bass (Jaramillo 2006) and 6.6 mg/kg dw in rainbow trout (Hilton and Hodson 1983). Several studies have identified a range of dietary doses and associated whole body residues that maximize growth and survival relative to that of fish fed lower dietary doses and which subsequently contain lower whole body selenium residues. Whole body Se residues associated with nutritional sufficiency based on maximal growth and/or survival of all North American species except for hybrid striped bass (Jaramillo 2006) range between 0.2 – 3.63 mg/kg dw (Table D-23). For hybrid striped bass, Jaramillo (2006) observed that maximum weight gain occurred in selenite supplemented diets containing 1.19 mg/kg dw Se, which resulted in whole body Se residues of 5.13 mg/kg dw. Jaramillo (2006) also exposed hybrid striped bass to seleno-DL-methionine supplemented diets containing 0.90 mg/kg dw, which resulted in the maximum weight gain of all seleno-DL-methionine supplemented diets tested, and a whole body Se residue of 7.2 mg/kg dw.

The nutritional sufficiency study of Rider et al. (2009) with rainbow trout is unique in that it determined dietary and whole body selenium requirements for both stressed and unstressed fish. Rider et al. (2009) observed that rainbow trout stressed by a combination of low water levels in holding tanks and twice daily handling of fish by 30 second aerial exposure in dip nets resulted in a higher nutritional requirement for selenium than was observed in fish not subjected to the stress routine. They concluded that trout exposed to physical stressors could benefit from an additional 0.3 – 2.0 mg/kg dw additional selenium supplementation over and above the Se content of nutritionally Se sufficient diets for fish not undergoing stress.

The fish with the highest known nutritional requirement for selenium is the non-North American resident North African catfish (*Clarias gariepinus*). Abdel-Tawwab et al. (2007) determined in a 12 week study with fingerlings that Se dietary doses of 1.04 mg/kg dw and 3.67 mg/kg dw were associated with suboptimal and maximum weight gains of the catfish, respectively. Catfish survival was 100% in both the Se-deficient and Se-sufficient dietary dose exposures during the 12 week study period. The respective whole body selenium tissue residues at the end of the 12 week study were 4.72 mg/kg dw in the Se-deficient fish and 15.43 mg/kg dw in the fish fed the nutritionally sufficient Se diet. North African catfish (Abdel-Tawwab et al. 2007) is the only known fish species with an identified whole body nutritional requirement for Se higher than the national aquatic life criterion for whole body Se in fish.

NMED Exhibit 59

Table E-24. Studies with both empirically measured selenium dietary doses and whole body residues associated with nutritional deficiency and sufficiency in fish.

Species	Lifestage / Size Wet wt	Exposure duration	Ingested dietary dose Se mg/kg dry wt.	Se chemical form	Whole body Se mg/kg dry wt	Deficiency or Sufficiency	Deficiency symptoms Basis for sufficiency determination	Reference
Malabar grouper (*Epinephelus malabaricus*)	Juvenile 12.2 g	8 weeks	0.21	Basal diet	0.64	Deficiency	Suboptimal weight gain and feed efficiency	Lin and Shiau 2005
Prussian carp (*Carassius gibelio*)	Juvenile 2.74 g	100 days	0.47	Seleno-methionine	1.0	Deficiency	Suboptimal growth, feeding rate and feed conversion rate	Han et al. 2011
Common carp (*Cyprinus carpio*)	Juvenile 26.9 g	120 days	0.04	Basal diet	1.04	Deficiency	Reduced growth and survival	Gaber 2007
Atlantic cod (*Gadus morhua*)	Larvae 0.16 g (estimated from dry wt of larvae	23 days	1.4	Basal diet	1.1	Deficiency	Larval survival 32% lower compared to larvae fed selenium-enriched diet	Hamre et al. 2008
Cobia (*Rachycentron canadum*)	Juvenile 6.27 g	10 weeks	0.21 - 0.62	0.21 = Basal diet, 0.62 = seleno-DL-methionine	1.13 - 2.11	Deficiency	Statistically significantly reduced specific growth rate and survival	Liu et al. 2010
Coho salmon (*Oncorhynchus kisutch*)	Smolt 22.7 g	Hatchery reared	0.7 - 0.9	Not given	1.974	Deficiency	Survival of hatchery reared smolts 1.5 - 2.0x lower than wild smolts	Felton et al. 1990
Atlantic salmon (*Salmo salar*)	Fry 0.1 g	4 weeks	0.03 - 0.04	Basal diet	2.7	Deficiency	Decreased survival relative to fry fed diet supplemented with 0.1 µg/g Se and 0.5 IU/g vitamin E	Poston et al. 1976
North African catfish (*Clarias gariepinus*)	Fingerling 68.6 g	12 weeks	1.04	Organic Se	4.72	Deficiency	Suboptimal weight gain and specific growth rate	Abdel-Tawwab et al. 2007
Rainbow trout (*Oncorhynchus mykiss*)	Juvenile 0.6 g	16 weeks	0.6 - 6.6	Selenite $Na_2SeO_3 \cdot 5H_2O$	0.2 - 1.0	Sufficiency	No deficiency or toxicity signs on growth	Hilton and Hodson 1983

NMED Exhibit 59

APPENDIX F: TOXICITY OF SELENIUM TO AQUATIC PLANTS

NMED Exhibit 59

1.0 SELENITE

Data are available on the toxicity of selenite to 13 species of freshwater algae and plants (Table F-1). Results ranged from an LC_{50} of 70,000 µg/L for the green alga, *Chlorella ellipsoidea* (Shabana and El-Attar 1995) to 522 µg/L for incipient inhibition of the green alga, *Scenedesmus quadricauda* (Bringmann and Kuhn 1977a, 1978a,b, 1979, 1980b). Foe and Knight (Manuscript) found that 75 µg/L decreased the dry weight of *Selenastrum capricornutum* (Table F-1). Wehr and Brown (1985) reported that 320 µg/L increased the growth of the alga *Chrysochromulina breviturrita*.

The 96-hr EC_{50} for the saltwater diatom, *Skeletonema costatum*, is 7,930 µg/L, based on reduction in chlorophyll *a* (Table F-1). Growth of *Chlorella* sp., *Platymonas subcordiformis*, and *Fucus spiralis* increased at selenite concentrations from 2.6 to 10,000 µg/L (Table F-1). Other marine algae exposed to selenite from 14 to 60 days had no observed effect concentrations (NOAEC) that ranged from 1,076 to 107,606 µg/L. These data suggest that saltwater plants will not be adversely affected by concentrations of selenite that do not affect saltwater animals.

2.0 SELENATE

Growth of several species of green algae was affected by concentrations ranging from 100 to 40,000 µg/L (Table F-1). Blue-green algae appear to be more tolerant to selenate with 1,866 µg/L being the lowest concentration reported to affect growth (Kiffney and Knight 1990). Kumar (1964) found that a blue-green alga developed and lost resistance to selenate. The difference in the sensitivities of green and blue-green algae to selenate might be of ecological significance, particularly in bodies of water susceptible to nuisance algal blooms. For example, Patrick et al. (1975) reported that a concentration of 1,000 µg/L caused a natural assemblage of algae to shift to a community dominated by blue-green algae.

The saltwater coccolithophore, *Cricosphaera elongata*, had reduced growth when exposed to 41,800 µg/L selenate for 14 days (Boisson et al. 1995). Seven other saltwater algal species investigated by Wong and Oliveira (1991a) exhibited NOEC growth values that ranged from 1,043 to 104,328 µg/L. At 10,000 µg/L, selenate is lethal to four species of saltwater phytoplankton and lower concentrations increase or decrease growth (Table F-1). Wheeler et al. (1982) reported that concentrations as low as 10 µg/L reduced growth of *Porphyridium cruentum* (Table F-1).

Although selenite appears to be more acutely toxic than selenate to most aquatic animals, this does not seem to be true for aquatic plants. Selenite and selenate are about equally toxic to the freshwater algae *Anabaena cylindrica*, *Anabaena flos-aquae*, *Anabaena variabilis*, *Anacystis nidulans*, and *Scenedesmus dimorphus* (Kiffney and Knight 1990; Kumar and Prakash 1971; Moede et al. 1980) and the saltwater algae *Agemenellum quadroplicatum*, *Chaetoceros vixvisibilis* and *Amphidinium carterae* (Wong and Oliveira 1991a). The two oxidation states equally stimulated growth of *Chrysochromulina*

NMED Exhibit 59

breviturrita (Wehr and Brown 1985). On the other hand, selenate is more toxic than selenite to the freshwater *Selenastrum capricornutum* (Richter 1982; Ibrahim and Spacie 1990) and the saltwater *Chorella* sp., *Platymonas subcordiformis* and *Nannochloropsis oculata* (Wheeler et al. 1982; Wong and Oliveira 1991a). In addition, Fries (1982) found that growth of thalli of the brown macroalga, *Fucus spiralis*, was stimulated more by exposure to selenite at 2.605 μg/L than to the same concentration of selenate.

A Final Plant Value, as defined in the Guidelines, cannot be obtained because no test in which the concentrations of selenite or selenate were measured and the endpoint was biologically relevant has been conducted with an important aquatic plant species.

NMED Exhibit 59

Test procedures test material or results were not adequately described by Botsford (1997), Botsford et al. (1997, 1998), Bovee (1978), Gissel-Nielsen and Gissel-Nielsen (1973, 1978), Greenberg and Kopec (1986), Mauk (2001), and Nassos et al. (1980) or when the test media contained an excessive amount (>200 μg/L) of EDTA (Riedel and Sanders (1996).

NMED Exhibit 59

Some data obtained from tests conducted with just one exposure concentration to evaluate acute or chronic toxicity were not used (e.g., Bennett 1988; Heinz and Hoffman 1998; Munawar et al. 1987; Pagano et al. 1986; Wolfenberger 1986).

Kaiser (1980) calculated the toxicities of selenium(IV) and selenium(VI) to *Daphnia magna* based on physiochemical parameters. Kumar (1964) did not include a control treatment in the toxicity tests. The daphnids were probably stressed by crowding in the tests reported be Schultz et al. (1980). Siebers and Ehlers (1979) exposed too few test organisms as did Owsley (1984) in some tests.

Selenium Concentrations Reported in Wild Aquatic Organisms Were Insufficient to Calculate BAF

APPENDIX H: CALCULATION OF EF VALUES

NMED Exhibit 59

EPA calculated EF values by searching its database of selenium measurements and identifying all the selenium measurements from algae, detritus, or sediment. EPA then searched for corresponding water column measurements from samples collected at the same aquatic site within one year of the particulate sample. If more than one water measurement was available for any given particulate measurement, the median was used. For each of these matched pairs of particulate and water measurements, EPA calculated the ratio of particulate concentration to water concentration. If more than one ratio for any given category of particulate material (algae, detritus, or sediment) was calculated at an aquatic site, EPA used the median ratio. The geometric mean of the algae, detritus, and sediment ratios was used as the site *EF*. Because there were at most only 3 possible values (one for algae, one for detritus, and one for sediment), EPA used the geometric mean in order to reduce the potential for one of the values to have excessive influence on the final site *EF* value. Sites with insufficient data to fulfill these criteria are left blank.

EPA evaluated differences in bioaccumulation between different categories of aquatic systems by analyzing EF values for different categories. EPA sequentially consolidated categories and examined differences in the distribution of EF values between categories. See text for a complete description of this analysis.

APPENDIX I: OBSERVED VERSUS PREDICTED EGG-OVARY CONCENTRATIONS

NMED Exhibit 59

The following table includes data for 317 individual fish tissue selenium measurements from the 64 sites where EFs could be calculated. Observed egg-ovary fish tissue measurements were compared to predicted egg-ovary fish tissue measurements calculated using equation 22 of the main text, also shown here for convenience.

$$C_{egg-ovary} = C_{water} \times TTF^{composite} \times EF \times CF \quad \text{(Equation 22)}$$

These data were used to generate the observed to predicted egg-ovary concentration Figure 6.3 of the main text. When the measured tissue type was either muscle or whole body, it was converted to egg-ovary using taxa specific conversion factors. The predicted and measured concentrations are highly correlated ($r = 0.82$, $t_{(315)} = 25.30$, $P < 0.001$).

NMED Exhibit 59

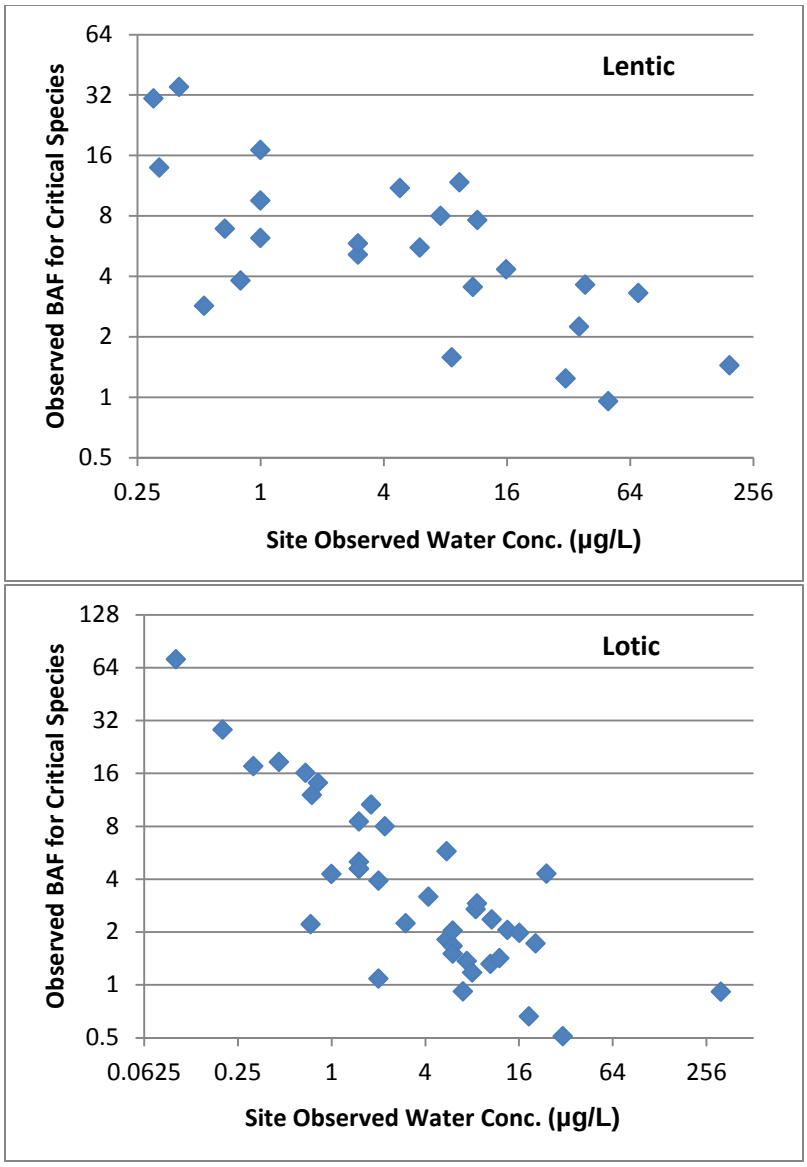
The ratio of predicted versus observed tissue concentrations in the above table can be compared against the main text Table 3.13 water concentrations that would be predicted to occur if each site's egg-ovary tissue concentration were at the criterion level. Figure I-1 shows the results. It can be seen that for those sites (in the left portion of each graph) where tissue concentrations equal to the egg-ovary criterion would be predicted to yield water concentrations not far on either side of the water criteria values, the predicted-to-observed tissue concentration ratios are not particularly biased relative to a ratio of 1.0. This indicates that the model is performing reasonably well for those sites strongly influencing the derived values of the water criteria.

The derivation of the water criteria concentrations involves an assumption of linearity in projecting the water concentration that would correspond to a tissue concentration equal to the tissue criterion. Figure I-2 suggests that high BAFs tend to be associated with low water concentrations, and low BAFs with high water concentrations. At the low concentrations associated with the 20^{th} percentile model-predicted BAF, the linearity assumption would appear to be environmentally conservative. At high concentrations, the opposite situation would occur, but overall, because the criterion is based on the 20^{th} percentile, the linearity assumption appears to be protective.



NMED Exhibit 59

Figures I-1. For lentic (left panel) and lotic (right panel) waters, predicted-to-observed fish-tissue concentration ratio for each of the 65 sites, plotted versus each site's Table 3.13 water concentration that would be predicted to occur if its tissue levels were at the egg-ovary tissue criterion level.

Corresponding to how the water criteria concentrations were derived, for sites with multiple fish species, the plotted ratio is for the species having the highest predicted tissue-to-water ratio (i.e., highest predicted BAF). For sites having multiple samples of that species, the plotted value is the average predicted-to-observed ratio for that species.

NMED Exhibit 59

Figures I-2. For lentic (left panel) and lotic (right panel) waters, observed BAFs (egg-ovary tissue-to-water concentration ratios) versus observed water concentration (both from the above table), for each site's fish species used in Table 3.13 (that is, for the species used in the water criteria calculations).

For sites having multiple samples of such species, tissue concentrations were averaged. Because nearly all samples were either whole body or muscle, the graphed BAFs include application of the CF, to normalize all samples to egg-ovary tissue. Since the CFs have been are assumed to be independent of concentration, the graphs do not reflect any potential CF nonlinearities, if they exist.

NMED Exhibit 59

APPENDIX J: SUPPLEMENTARY INFORMATION ON SELENIUM BIOACCUMULATION IN AQUATIC ANIMALS

NMED Exhibit 59

1.0 EFFECTS OF GROWTH RATE ON THE ACCUMULATION OF SELENIUM IN FISH

EPA analyzed the effect of the growth rate parameter *g* when estimating selenium bioaccumulation using the mechanistic bioaccumulation modeling described in Equation 1 of the main text. Because the addition of tissue associated with growth could have a dilution effect on the chemicals present in tissue, a parameter representing growth rate is present in the denominator of Equation 1. Indeed, growth can be an important factor in the bioaccumulation of very hydrophobic chemicals with low excretion rates such as polychlorinated biphenyls, (Connolly and Pedersen 1988). However, the effect of growth may not be as important for selenium because of its unique biogeochemical characteristics, route of exposure, and role as a micronutrient.

EPA tested the effect of the growth rate parameter *g* on estimates of selenium bioaccumulation using Equation 1 with different food web scenarios. Increasing growth rates from 0 (no growth) to 0.2/day (a relatively high rate of growth) reduced selenium concentrations in trophic level 2 and 3 organisms by as much as a factor of 10 to 20. Thus incorporating growth rate in Equation 1 could result in significant dilution of selenium and lower estimates of selenium bioaccumulation.

Although increasing the value of the growth parameter g in Equation 1 reduces estimates of selenium bioaccumulation, this simple analysis neglects an important physiological linkage between growth and food consumption. Organisms must consume enough food to support growth and meet their energy requirements for respiration, specific dynamic action, waste loss, and reproduction. These physiological requirements suggest that higher growth rates are associated with greater rates of food consumption. Because food consumption is the primary route of selenium exposure in aquatic organisms, increased selenium exposure associated with higher food consumption could counterbalance the dilution of selenium in tissue associated with higher growth rates.

EPA tested the effects of growth on estimates of selenium bioaccumulation using Equation 1 when increased food consumption was associated with higher growth rates. EPA modified Equation 1 to incorporate a simple relationship for bioenergetics (Thomann et al. 1992) and applied the model to reexamine the sensitivity of selenium bioaccumulation to growth rates in trophic level 2 and 3 organisms. The results of this analysis showed that increasing growth rates over two orders of magnitude increased selenium concentrations in trophic level 2 by a factor of 2, and decreased selenium concentrations in trophic level 3 by 10%. When growth rates were increased simultaneously in trophic levels 2 and 3, the selenium concentrations increased by less than a factor of 2. This analysis suggests that when bioenergetics is considered, selenium bioaccumulation is generally insensitive to organism growth rates. EPA believes that uncertainties in the toxicokinetic parameters of selenium far outweigh the effects on growth rate on selenium bioaccumulation. Thus, the growth rate parameter *g* was removed from Equation

NMED Exhibit 59

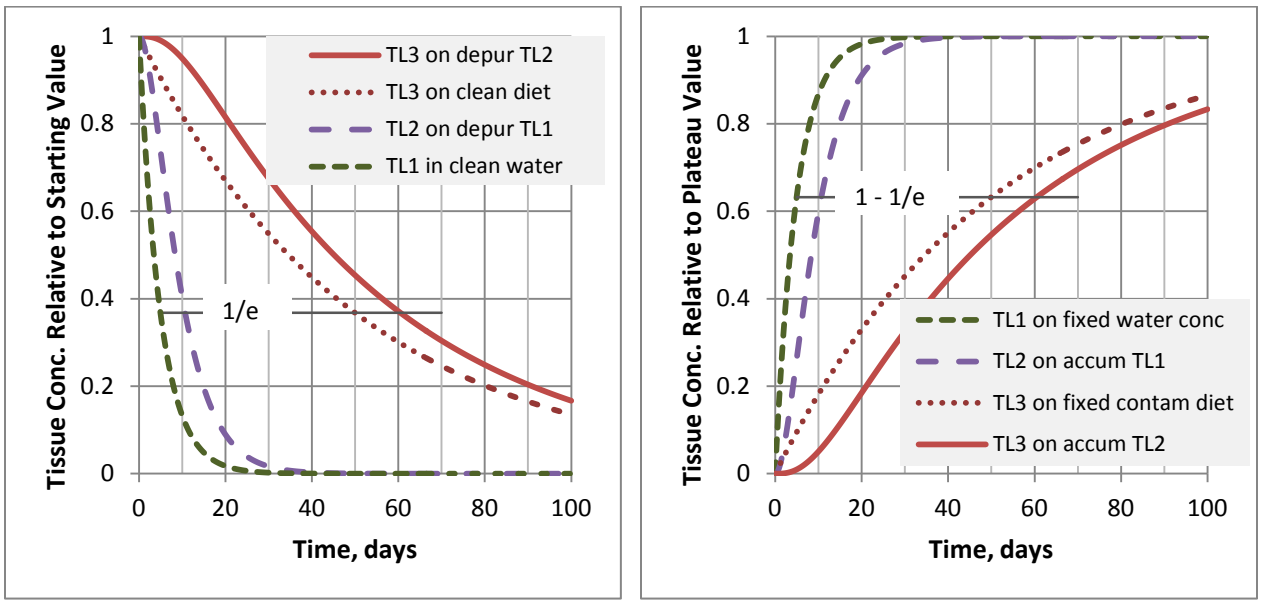
1 for the purpose of deriving a translation equation that could be used to implement a tissue-based selenium water quality criterion.

2.0 Analysis of the Relative Contribution of Aqueous and Dietary Uptake on the Bioaccumulation of Selenium

EPA analyzed the relative contributions of direct aqueous uptake versus ingestion of selenium in consideration of removing the uptake rate constant k_u from Equation 1 in Section 3.2 of the main text. Because an important exposure route for some chemicals is direct contact with water, an uptake rate constant k_u is present in the numerator of Equation 1. However, fish and invertebrate organisms absorb selenium primarily through the consumption of food rather than from direct aqueous uptake (Forester 2007; Lemly 1985; Luoma et al. 1992). Thus, removing the uptake rate constant k_u could simplify Equation 1 while maintaining the key determinants of selenium bioaccumulation.

EPA tested the relative contribution of aqueous versus dietary uptake of selenium using a version of Equation 1 that incorporates both exposure pathways (Thomann et. al. 1992). For trophic level 2, selenium bioaccumulation was estimated for a range of uptake rates that varied according to the respiration rate and aqueous transfer efficiency of selenium relative to dissolved oxygen. For trophic level 3, uptake rates were varied within a range of values reported in Besser et al. (1993) and Bertram and Brooks (1986).

EPA's analysis showed that diet accounted for 34% - 92% of selenium bioaccumulation at trophic level 2, with a median of 74%. At trophic level 3, diet accounted for 62% - 100% of tissue selenium, with a median of 95%. Thus, disregarding aqueous uptake of selenium only resulted in a small (~5%) reduction in estimated selenium bioaccumulation in trophic level 3 organisms. These results are consistent with previous studies indicating that diet is the primary exposure route of selenium, and suggests that the uptake rate constant for selenium can be removed from Equation 1 with negligible effect for higher trophic levels organisms.



3.0 Kinetics of Accumulation and Depuration: Averaging Period

3.1 Background

For setting averaging periods for aquatic life criteria, U.S. EPA (1995b) used the concept that the criterion averaging period should be less than or equal to the "characteristic time" describing the toxic speed of action. In the context of the water-borne direct toxicity of metals, characteristic time = 1/k, where k is the first-order kinetic coefficient in a toxico-kinetic model fitted to the relationship between LC50 and exposure duration.

NMED Exhibit 59

In the context of selenium bioaccumulation in a single trophic level, k would the first-order depuration coefficient, and 1/k would equal the time needed to depurate to a concentration of 1/e times the initial concentration (where e=2.718). For depuration of multiple trophic levels sequentially, the characteristic time is likewise the time needed for c/c_o to reach a value of 1/e, as shown in Figure J-1a. The accumulation curve is the inverted depuration curve, as shown in Figure J-1b.

Figures J-1 a & b. Depuration and accumulation behavior for algae-detritus-sediment k=0.2/day, invertebrate k=0.2/day and fish k=0.02/day, calculated with time step = 0.1 day.
Concentration is expressed as a dimensionless ratio: concentration at time t divided by either starting concentration (J1a) or plateau concentration (J1b).

In the Figures J-1 a & b examples, the characteristic time for algae-detritus-sediment is 5 days, the characteristic time for invertebrates on an invariant diet is 5 days, the characteristic time for fish on an invariant diet is 50 days, and the characteristic time for fish on an invertebrate diet that is itself depurating or accumulating is the approximate sum of the individual characteristic times, or ~60 days.

In contrast to the model depuration rate, k, the model uptake rate (AE, assimilation efficiency, multiplied by IR, intake rate) does not affect the characteristic response time. Rather it affects the magnitude of the accumulation plateau. Uptake rate thus affects the TTF value itself but is not relevant to setting an averaging period.

Because short averaging periods are more environmentally conservative than long averaging periods, selecting parameter values for fast kinetics is more environmentally conservative. Figure J1 reflects environmentally conservative choices for k values.

NMED Exhibit 59

3.2 Approach for Modeling Effects of Time-Variable Se Concentrations

Expression of concentrations. None of the concentrations in this analysis are expressed in ordinary units of concentration. All concentrations are modeled as values normalized to their allowable benchmark concentration – that is, concentration = 1 for a particular medium (water, algae-detritus-sediment, invertebrates, or fish) means that the medium is at its criterion concentration or corresponding benchmark. It is assumed that the benchmarks correctly align – water held at its benchmark concentration will ultimately yield Trophic Levels 1, 2, and 3 at their respective benchmark concentrations. The Trophic Level 3 benchmark is the reproductive EC10 for the 5th percentile taxon: i.e., the fish tissue criterion.

Formulation of the bioaccumulation model for kinetic analysis. For algae-detritus-sediment, for invertebrates, and for fish, accumulation at time t equals accumulation at time t-1 plus intake minus depuration, as follows:

Algae-detritus-sediment:

$$C_{TL1}[t] = C_{TL1}[t\text{-}1] + k_{uptake}\, C[t\text{-}1]water - k_{TL1}\, C_{TL1}[t\text{-}1]$$

Invertebrates:

$$C_{TL2}[t] = C_{TL2}[t\text{-}1] + AE_{TL2}\, IR_{TL2}\, C_{TL1}[t\text{-}1] - k_{TL2}\, C_{TL2}[t\text{-}1]$$

Fish:

$$C_{TL3}[t] = C_{TL3}[t\text{-}1] + AE_{TL3}\, IR_{TL3}\, C_{TL2}[t\text{-}1] - k_{TL3}\, C_{TL3}[t\text{-}1]$$

For algae-detritus-sediment, the depuration rate k is assigned a value of 0.2/day, similar to the sum of depuration and growth-dilution rate coefficients used by Brix and DeForest (2008). Because a lentic system would involve the slower kinetics of sediment exchange, the rapid rate used here implies a lotic system.

For invertebrates, a value of 0.2/day was assigned, considerably higher than those for *Lumbriculus*, Asian clam, zebra mussel, but close to those of mayfly and copepods, which are very small in size. As previously mentioned, higher k (more rapid kinetics) is an environmentally conservative assumption in this context.

For fish, the median depuration coefficient measured by Bertram and Brooks (1986) for 6-9 month-old (early adult) fathead minnows was used, providing a k_{TL3} value of 0.02/day. Because of the small size of adults of this species, this represents faster kinetics than would likely be applicable the salmonids and centrarchids of greatest concern for selenium toxicity. The striped bass k value of Baines et al. (2002) is inapplicable here because it was measured in the early juvenile life stage, a size that is too small to be relevant to reproductive impairment stemming from exposure of adult females. The concentration in fish could be equivalently viewed as either whole body or egg-ovary, relative to their

NMED Exhibit 59

respective benchmarks. That is, partitioning within body of the fish is assumed not to involve a time delay.

The value of a TTF is given by AE x IR/k (or k_{uptake}/k for algae-detritus-sediment). Concentrations in TL1, TL2, and TL3 are normalized to their benchmarks, meaning that all benchmark concentrations have a value of 1.0. In this normalized context, the TTFs must also equal 1.0, since upon reaching steady state, TL1 at its benchmark will yield TL2 at its benchmark, which in turn will yield TL3 at its benchmark. Again, the analysis is not intended to reflect actual concentrations, merely portray temporal behavior. Since 1 = TTF = AE x IR/k, it follows that AE x IR = k within this normalized framework. Although only the product AE x IR is relevant, they are retained as distinct parameters to maintain parallelism with remainder of the criterion document. AE was assigned a value of 0.5 for fish and invertebrates, and IR = k/AE in the normalized framework.

Time step durations of 0.1-1.0 day were considered. Short time steps increase accuracy by decreasing the numerical dispersion inherent in expressing C[t] = f(C[t-1]). A time step of 0.5 day was found to yield sufficient accuracy, as measured by predicted values at the characteristic time for depuration or accumulation (per Figure J-1).

Prediction of Effects. The effect level associated with the tissue concentration at any time t is calculated via the log probit concentration-response curve, one of the commonly used sigmoid curves. It assumes that the sensitivities in the underlying population are log-normally distributed such that the concentration yielding effects on k percentage of the population is given by:

$$EC_k = EC50 \exp(\sigma z)$$

where σ is the inverse of the concentration-response curve slope and z is the normal deviate corresponding to k percent (e.g., for k=10%, z=NORMSINV(0.1)=−1.28155). Among the reproductive impairment studies presented in Appendix C, an approximate median ratio for EC50/EC10 is 1.5. This translates to σ=0.3164.

NMED Exhibit 59

Since the fish tissue criterion concentration equals 1.0 in this normalized framework, at any time t, the fractional level of effect corresponding to any value of C_{TL3} is given by:

Fractional Effect[t] = NORMSDIST(z[t])

where z[t] is given by:

$z[t] = LN(C_{TL3}[t]/1.5)/0.3164$

Exposure Scenarios. Three exposure scenarios were evaluated under which the water criterion was just barely attained. The first two are absolute worst case scenarios, in which the 30-day average water concentration remains continuously at the criterion concentration at all times. The third is a realistic scemario.

1. Steady concentrations at the criterion: this is worst-case continuous exposure. In the real world this could not occur because water concentrations vary substantially over time. For the 30-day average concentration not to exceed more than once in three years, the realistically varying daily concentrations must remain well below the criterion concentration a large majority of the time.

2. Uniform 1-day spikes at 30X the water criterion concentration, occurring at uniform 30-day intervals (i.e., separated by 29 days of zero concentration) such that the 30-day average always equals the criterion. This is the worst-case intermittent scenario, attaining the criterion through a time series that continually maximizes the 30-day average exposure at the water criterion concentration while also imposing the highest variability possible from spikes of 1-day duration. In the real world intermittent runoff sources do not occur at uniform intervals: merely averaging 30-days between discharges would yield an exceedance each time the discharge occurred with less than 30-days spacing. Further, the once-per-month peak concentrations could never be controlled at exactly 30X the chronic water criterion per the above discussion of the first scenario.

   It is because they lack real-world random variability that the above two scenarios are not realistic. They are used as absolute worst cases for purposes of comparison. The following third scenario represents a realistic and indeed typical situation for continuous exposure:

3. Log-normally distributed, smoothly variable concentrations with the 30-day average exceeding the criterion once in three years when counted using the procedure of EPA (1986). The log

NMED Exhibit 59

standard deviation of 0.5 applied here represents typical real-world time variability for continuously flowing waters. The log serial correlation coefficient $\rho = 0.8$ represents that typical of smaller streams.

With respect to maximizing toxic effects while attaining the criterion, Scenarios #1 and #2 are absolute worst cases. In contrast, Scenario #3 represents typical time variability in ambient waters. This third scenario requires randomly generated concentrations (having specified target statistical characteristics). Multiple runs of long series are therefore needed to assure some reasonable degree of accuracy. A minimum of 20 runs of random series of 3000 days were used. The concentrations at each half-day time step were generated by the following formula:

*C[t]water = C[t-1]water^(ρ′) * GM^(1-ρ′) * EXP{σ * SQRT(1-ρ′^2)*NORMSINV(RAND)}*

where ρ′ (rho prime) is the desired serial correlation coefficient between half-day time steps: ρ′=SQRT(ρ) [approximation], where ρ (rho) is the desired serial correlation coefficient between daily values; GM is the desired geometric mean or median, and σ is the desired log standard deviation. The above formula allows a time series with the desired statistical characteristics to be generated.

3.2.1 Model Results

3.2.1.1 Steady concentrations at the water criterion concentration.

No graphic is needed to explain this scenario. With water steady at its criterion, algae-detritus-sediment and invertebrates are likewise steady at their benchmark concentrations, and fish tissue is at its criterion concentration. For the 5th percentile taxon, the effect would thus be 10% since the concentration is steady at the EC10.

3.2.1.2 Uniformly spaced spikes at maximum concentrations

Figure J-2. Scenario 2, uniform 1-day spikes at 30X the water criterion concentration, occurring at uniform 30-day intervals such that the 30-day average always equals the criterion. Read invertebrate and fish tissue concentrations on left scale, water concentrations on right scale. Time=0 does not represent the beginning of exposure; prior to Time=0 the same exposure pattern had been going on for a long time (e.g., 10,000 days).

NMED Exhibit 59

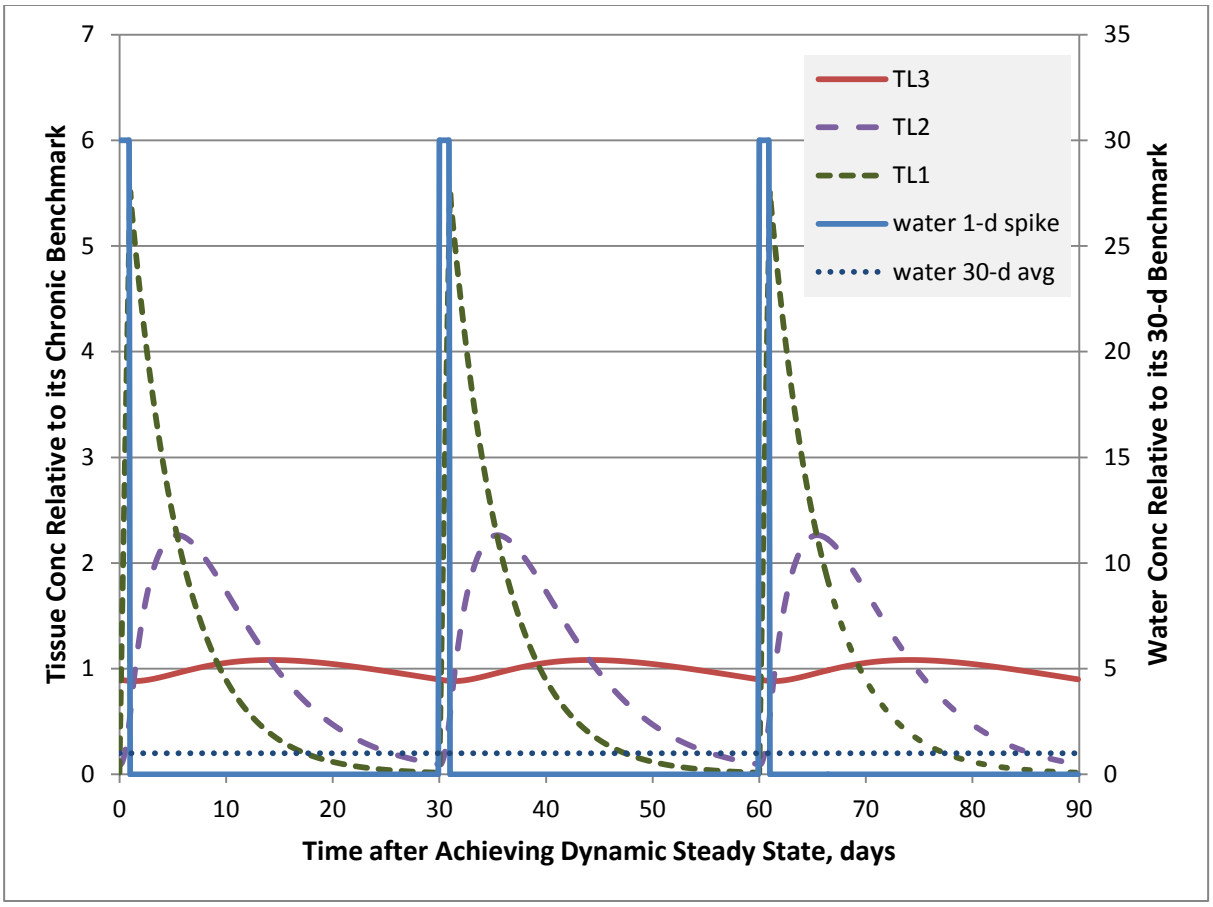


Figure J-2. Uniform 1-day spikes at 30X the water criterion concentration, occurring at uniform 30-day intervals such that the 30-day average always equals the criterion.
Tissue and water concentrations are expressed as dimensionless ratios relative to their respective criteria or benchmarks, as explained in the text.

With their more rapid kinetics, TL1 and TL2 tissue concentration swings are much more drastic than TL3 (fish) tissue concentration swings, but were the spike to continue as a steady exposure 30-fold above the water benchmark, TL1, TL2, and TL3 would all ultimately plateau at 30-fold above their respective benchmarks.

The key point here is that attaining the 30-day average via 1-day spikes spaced 30 days apart generates a small oscillation in fish tissue concentrations. Averaged over the 30-days, the fish tissue concentrations exactly attain their criterion and the predicted effect is 10%.

3.2.1.3 Log-normally distributed, smoothly varying concentrations

This is the most realistic scenarios, corresponding to typical variability observed in streams.

NMED Exhibit 59

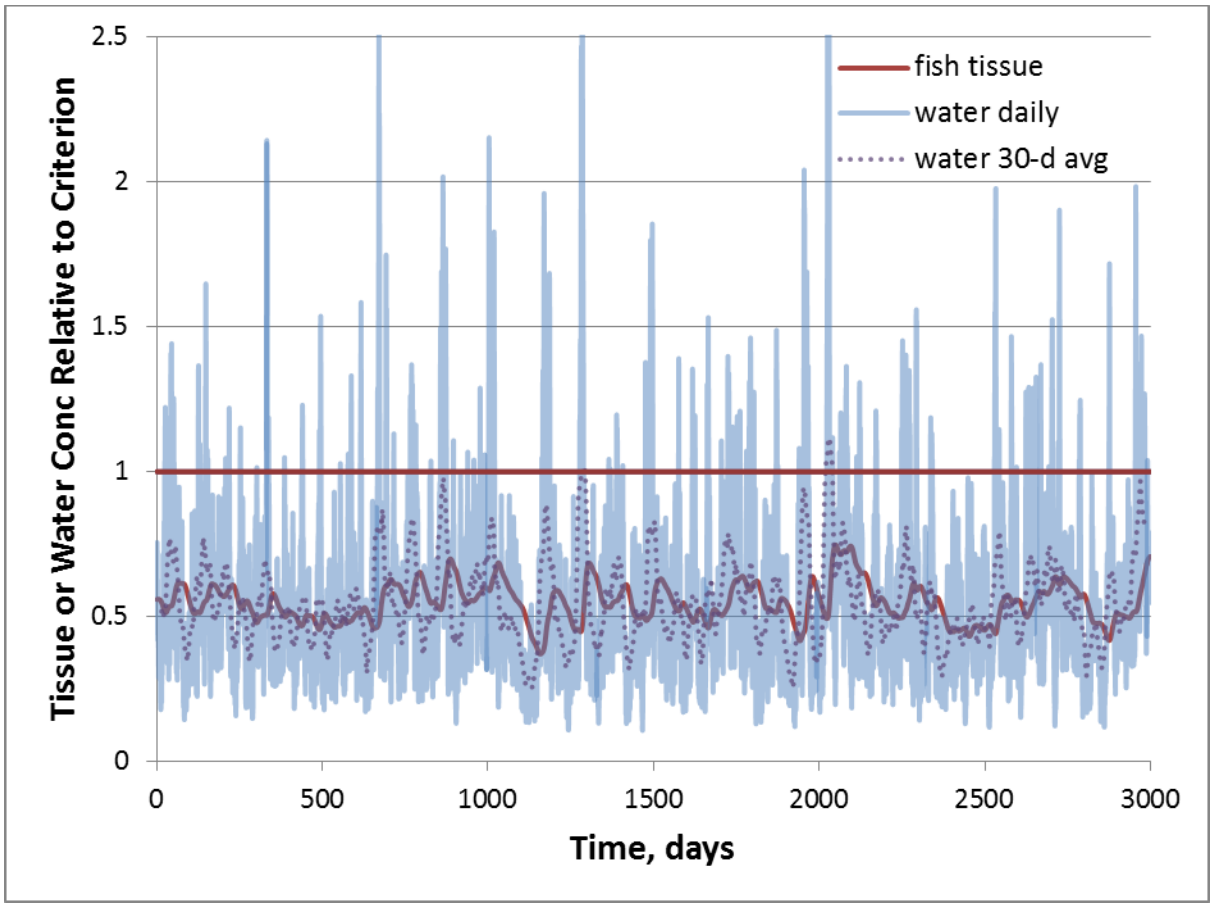

Figure J-3. A typical example of log-normally distributed, smoothly variable concentrations. The standard deviation of natural logs is 0.5 and the serial correlation coefficient of logs is 0.8 for daily values, both typical real-world situations. (The compression of 3000 days into the graph might make it difficult to recognize that the time series is smoothly varying – it has serial correlation.) At time=0, TL1, TL2, and TL3 begin at their average concentrations.

In the Figure J-3 example run, instantaneous water concentrations exceed the 30-day average criterion 7% of the time. The 30-day average concentrations exceed the criterion 1.05 times per 3 year period, counted per the EPA (1986) counting method. Tissue concentrations do not exceed their criterion at any time, and the aggregate effect is 0.12%.

In contrast to the previous scenario, the elevated concentrations here are random in their magnitude, duration, and spacing. This randomness reduces the average exposure (and aggregate effect) compatible with attainment of the 30-day average water target.

3.2.2 Summary of Scenario Results

Because Scenario 3 involves generation of random concentrations, the above graphs show just one run (3000 days) for each. Full results for the 20 runs of that scenario are shown below.

NMED Exhibit 59

Scenario	Water: # 30-day avg. exceedances / 3-yr 1	Water: % of time exceeding	Tissue: % of time exceeding	Mean effect for 5th %ile Taxon	Comment
1. Steady	0.00	0.00	0.00	10.0	Steady at water and tissue benchmarks
2. Uniform spikes	0.00	3.33	56.7	10.0	30-d avg water conc. remains steady at benchmark (Fig. J2)
3. Smooth variable	1.01	7.8	0.00	0.18	Median=0.49 x benchmark, log stdev=0.5, rho(daily)=0.8 (e.g., Fig. 5) 2
1. Counting procedure for 30-d avg. exceedances is that of U.S. EPA (1986). 2. Results for Scenario 3 are average of 20 runs of 3000 days, each run with 0.6-1.4 exceedances / 3 yr. Runs not yielding exceedances within these bounds were not used. Among the 20 runs used, the effect CV=0.35.					

It can be concluded that the kinetics of selenium accumulation and depuration are sufficiently slow that applying a 30-day averaging period to the water criterion concentration affords protection even under unrealistic worst case conditions.

3.2.3 Example Responses to Increases in Water Concentrations

The previous Figures J-2 and J-3 illustrate situations after achievement of a dynamic steady state, where daily water concentrations change but longer-term mean water concentrations do not change. Given the same kinetic parameters as used above (i.e., yielding a 60-day characteristic time), this section addresses the rate at which tissue concentrations respond to increases in mean water concentrations, for example as would result from a new source. This is similar to the rising curve previously shown in Figure J-1b. The rapid kinetics used here for the water-TL1 step imply a small lotic system having little involvement of the bed sediments.

3.2.3.1 Step-function example

This example addresses the question: If water concentrations are increased to a level that is slightly too high, ultimately (at Time=∞) yielding fish-tissue concentrations at the EC20 instead of the EC10, how long would it take for those tissue concentrations to rise to a level that exceeds the (EC10-based) criterion?

Prior to Time=0 in this example the concentrations in TL3 had been at a moderate background concentration of 0.406 times the criterion, corresponding to the median West Virginia reference-site egg concentrations tabulated by West Virginia Department of Environmental Protection (2010). The concentrations in TL1 and TL2 are likewise assumed to have been at 0.406 normalized to their corresponding benchmarks. At Time=0 the water concentrations increase such that ultimately they will

NMED Exhibit 59

produce an effect 10% higher than the target, thus at the EC20 of the hypothetical 5th percentile sensitive species. For typical selenium concentration-response slopes, this is 1.15-fold above the EC10. Figure J4 illustrates this scenario, which shows that 90 days are needed for TL3 concentrations to rise above the criterion.

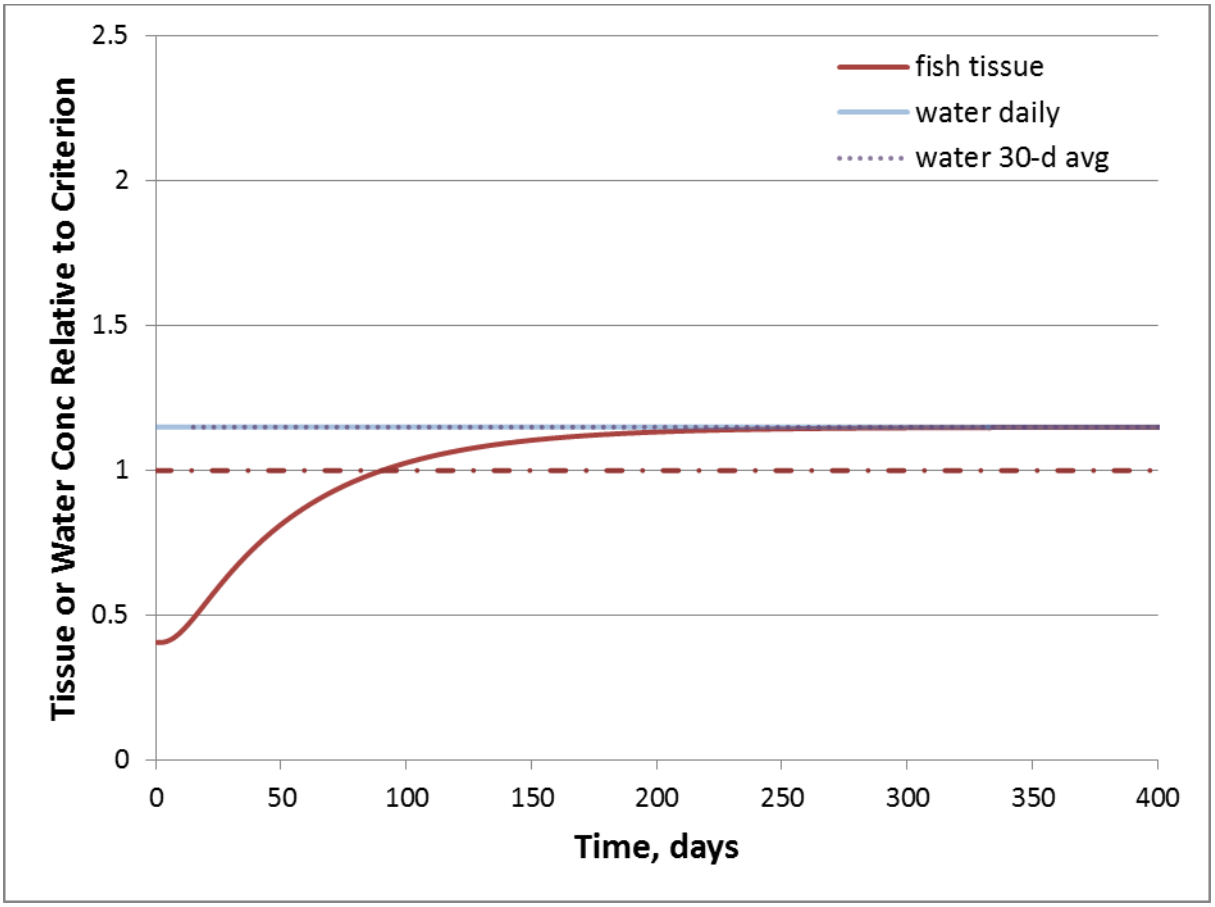

Figure J-4. TL3 concentration responding to a Time=0 step-function increase in water concentration that remains time-invariant thereafter.
Given that the water concentration is too high, ultimately yielding tissue concentrations at the hypothetical sensitive species EC20, 1.15-fold above the criterion, and given the previously presented kinetic parameters, it is calculated to take 90 days for TL3 concentrations to rise above the criterion.

NMED Exhibit 59

3.2.3.2 Continuously time-variable example for flowing waters

To provide more realism, this example considers typical time variability, following up on Figure J3. In this example, prior to Time=0, TL1, TL2, and TL3 concentrations were at a low background concentration, 0.1 normalized to their criterion or respective benchmark. At Time=0 begin water concentrations having median = geometric mean = 0.49 normalized as a dimensionless ratio, concentration/criterion. Because the water concentrations are log-normally distributed, with log standard deviation = 0.5, the arithmetic mean is higher than the median and has the normalized value 0.56. If the simulation went on for a very long time, this time series (designed to have geometric mean 0.49 times the criterion, log standard deviation 0.5, and log serial correlation coefficient 0.8) would average one exceedance every three years, when exceedances are counted using the EPA (1986) approach. Figure J-5 shows a typical short series of 400 days.

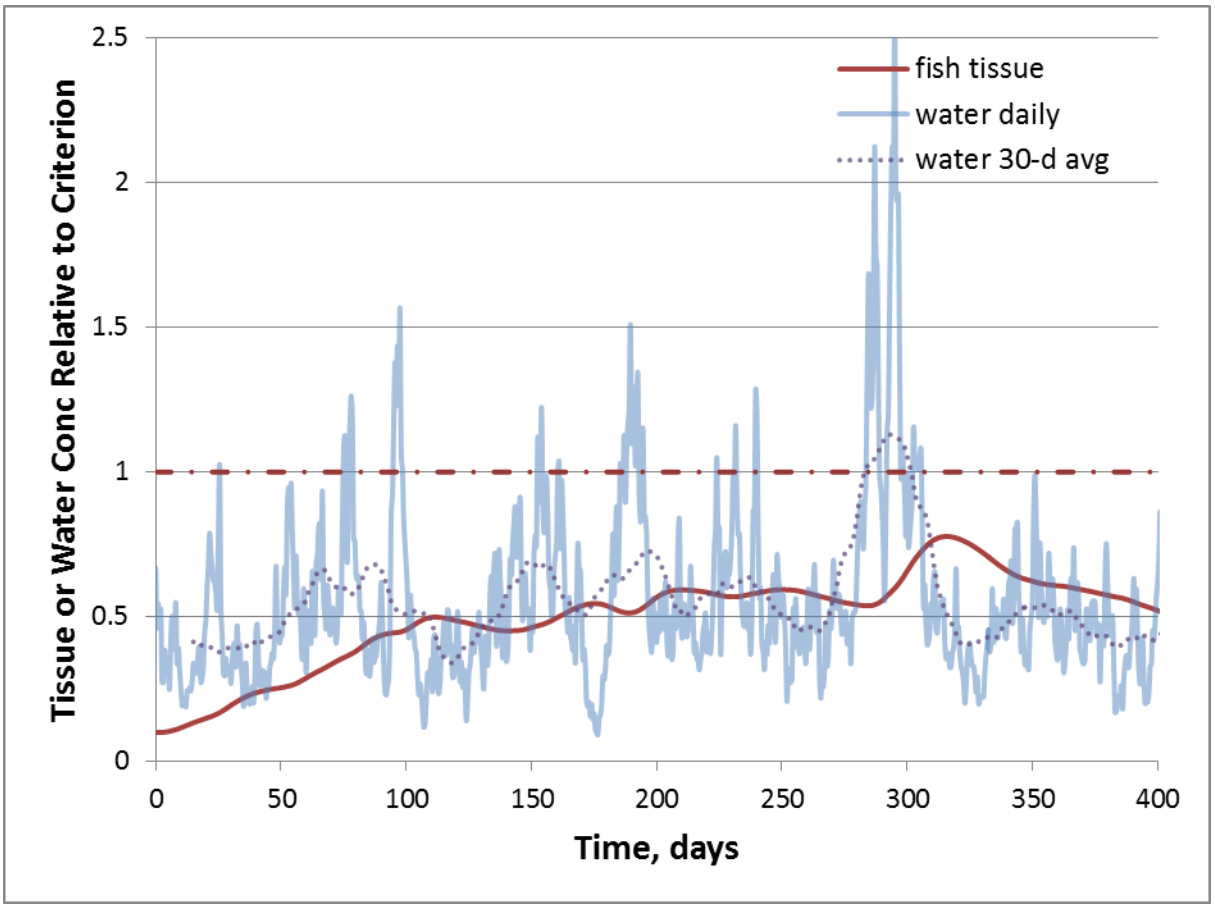

Figure J-5. Flowing water example of TL3 concentration starting at a concentration of 0.1 normalized to the criterion, and responding to randomly varying log-normally distributed water concentrations having median 0.49 (expressed as a dimensionless ratio: concentration/criterion), log standard deviation 0.5, and log serial correlation coefficient 0.8.
Again, all concentrations are as dimensionless ratios relative to the criteria concentrations.

NMED Exhibit 59

Several points are worth noting. Because the water concentrations happen (by chance) to be below average for the first 50 days, the TL3 concentrations rise somewhat slowly during that period. Were they to be above average during that period, the TL3 concentrations would more rapidly approach their dynamically varying plateau. In such a short time series it is not graphically apparent what the long-term average TL3 concentration will be; however, because the long-term arithmetic mean water concentration would be 0.56 (normalized the its criterion), the TL3 concentration would likewise end up averaging 0.56 normalized to its criterion, if tracked for many years.

It is also worth noting that most 400-day series of the type shown in Figure J-5 would not have occurrences of 30-day average concentrations above the criterion (as suggested by Figure J-3). This particular random series does have a period of 30-day average exceedances, near Day 300, but it does not persist long enough to cause the TL3 concentration to approach its criterion.

Lastly, it should be noted that when concentrations are randomly varying as in Figure J-5, the water concentrations that one observes are highly dependent on when the samples are taken. The TL3 concentrations observed are far less dependent on when the samples are taken (after the plateau is approached), but time variations, although muted, are still present.

The example scenarios depicted here show lotic time to steady state of approximately 3 months to less than 1 year under different discharge scenarios including both continuous and intermittent discharges. The scenarios also assume that the new selenium input is from one source; multiple new sources particularly with varying discharge patterns, might have a different response time and pattern for various trophic levels.

The example is likely not appropriate for lentic systems, because they would not be expected to have the rapidly varying water concentrations of Figure J-5. In addition, the water-to-TL1 kinetics would likely be slower in lentic systems with new or time-varying sources because of the role of bottom sediments acting as a reservoir in recycling selenium. Ultimately this should yield slower rising and smoother TL3 concentrations compared to those in Figure J-5.

NMED Exhibit 59

APPENDIX K: TRANSLATION OF A SELENIUM FISH TISSUE CRITERION ELEMENT TO A SITE-SPECIFIC WATER COLUMN VALUE

NMED Exhibit 59

1.0 TRANSLATING THE CONCENTRATION OF SELENIUM IN TISSUE TO A CONCENTRATION IN WATER USING MECHANISTIC BIOACCUMULATION MODELING

Introduction:

EPA recommends fish tissue elements of the selenium criterion supersede water column elements under steady state conditions because the selenium concentration in fish tissue is a more sensitive and reliable indicator of the negative effects of selenium in aquatic life. However, implementation of a fish tissue criterion element can be challenging because many state and tribal Clean Water Act (CWA) programs prefer the expression of water quality criteria as an ambient concentration in the water-column. Therefore, EPA also recommends two monthly average water-column criterion elements, one for lotic (flowing) waters, and the other for lentic (still) waters. EPA derived all water column criterion elements from the egg/ovary criterion element representing a protective selenium concentration for fish species populations. Thus the water column criterion elements also represent protective selenium concentrations for fish species populations. If threatened or endangered fish species are present, states and tribes may need to derive alternative water column elements with a refined protection goal that account for site-specific bioaccumulation characteristics.

EPA derived water-column criterion elements by modeling selenium bioaccumulation in aquatic systems. The EPA worked with the United States Geological Survey to derive a translation equation utilizing a mechanistic model of bioaccumulation previously published in peer-reviewed scientific literature (Luoma et. al., 1992; Wang et. al., 1996; Luoma and Fisher, 1997; Wang, 2001; Schlekat et al. 2002b; Luoma and Rainbow 2005; Presser and Luoma 2006; Presser and Luoma 2010; Presser 2013). EPA translated the selenium egg-ovary criterion element into two set(s) of site-specific water concentration values (lentic and lotic), and used the distribution(s) of those water column values to derive the respective water-column criterion elements. This appendix describes approaches that states and tribes may choose to use regarding application of this same mechanistic modeling approach (or alternatively an empirical bioaccumulation factor (BAF) approach) to translate a fish tissue criterion element (egg-ovary, whole body, or muscle) into site-specific water-column concentrations to more precisely manage selenium in specific aquatic systems.

The relationship between the concentration of selenium in the tissues of fish and the concentration of selenium in the water column can vary substantially among aquatic systems. The species of fish, the species and proportion of prey, and a variety of site-specific biogeochemical factors affect selenium bioaccumulation and thus determine the allowable concentration of selenium in ambient water protective of aquatic life. States and tribes may choose to adopt the results of site-specific water column translations as site-specific criteria (SSC) or adopt a translation procedure into state or tribal water quality

NMED Exhibit 59

standards. Under both options, the water quality standards revisions must be approved by EPA under Section 303(c) of the Clean Water Act. If a state or tribe adopts a translation procedure that will be implemented by other CWA programs, it must be scientifically defensible, produce repeatable, predictable outcomes, and result in criteria that protect the applicable designated use. Examples of such approaches include the mechanistic modeling approach and the empirical BAF approach described within this Appendix.

EPA considered both mechanistic and empirical modeling approaches to translate the selenium egg-ovary criterion element into water column concentration elements. A mechanistic modeling approach uses scientific knowledge of the physical and chemical processes underlying bioaccumulation to establish a relationship between the concentrations of selenium in the water column and the concentration of selenium in the tissue of aquatic organisms. The mechanistic modeling approach enables formulation of site-specific models of trophic transfer of selenium through aquatic food webs and translation of the egg-ovary criterion element into an equivalent site-specific water concentration. The empirical modeling approach establishes a relationship between concentrations of selenium in fish tissue and ambient water directly by measuring selenium concentrations in both media and calculating the ratio of the two concentrations. The ratio (BAF) can then be used to estimate the target concentration of selenium in the water column as related to the adopted fish tissue element.

Both the mechanistic and empirical modeling approaches have advantages and disadvantages that should be considered before deciding which approach to use. On the one hand, the mechanistic modeling approach has the advantage of not requiring extensive fish tissue sampling and analysis by using knowledge of aquatic system food webs. However, uncertainty in the selection of model parameters increases uncertainty in the outcome leading to a reduction in defensibility. Of particular concern with respect to the mechanistic model EPA developed is the selection of the value for the enrichment factor parameter *EF* (discussed in more detail below). On the other hand, the empirical BAF approach is conceptually and computationally simpler because it relies only on field measurements and does not require extensive knowledge of the physical, chemical, or biological characteristics of the aquatic system. However, obtaining a sufficient number of measurements in fish tissue and water may be logistically difficult and/or more expensive.

The appropriate modeling approach to use when translating the selenium egg-ovary criterion element to a site-specific water-column concentration depends on individual circumstances and site-specific characteristics. The mechanistic modeling approach may be a useful method in situations where there is little or no data on the amount of selenium in an aquatic system, the empirical BAF approach may be desirable in circumstances where in fish tissue and water data are available. Below is a description of

NMED Exhibit 59

methodology than can be used to translate the egg-ovary criterion element to a site-specific water-column concentration for site-specific management of selenium.

1.1 Relating the Concentration of Selenium in Fish Tissue and Water using the Mechanistic Modeling Approach

The relationship between the concentration of selenium in the eggs or ovaries of fish and the concentration of selenium in the water column is given in Equation K-1 (Equation 18 from the main text):

$$C_{water} = \frac{C_{egg-ovary}}{TTF^{composite} \times EF \times CF} \qquad \textit{(Equation K-1)}$$

Where:

C_{water} = the concentration of selenium in water (µg/L),

$C_{egg\text{-}ovary}$ = the concentration of selenium in the eggs or ovaries of fish (µg/g),

$TTF^{composite}$ = the product of the trophic transfer factor (*TTF*) values of the fish species that is the target of the egg-ovary criterion element and the *TTF* values of all lower trophic levels in its food web (no units of measurement, see explanation below).

EF = the steady state proportional bioconcentration of dissolved selenium at the base of the aquatic food web (L/g),

CF = the species-specific proportion of selenium in eggs or ovaries relative to the average concentration of selenium in all body tissues (no units of measurement).

The basic principles expressed in Equation K-1 are illustrated in the conceptual model shown in Figure K-1.

Selenium dissolved in surface water enters aquatic food webs by becoming associated with trophic level 1 primary producer organisms (e.g., algae) and other biotic (e.g., detritus) and abiotic (e.g., sediment) particulate material. An enrichment function (*EF*) quantifies the bioconcentration of selenium in particulate material and thus its bioavailability in the aquatic system. The parameter *EF* is a single value that represents the steady state proportional concentration of selenium in particulate material relative to the concentration of selenium dissolved in water.

NMED Exhibit 59

Organic particulate material is consumed by trophic level 2 organisms (usually aquatic invertebrates, but also some fish species that are herbivores/detritivores) resulting in the accumulation of selenium in the tissues of those organisms. Trophic level 2 invertebrates are consumed by trophic level 3 fishes resulting in further accumulation of selenium in the tissues of those fish. Bioaccumulation of selenium from one trophic level to the next is quantified by a trophic transfer factor (*TTF).* A *TTF* is a single value that represents the steady state proportional concentration of selenium in the tissue of an organism relative to the concentration of selenium in the food it consumes. Different species of organisms metabolize selenium in different ways. Thus each species is associated with a specific *TTF* value. Because the trophic transfer of selenium through all trophic levels is mathematically equal to the product of the individual *TTF* values, all consumer-resource interactions in a particular aquatic ecosystem are simplified in Equation K-1 by representing the product of all the individual *TTF* values as the single parameter $TTF^{composite}$.

Fish accumulate selenium in different tissues of the body in differing amounts. Species physiology, age, diet, sex, and spawning status are some of the factors that affect selenium partitioning in body tissues. Because the primary selenium criterion element is expressed as a concentration in the eggs and/or ovaries, a conversion factor (*CF*) quantifies the relationship between the concentration of selenium in the eggs and/or ovaries and the average concentration of selenium in the whole body or muscle tissues. The parameter *CF* in Equation K-1 is a single value that represents the steady state proportional concentration of selenium in the eggs and/or ovaries relative to the average concentration of selenium in all body tissues. Different species of fish accumulate selenium in their eggs and ovaries to different degrees. Thus each species of fish is associated with a specific *CF* value.

NMED Exhibit 59

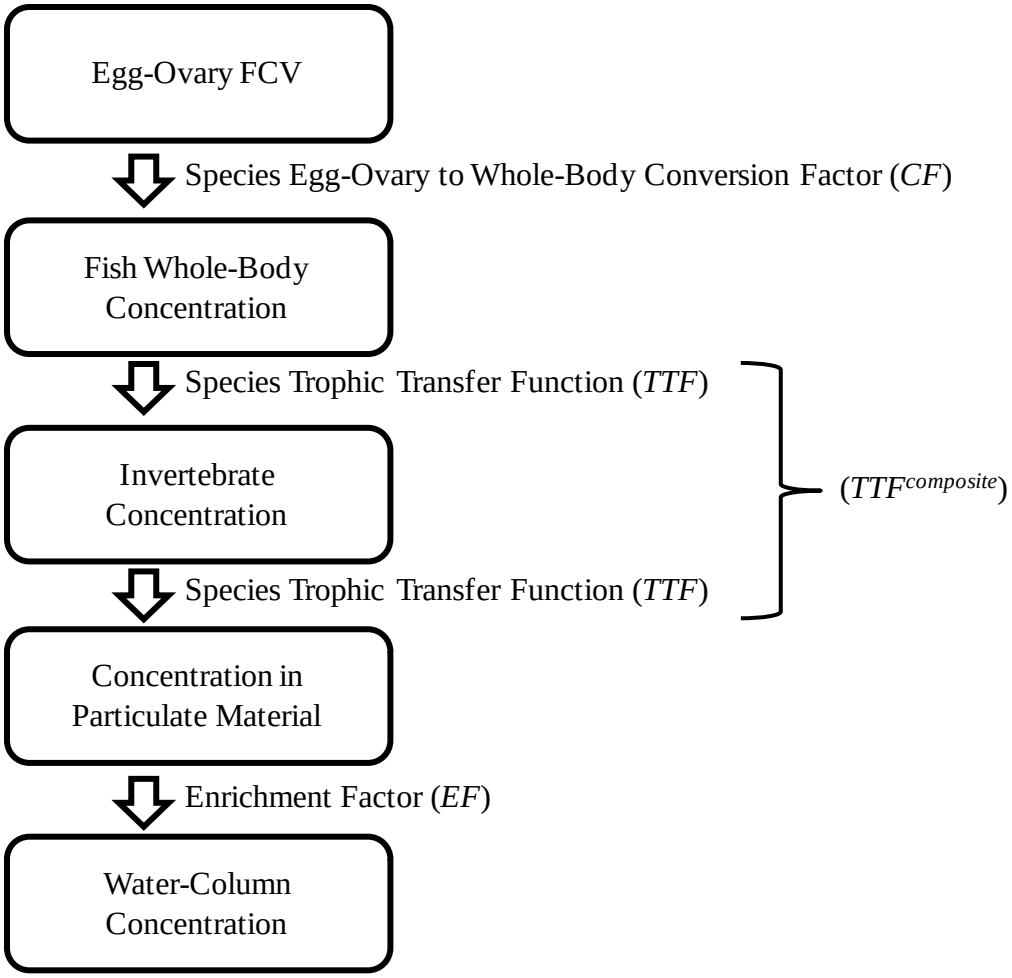

Figure K-1. Conceptual model for translating the egg-ovary FCV to a water-column concentration.
Note: States may want to use the whole body or muscle criterion elements as the starting point for site specific translation to a water column concentration.

Once the parameters that quantify the transfer of selenium through each step in this pathway are identified, they can be used with Equation K-1 to translate the egg-ovary criterion element to a site-specific concentration of selenium in the water column (i.e., target water column concentration).

Because each *TTF* value is species-specific, it is possible to differentiate bioaccumulation in different aquatic systems by modeling the food web of the target fish species. For example, where the food web contains more than 3 trophic levels, $TTF^{composite}$ can be represented as the product of all *TTF* values for each trophic level given in Equation K-2, which is a generalization of Equation 10 from the main text:

NMED Exhibit 59

$$TTF^{composite} = TTF^{TL2} \times TTF^{TL3} \times \ldots \times TTF^{TLn} \qquad \textit{(Equation K-2)}$$

Where:

$TTF^{composite}$ = the product of all *TTF* values at all trophic levels.

TTF^{TLn} = the *TTF* value of the highest trophic level.

The consumption of more than one species of organism at the same trophic level can also be modeled by expressing the *TTF* value at a particular trophic level as the average *TTF* values of all species at that trophic level weighted by the proportion of species consumed given as Equation K-3 (Equation 11 in the main text):

$$\overline{TTF}^{TLx} = \sum_i \left(TTF_i^{TLx} \times w_i \right) \qquad \textit{(Equation K-3)}$$

Where:

TTF_i^{TLx} = the trophic transfer factor of the i^{th} species at a particular trophic level

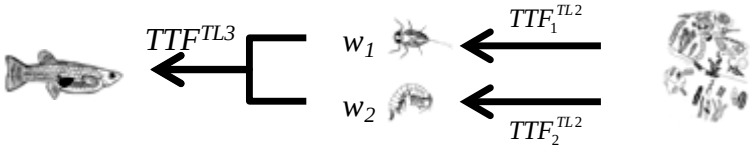
w_i = the proportion of the i^{th} species consumed.

These concepts can be used to formulate a mathematical expression of $TTF^{composite}$ that models selenium bioaccumulation in a variety of aquatic ecosystems. Figure K-2 illustrates five hypothetical food web scenarios and the formulation of $TTF^{composite}$ for each of them. For each scenario, the value of $TTF^{composite}$, the *CF* value associated with the targeted fish species, and the site-specific *EF* value can be used with Equation K-1 to translate the egg-ovary criterion element to a site-specific water concentration value. The hypothetical food web models in Figure K-2 are a few possible examples of food web models for illustrative purposes. It is desirable to derive and use of a food web model that best represents the aquatic system for which the water column translation will apply. The general steps for deriving a site-specific translation of the egg-ovary criterion element to a water concentration value are described below.

NMED Exhibit 59

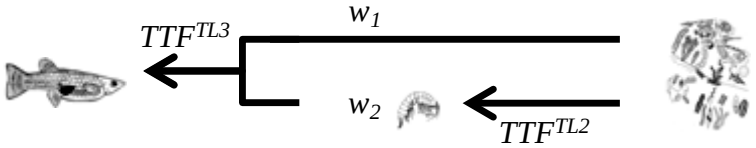
A) Three trophic levels (simple):

$$TTF^{composite} = TTF^{TL3} \times TTF^{TL2}$$



B) Four trophic levels (simple):

$$TTF^{composite} = TTF^{TL4} \times TTF^{TL3} \times TTF^{TL2}$$



C) Three trophic levels (mix within trophic levels):

$$TTF^{composite} = TTF^{TL3} \times \left[\left(TTF_1^{TL2} \times w_1\right) + \left(TTF_2^{TL2} \times w_2\right)\right]$$

D) Three trophic levels (mix across trophic levels):

$$TTF^{composite} = \left(TTF^{TL3} \times w_1\right) + \left(TTF^{TL3} \times TTF^{TL2} \times w_2\right)$$

E) Four trophic levels (mix across trophic levels):

$$TTF^{composite} = \left[\left(TTF^{TL4} \times TTF^{TL3} \times w_1\right) + \left(TTF^{TL4} \times w_2\right)\right] \times TTF^{TL2}$$

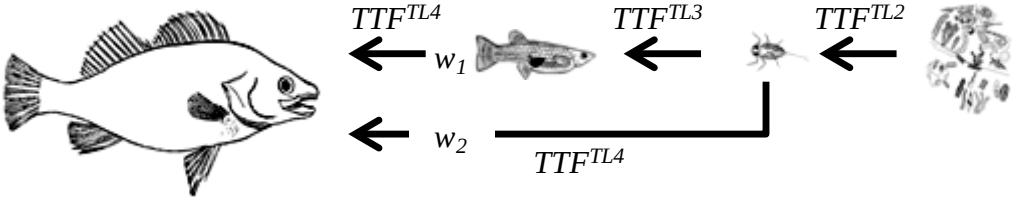


Figure K-2. Example mathematical expressions of $TTF^{composite}$ representing different food-web scenarios.

$TTF^{composite}$ quantitatively represents the trophic transfer of selenium through all dietary pathways of a targeted fish species. The mathematical expression of the food web model is used to calculate a value for $TTF^{composite}$ using appropriate species-specific *TTF* values and the proportions of each species consumed at each trophic level. See text for further explanation.

NMED Exhibit 59

1.2 Steps for Deriving a Site-Specific Water Concentration Value from the Egg-Ovary Criterion Element

Below are the steps for deriving a site-specific water concentration value from the selenium egg-ovary criterion element using EPA's mechanistic model approach:

1) Identify the appropriate target fish species.
2) Model the food web of the targeted fish species.
3) Identify appropriate *TTF* values by either:
    a. selecting the appropriate *TTF* values from a list of EPA-derived values, or
    b. deriving *TTF* values from existing data, or
    c. deriving *TTF* values by conducting additional studies, or
    d. extrapolating *TTF* values from existing values.
4) Determine the appropriate value of *EF* by either
    a. deriving a site-specific *EF* value from field measurements, or
    b. deriving an appropriate *EF* value from existing data, or
    c. extrapolating from *EF* values of similar waters.
5) Determine the appropriate *CF* value by either,
    a. selecting the appropriate *CF* value from a list of EPA-derived values, or
    b. deriving a *CF* value from existing data, or
    c. deriving a *CF* value by conducting additional studies, or
    d. extrapolating a *CF* value from existing values.
6) Translate the selenium egg-ovary criterion element into a site-specific water concentration value using Equation K-1.

Below are detailed descriptions of each step followed by example calculations using a variety of hypothetical scenarios. EPA is providing this information to support help states and tribes that choose to develop selenium water column values from the egg-ovary criterion element or develop translation procedures. Successful application of the mechanistic approach described here requires use of particular food web models and parameter values that are appropriate for particular aquatic systems.

1.2.1 Identify the Appropriate Target Fish Species

1.2.1.1 When fish are present

In developing a site-specific translation of the egg-ovary criterion element, the user wshould select whether to use a mechanistic model or empricial (BAF) approach. This decision will in large part

NMED Exhibit 59

determine the data and information requirements. A mechanistic model approach will likely require information on the spatial and temporal distribution of aquatic organisms, and may require measurements of selenium in ambient water and particulate material. An empirical model approach will use measurements of selenium is fish tissue and ambient water.

Developing a site-specific translation of the egg-ovary criterion element will also entail selection of which species of fish to target. The concentration of selenium in eggs and ovaries is the most sensitive and consistent indicator of toxicity. However, toxicity and bioaccumulation potential can vary among species. Species in the families Acipenseridae, Centrarchidae, and Salmonidae are particularly sensitive to selenium (Table 3.3 in the main document), whereas species such as stoneroller species, creek chub, blackside dace, and white sucker have documented tolerance to selenium and can be found in selenium contaminated systems (NAMC 2008, Presser 2012). Green sunfish accumulate less selenium than other species with comparable exposures in the same aquatic system (Hitt and Smith 2015). Selection of the fish species in the aquatic system with the greatest selenium sensitivity and bioaccumulation potential is recommended.

Several additional factors should also be considered in deciding which species to target when developing a site-specific translation of the egg-ovary criterion element. Anadromous species (species that migrate from salt water to spawn in fresh water) should generally avoided because selenium exposure and bioaccumulation occurs over a relatively long period through the consumption of locally contaminated aquatic organisms. Additionally considerations include whether the fish species selected typically consume organisms known or suspected to readily bioaccumulate selenium (e.g., mollusks). For example, high concentrations of selenium in San Francisco Bay white sturgeon are associated with their consumption of *Potamocorbula amurensis*, a bivalve in close proximity to selenium-contaminated sediments that rapidly and efficiently accumulates selenium (Stewart et al. 2004). In contrast, striped bass from the same aquatic system have substantially lower concentration of selenium in their tissues because their zooplankton-based food web has substantially lower selenium bioaccumulation characteristics (Schlekat et al. 2004; Stewart et al. 2004). The 2016 selenium criterion was developed for freshwater, but if considering other ecosystems, it may be worth noting that salinity may also affect bioaccumulation of selenium. Freshwater mollusks tend to have relatively higher *TTF* values when compared to other freshwater invertebrate taxa (e.g., aquatic insects), but they are lower than mollusks in marine or brackish systems (and particularly *P. amurensis*, an invasive clam in the San Francisco Bay). In aquatic systems with resident fish species of unknown selenium sensitivity and bioaccumulation potential, other factors such as ecological significance could be considered when choosing a target species.

Data from fisheries or biological surveys or other biological assessments could be considered to determine the fish species that reside in specific surface waters. State and tribal resource agency personnel

NMED Exhibit 59

familiar with fish sampling activities could also be a source of information on resident fish species. General information on the fish species present in state and tribal surface waters may also be found at:

- State Fish and Game agencies
- U.S. Fish and Wildlife Service (http://www.fws.gov)
- U.S. Geological Survey (http://www.usgs.gov)
- NatureServe.org (http://www.natureserve.org)
- Fishbase (http://www.fishbase.org)
- State or local sources of biological information (e.g. Biota Information System of New Mexico at http://www.bison-m.org)

Measurements of selenium in fish tissue would most reflect the ecosystem if adult (reproductively mature) fish are sampled. Selenium measurements in fish tissue will likely be more stable in adult fish because they are more likely to have a stable prey base. Reproductively mature (ripe or gravid) females would be needed for measures selenium in eggs and/or ovary tissue for comparison to the the egg-ovary tissue criterion element. It would be prudent to avoid sampling ovary tissue "post-spawn" due to a potential decrease in selenium concentration presumably due to the loss of selenium through spawning and release of eggs with relatively high concentrations of selenium. Consideration of closely related taxonomic surrogates (same genus or family) for threatened or endangered species may be useful.

Figure K-3 shows an example decision tree that may help in selection of the appropriate fish species for deriving a site-specific water concentration value from the selenium egg-ovary, whole-body, or muscle FCV. The use of taxonomic hierarchies for anlysis utilizes evolutionary relationships to infer biological similarities among organisms (Suter 1993). Additional information on fish tissue sampling (e.g., species selection, temporal and spatial considerations) is under development and will be published in the form of a technical support document (TSD) by the EPA in the near future.

NMED Exhibit 59

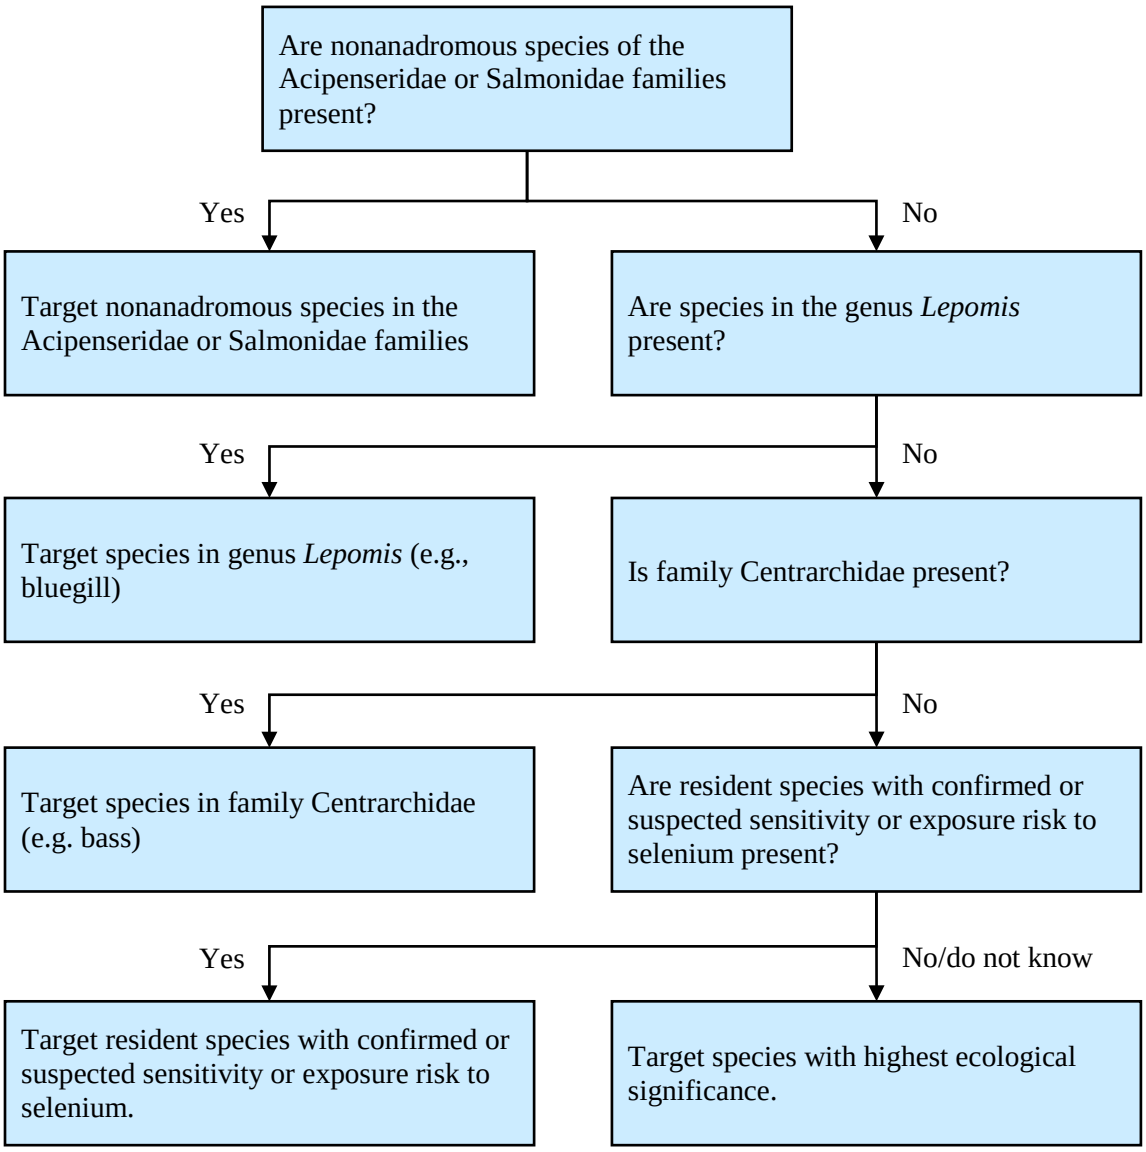

Figure K-3. Recommendeed decision process for selection of the fish species to use when deriving a water concentration from the selenium egg-ovary FCV.
This decision tree is also generally applicable when using the whole body or muscle tissue as the starting point for development of SSC, particularly when using the BAF approach.

1.2.1.2 When fish are absent from a site

Some aquatic systems do not contain resident fish. Fish may be absent from a waterbody because of intermittent or persistent low flows, physical impediments such as waterfalls or impoundments, lack of adequate habitat for feeding and/or spawning, or intolerable aquatic conditions related to pH, turbidity, temperature, salinity, total dissolved solids, chemical contaminants, or pathogens. These conditions could be due to natural or anthropogenic causes. Some streams may be naturally intermittent or ephemeral, or

NMED Exhibit 59

they might exhibit low or intermittent flows because of impoundments or water draw-down for agricultural irrigation, industrial uses, drinking water supply, or other uses.

When fish are absent from a waterbody, consideration of sampling the most sensitive fish species inhabiting nearby, most proximate downstream waters may be useful in order to understand selenium bioaccumulation potential in such systems. Although the upper reaches of some aquatic systems may not support fish communities, the invertebrate organisms that reside there may tolerate high concentrations of selenium and pose a selenium risk to predator fish if transported downstream. Users may choose to evaluate upstream waters without fish by measuring the selenium concentration in water, biotic and/or abiotic particulate material, and/or the tissues of invertebrate aquatic organisms that reside there. Because selenium associated with particulate material and invertebrate organisms can be transported downstream during intermittent high flows, elevated concentrations of selenium in the tissues of downstream fish could indicate upstream sources of selenium that require a more detailed evaluation of upstream conditions.

1.2.2 Model the Food-Web of the Targeted Fish Species

After selecting the target fish species, model users should formulate a mathematical expression of the target species food-web that will be used to calculate the value of $TTF^{composite}$. As discussed previously, $TTF^{composite}$ is the product of the *TTF* values across trophic levels of the target fish species food-web. The complexity of the food-web model will depend on the species of fish that is targeted, the diversity of prey species in the aquatic system, and the amount of information that is available. Many of the same information sources used to identify the targeted fish species in a waterbody could also be used to obtain information about its food web. The types and proportions of food organisms the targeted fish species consumes can be directly assessed through studies that examine stomach contents or from information gathered through biological assessments. If site-specific information is not available, model users could estimate the target fish species food-web using publicly available databases such as NatureServe (http://www.natureserve.org). For example, the NatureServe database record for fathead minnow in the HUC watershed #5040004 in Ohio indicates under the heading: “Ecology and Life History - Food Comments,” the fathead minnow “feeds opportunistically in soft bottom mud; eats algae and other plants, insects, small crustaceans, and other invertebrates (Becker 1983, Sublette et al. 1990).”

Additional sources of information include:

- FishBase (http://www.fishbase.org). FishBase is a relational database developed at the World Fish Center in collaboration with the Food and Agriculture Organization of the United Nations (FAO) and many other partners.

1.2.3 Identify Appropriate *TTF* Values

The food-web model uses appropriately selected species-specific *TTF* values (and, if appropriate, proportions within the same trophic level). Model users identify the appropriate *TTF* values by using one of the following four procedures, or by using other scientifically defensible methods.

1.2.3.1 Select the appropriate *TTF* values from the provided list of EPA-derived values

Species-specific TTF values represent the steady state proportional concentration of selenium in the tissue of an organism relative to the concentration of selenium in the food it consumes. EPA-derived *TTF* values for aquatic invertebrates and fish are provided in Tables K-1 and K-2 (Tables 3.10 and 3.11 in main text; see also main text for a complete explanation of the procedure EPA used to derive these values).

NMED Exhibit 59

Table K-1. EPA-derived Trophic Transfer Factor (TTF) values for freshwater aquatic invertebrates.

AE = Assimilation efficiency (%), IR = Ingestion rate (g/g-d), k_e = Elimination rate constant (/d).

Common name	Scientific name	AE	IR	k_e	TTF
Crustaceans					
amphipod	*Hyalella azteca*	-	-	-	1.22

black bullhead	*Ameiurus melas*	-	-	-	0.85
channel catfish	*Ictalurus punctatus*	-	-	-	0.68

The *TTF* values from these lists could be used exclusively, or in conjunction with *TTF* values obtained from other sources (see below). Note that these tables do not represent an exhaustive list of all *TTF* values that may be required to calculate a site-specific water concentration value. If this list does not include a required *TTF* value, another approach could be considered to obtain an appropriate value.

1.2.3.2 Deriving *TTF* values from existing data

If model users cannot obtain one or more required *TTF* values from Tables K-1 and/or K-2, species-specific *TTF* values could be derived using existing data. One approach for deriving species-specific *TTF* values is to use the physiological coefficients representing food ingestion rate (*IR)*, selenium efflux rate (k_e), and selenium assimilation efficiency (*AE*) to calculate a *TTF* value using Equation K-4 (Equation 3 from the main text, Reinfelder et al. 1998**)** given as:

NMED Exhibit 59

$$TTF = \frac{AE \times IR}{k_e} \qquad \textit{(Equation K-4)}$$

Where:

TTF = species-specific trophic transfer factor

AE = species-specific assimilation efficiency (%)

IR = species-specific ingestion rate (g/g-d)

k_e = species-specific efflux rate constant (/d)

The physiological coefficients *IR*, *AE* and are species-specific values. Values for AE and k_e can only be derived from laboratory studies. Values for IR may be derived from laboratory studies or obtained from published literature. After the three physiological coefficients are obtained, a *TTF* value can be calculated using Equation K-4.

Another way to derive species-specific *TTF* values is to empirically assess the relationship between the selenium concentration in the tissue of organisms and the selenium concentration in the food they consume using paired measurements from field studies. Species-specific *TTF* values can be derived from such measurements by calculating ratios, using regression techniques, or other scientifically defensible methods.

Model users could choose to use the same approach EPA used to calculate species-specific *TTF* values. EPA derived *TTF* values using a combination median and regression approach. EPA defined the *TTF* value for any trophic level as:

$$TTF^{TLn} = \frac{C_{tissue}^{TLn}}{C_{food}^{TLn}} \qquad \textit{(Equation K-5)}$$

Where:

TTF^{TLn} = The trophic transfer factor of a given trophic level,

C_{tissue}^{TLn} = The selenium concentration (mg/kg dw) in the tissues of the consumer organism,

C_{food}^{TLn} = The selenium concentration (mg/kg dw) in the consumer organism's food.

EPA used the median of the ratios given in Equation K-5 as the species-specific *TTF* value, but only if an empirical relationship between the paired measurements could be confirmed by linear

NMED Exhibit 59

regression analysis. EPA considered the relationship acceptable if a linear regression of tissue selenium concentration on food selenium concentration resulted in both a statistically significant fit ($P < 0.05$) and a positive slope (i.e., selenium concentrations in the consumer increases with increasing selenium in food).

1.2.3.3 Deriving *TTF* values by conducting additional studies

Additional studies could be conducted to obtain the data needed to derive *TTF* values for specific needs, or to revise existing *TTF* values, if the existing *TTF* values do not appear to be appropriate for a particular aquatic system.

1.2.3.4 Extrapolating *TTF* values from existing values

If one or more necessary *TTF* values are not available, and the information needed to derive a species-specific *TTF* value is not available or impractical to obtain, model users could consider extrapolating a new *TTF* value from other known *TTF* values. One possible method to extrapolate a *TTF* value is to sequentially consider higher taxonomic classifications until one or more of the organisms with a known *TTF* value matches the taxon being considered. If the lowest matching taxon is common to more than one of the available *TTF* values, the average *TTF* from the matching table entries could be used. The use of taxonomic hierarchies in this way utilizes evolutionary relationships to infer biological similarities among organisms (Suter 1993).

EPA used such an extrapolation approach to derive some of the *TTF* values necessary to develop the water column criterion elements. For example, the *TTF* value for *Chrosomus eos* (northern redbelly dace) was not available. *TTF* values were also not available for other species in the genus *Chrosomus*, but *TTF* values were available for species in the family Cyprinidae, including *Rhinichthys atratulus* (blacknose dace), *Cyprinus carpio* (common carp), *Semotilus atromaculatus* (creek chub), *Pimephales promelas* (fathead minnow), *Cyprinella lutrensis* (red shiner), *Richardsonius balteatus* (redside shiner), and *Notropis stramineus* (sand shiner). Because Cyprinidae is the lowest taxonomic classification where *Chrosomus eos* matches one or more species with an available *TTF* value, EPA used the median *TTF* value of blacknose dace, common carp, creek chub, fathead minnow, red shiner, redside shiner, and sand shiner as the *TTF* value for northern redbelly dace.

1.2.4 Determine the Appropriate *EF* Value

The selenium enrichment function (*EF*) value represents the bioavailability of selenium at the base of the aquatic food web. The base of the aquatic food web includes phytoplankton, periphyton, detritus, inorganic suspended material, biofilm, sediment and/or attached vascular plants (Presser and Luoma, 2010). EPA refers to this mixture of living and non-living entities as particulate material. The parameter *EF* varies more widely across aquatic systems than any other parameter, and is influenced by

NMED Exhibit 59

the source and form of selenium, water residence time, the biogeochemical characteristics of the waterbody, and the type of particulate matter collected. Because *EF* can vary greatly across waterbodies, this parameter has the greatest potential to introduce uncertainty in the translation from an egg-ovary selenium concentration to a water column concentration. For this reason, use *EF* values derived from site-specific data is recommended whenever possible in applying the model. One of the following four procedures could be used to derive *EF* values, or other scientifically defensible methods could be used.

1.2.4.1 Deriving a site-specific *EF* value from field measurements

Equation 12 from the main text defines the parameter *EF* as the ratio of the concentration of selenium in particulate material to the concentration of selenium dissolved in water given as:

$$EF = \frac{C_{particulate}}{C_{water}} \qquad \textit{(Equation K-6)}$$

Where:

$C_{particulate}$ = Concentration of selenium in particulate material (µg/g)

C_{water} = Concentration of selenium dissolved in water (µg/L)

EF = Enrichment Function (L/g)

To calculate a site-specific *EF* value, EPA first calculates the ratio of each individual particulate measurement and its associated water measurement (if more than one water measurement is available for any given particulate measurement, the median water measurement is used). If more than one ratio for any given category of particulate material is available (e.g., more than one ratio of algae to water), EPA takes the median of the ratios. EPA then calculates the geometric mean of the median ratios for each category of particular material as the site *EF* value. EPA only uses sediment measurements if there are at least one measurement from either algae or detritus.

Deriving a site-specific *EF* value in this manner is a relatively straightforward procedure. However, consideration of data that appropriately accounts for the spatial and temporal variability of an aquatic system would be useful in the development of any sampling plan. Aquatic system characteristics such as dimension, volume, shape, residence time, velocity, and growing season are a few important factors that should be considered in designing a sampling plan that will adequately account for variability. State and Federal agencies (USGS, ACOE) as well as watershed groups may be useful sources of information that can help characterize the temporal and spatial variability at a particular aquatic system. When developing the selenium criterion, EPA observed a relatively lower correlation between the selenium concentration in water and abiotic (benthic sediments) particulate samples compared to the same analysis between water and biotic (algae and detritus) particulate samples, resulting in EPA's decision

NMED Exhibit 59

that calculation of any site-specific *EF* values include information from at least one type of biotic particulate indeveloping its criteiron. Prioritization of sampling of biotic particulate material over abiotic samples should be considered. Regaridng selenium measurements from abiotic particulate material, consideration of utilizing at least one type of biotic particulate material when deriving the *EF* value of an aquatic system is recommended.

Site-specific *EF* values using particulate and water samples that are as spatially and temporally coincident as possible would be considered the most robust. Although EPA's analysis of particulate and water samples from a sample population of aquatic systems found that samples taken within one year of each other, based on data availability, were appropriate in deriving the national criterion (Figure 3.5 in the main document), a site-specific EF value would ideally involve collecting particulate and water samples at the same location and time to ensure their representativeness of sirte-specific conditions. One simple and effective sampling and analysis scenario would be to collect water samples or a combination of particulate and water samples, separate the particulate material from the water in each sample by filtering, measure the concentration of selenium in the separated water and particulate material, compute the ratio of the two measurements from each sample, and then calculate the mean or median of all the ratios.

Selenium bioaccumulation occurs more readily in aquatic systems with longer residence times (such as lakes, reservoirs, oxbows, and wetlands) and with fine particulate sediments high in organic carbon. A well-planned sampling protocol was developed in association with the development of a site-specific water-column criterion for selenium in the San Francisco Bay Delta[2]. States and tribes may also want to consult Doblin et al. (2006) for specific particulate sampling methods. EPA's National Rivers and Streams Assessment[3] also provides methods for quantitative periphyton sampling that commonly represents the base of many aquatic food webs. Analytical methods to measure selenium in particulate material and in water are discussed in Appendix L.

1.2.4.2 Deriving an appropriate *EF* value from existing data

If suitable and sufficient site-specific measurements of selenium in particulate material and water are already available, the model user may be able to use that data to derive an appropriate *EF* value. However, it would be important to ensure that the data represents current conditions, were collected and analyzed using scientifically sound sampling and analytical techniques, and proper quality assurance and quality control protocols were implemented.

1.2.4.3 Extrapolating from *EF* values of similar waters

[2] https://www3.epa.gov/region9/water/ctr/selenium-modeling_admin-report.pdf

[3] https://www.nemi.gov/methods/method_summary/12558/ (EPA-841-B-07-009) and https://www.nemi.gov/methods/method_summary/12565/ (EPA-841-B-12-009)

NMED Exhibit 59

In circumstances where a site-specific, field-derived *EF* value is not available or practical to develop, an *EF* value from one or more aquatic systems with similar hydrological, geochemical, and biological characteristics could be used to estimate *EF*. However, there is a possibility of introducing significant uncertainty when using *EF* values extrapolated from other aquatic systems. More information on this topic is contained in Appendix H of this document.

1.2.5 Determine the Appropriate *CF* Value

1.2.5.1 Selecting the appropriate *CF* value from the list of values that were used to derive EPA's recommended water criteria concentration values

The parameter *CF* represents the species-specific proportion of selenium in eggs or ovaries relative to the average concentration of selenium in all body tissues. EPA derived species-specific *CF* values for 20 species of fish from studies that measured selenium concentrations in both eggs and/or ovaries and in whole body and/or muscle. These *CF* values can be found in Appendix B and are reproduced below (Table K-3).

Table K-3. Selenium Whole Body to Egg-Ovary Conversion Factors (*CF*).

Common name	Median ratio (Cegg-ovary/ Cwhole-body)	Median ratio (Cegg-ovary/ Cmuscle)	Muscle to whole-body correction factor	Final CF values
Species				
Bluegill	2.13			2.13
Bluehead sucker	1.82			1.82
Brook trout		1.09	1.27	1.38
Brown trout	1.45			1.45
Creek chub	1.99			1.99
Common carp	1.92			1.92
Cutthroat trout	1.96			1.96
Desert pupfish	1.20			1.20
Dolly Varden		1.26	1.27	1.61
Fathead minnow	1.40			1.40
Flannelmouth sucker	1.41			1.41
Green sunfish	1.45			1.45
Mountain whitefish		5.80	1.27	7.39
Northern pike		1.88	1.27	2.39
Rainbow trout		1.92	1.27	2.44

NMED Exhibit 59

Common name	Median ratio (Cegg-ovary/ Cwhole-body)	Median ratio (Cegg-ovary/ Cmuscle)	Muscle to whole-body correction factor	Final CF values
Razorback sucker		2.31	1.34	3.11
Roundtail chub	2.07			2.07
Smallmouth bass	1.42			1.42
White sturgeon		1.33	1.27	1.69
White sucker	1.38			1.38
Genus				
Catostomus				1.41
Gila				2.07
Lepomis				1.79
Micropterus				1.42
Oncorhynchus				1.96
Family				
Catostomidae				1.41
Centrarchidae				1.45
Cyprinidae				1.95
Salmonidae				1.71
Order				
Cyprinodontiformes				1.20
Perciformes				1.45
Class				
Actinopterygii				1.45

The data and methods used to derive the *CF* in this table are described in Appendix B.

NMED Exhibit 59

1.2.5.2 Deriving a *CF* value from existing data

The parameter *CF* is mathematically expressed as Equation K-7 (Equation 16 in the main text):

$$CF = \frac{C_{egg-ovary}}{C_{whole-body}} \qquad \textit{(Equation K-7)}$$

Where:

CF = Whole-body to egg-ovary conversion factor (dimensionless ratio).

$C_{egg\text{-}ovary}$ = Selenium concentration in the eggs or ovaries of fish (µg/g)

$C_{whole\text{-}body}$ = Selenium concentration in the whole body of fish (mg/kg).

If suitable and sufficient data are available, a model user could derive a species-specific *CF* value using the same numerical methods described above to calculate the parameter *EF*. The median of the ratios given in Equation K-7 could be used as the species-specific *CF* value, but only if an empirical relationship between the paired measurements could be confirmed by linear regression analysis. IN deriving the national criterion, EPA considered it to be acceptable if a linear regression of egg-ovary selenium concentration on whole body selenium concentration resulted in both a statistically significant fit ($P < 0.05$) and a positive slope. Other scientifically defensible methods could be used. Regardless of the method used, the user should ensure that the data used to derive *CF* values were collected using adequate quality assurance and quality control protocols.

1.2.5.3 Deriving a *CF* value by conducting additional studies

Additional studies could be performed to obtain data needed to derive *CF* values for specific needs or to revise existing *CF* values if there is reason to believe doing so may increase the accuracy of the resulting water concentration value. Analytical methods to measure selenium in tissue are discussed in Appendix L. Where appropriate, additional data could be obtained as part of a NPDES permit application by invoking authority under CWA section 308 (or comparable state or tribal authority) to require NPDES-regulated facilities to collect information necessary to develop permit limits**.**

1.2.5.4 Extrapolating the CF value from the list of values that were used to derive EPA's recommended water criteria concentration values

If one or more necessary *CF* values are not available, and the information needed to derive a species-specific *CF* value is not available or impractical to obtain, a model user could could consider extrapolating a new *CF* value from other known *CF* values. One possible method to extrapolate a *CF* value is to use the same taxonomic approach EPA uses for *TTF* values that are not available for specific

NMED Exhibit 59

species (Section 1.2.3.4). Sequentially consider higher taxonomic classifications could be considered until one or more of the fish species with a known *CF* value matches the taxon being considered. If the lowest matching taxon is common to more than one of the available *CF* values, the average *CF* value from the matching table entries could be used.

1.2.6 Translate the Selenium Egg-Ovary Criterion Element into a Site-Specific Water Concentration Value using Equation K-1

Model users could derive a site-specific water concentration value from the egg-ovary criterion element value using Equation K-1 with appropriate values of *CF*, $TTF^{composite}$ (derived from the product of the individual *TTF* values from each trophic level) and *EF*. Note that NPDES permitting regulations at 40 CFR § 122.45(c) requires that a Water Quality-Based Effluent Limit (WQBEL) for metals be expressed as total recoverable metal, unless an exception is met under 40 CFR § 122.45(c)(1)-(3). Equation K-1 assumes selenium concentrations dissolved in water. While states and tribes may express ambient water quality criteria in water quality standards as dissolved selenium, an additional step would be necessary to convert the dissolved selenium concentration to a total recoverable selenium concentration for the purpose of NPDES permitting. Guidance for converting expression of metal concentrations in water from dissolved to total recoverable can be found in *Technical Support Document for Water Quality-based Toxics Control* (U.S. EPA 1991) and *The Metals Translator: Guidance for Calculating a Total Recoverable Permit Limit from a Dissolved Criterion* (U.S. EPA 1996).

1.3 Managing Uncertainty using the Mechanistic Modeling Approach

Uncertainty in the translation of the egg-ovary criterion element to a water column value using the mechanistic bioaccumulation modeling approach (Equation K-1) can arise from several sources. These include:

- Measurement error when deriving input parameters,
- Inaccurate food web models due to misidentification and/or incorrect proportions of prey organisms,
- Inaccurate or inappropriate *EF*, *TTF*, and/or *CF* values,
- Biological variability,
- Unaccounted factors affecting bioaccumulation (e.g. selenium speciation), and
- Other unknown factors.

The most influential step in selenium bioaccumulation occurs at the base of aquatic food webs (Chapman et al. 2010). The parameter *EF* characterizes this step by quantifying the partitioning of

NMED Exhibit 59

selenium between the dissolved and particulate state. *EF* can vary by at least two orders of magnitude across aquatic systems (Presser and Luoma 2010). The greatest reduction in uncertainty could be achieved when translating a fish tissue concentration of selenium to a water column concentration using Equation K-1 by using temporally and spatially coincident site-specific empirical observations of dissolved and particulate selenium of sufficient quality and quantity to accurately characterize *EF*.

Presser (2013) provides several recommendation to reduce uncertainty in an ecosystem scale approach to deriving a site-specific selenium water column criterion in a coal mining impacted area of West Virginia. Suggested actions to reduce uncertainty include:

- Obtaining temporally matched pairs of selenium measurements in dissolved and particulate material across a broad range of sites to ensure the samples accurately characterize the aquatic system and to assess sample variability;
- Characterizing particulate material across seasons to better define the base of the food web;
- Evaluating aquatic systems variables such as residence time, watershed dilution, and physical habitat attributes on as fine a scale as possible;
- Refining model assumptions to accurately characterize dietary preferences and composition of fish, and develop additional *TTF* values if necessary;
- Identify and target fish species particularly sensitive to selenium;
- Consider temporal changes in the bioaccumulation potential of the aquatic system and changes in selenium sensitivity over the life cycle of fish; and
- Consider variability in hydrology and selenium discharges.

The suitability of selected equation parameters could be determined by obtaining fish tissue and water column measurements of selenium from small-scale field studies, use of equation K-1 to estimate one measurements using the other, and comparison of the estimated concentration with the actual concentration (see Section 6.2.1 of the main document for a description of EPA's validation approach).

1.4 Example Calculations

Below are six hypothetical examples that demonstrate how to translate the egg-ovary FCV to a site-specific water concentration criterion using Equation K-1. These examples encompass a variety of hypothetical aquatic systems with various fish species and food webs. For these hypothetical examples, species-specific *TTF* values were taken from Tables K-1 and K-2, and *CF* values were taken from Table K-3. To calculate EF in these examples, the EPA used a hypothetical water concentration of 5 µg/L and the hypothetical particulate concentrations of 4.25 µg/g and 8.75 µg/g in lotic and lentic aquatic systems, respectively.

NMED Exhibit 59

1.4.1 Example 1

Bluegill (*Lepomis macrochirus*) in a river that consume mostly amphipods:

Current water concentration (µg/L)	5.00
Current particulate concentration (mg/kg)	4.25
Trophic transfer factor for bluegill (TTF^{TL3})	1.03
Trophic transfer factor for amphipods (TTF^{TL2})	1.22
Egg-ovary to whole-body conversion factor for bluegill (CF)	2.13
Selenium egg-ovary FCV (mg/kg)	15.1

$$\mathrm{EF} = \frac{\mathrm{C_{particulate}}}{\mathrm{C_{water}}}$$

$$EF = \frac{4.25}{5.00}$$

= 0.85 L/g

$$C_{water} = \frac{C_{egg-ovary}}{TTF^{composite}\ x\ EF\ x\ CF}$$

$$TTF^{composite} = TTF^{TL3} \times TTF^{TL2}$$
$$= 1.03 \times 1.22$$
$$= 1.26$$

$$C_{water} = \frac{15.1}{1.26 \times 0.85 \times 2.13}$$

= 6.62 µg/L

NMED Exhibit 59

1.4.2 Example 2

Fathead minnow (*Pimephales promelas*) in a river that consume mostly copepods:

Current water concentration (µg/L)	5.00
Current particulate concentration (mg/kg)	4.25
Trophic transfer factor for fathead minnow (TTF^{TL3})	1.57
Trophic transfer factor for copepods (TTF^{TL2})	1.41
Egg-ovary to whole-body conversion factor for fathead minnow (CF)	1.40
Selenium egg-ovary FCV (mg/kg)	15.1

$$EF = \frac{C_{particulate}}{C_{water}}$$

$$EF = \frac{4.25}{5.00}$$

= 0.85 L/g

$$C_{water} = \frac{C_{egg-ovary}}{TTF^{composite} \; x \; EF \; x \; CF}$$

$TTF^{composite} = TTF^{TL3} \times TTF^{TL2}$

$= 1.57 \times 1.41$

$= 2.21$

$$C_{water} = \frac{15.1}{2.21 \times 0.85 \times 1.40}$$

= 5.74 µg/L

NMED Exhibit 59

1.4.3 Example 3

Bluegill (*Lepomis macrochirus*) in a lake that consume mostly aquatic insects:

Current water concentration (µg/L)	5.0
Current particulate concentration (mg/kg)	8.75
Trophic transfer factor for bluegill (TTF^{TL3})	1.03
Trophic transfer factor for aquatic insects (median of Odonates, Water boatman, Midges, and Mayflies) (TTF^{TL2})	2.14
Egg-ovary to whole-body conversion factor for bluegill (CF)	2.13
Selenium egg-ovary FCV (mg/kg)	15.1

$$EF = \frac{C_{particulate}}{C_{water}}$$

$$EF = \frac{8.75}{5.00}$$

= 1.75 L/g

$$C_{water} = \frac{C_{egg-ovary}}{TTF^{composite} \; x \; EF \; x \; CF}$$

$TTF^{composite}$ = $TTF^{TL3} \times TTF^{TL2}$

= 1.03 x 2.14

= 2.20

$$C_{water} = \frac{15.1}{2.20 \times 1.75 \times 2.13}$$

= 1.84 µg/L

NMED Exhibit 59

1.4.4 Example 4

Fathead minnow (*Pimephales promelas*) in a river that consume approximately ⅔ copepods and ⅓ aquatic insects:

Current water concentration (µg/L)	5.0
Current particulate concentration (mg/kg)	4.25
Trophic transfer factor for fathead minnow (TTF^{TL3})	1.57
Trophic transfer factor for copepods and aquatic insects (TTF^{TL2}) Copepods = 1.41 Average of all aquatic insects = 2.14 $TTF^{TL2} = \sum_{i=1}^{n}(TTF_i \times w_i)$ $= (1.41 \times ⅔) + (2.14 \times ⅓)$ $= 1.65$	1.65
Egg-ovary to whole-body conversion factor for fathead minnow (CF)	1.40
Selenium egg-ovary FCV (mg/kg)	15.1

$$EF = \frac{C_{particulate}}{C_{water}}$$

$$EF = \frac{4.25}{5.00}$$

= 0.85 L/g

$$C_{water} = \frac{C_{egg-ovary}}{TTF^{composite} \; x \; EF \; x \; CF}$$

$TTF^{composite} = TTF^{TL3} \times TTF^{TL2}$

= 1.57 × 1.65

= 2.59

$$C_{water} = \frac{15.1}{2.59 \times 0.85 \times 1.40}$$

= 4.90 µg/L

NMED Exhibit 59

1.5.5 Example 5

Flathead chub (*Platygobio gracilis*) in a river with a diet of approximately 80% aquatic insects and 20% algae:

Current water concentration (µg/L)	5.0
Current particulate concentration (mg/kg)	4.25
Trophic transfer factor of flathead chub: Lowest matching taxon is the family Cyprinidae. Therefore, the TTF value of Cyprinidae is used (TTF^{TL3})	1.20
Trophic transfer factor for insects (TTF^{TL2}) Average of all aquatic insects = 2.14	2.14
Egg-ovary to whole-body conversion factor for flathead chub (species-specific value not available, so median CF for family Cyprinidae is used). (CF)	1.95
Selenium egg-ovary FCV (mg/kg)	15.1

$$EF = \frac{C_{particulate}}{C_{water}}$$

$$EF = \frac{4.25}{5.00}$$

= 0.85 L/g

$$TTF^{composite} = [TTF^{TL3} \times TTF^{TL2} \times w_1] + [TTF^{TL3} \times w_2]$$

Where:
w_1 = Proportion of fathead chub diet from insects; and
w_2 = Proportion of fathead chub diet from algae

$$TTF^{comb} = [1.20 \times 2.14 \times 0.8] + [1.20 \times 0.2]$$
= 2.29

$$C_{water} = \frac{C_{egg-ovary}}{TTF^{composite} \; x \; EF \; x \; CF}$$

$$C_{water} = \frac{15.1}{2.29 \times 0.85 \times 1.95}$$

= 3.98 µg/L

NMED Exhibit 59

1.5.6 Example 6

Largemouth bass (*Micropterus salmoides*) in a large river that consume mostly Western mosquitofish (*Gambusia affinis*) that consume approximately ¾ insects and ¼ crustaceans:

Current water concentration (µg/L)	5.0
Current particulate concentration (mg/kg)	4.25
Trophic transfer factor of largemouth bass (TTF^{TL4})	1.39
Trophic transfer factor of Western mosquitofish (TTF^{TL3})	1.21
Trophic transfer factor for insects and crustaceans (TTF^{TL2}) Median all Insects – 2.14 Median all Crustaceans – 1.41 $TTF^{TL2} = \sum_{i=1}^{n}\left(TTF_i^{TL2} w_i\right)$ = (2.14 x 0.75) + (1.41 x 0.25) = 1.96	1.96
Egg-ovary to whole-body conversion factor for largemouth bass (species-specific value not available, so median CF for genus Micropterus is used) (CF)	1.42
Selenium egg-ovary FCV (mg/kg)	15.1

$$EF = \frac{C_{particulate}}{C_{water}}$$

$$EF = \frac{4.25}{5.00}$$

= 0.85 L/g

$TTF^{composite} = TTF^{TL4} \times TTF^{TL3} \times TTF^{TL2}$
$= 1.39 \times 1.21 \times 1.96$
$= 3.30$

$$C_{water} = \frac{C_{egg-ovary}}{TTF^{composite} \; x \; EF \; x \; CF}$$

$$C_{water} = \frac{15.1}{3.30 \times 0.85 \times 1.42}$$

= 3.79 µg/L

NMED Exhibit 59

2.0 TRANSLATING THE CONCENTRATION OF SELENIUM IN TISSUE TO A CONCENTRATION IN WATER USING BIOACCUMULATION FACTORS (BAF)

2.1 Summary of the BAF Approach

A bioaccumulation factor (BAF) is the ratio (in milligrams/kilogram per milligrams/liter, or liters per kilogram) of the concentration of a chemical in the tissue of an aquatic organism to the concentration of the chemical dissolved in ambient water at the site of sampling (U.S. EPA 2001c). BAFs are used to relate chemical concentrations in aquatic organisms to concentrations in the ambient media of aquatic ecosystems where both the organism and its food are exposed and the ratio does not change substantially over time. The BAF is expressed mathematically as:

$$BAF = \frac{C_{tissue}}{C_{water}} \qquad \textit{(Equation K-8)}$$

Where:

BAF	=	bioaccumulation factor derived from site-specific field-collected samples of tissue and water (L/kg)
C_{tissue}	=	concentration of chemical in fish tissue (mg/kg)
C_{water}	=	ambient concentration of chemical in water (mg/L)

The site-specific BAF can then be applied to the tissue criterion to solve for a target site-specific water column criterion (C_{target}):

$$C_{target} \times \frac{C_{egg-ovary\ criterion}}{BAF} \qquad \textit{(Equation K-9)}$$

Where:

C_{target}	=	site-specific water criterion concentration (mg/L)
$C_{egg\text{-}ovary\ criterion}$	=	national egg-ovary tissue criterion (15.1 mg Se/kg dw)
BAF	=	bioaccumulation factor derived from site-specific field-collected samples of tissue and water (L/kg)

To translate a fish tissue criterion to a water concentration value, a site-specific, field-measured BAF for the waterbody could be developed, and then a water concentration criterion could be calculated using Equation K-9. Detailed information about how to derive a site-specific, field-measured BAF is provided in *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (2000) Technical Support Document Volume 3: Development of Site-specific Bioaccumulation*

NMED Exhibit 59

Factors (U.S. EPA 2009). Although this guidance was developed for deriving human health criteria, the methodological approach is also applicable to the derivation of aquatic life criteria. The following example illustrates the calculation of a site specific water column criterion using the BAF approach.

2.1.1 Example: Derivation of a site specific water column criterion for a waterbody impacted by selenium

Available data for a hypothetical site indicate that the average egg/ovary tissue concentration of selenium for the bluegill (*Lepomis macrochirus*) is 22 mg/kg (dw). This concentration exceeds the USEPA proposed egg/ovary criterion of 15.1 mg/kg (dw). The ambient selenium water column concentration at that hypothetical site is 4.0 µg/L. The following calculation shows how to derive a target water column that would achieve a site-specific criterion using the bioaccumulation factor (BAF) approach.

Site specific selenium egg/ovary concentration (bluegill; mg/kg dw)	22.0
Selenium egg/ovary criterion (mg/kg, dw)	15.1
Ambient selenium water column concentration (µg/L)	4.0
Target water column concentration (µg/L)	X

Set up proportional equation to solve for allowable water column concentration:

$$\frac{Site\ specific\ egg/ovary\ conc.\ (\frac{mg\ Se}{kg\ dw})}{Site\ specific\ water\ concentration\ (\frac{\mu g\ Se}{L})} = \frac{Criterion\ egg\ ovary\ conc.\ (\frac{mg\ Se}{kg\ dw})}{Target\ water\ concentration\ (\frac{\mu g\ Se}{L})}$$

Solve for the target water concentration that will achieve a site-specific criterion:

$$\frac{22.0\ (\frac{mg\ Se}{kg\ dw})}{4.0\ (\frac{\mu g\ Se}{L})} = \frac{15.1\ (\frac{mg\ Se}{kg\ dw})}{Target\ water\ concentration\ (\frac{\mu g\ Se}{L})}$$

Target water concentration = 2.75 µg/L.

2.2 Managing Uncertainty using the BAF Approach

Uncertainty can be introduced when using the BAF approach to derive a water concentration value from a fish tissue criterion concentration. Inaccurate water concentration values can result when BAFs are derived from water and fish tissue concentration measurements that are obtained from sources that do not closely represent site characteristics, or from field data collected from large-scale sites that encompass multiple water bodies or ecosystems. Most of this uncertainty results from differences in the

NMED Exhibit 59

bioavailability of selenium between the study sites where measurements are made to derive the BAF, and the site(s) to which the BAF is used to derive needed water concentration values.

Because of uncertainties associated with the BAF approach, EPA does not recommend developing BAFs from data extrapolated from different sites or across large spatial scales. EPA's Framework for Metals Risk Assessment (U.S. EPA 2007) outlines key principles about metals and describes how they should be considered in conducting human health and ecological risk assessments due the the effects of water chemistry on bioavilability of such chemicals. The current science does not support the use of a single, generic threshold BAF value as an indicator of metal bioaccumulation. The use of BAFs are appropriate only for site-specific applications where sufficient measurements have been taken from the site of interest and there is little or no extrapolation of BAF values across differing exposure conditions and species.

The preferred approach for using a BAF to implement the selenium fish tissue criterion is to calculate a site-specific, field-measured BAF from data gathered at the site of interest, and to apply that BAF to that site. A site-specific, field-measured BAF is a direct measure of bioaccumulation in an aquatic system because the data are collected from the aquatic ecosystem itself and thus reflects real-world exposure through all relevant exposure routes. A site-specific, field-measured BAF also reflects biotic and abiotic factors that influence the bioavailability, biomagnification, metabolism, and biogeochemical cycling of selenium that might affect bioaccumulation in the aquatic organism or its food web. Appropriately developed site-specific, field-measured BAFs are appropriate for all bioaccumulative chemicals, regardless of the extent of chemical metabolism in biota from a site (U.S. EPA 2000).

Although a site-specific, field-measured BAF is a direct measure of bioaccumulation, its predictive power depends on a number of important factors being properly addressed in the design of the field sampling effort. For example, sampling in areas with relatively long water residence times should be a priority because selenium bioaccumulation occurs more readily in aquatic systems with longer residence times (such as wetlands, oxbows, and estuaries) and with fine particulate sediments high in organic carbon. In addition, migratory species should generally not be used because their exposure to selenium could reflect selenium concentrations in areas other than where the fish were caught. Fish may also need to be sampled and BAF values recalculated if selenium levels significantly change over time because BAFs are known to be affected by the ambient concentration of the metals in the aquatic environment (McGeer et al. 2003; Borgman et al. 2004; DeForest et al. 2007). States and tribes should refer to *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (2000) Technical Support Document Volume* (U.S. EPA 2009) for guidance on appropriate methods for developing a site-specific, field-derive BAF.

NMED Exhibit 59

The advantage of using the BAF approach is its relative simplicity, especially when the data necessary to derive the BAF is already available. Furthermore, the BAF approach is completely empirical and does not require any specific knowledge about the physical, chemical, or biological characteristics of the waterbody. The relationship between the concentration of selenium in fish tissue and water is directly determined by direct measurements in these media. This may be advantageous when there are uncertainties with how to collect a particulate sample that is representative of the base of the food web, or dilution concerns (e.g., sandy streams with little surface area for algae sampling and high potential for sand contamination of a benthic sediment sample).

Limitations of the BAF approach should be considered before deciding if this method is appropriate for translating the selenium FCV to a water concentration value. One disadvantage of the BAF approach is the considerable effort and resources necessary to collect sufficient data to establish the relationship between tissue and water concentrations. Resource use increases as the spatial scale and complexity of the aquatic system increases. Furthermore, the BAF approach does not allow extrapolation across species, space, and large time scales because the site-specific factors that might influence bioaccumulation are integrated within the tissue concentration measurements and thus cannot be individually adjusted to extrapolate to other conditions. Thus, site-specific, field-measured BAFs only provide an accounting of the uptake and accumulation of selenium for an organism at a specific site and point in time. This is more important in lotic habitats, since the kinetics of selenium bioaccumulation may be very different at a site upstream or downstream from the site of interest.

As noted previously, NPDES permitting regulations at 40 CFR § 122.45(c) require WQBELs for metals be expressed as total recoverable metal unless an exception is met under 40 CFR § 122.45(c)(1)-(3). Guidance for converting expression of metals in water from dissolved to total recoverable can be found in *Technical Support Document for Water Quality-based Toxics Control* (U.S. EPA 1991) and *The Metals Translator: Guidance for Calculating a Total Recoverable Permit Limit from a Dissolved Criterion* (U.S. EPA 1996). Whether or not a water concentration value derived from a site-specific, field-derived BAF requires conversion from dissolved to total recoverable selenium depends on how the BAF is developed. Generally, conversion would not be necessary if the BAF is derived from water concentration values that measure total selenium; however, conversion would be necessary if the BAF was derived from water concentration values that measured dissolved selenium. Table K-4 compares some of the principle characteristics of the mechanistic bioaccumulation modeling approach or the BAF approach for translating the selenium FCV to a water concentration.

NMED Exhibit 59

3.0 COMPARISON OF MECHANISTIC BIOACCUMULATION MODELING AND BAF APPROACHES

Data from Saiki et al. (1993) are used here to illustrate an example comparison of the two translation approaches, the mechanistic bioaccumulation modeling approach and the bioaccumulation factor (BAF) model approach. Definitive selenium measurements for all ecosystem compartments (e.g., water, algae, etc.) are available for two species, bluegill and largemouth bass, at four sites. Food web pathways were calculated using results of gut content analysis. Although Saiki et al. (1993) satisfies the minimum requirements for a site specific translation, it represents a sparse dataset, with only two measurements per ecosystem compartment, one for the spring and fall of 1987, respectively. For purposes of this exercise, samples from the same site collected at different time periods will be treated as replicate data; however, EPA recommends using larger sample sizes collected during the same time period when calculating a site specific criterion.

Selenium data used to calculate site specific water criteria are included in Table K-4. Median concentrations and coefficients of variation for each ecosystem compartment at each site are included in Table K-5. Because at most only two concentrations were available for each ecosystem, site median are equal to site averages. Site specific translations for both approaches will be calculated using median selenium concentrations.

NMED Exhibit 59

Table K-4. Selenium concentrations in ecosystem compartments for four sites described in Saiki et al. (1993).
Water concentrations expressed as µg/L, all other concentrations expressed as mg/kg dw.

Site	Date	Water	Algae	Detritus	Amphipod	Chironomid	Crayfish	Zooplankton	Bluegill	Largemouth Bass
Mud Slough at Gun Club Road	Fall 1987	3	7.40	22	4.6	8.9	5.2	2.4	6.4	6.8

NMED Exhibit 59

3.1 Translation using the BAF Approach

Site specific BAFs were calculated for bluegill and largemouth bass at each of the four sites (Table K-6). A site-specific water criterion was calculated for each species at the four sites using equation K-8, which is equivalent to the BAF example shown in the previous section. The site specific criterion calculation for bluegill at site "Salt Slough at the San Luis National Wildlife Refuge" is included below as an example.

$$BAF = \frac{C_{tissue}}{C_{water}} = \frac{4.4\ \mu g/g}{8\ \mu g/L} = 0.55\ L/g$$

$$C_{water\ criterion} = \frac{C_{tissue\ criterion}}{BAF} = \frac{8.5\ mg/kg}{0.55\ L/g} = 15.5\ \mu g/L$$

The whole body tissue criterion of 8.5 mg/kg is used here because whole body fish tissue selenium measurements were made. If site specific egg ovary fish tissue had been measured, then the egg ovary tissue criterion of 15.1 mg/kg would have been used.

Table K-6. Site and species specific translated water concentrations using the BAF translation approach.

		Bluegill:			**Largemouth Bass:**		
Site	**Water (µg/L)**	**WB Se (mg/kg)**	**BAF (L/g)**	**Water SSC[a] (µg/L)**	**WB Se (mg/kg)**	**BAF (L/g)**	**Water SSC[a] (µg/L)**
Mud Slough at Gun Club Road	6.0	5.70	0.95	8.95	6.85	1.14	7.45
Salt Slough at the San Luis National Wildlife Refuge	8.0	4.40	0.55	15.45	4.35	0.54	15.63
San Joaquin R. above Hills Ferry Road	7.0	3.00	0.43	19.83	2.30	0.33	25.87
San Joaquin R. at Durham Ferry State Recreation Area	1.0	1.95	1.95	4.36	1.75	1.75	4.86

a – Site specific criterion based on BAF for respective species.

At each site, the lowest translated water criterion for all species is used as the site specific criterion. At site "Mud Slough at Gun Club Road," the site specific criterion is based on the translated concentration for largemouth bass, and at the other 3 sites, the site specific criterion is based on the translated concentration for bluegill. Site specific water concentrations calculated using the BAF approach range from 4.4 to 19.8 µg/L Table K-6).

NMED Exhibit 59

3.2 Translation using the Mechanistic Bioaccumulation Modeling Approach

The first step in the bioaccumulation modeling approach is the calculation of site specific enrichment factors (*EF*s). Because both algae and detritus selenium concentrations were available, the first step was the calculation of separate *EF*s for algae and detritus at each site, following the procedures described in section 1.2.4.1. Algal and detrital *EF*s, respectively, were calculated using the median of all Se concentrations in algae (or detritus) at a site by the median of all Se concentrations in water at the same site. After calculating separate algal and detrital *EF*s, the final *EF* at each site was calculated as the geometric mean of the algal and detrital *EF* at a given site. Algal, detrital, and site *EF*s are shown in Table K-7.

Table K-7. Se concentrations in water, algae, detritus, and site specific *EF*s.

Site	Water (µg/L)	Algae (mg/kg)	Detritus (mg/kg)	EF (L/g)
Mud Slough at Gun Club Road	6.0	4.50	14.95	1.37
Salt Slough at the San Luis National Wildlife Refuge	8.0	1.39	8.40	0.43
San Joaquin R. above Hills Ferry Road	7.0	1.25	5.00	0.36
San Joaquin R. at Durham Ferry State Recreation Area	1.0	0.45	1.25	0.75

As an example, the EF calculation for site "Salt Slough at the San Luis National Wildlife Refuge" is shown below.

$$EF_{algae} = \frac{C_{algae}}{water}\ ;\ EF_{detritus} = \frac{C_{detritus}}{water}$$

$$EF_{site} = \sqrt{\left(EF_{algae} \times EF_{detritus}\right)}$$

$$EF_{algae} = \frac{1.39\ mg/kg}{8.0\ \mu g/L};\ EF_{detritus} = \frac{8.4\ mg/kg}{8.0\ \mu g/L}$$

$$EF_{site} = \sqrt{(0.17 \times 1.05)}$$

$$EF_{site} = 0.43\ L/g$$

The second step in the bioaccumulation modeling approach is the calculation of site specific composite trophic transfer factors ($TTF^{composite}$). Based on gut content analysis, bluegill diets consisted of

NMED Exhibit 59

47% amphipods, 23% chironomids, and 30% zooplankton, while largemouth bass diets consisted of 73% bluegill and 27% crayfish.

The composite TTF for bluegill was calculated using the following equation:

$$TTF^{composite} = [TTF^{TL3} \times TTF^{TL2} \times w_1] + [TTF^{TL3} \times TTF^{TL2} \times w_2] + [TTF^{TL3} \times TTF^{TL2} \times w_3]$$

Where:

W_1 = proportion of diet from amphipods,

W_2 = proportion of diet from chironomids, and

W_3 = proportion of diet from zooplankton.

For each of the 3 species in the bluegill diet, site specific TTF^{TL3} and TTF^{TL2} were calculated separately. Using median concentrations from Table K-5, $TTF^{composite}$ were calculated for each of the sites and are included in Table K-8.

Table K-8. Trophic transfer factors (TTFs) for bluegill and bluegill prey.

	TL2 TTFs:			**TL3 TTFs:**			**$TTF^{composite}$:**
Site	**Amphipod**	**Chironomid**	**Zooplankton**	**BG-Amph**	**BG-Chiro**	**BG-Zoo**	**Bluegill**
Mud Slough at Gun Club Road	0.41	0.83	0.40	1.44	0.71	1.46	0.59
Salt Slough at the San Luis National Wildlife Refuge	0.73	1.26	0.91	1.24	0.72	0.99	0.90
San Joaquin R. above Hills Ferry Road	1.06	1.62	1.10	0.91	0.59	0.87	0.96
San Joaquin R. at Durham Ferry State Recreation Area	1.53	1.83	2.01	1.50	1.26	1.15	2.30

As an example, the bluegill $TTF^{composite}$ for site "Salt Slough at the San Luis National Wildlife Refuge" is shown below.

$$TTF^{composite} = [1.24 \times 0.73 \times 0.47] + [0.72 \times 1.26 \times 0.23] + [0.99 \times 0.91 \times 0.30]$$

$$TTF^{composite} = 0.90$$

NMED Exhibit 59

The composite TTF for largemouth bass was calculated using the following equation:

$$TTF^{composite} = [TTF^{TL4} \times TTF^{TL3} \times TTF^{TL2} \times w_1] + [TTF^{TL3} \times TTF^{TL2} \times w_2]$$

Where:

W_1 = proportion of diet from bluegill, and

W_2 = proportion of diet from crayfish

For the proportion of the largemouth bass diet consisting of bluegill, TTF^{TL3} x TTF^{TL2} was equal to the $TTF^{composite}$ for bluegill. As was the case for bluegill, site specific TTFs were calculated for each species, and are included in Table K-9.

Table K-9. Trophic transfer factors (TTFs) for largemouth bass and largemouth bass prey.

	Crayfish dietary fraction:		Bluegill dietary fraction:		$TTF^{composite}$:
Site	**Crayfish**	**LMB-Cray**	**Bluegill[a]**	**LMB-BG**	**LMB**
Mud Slough at Gun Club Road	0.49	1.43	0.59	0.70	0.49
Salt Slough at the San Luis National Wildlife Refuge	0.64	1.38	0.90	0.89	0.82
San Joaquin R. above Hills Ferry Road	0.58	1.28	0.96	0.74	0.71
San Joaquin R. at Durham Ferry State Recreation Area	1.22	1.69	2.30	2.06	4.03

a – $TTF^{composite}$ for bluegill.

As an example, the largemouth bass $TTF^{combined}$ for site "Salt Slough at the San Luis National Wildlife Refuge" is shown below.

$$TTF^{composite} = \left[TTF^{TL4} \times TTF_{bluegill}^{composite} \times w_1\right] + [TTF^{TL3} \times TTF^{TL2} \times w_2]$$

$$TTF^{composite} = [0.89 \times 0.90 \times 0.73] + [1.38 \times 0.64 \times 0.27]$$

$$TTF^{composite} = 0.82$$

After calculating site and species specific EF and $TTF^{combined}$, site specific water criterion concentrations were calculated using a modified version of equation K-1, shown below.

NMED Exhibit 59

$$C_{water\ criterion} = \frac{C_{tissue\ criterion}}{EF\ x\ TTF^{composite}}$$

The site specific criterion calculation for bluegill at site "Salt Slough at the San Luis National Wildlife Refuge" is included below as an example.

$$C_{water\ criterion} = \frac{8.5\ mg/kg}{0.43\ L/g\ x\ 0.90} = 22.1\ \mu g/L$$

Because the selenium in fish tissue at these sites were measured as whole body concentrations, the whole body criterion of 8.5 µg/L is used, and an egg-ovary to whole body conversion factor is not required. As with the BAF approach, the lowest translated water criterion for all species is used as the site specific criterion. At site "San Joaquin R. at Durham Ferry State Recreation Area," the site specific criterion is based on the translated concentration for largemouth bass, and at the other 3 sites, the site specific criterion is based on the translated concentration for bluegill. Site specific water concentrations calculated using the mechanistic bioaccumulation modeling approach are more variable than concentrations calculated using the BAF approach, and range from 2.8 to 33.3 µg/L Table K-10). At all sites using both methods, the translated site specific water concentration criteria were higher than the measured water concentrations.

Table K-10. Site and species specific translated water concentrations using the mechanistic bioaccumulation modeling approach.

		Bluegill:			Largemouth Bass:		
Site	**EF (L/g)**	**WB Se (mg/kg)**	**TTF**	**Water SSC (µg/L)**	**WB Se (mg/kg)**	**TTF**	**Water SSC (µg/L)**
Mud Slough at Gun Club Road	1.37	5.70	0.59	10.61	6.85	0.49	12.65
Salt Slough at the San Luis National Wildlife Refuge	0.43	4.40	0.90	22.14	4.35	0.82	24.18
San Joaquin R. above Hills Ferry Road	0.36	3.00	0.96	24.79	2.30	0.71	33.31
San Joaquin R. at Durham Ferry State Recreation Area	0.75	1.95	2.30	4.95	1.75	4.03	2.83

3.3 Summary Comparison of the Mechanistic Bioaccumulation and BAF Approaches

A comparison of the mechanistic bioaccumulation and BAF approaches is included in Table K-11.

NMED Exhibit 59

Table K-11. Comparison of mechanistic bioaccumulation and BAF approaches.

Mechanistic bioaccumulation modeling	Bioaccumulation Factor (BAF)
Knowledge of the aquatic system needed	No information on aquatic system needed
Choice of input parameters at discretion of state or tribe	No input parameters to choose
Species-specific	Species-specific
Can be applied at different sites if site *EF* can be estimated.	Site-specific
Fish tissue sampling not required for translation	Fish tissue and water sampling required

NMED Exhibit 59

APPENDIX L: ANALYTICAL METHODS FOR MEASURING SELENIUM

NMED Exhibit 59

The Clean Water Act (CWA) establishes an EPA approval process for certain analytical methods used in the National Pollutant Discharge Elimination System (NPDES) program and for section 401 certifications. EPA has several approved methods for measuring selenium in water under 40 CFR § 136. EPA generally requires the use of EPA-approved methods for the NPDES program and for CWA section 401 certifications issued by states and tribes (40 CFR § 136.1). However, since there are no EPA approved methods for the analysis of selenium in fish tissue, states and tribes may use analytical methods not approved by EPA to evaluate the attainment of water quality standards or to develop or implement Total Maximum Daily Loads provided that these methods are scientifically sound (40 CFR 122.21(g)(7)).

Implementation of a water quality standard for selenium may require the ability to detect and measure the concentration of selenium in effluent, ambient water, tissue, and other media that is below the detection limit or limit of quantitation that some analytical methods can provide. States and tribes should choose an analytical method that is sufficiently sensitive to implement its water quality standard for selenium. Below are descriptions of some of the methods available for measuring selenium concentrations with sufficient sensitivity to implement EPA's recommended selenium criterion. Complete descriptions of analytical methods appropriate for analyzing selenium in different media can be found in the National Environmental Methods Index at http://www.nemi.gov.

1.0 General Considerations when Measuring Concentrations of Selenium

The oxidation states of selenium dissolved in surface water are usually selenate (+6), selenite (+4), and organo-selenium (-2). The presence of selenium in different oxidation states complicates some analytical methods (Presser and Ohlendorf 1987). EPA recommends using standard reference samples to check for the percentage recovery of each species of selenium (selenate, selenite and organo-selenium) during initial testing of selenium methodologies for quality control and assurance.

If water samples are not filtered, particulate species such as elemental selenium and particulate organo-selenium will also be measured. In addition, federal regulations at 40 CFR §122.45(c) generally requires considering total recoverable metals when establishing effluent limits and reporting requirements.

2.0 Analytical Methods Recommended for Measuring Selenium in Water

EPA has several approved analytical methods under 40 CFR § 136 specifically for measuring total selenium in water. These regulations state that measurements for NPDES permit applications and permittee reporting should be made using analytical methods approved by EPA. Because EPA has

NMED Exhibit 59

approved methods for analyzing selenium in water, these methods must be used for NPDES permits (40 CFR § 122.21(g)(7), 122.41(j), 136.1, 136.3, and 136.6).

A complete list of EPA-approved analytical methods for selenium can be found at: http://www.epa.gov/waterscience/methods/method/. Three EPA-approved methods that may be sufficiently sensitive[4] for the purposes of implementing a selenium water quality criterion are listed below (Table L-1).

Table L-1. Suggested EPA-Approved Methods for Selenium in Water

Method	Technique	Method detection limit
American Public Health Standard Method 3114 B (2009) or 3114 C (2009)	Hydride generation atomic absorption spectrometry (HG-AAS)	2 µg/L
EPA Method 200.8, Rev 5.4 (1998)	Inductively coupled plasma mass spectrometry (ICP-MS)	7.9 µg/L
EPA Method 200.9, Rev.2.2 (1994)	Stabilized temperature graphite furnace atomic absorption (STGF-AA)	0.6 µg/L

2.1 American Public Health Standard Method 3114 B

For measuring selenium in water, American Public Health Standard Method 3114 B uses the HG-AAS technique. Method 3114 B has a method detection limit (MDL) of 2 µg/L. Samples for dissolved analytes should be filtered on-site through 0.45-micron capsule filters certified free of trace-element contamination or other appropriate filtering equipment (Wilde et al. 1999). Dissolved samples should be preserved with high purity hydrochloric acid or nitric acid to a pH less than 2.

For measuring total selenium, samples should not be filtered. In addition, all selenium in the sample should be in the form of selenite (+4). Thus, the following pre-treatment steps to convert all selenium in the sample to selenite are critical when using the HG-AAS method:

1. Boiling with persulfate to oxidize and digest organic material.
2. Boiling with hydrochloric acid to reduce selenate species to selenite.
3. Reduction by sodium borohydride to hydrogen selenide in the quartz tube of the AAS.

[4]For more information on choosing a sufficiently sensitive method, see the memorandum *Analytical Methods for Mercury in National Pollutant Discharge Elimination System (NPDES) Permits* from James A. Hanlon, Director of the Office of Wastewater Management, dated August 23, 2007, available at http://www.epa.gov/npdes/pubs/mercurymemo_analyticalmethods.pdf.

NMED Exhibit 59

Optimal conversion conditions are essential for accurate results because too mild a reduction could lead to incomplete reduction of selenate and too rigorous a reduction could lead to plating out of elemental selenium (Cutter 1987, 1983; Presser and Barnes 1984, 1985).

Method 3114 B has the advantage that it is a fully validated method, is commonly used by many laboratories, is relatively inexpensive, is less susceptible to background interference (Cutter 1987, 1983; Presser and Barnes 1984, 1985), and has sufficient sensitivity to accurately measure what can be expected in many lotic aquatic systems. However, this method may not be sufficiently sensitive for some lentic aquatic systems where relatively lower selenium concentrations may need to be measured. If no selenium is detected in a lentic system using this method, EPA recommends using a more sensitive analytical method.

2.2 EPA Method 200.8

EPA method 200.8 has a MDL of 7.9 µg/L using the ICP-MS analytical technique. This method has the advantage that no pre-treatment steps are necessary. However, this method may not be sufficiently sensitive in many applications of the selenium criterion (Lamothe et al. 1999). If no selenium is detected using this method, EPA recommends monitoring with a more sensitive method.

2.3 EPA Method 200.9

Method 200.9 has a MDL of 0.6 µg/L using the STGF-AA analytical technique. This method has the advantage that it can detect selenium at very low concentrations. However, graphite furnace techniques require careful matrix matching.

Of these three EPA approved methods, Method 3114B using the HG-AAS technique is the most cost-effective, with sufficient sensitivity and relatively low risk of interference in most cases. EPA Method 200.8 may be used where appropriate, such as when selenium concentrations in effluent are known to be higher than 7.9 µg/L. EPA Method 200.9 may be used if a very low MDL is needed. Some additional methods not approved by EPA that states and tribes might consider are:

- Collision/Reaction Cell Inductively Coupled Plasma Mass Spectroscopy (cICP-MS) (Garbarino et al. 2005) - A relatively new technique that is a sensitive and selective detector for metal analysis. However, isobaric interference can cause problems for quantitative determination as well as identification based on the analyte pattern. Collision cells, reaction cells or other interfaces reducing sample matrix effects that might otherwise interfere in the mass selective determinative step are allowed in CWA analyses provided the method performance specifications relevant to ICP-MS measurements are met

NMED Exhibit 59

- Fluorometric Analysis - a wet chemistry technique using diaminonapthalene. This method also achieves acceptable precision and accuracy on standard reference samples (Olson 1969; Olson et al. 1975; American Public Health Association Standard Method 3500, on-line version).

Methods for measuring different species of selenium dissolved in water are also available. These methods determine the species of dissolved selenium present in a sample through differential digestion and hydride generation atomic adsorption spectrophotometry (Cutter 1978, 1983; Presser and Barnes, 1984; 1985; May et al. 2007). Selenite can be measured in samples with no pre-treatment. Selenate plus selenite can be measured in samples subjected to boiling with hydrochloric acid. Subtraction of the measured selenite fraction from the measured combined fraction would yield a measure of the selenate fraction. If a sample is analyzed to measure total dissolved selenium as described above, then measurements of the combined fraction can be subtracted to yield measurements of the dissolved organo-selenium fraction.

3.0 ANALYTICAL METHODS AVAILABLE FOR MEASURING SELENIUM IN FISH TISSUE

EPA does not have approved methods under 40 CFR § 136 for measuring selenium in fish tissue. However, states and tribes are not required to use EPA-approved methods for monitoring and assessment of criteria attainment or other activities not related to permit applications or reports.

The techniques described above for analyzing selenium in water (HG-AAS, ICP-MS, and STGF-AA) can be used to measure selenium in fish tissue if the samples are made soluble. Tissue samples are homogenized and digested prior to analysis using strong acid or dry-ashing digestion as described below. A review of sample digestion techniques has been published (Ihnat 1992). Standard reference materials, analytical duplicates, and matrix spike samples are recommended to determine the applicability of a selected digestion procedure.

3.1 Strong acid digestion

Solid samples can be subjected to strong acid digestion to break down mineral and organic matrices. Samples are typically dried and homogenized before digestion. Determination of percent moisture may be part of the drying procedure. Note that some strong acid digestion methods may not be suitable for fish tissue. Strong acid digestion methods are categorized by the type of material or amount of organic material present (e.g., solid waste; biological tissue, plants, soil, sediment, rock, coal) and degrees of tissue solubilization needed (extraction, leachate, or complete destruction). Methods differ in acid mixture and degree and type of heating (EPA Method 3050B, Revision 2, 1996; EPA Method 200.2,

NMED Exhibit 59

Revision 2.8, 1994; Briggs and Crock, 1986; Taggart, 2002, chapters I, J, and K). High boiling acids (perchloric and sulfuric) may lead to a loss of selenium if solutions are heated to dryness.

3.2 Dry-ashing digestion

Dry-ashing digestion is applicable to biological samples (Brumbaugh and Walther, 1989; May et al., 2007). Biological samples are normally lyophilized (freeze-dried) and homogenized before digestion. Determination of percent moisture may be part of the drying procedure. Dried solid samples are:

1. Boiled in nitric acid for solubilization and oxidation
2. Ashed at 500º C with magnesium nitrate to complete oxidation and decompose remaining organic material
3. Heated with hydrochloric acid to dissolve the ash and reduce selenium to the selenite (+4) state required for detection by HG-AAS.

3.3 Analytical methods available for measuring selenium in particulate material

There are no 40 CFR § 136 methods for analyzing selenium in particulate material. However, states and tribes are not required to use EPA-approved methods for monitoring and assessment of criteria attainment or other activities not related to permit applications or reports.

The techniques described above for analyzing selenium in water (HG-AAS, ICP-MS, and STGF-AA) can be used to measure selenium in particulate material after the sample has been separated from the water and pre-treated using the same methods used for fish tissue. In order to obtain a particulate material sample, a water column sample should be filtered to separate the particulate material and bed sediment. Various techniques for collection of suspended particulate material using filtration are available from the EPA (e.g. Method 1669) and the U.S. Geological Survey (Moulton et al. 2002; USGS, Britton and Greeson 1987). These techniques include:

- EPA Method 1669 (1996) includes filtration through a 0.45 µm capsule filter at the field site.
- USGS protocols for collection of phytoplankton and seston in rivers and streams as part of their National Water Quality Assessment Program for watershed and habitat assessment (http://water.usgs.gov/nawqa/protocols.html).
- Textbooks such as *Limnological Analyses* address sampling of lakes using traditional techniques including phytoplankton nets. (Wetzel and Likens 1991).
- Sampling of suspended material from estuaries where particulates are a substantial part of the ecosystem is described in Doblin et al. (2005) as part of their work on the San Francisco Bay-Delta Estuary.
- Separating suspended sediment using high-speed centrifugation and decantation when the concentration of particulate material is relatively low (Horowitz et al. 1989).

APPENDIX N: COMPARISON OF APPROACHES FOR CALCULATING SELENIUM TISSUE CONVERSION FACTORS

NMED Exhibit 59

1.0 COMPARISON OF THE MEDIAN RATIO AND REGRESSION APPROACHES

Regression analysis and the application of median ratios are two approaches that can be used to quantify the relationship between two variables, such as the concentration of selenium within two tissue types. When concentrations in the two tissues are plotted, each point represents the ratio of one tissue type to another. A regression analysis calculates the line that best fits those tissue concentrations, which is characterized by both a slope and a y-intercept. In contrast, the median ratio is a single value representing the 50^{th} centile of all ratios. Conversion factors (CFs) are presently calculated as the median ratio of two tissue types. The use of median ratios grew out of the goal of patterning the translation procedure after the Luoma and Presser selenium bioaccumulation model, where field derived factors representing the transfer of selenium from one ecosystem compartment to another were represented as single values calculated using constrained (y-intercept passes through the origin) regression. Median ratios were implemented to produce a single value that was operationally similar to a constrained regression slope, but that was free from the issues associated with constrained regression, particularly cases where the y-intercept was notably different from zero, which would result in slopes that were highly divergent from slopes derived using conventional regression. Both median ratios and conventional regression (with or without log transformation) are far superior to constrained (no y-intercept) regression. The following discussion will compare median ratios and conventional linear regression.

A median is a measure of central tendency that is free from all parametric assumptions associated with linear regression. As the 50^{th} centile of all y/x ratios, it is independent of the effects of outliers or the overall distribution of ratios. As implemented in the criterion document, median ratios were assumed to be representative of the linear relationship between the concentration in tissue y to the concentration in tissue x. This assumption was tested with a pre-screening procedure using conventional linear regression. If the regression model had a positive slope and was statistically significant at $P<0.05$, then the relationship was assumed to be positive and linear, and a median ratio was used as representative of that linear relationship.

A log-log regression includes both a slope and a y-intercept. Because they apply to log space, these parameters mean something different than similar parameters in arithmetic space. Linear relationships in log space translate back to power functions in arithmetic space. That is, the log space straight line function:

NMED Exhibit 59

$$\log(EO) = m \cdot \log(WB) + b \qquad (1)$$

translates to:

$$EO = a \cdot WB^{m} \qquad (2)$$

where the coefficient $a=10^{b}$. The log-log plot intercept b represents the value of log EO when WB=1 mg/kg (that is when log(WB)=0).

The key point when comparing log-log regression to the median ratio approach is that when log-log slope m=1, then Equation 2 reduces to a simple direct proportion EO = a·WB in arithmetic space**.** Figure N-1 illustrates the behavior of CF (that is, the ratio EO/WB), depending on whether the log-log slope m of the plot of log(EO) versus log(WB) has a value 1, >1, or <1.

NMED Exhibit 59

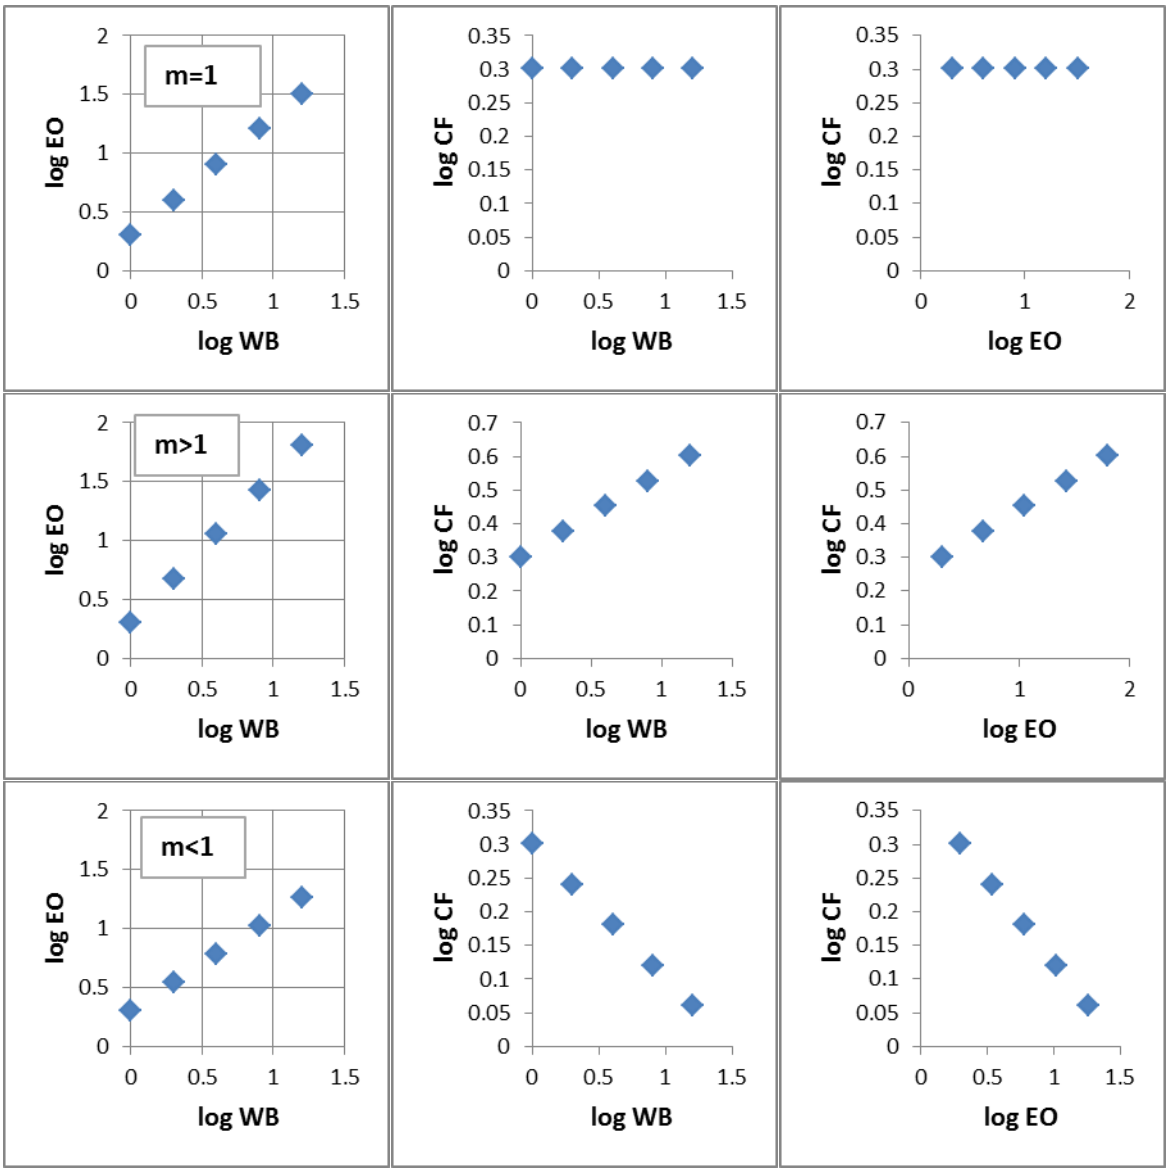

Figure N-1. Idealized illustration (sans scatter) of the effect of log-log slope, m, on whether CF is stable, increases, or decreases with concentration (whether measured as WB in column 2 or EO in column 3).

Top row: m=1. Second row: m=1.25. Bottom row: m=0.8. In all cases, CF=EO/WB, but the three rows were not designed to yield the same median CF. Were the five idealized data points replaced by a large number of well-behaved real-world data points, the straight lines would tend to be replaced by oval clouds of points having the illustrated slopes.

When the log-log slope m≈1, CF does not change with concentration. In that case, CF is the simple proportionality constant as assumed in all previous versions of the criterion document. When m is noticeably different from 1, CF changes with concentration, and we would solve for its value at the EO criterion concentration. If the EO criterion concentration is not near the median EO value in the graphed data, then the regression-calculated CF value may differ somewhat from the median CF.

While both a median ratio and a linear regression account for all of the plotted values within a particular relationship, the regression model is derived from the specific locations of every data point, whereas the median is derived independent of the specific distribution of the data points. In this way, a regression contains more information about the entire data distribution, and as such, is more affected by deviations from linearity. This second point can be an advantage or a disadvantage, depending on the data distribution. For some CF relationships in the database, there is evidence of slight non-proportionality, in which the y/x ratios at higher concentrations are different than the y/x ratios at lower concentrations. In these instances, a log transformation of the tissue concentrations will serve to better linearize the overall relationship, so that the resulting regression model will better capture the y/x relationship across the full concentration range. The median ratio of these models will be the same regardless of whether or not the data are transformed. However, because the use of median ratios is based on the assumption of proportionality, CFs calculated using regression of log transformed values will provide slightly more accurate representations of the relationship across the full concentration range than a median ratio, for those datasets that show some evidence of non-proportionality. An exception would be a case where the midpoint of the data distribution, where the median ratio is more likely to be located, is similar to the criterion concentration. In these instances the median ratio would be expected to be similar the regression based CF regardless of slope. Finally, for those datasets that do not show this effect, selection of either the median ratio or the regression based CF approach are both equally valid approaches.

Another source of uncertainty can occur for species with a CF derived from a narrow concentration range that does not encompass the criterion concentration. In these instances, the slope of the regression model may not be representative of the slope had there been concentrations bracketing the criterion. Similarly, the median of the concentration ratios within this small range may not be representative of the median ratio if there had been concentrations bracketing the criterion. However, it may be preferable, or "safer", to use a non-parametric median rather than the result of an extrapolated regression equation, particularly when the regression is based on few data points (no matter how good r^2 is).

To conclude, CFs calculated from median ratios have the advantages of simplicity, being easier to explain and implement, and they are "safer" in the sense that they are not affected by outliers or the distribution of variance across the data range. CFs calculated from log regression include more

NMED Exhibit 59

information about the entire data distribution, but can be sensitive to outliers. CFs calculated from the two approaches can diverge in cases where the data range does not encompass the criterion concentration, particularly in cases those where the log transformed slope is also much greater or less than one. Overall, the median ratio and log regression approaches generate similar CFs for this dataset, and have little effect on the translated water criterion elements.

In general, as indicated by the idealized data in Exhibit A, the median and the TLS regression-predicted CF will be similar under either of the following conditions: (a) log-log EO/WB slope near 1.0, or (b) criterion near the middle of the observed data range of tissue concentrations for the species. They are likely to differ from each other when both of the following conditions simultaneously occur: (c) log-log slope distant from 1.0, and (d) criterion distant from the center of the data range.

2.0 COMPARISON OF THE ORDINARY LEAST SQUARES AND TOTAL LEAST SQUARES REGRESSION APPROACHES

The calculation of conversion factors using linear regression following log transformation addresses the issues associated with non-proportional relationships between Se in different tissues, and is the approach recommended by several public commenters. Conventional ordinary least squares (OLS) regression results can vary depending on which tissue type is assigned to the x and y axis, respectively. This is because OLS regression assumes that the variable on the y axis is dependent on the variable on the x axis, and the resulting regression is the line that minimizes the sum of the squared distances between observed y-values and predicted y-values. OLS regression assumes that the values on the x-axis have no uncertainty. For datasets such as the paired tissue concentrations used to calculate CF, there is no dependency between the selenium concentrations in one tissue type to another tissue type, and concentrations in both tissue types are equally uncertain. Because of this, we could assign either tissue type to either axis, and the resulting CF would be slightly different. By convention, we assign egg-ovary to the y-axis when comparing it to whole-body or muscle, and we assign muscle to the y-axis when comparing it to whole-body, because these are the ratios used in the translation equations. While CFs using median ratios are not affected by axis assignment, CFs using OLS are, for reasons described above.

An alternative regression approach that corrects this issue is total least squares (TLS) regression. TLS regression is preferable to OLS regression in cases where there is error associated with each of the variables, and there is no dependency of one variable on the other. With TLS, the regression is the line that minimizes the sum of the squared distances between observed predicted x- and y-values, and produced the same result regardless of which variable is assigned to which axis. Curves drawn by eye tend to mimic TLS, not OLS. Without thinking about it, the person drawing the line naturally attempts to

NMED Exhibit 59

minimize both vertical and horizontal errors. However, a significant disadvantage of TLS regression is that Excel has no built-in function to perform it, and many readers will be unfamiliar with it.

Table N-1 shows the effect of the different calculation procedures (median ratio, log OLS regression - xyOLS, log OLS regression with reversed axes - yxOLS, and log TLS regression) on all directly measured CFs. Median ratio CFs tend to diverge from regression based CFs for datasets where log-log slopes are markedly different than 1 and the criterion is not near the center of the observed concentrations. CFs calculated from TLS regression nearly always fall between CFs calculated from OLS regression with and without the axes reversed, and are not affected by axis order.

NMED Exhibit 59

	Directly calculated conversion factors for each tissue ratio, by method											
	EO/WB				M/WB				EO/M

Table N-1. Comparison of all directly calculated conversion factors by method.
Methods include median ratio (Ratio), log ordinary least squares (xyOLS), log ordinary least squares with axes reversed (yxOLS), and log total least squares (logTLS). Regression based CFs were calculated at the egg ovary criterion concentration of 15.1 mg/kg. Muscle to whole body (M/WB) CFs were calculated at the muscle concentration at the egg-ovary criterion.

The following examples illustrate the differences between OLS and TLS regressions, and the effect of axis assignment on CF.

2.1 Example 1 – Flannelmouth Sucker (Egg-ovary/Whole-body)

CF by approach: (1.41 –median ratio, 1.13 – log OLS, 1.86 – log OLS with reversed axes, 1.48 – log TLS)

Model comparison 1a - Regression model results and calculation of CF (Egg-ovary y-axis; Whole-body x-axis):

OLS: log (Egg-ovary) = (0.7966 x (log Whole-body)) + 0.2857

log (Whole-Body) = (log (16 mg/kg) – 0.2857)/0.7966 = 1.153

CF at egg-ovary criterion = 10^((log Egg-ovary) – (log Whole-body)) = 1.13

TLS: log (Egg-ovary) = (0.9877 x (log Whole-body)) + 0.1843

log (Whole-Body) = (log (16 mg/kg) – 0.1843)/0.9877 = 1.033

CF at egg-ovary criterion = 10^((log Egg-ovary) – (log Whole-body)) = 1.48

In Figure N-2, the fitted regression lines do not appear particularly divergent; however, these points cover a relatively narrow (and low), concentration range. At the criterion concentration (log E/O = 1.204), the predictions lines are more divergent, resulting in the differences between the CFs. Also, note that the TLS slope is close to 1. The resulting TLS-derived CF is similar to the median ratio CF (1.48 vs 1.41). In contrast, the OLS slope is lower than 1, resulting in a CF for the OLS model that is notably different than the median ratio CF (1.13 vs 1.41).

NMED Exhibit 59

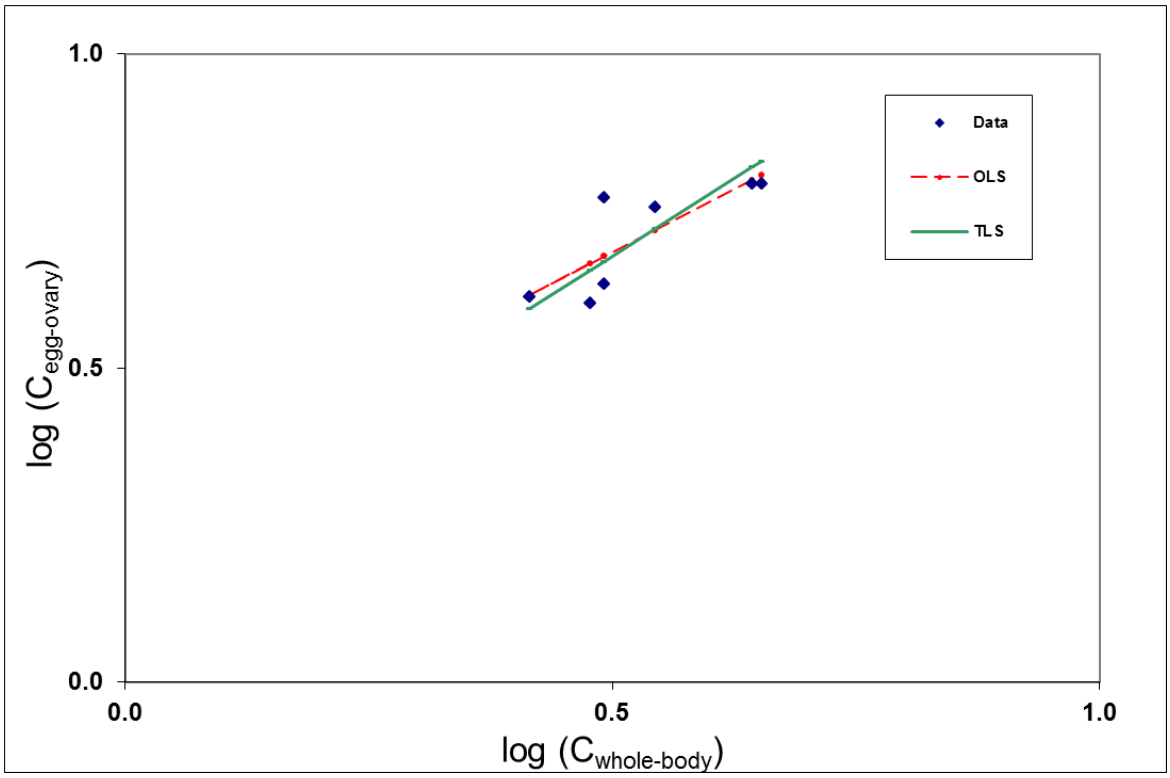

Figure N-2. OLS vs. TLS regression model fits for flannelmouth sucker.
Egg-ovary concentrations are on the y-axis and whole-body concentrations are on the x-axis.

Model comparison 1b - Regression model results and calculation of CF (Egg-ovary x-axis; Whole-body y-axis):

OLS: log(Whole-body) = (0.8126 x (log Egg-ovary)) - 0.0450 = 0.9335

CF at egg-ovary criterion = 10^((log Egg-ovary) – (log Whole-body)) = 1.86

TLS: log(Whole-body) = (1.012 x (log Egg-ovary)) - 0.1866 =1.033

CF at egg-ovary criterion = 10^((log Egg-ovary) – (log Whole-body)) = 1.48

At first glance, Figure N-3 appears very similar to Figure N-2. However, note that the axes are reversed, and because we are now solving for y (whole body concentration at egg-ovary criterion concentration), the shallower slope of the reverse OLS figure results a whole body concentration at the egg-ovary criterion lower than in the upper figures, which in turn results in a larger CF. Also, note that the TLS model is a mirror image of the model in Figure N-3, and as such has the same calculated CF. As above, the TLS slope is close to 1, with a TLS-derived CF that is similar to the median ratio CF (1.48 vs 1.41). In contrast, the OLS slope is lower than 1, resulting in an OLS-derived CF that is notably different than the median ratio CF (1.86 vs 1.41).

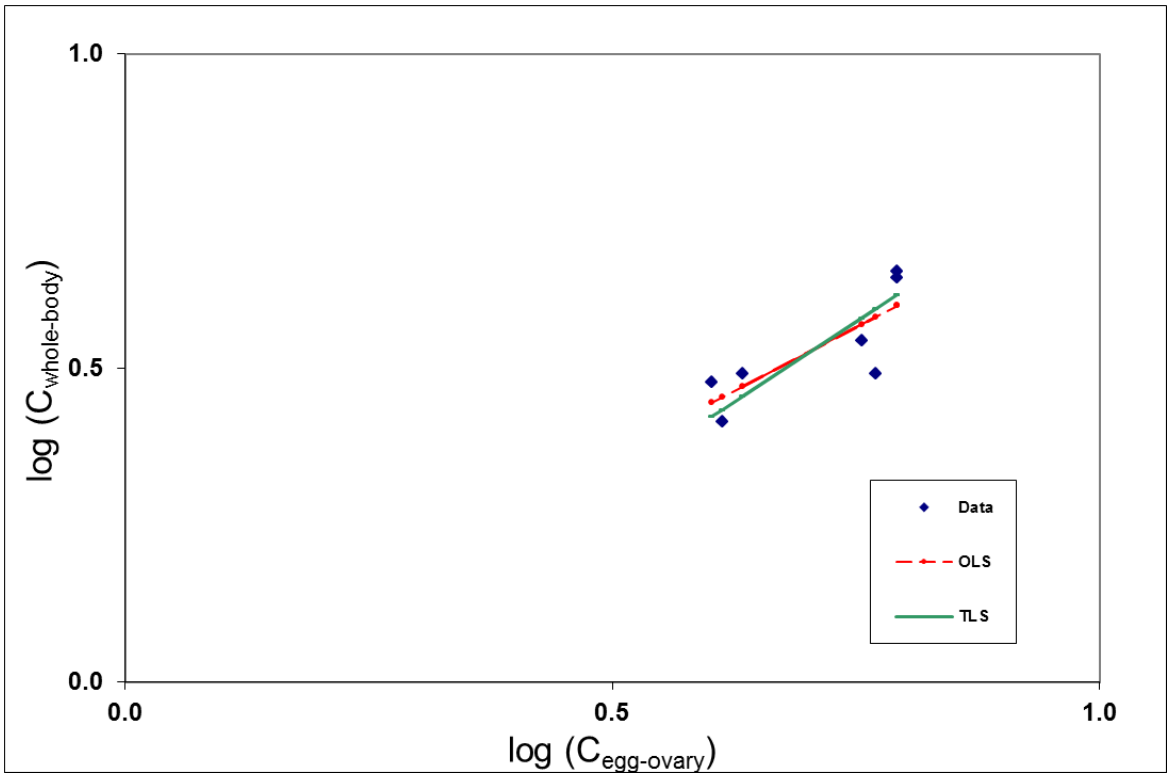

Figure N-3. OLS vs. TLS regression model fits for flannelmouth sucker.
Egg-ovary concentrations are on the x-axis and whole-body concentrations are on the y-axis.

2.2 Example 2 – Bluegill (Egg-ovary/Whole-body)

CF by approach: (2.13 –median ratio, 1.90 – log OLS, 2.07 – log OLS with reversed axes, 2.01 – log TLS)

Model comparison 2a - Regression model results and calculation of CF (Egg-ovary y-axis; Whole-body x-axis):

OLS: log(Egg-ovary) = (1.061 x (log Whole-body)) + 0.2227

log (Whole-Body) = (log (16 mg/kg) – 0.2227)/1.061 = 0.9250

CF at egg-ovary criterion = 10^((log Egg-ovary) – (log Whole-body)) = 1.90

TLS: log(Egg-ovary) = (1.240 x (log Whole-body)) + 0.0.0861

log (Whole-Body) = (log (16 mg/kg) – 0.0861)/1.240 = 0.9018

CF at egg-ovary criterion = 10^((log Egg-ovary) – (log Whole-body)) = 2.01

Compared to the OLS regression line, the slope of the TLS regression line is slightly steeper, resulting in a slightly larger calculated CF (Figure N-4). Even though the slopes are larger than 1, the data range encompasses the criterion concentration, which is close to the middle of the data distribution. As a result, the regression based CFs are similar overall to the median ratio CF.

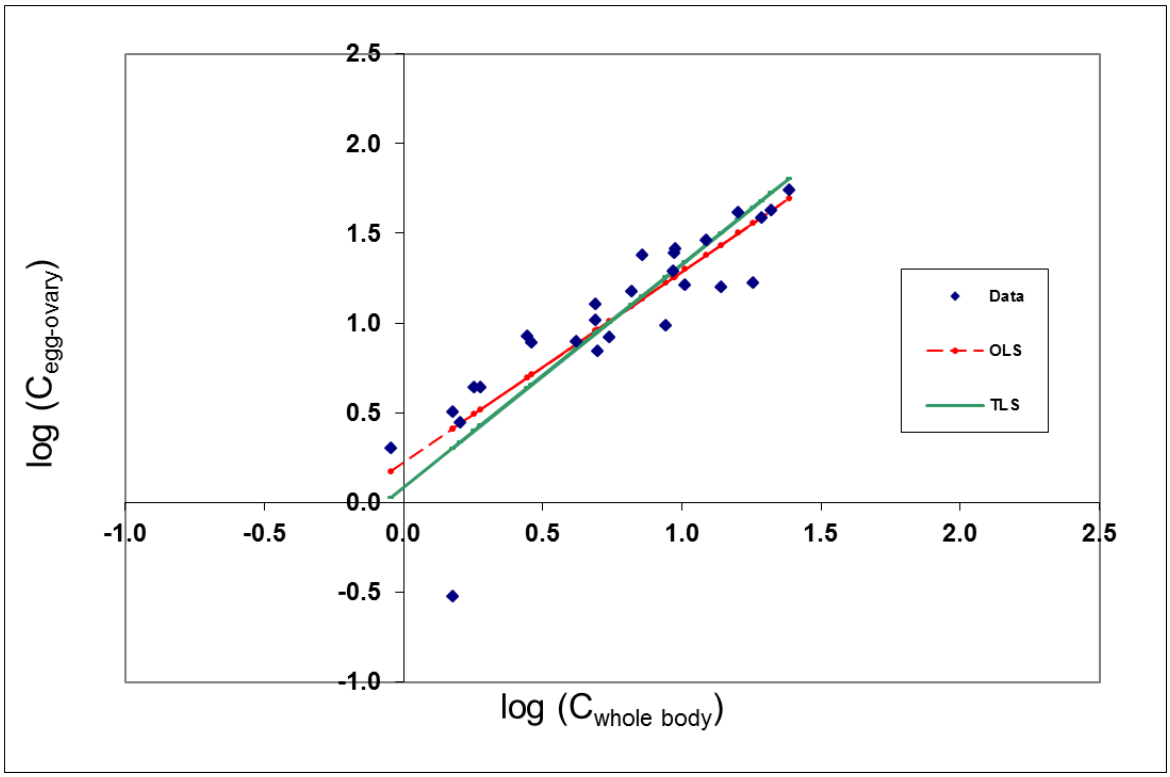

Figure N-4. OLS vs. TLS regression model fits for bluegill. Egg-ovary concentrations are on the y-axis and whole-body concentrations are on the x-axis.

NMED Exhibit 59

Model comparison 2b - Regression model results and calculation of CF (Egg-ovary x-axis; Whole-body y-axis):

OLS: log(Whole-body) = (0.7269 x (log Egg-ovary)) + 0.0129 = 0.8883

CF at egg-ovary criterion = 10^((log Egg-ovary) – (log Whole-body)) = 2.07

TLS: log(Whole-body) = (0.8066 x (log Egg-ovary)) - 0.0695 =0.9018

CF at egg-ovary criterion = 10^((log Egg-ovary) – (log Whole-body)) = 2.01

Compared to the OLS regression line, the slope of the TLS regression line is slightly steeper, resulting in a slightly smaller calculated CF (Figure N-5). Even though the slopes are less than 1, the data range encompasses the criterion concentration, which is also close to the middle of the data distribution. As a result, the regression based CFs are similar overall to the median ratio CF.

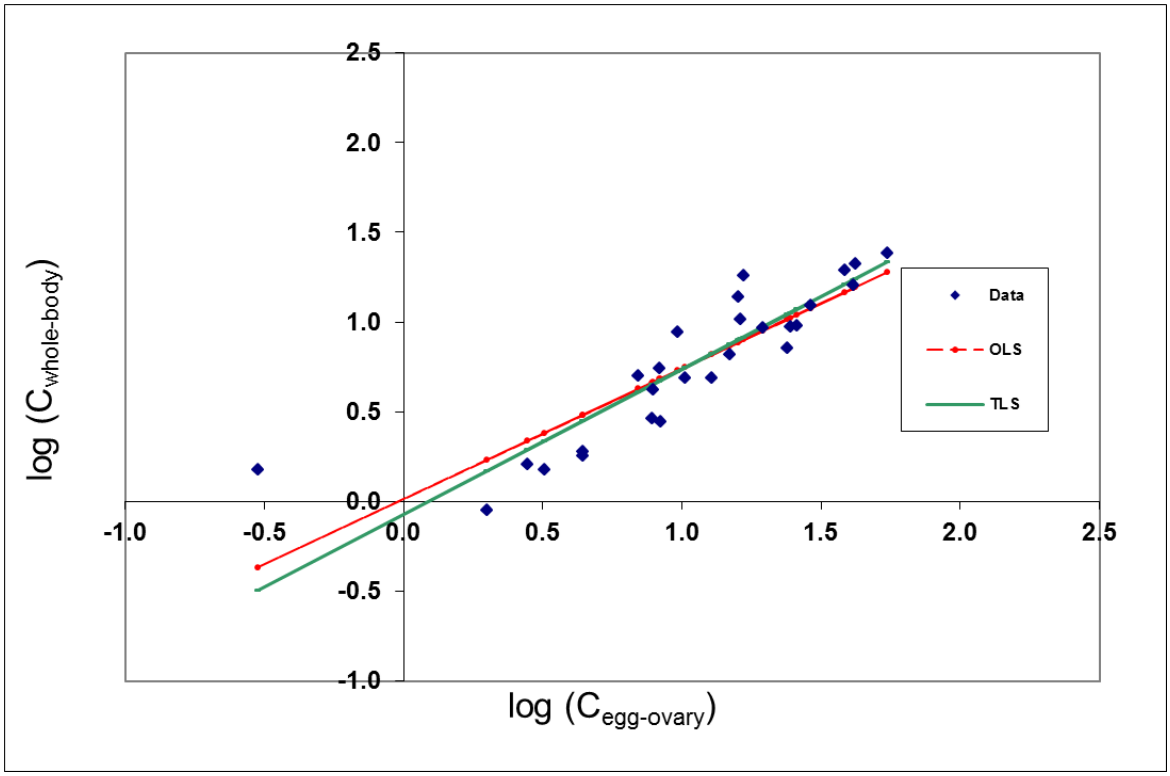

Figure N-5. OLS vs. TLS regression model fits for bluegill.
Egg-ovary concentrations are on the x-axis and whole-body concentrations are on the y-axis.

The effect of the CFs calculated by the different approaches has a minor effect on the final translated water criterion elements. Compared to the median ratio method, translated water criterion element concentrations are slightly higher using CFs calculated from the log OLS regression methods, CFs calculated from the reverse axis log OLS are slightly lower. Lentic translated water criterion element

NMED Exhibit 59

concentrations are the same using CFs from median ratios and log TLS regression methods, while lotic concentrations calculated from log TLS CFs are slightly lower compared to those calculated using median ratio CFs (**Table N-2**).

Table N-2. Translated water concentration criterion element criterion concentrations by CF calculation method.

Method	Lentic (µg/L)	Lotic (µg/L)
Median Ratio	1.5	3.1
log OLS regression	1.6	3.3
inverse log OLS regression	1.4	2.9
log TLS regression	1.5	2.9

3.0 COMPARISON OF MEDIAN- AND REGRESSION-BASED CONVERSION FACTORS TO CALCULATE CHRONIC VALUES FOR MUSCLE AND WHOLE BODY TISSUES

Besides being used in the translation of the egg-ovary (EO) tissue criterion to water, conversion factors (CF) were also used to convert egg-ovary (EO) chronic values (CV) to muscle or whole body tissue concentrations. These conversions were done when the data from a reproductive toxicity study did not have muscle or whole body selenium concentrations or if the latter tissue data was not usable to determine a chronic value. Directly calculated CVs using either muscle or whole body selenium measurements from a study was preferred over converted CVs in the determination of the final chronic value (= criterion).

Table N-3 provides a comparison of median-based and regression-based CFs when they are used to convert an EO selenium concentration to muscle or whole body. Regression-based CFs used total least squares (TLS) regression for the reasons stated above. The table lists each taxon in the reproductive toxicity data set and presents CVs that are either directly calculated or converted from the EO CV using either the median or TLS CF. Generally, the median-based and TLS-based CFs were similar for both tissue types and this similarity resulted in similar criteria (bottom row). The muscle criterion for the data set that contained directly calculated CVs and converted CVs was similar whether median or TLS CFs were used, 11.3 and 10.6, respectively. The whole body criterion was also similar using these two approaches, 8.5 and 9.6, respectively. The median-based CFs were selected based on reasons stated in the previous section.

NMED Exhibit 59

Table N-3. Comparison of muscle and whole body chronic values when calculated directly and converted from egg-ovary concentrations using median- and TLS regression-based conversion factors.

Taxon	EO CV	Muscle chronic values (CV) and conversion factors (CF)						Whole body chronic values (CV) and conversion factors (CF)					
		Direct + Median	Direct + TLS	Median CF	Median CV	TLS CF	TLS CV	Direct + Median	Direct + TLS	Median CF	Median CV	TLS CF	TLS CV

NMED Exhibit 60

Technical Support for Adopting and Implementing the EPA's 2016 Selenium Criterion in Water Quality Standards

While this document cites statutes and regulations that contain requirements applicable to water quality standards, it does not impose legally binding requirements on the EPA, states, authorized Tribes, other regulatory authorities, or the regulated community, and may not apply to a particular situation based upon the circumstances. The EPA, state, Tribal and other decision makers retain the discretion to adopt approaches on a case-by-case basis that differ from those provided in this technical support document as appropriate and consistent with statutory and regulatory requirements. The EPA may update this document as new information becomes available. In addition to this document, the EPA has related documents that provide considerations and recommendations on implementing criteria based on the national Clean Water Act (CWA) section 304(a) recommended selenium criterion for freshwater, which are available at the EPA's selenium website: https://www.epa.gov/wqc/aquatic-life-criterion-selenium.

USEPA	U.S. Environmental Protection Agency
WQBELs	Water quality-based effluent limits
WQC	Water quality criteria
WQS	Water quality standards

NMED Exhibit 60

Definitions[1]

Bioaccumulation
The uptake and retention of a chemical by an aquatic organism from all surrounding media (e.g., water, food, sediment).[2]

Critical species
In the context of the recalculation procedure, a resident species that (a) is commercially or recreationally important at the site, or (b) is listed as threatened or endangered under section 4 of the Endangered Species Act, or (c) is a species for which there is firm evidence that its loss would yield an unacceptable impact on the site's commercially or recreationally important species, endangered species, abundances of a variety of other species, or structure or function.[3]

Dissolved total selenium
All species of selenium that are dissolved into the water column and that would be measured in a water sample after it has been passed through a 0.45 µm membrane filter.[4]

Performance-based approach
A water quality standard that is a transparent process, rather than a specific outcome (such as the concentration portion of a criterion for a pollutant). This process or methodology is sufficiently detailed and has suitable safeguards that ensure predictable, repeatable outcomes. Approval of this process or methodology by the EPA would also serve for CWA purposes as the approval under CWA section 303(c)[5] of each outcome generated from following that process or method.[6]

Site-specific criterion/site-specific criterion element
Water quality criterion/criterion element that is modified to reflect site-specific conditions. For selenium, a criterion/criterion element that is developed to protect aquatic life at a particular

---

site, usually by taking into account a site's physical, chemical, and/or biological conditions (i.e., water quality characteristics or species composition).[7]

Steady-state

An organism is in steady-state when the rates of chemical uptake and depuration are equal and tissue concentrations remain constant over time.[8] For the purposes of the national CWA section 304(a) recommended selenium criterion, steady-state refers to conditions where sufficient time has passed after the introduction of a new or increased input of selenium into a waterbody or watershed of a waterbody such that fish tissue selenium concentrations are no longer increasing.

Water quality criterion element

A magnitude, frequency, and duration for a particular media type (e.g., fish tissue, water column), which are individual components of the overall water quality criterion. The water quality criterion elements for selenium are related through a hierarchy, with fish tissue criterion elements having primacy over water column criterion elements, and the egg-ovary fish tissue criterion element having primacy over all other criterion elements.

NMED Exhibit 60

1.0 Introduction

1.1 The EPA's National CWA Section 304(a) Recommended Chronic Aquatic Life Selenium Criterion in Freshwater

In 2016, the U.S. Environmental Protection Agency updated its national Clean Water Act (CWA) section 304(a) recommended chronic aquatic life criterion for selenium in freshwater systems to reflect the latest scientific information and, in 2021, issued an erratum, *2021 Revision to: Final Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016*.[9] The EPA's national CWA section 304(a) recommended selenium criterion still reflects the latest science and the EPA is not aware of any updated scientific information that would change this recommendation. The latest scientific information indicates that selenium toxicity to aquatic life is driven by dietary exposures and that the reproductive life-stages of egg-laying vertebrates are the most sensitive to the toxic effects of selenium. The recommended criterion has four criterion elements: (1) a fish egg-ovary criterion element; (2) a fish whole-body and/or muscle criterion element; (3) a water column criterion element (one value for lentic and one value for lotic aquatic systems); and (4) a water column intermittent criterion element (to account for potential chronic effects from short-term exposures to high concentrations in lentic and lotic aquatic systems) (see Table 1). Under the EPA's 2016 national CWA section 304(a) recommended selenium criterion, the fish tissue criterion elements have primacy over water column elements, except where there are no fish, where fish tissue data are not adequate, or for waterbodies with new or increased discharges where selenium concentrations in fish tissue might not have stabilized and reached steady-state. The EPA also recommends that the egg-ovary tissue criterion element has primacy over whole-body and muscle tissue criterion elements.

Toxicity data indicate that the selenium concentration in fish eggs and ovaries is the most robust and consistent measurement endpoint directly tied to adverse reproductive effects in aquatic organisms. Toxicity to developing embryos and larvae is directly linked to egg selenium concentration.[10] The EPA derived the whole-body, muscle tissue, and water column elements from the egg-ovary element so that states and authorized Tribes could more readily implement their water quality criteria (WQC) based on the EPA's national CWA section 304(a)

---

[9] In 2021, the EPA identified that the following text was missing from the second sentence in footnote 4 in the selenium criterion table: "When selenium inputs are increasing" and issued an erratum. The EPA corrected footnote 4 to state: "4. Water column values are based on dissolved total selenium in water and are derived from fish tissue values via bioaccumulation modeling. When selenium inputs are increasing, water column values are the applicable criterion element in the absence of steady-state condition fish tissue data." USEPA. 2021. *2021 Revision to: Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016.* EPA 822-R-21-006. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/system/files/documents/2021-08/selenium-freshwater2016-2021-revision.pdf.

[10] USEPA. 2021. *2021 Revision to: Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016.* EPA 822-R-21-006. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/system/files/documents/2021-08/selenium-freshwater2016-2021-revision.pdf.

recommended selenium criterion. The assessment of the available data on chronic selenium exposure for fish, invertebrates, and amphibians indicates that a criterion element derived from fish is expected to be protective of the aquatic community in a waterbody, since other taxa appear to be less sensitive to selenium than fish. The EPA did not develop an acute criterion for selenium when it updated the chronic criterion. Although selenium may cause acute toxicity at high concentrations, the most deleterious effects on aquatic organisms are due to selenium's bioaccumulative properties.

In the case of bioaccumulative compounds like selenium, acute toxicity studies do not address risks that result from chronic exposure to chemicals via the diet (through the food web pathway). Such studies also do not account for the accumulation kinetics of many bioaccumulative compounds, such as selenium, and may underestimate effects from long-term accumulation in some types of aquatic systems. Therefore, since acute studies do not address the primary exposure pathway for organisms to selenium and because chronic toxicity occurs at lower concentrations, an acute criterion was not included in the national CWA section 304(a) recommended selenium criterion. As described in the EPA's *2021 Revision to: Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016* (hereafter referred to as *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016*), the EPA also included an intermittent exposure criterion element to provide protection from the most significant chronic effects of selenium toxicity, reproductive toxicity, by protecting against selenium bioaccumulation in the aquatic ecosystem resulting from short-term, high concentration exposure events.[11]

The EPA recommends, as stated in the *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016*, that states and authorized Tribes[12] adopt into their water quality standards (WQS) a selenium criterion that includes all four criterion elements.[13] For more information see the EPA's *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016,* which can be found at https://www.epa.gov/system/files/documents/2021-08/selenium-freshwater2016-2021-revision.pdf.

[11] USEPA. 2021. *2021 Revision to: Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016.* EPA 822-R-21-006. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/system/files/documents/2021-08/selenium-freshwater2016-2021-revision.pdf.

[12] Throughout this document and in the CWA, the term "states" means the fifty states, the District of Columbia, the Commonwealth of Puerto Rico, the United States Virgin Islands, Guam, American Samoa, and the Commonwealth of the Northern Mariana Islands. The term "authorized Tribe" means those federally recognized Indian Tribes with authority to administer a CWA WQS program.

[13] USEPA. 2021. *2021 Revision to: Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016.* EPA 822-R-21-006. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/system/files/documents/2021-08/selenium-freshwater2016-2021-revision.pdf.

NMED Exhibit 60

Table 1. Summary of the Recommended Freshwater Selenium Ambient Chronic Water Quality Criterion for Protection of Aquatic Life.

Media Type	Fish Tissue[1]		Water Column[4]	
Criterion Element	**Egg-ovary[2]**	**Fish Whole-body or Muscle[3]**	**Monthly Average Exposure**	**Intermittent Exposure[5]**
Magnitude	15.1 mg/kg dry weight	8.5 mg/kg dry weight whole-body or 11.3 mg/kg dry weight muscle (skinless, boneless fillet)	1.5 µg/L in lentic aquatic systems 3.1 µg/L in lotic aquatic systems	$WQC_{int} = \frac{WQC_{30-day} - C_{bkgrnd}(1 - f_{int}}{f_{int}}$
Duration	Instantaneous measurement[6]	Instantaneous measurement[6]	30 days	Number of days/month with an elevated concentration
Frequency	Not to be exceeded	Not to be exceeded	Not more than once in three years on average	Not more than once in three years on average

1. Fish tissue elements are expressed as steady-state.
2. Egg-ovary supersedes any whole-body, muscle, or water column element when fish egg-ovary concentrations are measured, except as noted in footnote 4 below.
3. Fish whole-body or muscle tissue supersedes water column element when both fish tissue and water concentrations are measured, except as noted in footnote 4 below.
4. Water column values are based on dissolved total selenium in water and are derived from fish tissue values via bioaccumulation modeling. When selenium inputs are increasing, water column values are the applicable criterion element in the absence of steady-state condition fish tissue data.
5. Where $WQC_{30\text{-}day}$ is the water column monthly element for either lentic or lotic waters; C_{bkgrnd} is the average background selenium concentration; and f_{int} is the fraction of any 30-day period during which elevated selenium concentrations occur, with f_{int} assigned a value ≥0.033 (corresponding to 1 day).
6. Fish tissue data provide instantaneous point measurements that reflect integrative accumulation of selenium over time and space in fish population(s) at a given site.

1.2 Selenium Technical Support Materials

The EPA has prepared a four-volume set of documents to provide recommendations to states, authorized Tribes, and other agencies for implementing their WQC based on the national CWA section 304(a) recommended selenium criterion for aquatic life.[14] These four documents constitute the Technical Support Materials for the EPA's *Aquatic Life Ambient Water Quality*

[14] USEPA. 2021. *2021 Revision to: Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016.* EPA 822-R-21-006. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/system/files/documents/2021-08/selenium-freshwater2016-2021-revision.pdf.

NMED Exhibit 60

Criterion for Selenium–Freshwater 2016.[15] Each document of the set focuses on a specific aspect of implementation of WQC based on the national CWA section 304(a) recommended selenium criterion. Together, these four EPA documents provide information to assist states and authorized Tribes with adopting WQC based on the EPA's national CWA section 304(a) recommended selenium criterion and implementing them in various CWA programs.

1) *Technical Support for Adopting and Implementing the EPA's Selenium 2016 Criterion in Water Quality Standards*: Provides recommendations for the adoption and implementation of criteria based on the national CWA section 304(a) recommended selenium criterion, including the various flexibilities available to states and authorized Tribes using WQS tools.
2) *Technical Support for Fish Tissue Monitoring for Implementing the EPA's 2016 Selenium Criterion*: Provides an overview of how to establish or enhance existing fish tissue monitoring programs to facilitate implementation of fish tissue criterion elements based on the national CWA section 304(a) recommended selenium criterion.
3) *Frequently Asked Questions: Implementing Water Quality Standards Based on the EPA's 2016 Selenium Criterion in Clean Water Act Section 402 National Pollutant Discharge Elimination System Permits*: Provides information to help National Pollutant Discharge Elimination System (NPDES) permit writers understand what permitting guidance (i.e., state or tribal implementation procedures) may be appropriate to implement state and authorized tribal WQS based on the EPA's national CWA section 304(a) recommended selenium criterion. This set of FAQs also provides recommendations on how to establish water quality-based effluent limits (WQBELs) in NPDES permits.
4) *Frequently Asked Questions: Implementing the EPA's 2016 Selenium Criterion in Clean Water Act Sections 303(d) and 305(b) Assessment, Listing, and Total Maximum Daily Load Programs*: Provides information on how to complete assessments, list impaired waters, and develop total maximum daily loads (TMDLs) to implement EPA-approved[16] WQS that are based on the EPA's national CWA section 304(a) recommended selenium criterion.

[15] USEPA. 2021. *2021 Revision to: Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016.* EPA 822-R-21-006. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/system/files/documents/2021-08/selenium-freshwater2016-2021-revision.pdf.

[16] EPA-approved includes both WQS adopted by states, territories or authorized Tribes and approved by the EPA and WQS promulgated by the EPA.

NMED Exhibit 60

2.0 Adopting the EPA's National CWA section 304(a) Recommended Selenium Criterion

2.1 The Four-Part Criterion

As described in the EPA's *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016*,[17] the EPA recommends that states and authorized Tribes adopt into their WQS one selenium criterion composed of four criterion elements: two fish tissue criterion elements (i.e., egg-ovary and whole-body and/or muscle tissue) and two water column criterion elements (i.e., 30-day average and intermittent exposure). The EPA recommends that states and authorized Tribes clearly express all four criterion elements as part of a single criterion. Including all four recommended criterion elements of the selenium criterion in state or Tribal WQS ensures protection from excessive selenium when egg-ovary data are unavailable by allowing application of the criterion using other fish tissue or water column data. Along with the four criterion magnitude elements, the EPA also recommends adopting the corresponding durations and frequencies for each of the criterion elements.

States and authorized Tribes should clearly indicate in their WQS that fish tissue criterion elements supersede the water column criterion elements (except when selenium inputs are increasing and steady-state condition fish tissue data are not available), and that the egg-ovary criterion element supersedes all other criterion elements. Under the EPA's national CWA section 304(a) recommended selenium criterion, this hierarchy applies to all CWA implementation activities. The egg-ovary criterion element supersedes all other criterion elements because it was derived directly from toxicity data and served as the basis for deriving all the other criterion elements. This hierarchy should be described in a state or authorized Tribe's WQS, in footnotes accompanying the criterion. The EPA recommends using the footnotes provided with the national CWA section 304(a) recommended selenium criterion (Table 1) to clearly and accurately describe the hierarchical structure.

The fish tissue criterion elements of this criterion are expressed in dry weight concentrations. This is because many of the toxicity values used to derive the criterion were expressed as dry weights. Instructions for converting between dry weight and wet weight concentrations are provided in Appendix C of *Technical Support for Fish Tissue Monitoring for Implementing the EPA's 2016 Selenium Criterion*.[18]

The two monthly average water column values included in the national CWA section 304(a) recommended selenium criterion were derived for the protection of two different types of

NMED Exhibit 60

waterbodies, lentic and lotic waters. Lentic waters are waterbodies that consist of standing water, including waterbody types such as lakes and ponds. Lotic waters are waterbodies that consist of flowing waters, including waterbody types such as rivers and streams. The application of the appropriate water column value is based on best professional judgement of the state or authorized Tribe. Although states and authorized Tribes do not need to classify their waters based on these terms, they may find it useful to consider incorporating these criterion elements into any existing classifications for different types of waterbodies (e.g., lakes). One resource that may be helpful for states and authorized Tribes is a geospatial dataset the United States Geological Survey (USGS) developed on lotic and lentic waters, available at https://www.sciencebase.gov/catalog/item/5d420fbde4b01d82ce8da8e9.

The national CWA section 304(a) recommended selenium criterion is a chronic criterion. The EPA no longer recommends an acute criterion for short-term ambient exposures because aquatic organisms are exposed to selenium primarily through their diet. Since acute studies are conducted as water-only exposures, they do not address this primary exposure pathway for organisms and do not account for the slow accumulation kinetics of selenium. Additionally, chronic toxicity occurs at lower concentrations than acute toxicity, so protection from acute toxicity is provided by the chronic criterion. Given these properties of selenium, an acute criterion was not included in the national CWA section 304(a) recommended selenium criterion.

Selenium has the potential to bioaccumulate in aquatic food webs, where it can continue to pose a risk even after short-term elevations of the selenium concentration in the water column return to ambient levels. Therefore, the EPA's national CWA section 304(a) recommended selenium criterion includes an intermittent exposure water column criterion element to provide protection from long-term chronic effects that may be caused by short-term elevations above ambient background concentrations of selenium water column concentrations in aquatic systems.

If data for a particular criterion element are not available, WQC based on the national CWA section 304(a) recommended selenium criterion should be implemented with one of the other criterion elements, according to the hierarchy of the criterion. For example, if fish tissue data are not available, but water column data are, the criterion should be implemented using the water column criterion element. This situation may occur for fishless waters or when fish tissue data are not available because they were not collected or were not adequate. Fishless waters are defined as waters with insufficient instream habitat and/or flow to support a population of any fish species on a continuing basis, or waters that once supported populations of one or more fish species but no longer support fish (see the executive summary of the EPA's *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016*).[19]

[19] USEPA. 2021. *2021 Revision to: Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016.* EPA 822-R-21-006. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/system/files/documents/2021-08/selenium-freshwater2016-2021-revision.pdf.

As noted in the introduction of this document, the national CWA section 304(a) recommended selenium criterion is designed for the protection of aquatic life. As a result, when the national CWA section 304(a) recommended selenium criterion is adopted into state or Tribal WQS, it should be applied to all waterbodies with an aquatic life designated use and, by extension, all species within those waterbodies that are protected by that use. The assessment of the available data for fish, invertebrates, and amphibians indicates that fish are the most sensitive taxa to the impacts from selenium. As such, the criterion elements were derived from fish toxicity values to be protective of the entire aquatic community, not solely fish species. When all four criterion elements are applied together according to the hierarchy, they protect aquatic life from the chronic effects of exposure to selenium in waters that are both inhabited by fish and not inhabited by fish (i.e., fishless).

Table 1, reproduced from the USEPA 2021, provides an example of how the four-part criterion could be adopted into a state or authorized Tribe's WQS. The EPA recommends adopting this table, including the frequency and duration components, with all accompanying footnotes.

Footnote 1 in Table 1 indicates that the fish tissue concentrations of the criterion are expressed as steady-state. An organism is in steady-state when the rates of chemical uptake and depuration are equal and tissue concentrations remain generally constant over time.[20]

Footnotes 2 and 3 in Table 1 describe the structure of the criterion. They explain the primacy of the whole-body and/or muscle tissue criterion element over the water column criterion elements, and the egg-ovary criterion element over any other criterion element. This means when assessing a waterbody in steady-state conditions against WQC based on the national CWA section 304(a) recommended selenium criterion, egg-ovary data take precedence for assessment decisions followed by whole-body and/or muscle tissue data, and lastly by water column data (see *Frequently Asked Questions: Implementing the EPA's 2016 Selenium Criterion in Clean Water Act Sections 303(d) and 305(b) Assessment, Listing, and Total Maximum Daily Load Programs*).[21]

Footnote 4 in Table 1 states that the water column criterion elements of the national CWA section 304(a) recommended selenium criterion were derived from the egg-ovary criterion element via mechanistic bioaccumulation modeling.[22]

NMED Exhibit 60

Footnote 4 also indicates that when both steady-state fish tissue data are absent and selenium inputs to the waterbody (e.g., receiving stream) are increasing, the water column criterion element is the applicable criterion element. For the purposes of the EPA's national CWA section 304(a) recommended selenium criterion, steady-state refers to conditions where sufficient time has passed after the introduction of a new or increased input of selenium into a waterbody or watershed of a waterbody such that fish tissue selenium concentrations are no longer increasing.[23] New or increased inputs of selenium will likely result in higher selenium concentrations in the water column and food web; however, the increase in selenium concentrations in fish tissue is likely to occur at a slower rate than in the water column. When fish tissue data are not in steady-state and do not represent the total potential bioaccumulative effects of selenium in the aquatic ecosystem, the water column criterion element is more appropriate to protect the entire aquatic ecosystem. Fish tissue data should not be considered for CWA implementation of the criterion (e.g., NPDES permits program or CWA section 303(d) listing of impaired waters) until after selenium concentrations in fish tissue have stopped increasing due to new or increased selenium inputs to a waterbody or watershed of a waterbody. However, any fish tissue data, whether steady-state or not, that are higher than the fish tissue criterion elements indicate a potential impact on the aquatic community. Therefore, in the situation where the water column criterion element is met, but the fish tissue criterion element is exceeded, the EPA recommends developing a site-specific water column criterion element that more appropriately reflects a protective water column concentration for that site (see section 2.2 for more information on the development of site-specific water column criterion elements).

In the EPA's *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016*, "new inputs" are defined as new activities resulting in the release of selenium into a lentic or lotic aquatic system. These "new inputs" are both new and increased inputs of selenium and are referring to the release of a substantial amount of additional selenium from either anthropogenic point or nonpoint sources into a waterbody or watershed. New or increased selenium inputs do not refer to seasonal variability of selenium that occurs naturally within a system (e.g., spring run-off events or precipitation-driven pulses) or *de minimis* discharges. Examples of new or increased inputs include releases of additional selenium into the waterbody or watershed from the opening or expansion of petroleum refining facilities, the opening or expansion of mining operations where increased selenium is likely to be discharged, or other anthropogenic activities (such as irrigation of selenium-rich soils) that would substantially increase selenium loadings to a waterbody or watershed of a waterbody over time. Any available appropriate data, including data collected by the state or authorized Tribe, by permittees, and by other entities may be evaluated to determine if there are new or increasing selenium inputs.

[23] This definition of steady-state applies to the national CWA section 304(a) recommended selenium criterion. It does not apply to the discussion of steady-state modeling or conditions in the "Technical Support Document for Water Quality-based Toxics Control" (EPA/505/2-90-001, March 1991).

NMED Exhibit 60

A watershed is defined as "an area of land that drains water, sediment, and dissolved materials to a common receiving body or outlet" (i.e., waterbody).[24] For large waterbodies, a state or authorized Tribe may want to evaluate new or increased inputs of selenium within a portion of the watershed that is at or up to a hydrologic unit code level of eight digits in size or consider whether a different watershed size is warranted.

For implementation purposes, states and authorized Tribes may assume that the selenium concentration in fish tissue is in steady-state unless a substantial new or increased input of selenium has recently occurred in the waterbody's watershed. In general, the EPA estimates that once a new or increased input of selenium commences the concentration of selenium in fish tissue will reach steady-state after several months in lotic systems and longer time periods (e.g., two to three years) in lentic systems.[25] These time frames can be used as a general estimate of what is considered a recent input of selenium into a watershed. However, these values are general estimates and the time needed for fish tissue to achieve steady-state after a new or increased input of selenium to a waterbody has occurred is site-specific. Potential factors affecting steady-state conditions in an aquatic system can include: (1) the hydrodynamics of the aquatic system (e.g., particularly reservoirs with multiple riverine inputs and controlled releases of water into downstream waterbodies); (2) the location of the selenium input; and (3) the site-specific food web. Therefore, if states and authorized Tribes make the assumption that fish tissue is in steady-state, the EPA recommends documenting the rationale behind those assumptions to demonstrate that any resulting CWA decisions are protective and have a sound scientific rationale.

Alternatively, fish tissue data can be used to evaluate whether fish tissue concentrations are in steady-state. The EPA recommends monitoring fish tissue in the affected waterbody, starting when new or increased inputs of selenium begin (or before if possible) and continuing until fish tissue data demonstrate that selenium concentrations in fish tissue are no longer increasing. With sufficient and appropriate monitoring data, collected over several sequential sampling periods, the state or authorized Tribe can use appropriate statistical methods (one example is the Mann-Kendall statistical approach, but other statistical approaches may be used) to determine when the fish tissue concentrations are no longer increasing.[26]

When implementing state and Tribal criteria based on the national CWA section 304(a) recommended selenium criterion, if selenium inputs are decreasing in a waterbody, the

NMED Exhibit 60

hierarchy of the criterion should apply, and fish tissue criterion elements should take precedence for CWA implementation. Just as the concentration of selenium increases in fish tissue at a slower rate than it does in the water column, selenium concentration also decreases at a slower rate in fish tissue compared to the selenium concentration in the water column. Similarly, selenium can persist in an aquatic ecosystem, and it will take more time to decrease in sediment and biota than in the water column. When water column concentrations of selenium are decreasing, those concentrations may meet the water column criterion element before the fish tissue concentrations meet the fish tissue criterion elements. That is, there is a lag between decreasing water column concentrations of selenium and decreasing selenium concentrations in fish tissue. While the fish tissue selenium concentrations are elevated, effects on aquatic life are still possible. Therefore, the EPA recommends using the fish tissue criterion elements for the CWA implementation of WQC based on the national CWA section 304(a) recommended criterion when selenium inputs to a waterbody or the watershed of a waterbody are decreasing.

In footnote 4, the EPA intends for "dissolved total selenium," to have a defined meaning. Within that term, "total selenium" refers to the combination of all species of selenium that are dissolved into the water column and does not refer to the total recoverable form of selenium. Dissolved total selenium is the selenium that would be measured in a water sample after it has been passed through a 0.45 µm membrane filter.[27] In other words, the criterion is for dissolved selenium in total, not the individual species of selenium (e.g., selenite or selenate, individually).

Footnote 5 of Table 1 describes the equation and input parameters for the intermittent criterion element. The intermittent criterion element is a rearrangement of the 30-day average water column criterion element and was designed to help with permitting where discharges into waterbodies occur only intermittently, rather than continuously. CWA section 303(d) assessments of waterbodies should still be made using the 30-day average water column criterion element, but for waterbodies that have intermittent discharges, this criterion element can be used to determine proper limits for permits. NMED Exhibit 60

Questions: Implementing Water Quality Standards Based on the EPA's 2016 Selenium Criterion in Clean Water Act Section 402 National Pollutant Discharge Elimination System Permits.[30]

Footnote 6 of Table 1 explains the duration component of the fish tissue criterion elements. These criterion elements were developed to protect aquatic populations from negative impacts caused by selenium. Fish tissue data provide instantaneous point measurements that reflect integrative accumulation of selenium over time and space in the fish at a given site.[31] Thus, the recommended duration for the selenium criterion is an instantaneous measurement. States and authorized Tribes have flexibility in how they interpret a discrete fish sample to represent a given species' population at a site at a given time. Generally, fish tissue samples collected to calculate the central tendency of tissue concentrations for a species at a site are collected either in one sampling event, as a composite, or over a short time interval (less than a week) due to the logistical constraints and costs for obtaining samples. The EPA recommends defining a single sampling event as a week or less and does not recommend averaging fish concentrations across sampling events, but instead evaluating each sampling event separately for implementation purposes. The *Technical Support for Fish Tissue Monitoring for Implementing the EPA's 2016 Selenium Criterion* contains additional information on sampling fish populations.[32]

The frequency component of the fish tissue criterion elements of the national CWA section 304(a) recommended selenium criterion differs from the "once-in-three years on average" frequency of most other national CWA section 304(a) recommended aquatic life water column criteria. Selenium is a bioaccumulative pollutant; therefore, elevated levels of selenium in various ecological compartments (e.g., biota, surficial sediments) require a long period of time to decrease. As a result, the associated aquatic community requires a long time to recover following the reduction or removal of an elevated selenium exposure to a given system. The time frame to recover is variable and will depend on the biogeochemical processes of the system, including residence time and food web dynamics. Thus, the "once-in-three years on average" frequency component is not appropriate for selenium in fish tissue, as this could lead to sustained ecological impacts. Therefore, the recommended frequency for the fish tissue criterion elements of the national CWA section 304(a) recommended selenium criterion is "not

[30] USEPA. 2024. *Frequently Asked Questions: Implementing Water Quality Standards Based on the EPA's 2016 Selenium Criterion in Clean Water Act Section 402 National Pollutant Discharge Elimination Systems Permits.* EPA-820-R-24-002. NMED Exhibit 60

to be exceeded." For additional information regarding duration and frequency, see sections 2.7.6 and 2.7.7 of *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016*.[33]

In addition to the four-part criterion, states and authorized Tribes have the option of adopting a method to derive site-specific water column criterion elements, referred to by the EPA as a "performance-based approach." The EPA discusses a performance-based approach for a WQS in the preamble of the rule *EPA Review and Approval of State and Tribal Water Quality Standards*.[34] Here the EPA considers a performance-based approach to be a WQS that is a transparent process rather than a specific outcome. [35] The state or authorized Tribe can adopt a process, such as a criterion derivation methodology, rather than a specific outcome, such as a concentration of a pollutant. If a state or authorized Tribe adopts a process or methodology that is sufficiently detailed and has suitable safeguards that ensure predictable, repeatable outcomes, the EPA can approve that process as a WQS. Approval of this process or methodology would also serve for CWA purposes as the approval of each outcome generated from following that process or method. More information about this approach and what information should be included in the method can be found in section 2.2.1 of this document.

The EPA recommends the adoption of the entire national CWA section 304(a) recommended selenium criterion, including all of the criterion elements, footnotes, frequency, and duration. In addition, states and authorized Tribes have the option to develop, adopt, and submit for the EPA approval, site-specific criteria or criterion elements for individual sites (see sections 2.2 and 3.1 for information on options for developing and adopting site-specific criteria). While the EPA presents some methods for developing site-specific criteria in this document and in the national CWA section 304(a) recommended selenium criterion document, any method that is scientifically defensible and protective of the designated uses may be used to develop site-specific criteria. States and authorized Tribes also have the option of developing a methodology for deriving site-specific water column criterion elements for individual sites, which can be adopted as part of a WQS in addition to the four-part criterion and submitted to the EPA for review. If approved by the EPA, this process can be used to develop site-specific water column criterion elements for state and Tribal waters (see section 2.2.1 of this document).

2.2 Options for Site-specific Water Column Criterion Elements

The EPA recommends that when states and authorized Tribes adopt the national CWA section 304(a) recommended selenium criterion, they adopt all four criterion elements, including the 30-day average water column criterion element. States and authorized Tribes also have the

NMED Exhibit 60

additional option of adopting site-specific water column criterion elements, if desired (either through individual adoption or a performance-based approach). The relationship between the concentration of selenium in the tissues of fish and the concentration of selenium in the water column can differ substantially between different aquatic systems. The chemical form of selenium, species of fish, the species and proportion of prey, and a variety of site-specific biogeochemical factors affect selenium bioaccumulation and thus determine the allowable concentration of selenium in ambient water that is protective of aquatic life. Because of the site-specific nature of this relationship, the EPA provides two methodologies for deriving site-specific water column criterion elements:

1) The mechanistic modeling approach; and
2) The empirical bioaccumulation factor (BAF) approach.

The mechanistic modeling approach uses scientific knowledge of the physical and chemical processes underlying bioaccumulation to specifically model bioaccumulation and trophic transfer through the food web to establish a relationship between the concentrations of selenium in the water column and the concentration of selenium in the tissue of aquatic organisms. The EPA used this approach to derive the default water column criterion elements.[36] This approach generally requires the collection of particulate material and water samples and knowledge of the site's food web. The empirical bioaccumulation factor approach, on the other hand, establishes a site-specific relationship between water column selenium concentrations and fish tissue selenium concentrations by measuring both matrices directly and using the ratio between them to determine a site-specific water column criterion element. Both approaches are described in detail in Appendix K of *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016*.[37] Both methodologies provide acceptable approaches for translating the recommended fish tissue criterion elements into site-specific water column criterion elements. States and authorized Tribes may use either approach to develop a site-specific water column criterion element. The decision of which approach to use will likely be driven by which data is easiest to collect for a particular site.

In addition, a state or authorized Tribe can develop site-specific criteria using other methodologies if the methodologies are scientifically defensible and the criteria are based on a sound scientific rationale and protective of the applicable designated uses, pursuant to the CWA section 303(c) and the EPA's implementing regulations, including 40 Code of Federal Regulations (CFR) section 131.11. Where a state or authorized Tribe adopts the 304(a) recommended fish tissue criterion elements and the hierarchy of the criterion, and then adopts a site-specific water column criterion element, the hierarchy of the criterion still applies; fish tissue criterion elements take precedence over the site-specific water column criterion

[36] Presser, T.S. and S.N. Luoma. 2010. A methodology for ecosystem-scale modeling of selenium. *Integrated Environmental Assessment and Management* 6:685-710; Presser, T.S. and S.N. [37] Ibid.

NMED Exhibit 60

elements in the implementation of the criterion, unless selenium inputs are increasing in a waterbody.

One instance where a state or authorized Tribe may want to develop a site-specific water column criterion element for selenium is for fishless waters. Fishless waters are defined as waters with insufficient instream habitat and/or flow to support a population of any fish species on a continuing basis, or waters that once supported populations of one or more fish species but no longer support fish (see the executive summary of the EPA's *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016*).[38] Even though the national CWA section 304(a) recommended selenium criterion tissue elements are for fish tissue, the criterion is intended to protect an aquatic life designated use that would include other aquatic life, including invertebrates. In this instance, a site-specific water column criterion element for a fishless waterbody would need to be protective of the entire aquatic community present in that water and potentially downstream waters (40 CFR 131.10(b)). When deriving a site-specific water column criterion element for fishless waters, it may be appropriate to use the mechanistic model[39] to translate from either a fish tissue criterion element or an invertebrate toxicity threshold. Fish tissue criterion elements should be used to protect the whole aquatic community if fish populations were once supported in that waterbody or for protection of fish downstream, depending on the type of waterbody downstream and the fish present in that downstream waterbody. Invertebrate toxicity thresholds may be appropriate if fish currently and historically have not used the waterbody. Currently (April 2024), the EPA is not aware of sufficient toxicity data on invertebrates for an invertebrate toxicity threshold for selenium. However, as new toxicity data become available, this may be an appropriate taxa to use for deriving site-specific water column criterion elements for fishless waters. The appropriateness of that toxicity data will be evaluated on a case-by-case basis but should generally account for dietary exposure and evaluate survival, growth, and potentially reproductive effects. Potential downstream impacts should also be accounted for by evaluating trophic transfer factors and evaluating what impacts the selenium concentrations of the invertebrates may have on downstream fish species.

There is also one instance where the EPA specifically recommends developing a site-specific water column criterion element. This is when the ambient water column selenium concentrations in a waterbody/waterbody segment are meeting the national CWA section 304(a) recommended water column criterion elements, but the fish tissue concentrations are greater than the national recommended fish tissue criterion elements. In this situation, the elevated fish tissue concentrations may indicate an impact on the aquatic system and indicate

NMED Exhibit 60

that a water column criterion element lower than the national CWA section 304(a) recommended water column criterion element is needed to protect aquatic life.

There are two approaches to adopting and submitting site-specific selenium water column criterion elements to the EPA for review under section 303(c) of the CWA: 1) states and authorized Tribes may adopt and submit individual water column criterion elements each time they are derived; or 2) they may adopt and submit a performance-based approach for deriving site-specific water column criterion elements (see section 2.2.1). States and authorized Tribes should carefully consider the relative tradeoffs of each approach. The adoption and the EPA approval of individual site-specific water column criterion elements could potentially be simpler to apply in assessment, CWA section 303(d) listing and TMDL development, as well as in NPDES permit development since the implementation can immediately proceed with the established criterion element value rather than having the additional step of calculating the criterion element value using the criterion derivation methodology. On the other hand, the performance-based approach could provide states and authorized Tribes the flexibility to adaptively derive site-specific water column criterion elements to account for the most up-to-date data and information for the site without making it necessary for them to submit the site-specific water column criterion element to the EPA for review each time those criterion elements are derived. Under the performance-based approach, stakeholders would have the opportunity to provide comments on the derivation process (e.g., translation mechanisms and associated sampling plans, input parameters, and data analysis methods) during the WQS adoption process under CWA section 303(c) and the EPA's implementing regulations at 40 CFR Part 131. However, comments on the resulting site-specific water column criterion elements derived through the performance-based approach would be submitted as part of individual actions through each of the implementing programs, such as during a public notice for an NPDES permit. The performance-based approach could involve more coordination among the implementation programs to ensure that they are aiming to achieve the same desired condition in the waterbody. For more information on the performance-based approach, see *EPA Review and Approval of State and Tribal Water Quality Standards*.[40]

When developing site-specific water column criterion elements either through the adoption of individual site-specific water column criterion elements or a performance-based approach, states and authorized Tribes must ensure that the site-specific water column criterion elements are protective of the designated use and based on a sound scientific rationale (40 CFR 131.11(a)) and developed using scientifically defensible methods (40 CFR 131.11(b)(1)(iii)). To help ensure that the designated uses are protected, states and authorized Tribes may want to engage with local community stakeholders to evaluate how the waterbody is used and what species are present in the waterbody. If threatened or endangered fish species are present, states and authorized Tribes may need to derive alternative water column elements with a refined protection goal that account for site-specific bioaccumulation characteristics (both when individually adopting a site-specific water column criterion element or using a performance-based approach). The EPA recommends consulting with its regional offices early

[40] *EPA Review and Approval of State and Tribal Water Quality Standards*. 65 Fed. Reg. 24641 (Apr. 27, 2000).

NMED Exhibit 60

and often during the process. The EPA also recommends states and authorized Tribes periodically review the adopted criterion elements, including during the triennial WQS review process (33 USC 1313(c)(1); 40 CFR 131.20), to ensure that those water column criterion elements continue to protect the designated use over time.

2.2.1 Adoption of Site-specific Water Column Criterion Elements through a Performance-Based Approach

As previously mentioned, states and authorized Tribes can choose to adopt into their WQS and submit to the EPA a set of procedures to translate the fish tissue criterion elements into site-specific water column criterion elements. The EPA considers this a performance-based approach to developing site-specific water column criterion elements. Any translation procedure should be transparent, sufficiently detailed, and include suitable safeguards to ensure repeatable, predictable outcomes. In addition, the resulting water column criterion elements must protect the applicable designated use (including federally listed species, if present). If the EPA approves the procedures of the performance-based approach consistent with CWA section 303(c) and the EPA's implementing regulations at 40 CFR Part 131, each resulting site-specific water column criterion element generated consistent with that approach does not need to be individually adopted into the state or authorized Tribe's WQS or individually approved by the EPA under CWA section 303(c).

Importantly, for public transparency, the EPA strongly recommends states and authorized Tribes maintain a list of the resulting site-specific water column criterion elements and underlying data used for their respective derivations on their publicly accessible website. The EPA also strongly encourages states and authorized Tribes to coordinate closely with the EPA when developing a performance-based approach and when conducting the first few studies to develop site-specific water column criterion elements.

In *Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016,* the EPA provides recommendations for site-specific water column translation procedures in Appendix K.[41] States and authorized Tribes may consider the procedures described in this appendix as a starting point for developing a performance-based approach to derive site-specific water column criterion elements. Appendix K presents the general methods for conducting a site-specific water column translation by either the mechanistic model approach or the BAF approach. In addition, it presents a number of options for determining the values to use as input parameters in both of these methods. Interested states or authorized Tribes should decide which of those options they will use for their performance-based approach or describe in their WQS under which circumstances each option will be used.

[41] USEPA. 2021. *2021 Revision to: Aquatic Life Ambient Water Quality Criterion for Selenium–Freshwater 2016.* EPA 822-R-21-006. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/system/files/documents/2021-08/selenium-freshwater2016-2021-revision.pdf.

NMED Exhibit 60

In addition to the general methods provided in Appendix K, states and authorized Tribes should include additional methods in a performance-based approach that can help to make the procedure more transparent and repeatable. These could include methods for: 1) selecting sites and sampling locations within a site; 2) determining what aquatic species (including threatened and endangered species) are present at the site; 3) selecting target species; 4) selecting tissue type for sampling; 5) sampling plans, including spatial and temporal considerations at a site, whether individual or composite samples will be collected, the total number of samples that will be collected per replicate, and the number of replicates that will be collected; 6) extrapolating trophic transfer factors or conversion factors from existing data; and 7) specifying how data will be processed and analyzed. States and authorized Tribes should consider what level of protection will appropriately protect the designated aquatic life use of the waterbody, which will influence what percentile of the resulting data set should be used for the final criterion value. States and authorized Tribes should also account for spatial and temporal variability and assure that the resulting criterion element is protective of the entire site.

States and authorized Tribes' methods for their performance-based approaches should be clear and definitively state which methods will be followed in particular situations. For example, a state or authorized Tribe's performance-based approach should specifically address fishless waters by either including a method specifically designed to derive a site-specific water column criterion element for a fishless water (potentially translating from an invertebrate threshold when data for that are available) or specifying that the performance-based approach cannot be used to derive a site-specific water column criterion element for a fishless water. An example of a detailed performance-based approach is the *Draft Translation of Selenium Tissue Criterion Elements to Site-specific Water Column Criterion Elements for California Version 1, August 8, 2018*.[42]

If a state or authorized Tribe chooses to adopt a performance-based approach as part of a WQS, one method for incorporating the performance-based approach could be to adopt the national CWA section 304(a) recommended selenium criterion table (Table 1) into its WQS with the addition of a footnote that references the document that describes the state or authorized Tribe's translation methodology, sampling plans, and data analysis. By adopting such a footnote into the WQS, the state or authorized Tribe will have incorporated by reference their translation procedure that is scientifically defensible, produces repeatable, predictable outcomes and results in criterion elements that protect the applicable designated use. Any revisions to this document that has been incorporated by reference would be a revision to a WQS that would be subject to the EPA review under CWA section 303(c) and the EPA's implementing regulations at 40 CFR Part 131.

NMED Exhibit 60

2.2.2 Adoption of Site-specific Water Column Criterion Elements Individually

States and authorized Tribes can choose to adopt and submit to the EPA for review site-specific water column criterion elements each time they are derived and adopted. These site-specific water column criterion elements can be derived using one of the methodologies described in Appendix K or another scientifically defensible approach. These site-specific water column criterion elements must protect the designated use and must be reviewed and approved by the EPA under CWA section 303(c) and the EPA's implementing regulations at 40 CFR Part 131 before they are applicable for CWA purposes, such as NPDES permitting, waterbody assessment and listing, and TMDL development.

2.3 Relationship of the EPA's National CWA section 304(a) Recommended Selenium Criterion to the Great Lakes Initiative

The EPA's national CWA section 304(a) recommended selenium criterion does not supersede the requirements applicable to the Great Lakes at 40 CFR Part 132. Those requirements, known as the *Great Lakes Water Quality Guidance* (also known as the *Great Lakes Initiative* or *GLI*), apply to all streams, rivers, lakes, and other bodies of water within the U.S. portion of the Great Lakes drainage basin. For those waters, states and authorized Tribes must adopt WQS, including criteria, that are *consistent with (as protective as)* the WQS regulations the EPA promulgated on March 23, 1995 (see 60 FR 15366, March 23, 1995, and 40 CFR 132.1(b) and 132.4).

Under the Great Lakes system-specific regulations, if a state or authorized Tribe adopts a revised criterion for selenium, the EPA in its review must determine if the new criterion is as protective as the selenium chronic criterion (5 µg/L) promulgated in 40 CFR 132.6, Table 2, and whether all binding implementation procedures are as protective as the GLI procedures (see 40 CFR 132.5(g)). The EPA makes its approval/disapproval decisions about new and revised WQS on a case-by-case basis depending upon the supporting information. For waters within the Great Lakes Basin, states and authorized Tribes should evaluate whether the national CWA section 304(a) recommended selenium criterion meets the requirements at 40 CFR Part 132. The EPA would evaluate any proposed revised selenium criterion submitted as part of a state or authorized Tribe's new or revised WQS on a case-by-case basis, in accordance with the CWA and the EPA's implementing regulations at 40 CFR Parts 131 and 132.

3.0 Options for Implementing the EPA's Selenium Criterion

States and authorized Tribes have some flexibility when adopting the national CWA section 304(a) recommended selenium criterion. Options include, but are not limited to, deriving site-specific fish tissue criterion elements, deriving site-specific water column criterion elements (see section 2.2 of this document), adopting WQS variances, revising designated uses, and using

NMED Exhibit 60

compliance schedules. This section describes how each option could fit within a state or authorized Tribe's WQS adoption and implementation processes.

3.1 Site-specific Fish Tissue Criterion Elements

3.1.1 Site-specific Fish Tissue Criterion Elements Using the Species Recalculation Procedure[43]

The EPA's WQS regulation at 40 CFR 131.11(b)(1)(ii) provides states and authorized Tribes with the opportunity to adopt criteria that are "…modified to reflect site-specific conditions." As with any criterion, a site-specific criterion must protect the designated use, must be based on a sound scientific rationale, and is subject to the EPA review and approval or disapproval (40 CFR 131.11(a)).

One process that can be used to modify a criterion to reflect site-specific conditions is the recalculation procedure. The recalculation procedure is a process used to modify the taxonomic composition of the toxicity data set used for the species sensitivity distribution (SSD)[44] upon which a site-specific criterion is based, in order to better match the species assemblage that is expected to occur at the site. The recalculation procedure creates a site-specific toxicity data set (and corresponding SSD) that is appropriate for deriving a site-specific aquatic life criterion by correcting, adding, and/or deleting test results from the national toxicity data set for the pollutant of concern based on the resident species of the site. For site-specific recalculations at sites with limited diversity, "the underlying concept of having tests for a diversity of species is more fundamental than having tests for particular taxonomic groups that may be irrelevant to the site."[45] Therefore, recalculations can be performed, even if all of the minimum data requirements are not met. This procedure is intended to provide flexibility to states and authorized Tribes to derive site-specific criteria that best reflect the expected resident species at a site. The species recalculation procedure may result in site-specific criteria that differ from national CWA section 304(a) criteria recommendations (i.e., concentrations that are higher or lower than national recommendations) when there are demonstrated differences in sensitivity

[43] USEPA. 2013. *Revised Deletion Process for the Site-Specific Recalculation Procedure for Aquatic Life Criteria*. EPA 823-R-13-001. U.S. Environmental Protection Agency, Office of Water, Washington, DC. www.epa.gov/sites/production/files/2015-08/documents/revised_deletion_process_for_the_site-specific_recalculation_procedure_for_aquatic_life_criteria.pdf.

[44] For additional description of the derivation of the fish tissue criterion elements and the distribution of species sensitivities, see section 3.1.3 of USEPA 2021. [45] USEPA. 2013. *Revised Deletion Process for the Site-Specific Recalculation Procedure for Aquatic Life Criteria*. EPA 823-R-13-001. U.S. Environmental Protection Agency, Office of Water, Washington, DC. www.epa.gov/sites/production/files/2015-08/documents/revised_deletion_process_for_the_site-specific_recalculation_procedure_for_aquatic_life_criteria.pdf.

NMED Exhibit 60

between the expected resident aquatic species and those that were used to derive the national criteria recommendations.

Critical species should also be taken into consideration when using the recalculation procedure. A critical species is a resident species that (a) is commercially or recreationally important at the site; or (b) is listed as threatened or endangered under section 4 of the Endangered Species Act (states and authorized Tribes may also want to consider species that are candidates for protection under the Endangered Species Act as critical species); or (c) is a species for which there is firm evidence that its loss would yield an unacceptable impact on the site's commercially or recreationally important species, endangered species, abundances of a variety of other species, or structure or function.[46] The deletion process of the recalculation procedure should not be undertaken unless toxicity data are available for at least one species in each *class* of aquatic plants or animals that contains a *critical species*. For example, if the site has a salmonid that fits the designation of a critical species, the deletion process should not be undertaken unless toxicity data for a species in class teleostei[47] are available (possibly via new testing). It is important to note that species not present at the site, but included in the national criterion database, may be surrogates for other species that are present at the site, but not included in the national criterion database.

The EPA developed the national CWA section 304(a) recommended selenium criterion by first deriving an egg-ovary criterion element from egg-ovary toxicity data then deriving all other criterion elements from that egg-ovary criterion element. A state or authorized Tribe developing site-specific fish tissue criterion elements using the recalculation procedure could similarly start with deriving the egg-ovary criterion element and then deriving other fish-tissue criterion elements. States and authorized Tribes should also consider corresponding changes to the applicable water column criterion elements. See section 2.2 of this document for more information. Note that a state or authorized Tribe that is considering adopting the EPA's national CWA section 304(a) selenium criterion recommendations for the fish tissue criterion elements as recommended but is interested in developing site-specific water column values can proceed as described in section 2.2 of this document.

As with any criteria, states and authorized Tribes using the recalculation procedure should ensure that their site-specific criteria "…provide for the attainment and maintenance of the water quality standards of downstream waters" (40 CFR 131.10(b)). This requirement can be met in a number of ways, including using a combination of water quality standards, such as criteria (numeric criteria and/or narrative criteria) and general policies. Additional information

[47] Teleostei is currently listed as a class by the Integrated Taxonomic Information System (itis.gov). Osteichthyes was previously classified as a superclass that contained the classes Sarcopterygii and Actinopterygii, but those two taxa have now been elevated to superclasses and Teleostei has been elevated to class (https://www.itis.gov/servlet/SingleRpt/SingleRpt).

NMED Exhibit 60

about this requirement can be found in *Protection of Downstream Waters in Water Quality Standards: Frequently Asked Questions*.[48] In addition, states and authorized Tribes should consider how they will demonstrate that a species that is contained in the national data set but is being removed from that data set in order to derive the new site-specific criterion is not present at the site (or a surrogate for another species present at the site) before using the recalculation approach. For additional information on the procedure, see the EPA's *Revised Deletion Process for the Site-Specific Recalculation Procedure for Aquatic Life Criteria*.[49] States and authorized Tribes interested in developing site-specific fish tissue criterion elements based on the revised deletion process should engage their EPA Regional office early in the process to ensure the development of sound scientific analyses. The EPA cautions that the deletion process for site-specific criterion development is not appropriate for a performance-based approach because different survey techniques are needed at different sites to determine which species are present.

When developing site-specific criterion elements, consideration should be given to what area is defined as the site. In the general context of site-specific criteria, a "site" may be a state, region, watershed, waterbody, or segment of a waterbody. The site-specific criterion must provide adequate protection for the entire site, however the site is defined. For the recalculation procedure, all species that occur at the site need to be considered when deciding what species, if any, are to be deleted (or added) from (to) the data set. Unique populations or less sensitive uses within sites may justify a designation as a distinct site. If the site contains endangered or threatened species and/or their critical habitat, and the EPA's approval of the state or authorized Tribe's proposed site-specific criterion may affect these species or habitat, the EPA must engage in interagency consultation under the Endangered Species Act section 7(a)(2) with either or both the United States Fish and Wildlife Service and National Marine Fisheries Service, depending on the species, to ensure that the EPA's approval is not likely to jeopardize the continued existence of any threatened or endangered species or result in the destruction or adverse modification of critical habitat. During consultation, the EPA would consider the potential effect of its approval on the species and on the physical and biological features of the critical habitat as well as how the EPA's approval of the site-specific criterion may affect water quality required for the species within the critical habitat.

For additional information on site-specific WQC, see chapter 3 of the EPA's *Water Quality Standards Handbook*.[50]

3.1.2 Site-specific Criteria for Sites with Naturally Elevated Selenium Levels

Natural conditions are generally associated with the condition of ecological integrity, defined as the structure, composition, function, or diversity of a habitat in the absence of human disturbance or alteration.[51] For some areas in the U.S., selenium may be elevated in soils and waterbodies under natural conditions. States and authorized Tribes have two options when addressing areas that have naturally elevated selenium concentrations: (1) they may develop site-specific criteria for waterbodies in these locations (e.g., where the current aquatic life designated use is appropriate); or (2) they may refine or subcategorize the aquatic life designated use for waterbodies in these areas and set new criteria to be protective of the modified use (See section 3.3 of this document for more information on revising designated uses). These are two separate pathways for accomplishing the goal of setting appropriate criteria for these waterbodies.

To set a site-specific criterion using a natural conditions justification, states and authorized Tribes should demonstrate that the elevated levels of selenium are due to natural conditions and that no anthropogenic activities (e.g., agriculture, mining, irrigation, coal, or oil combustion) are responsible for elevating selenium concentrations in the waterbody. In many areas where soils are elevated in selenium, anthropogenic activities either release selenium or expose soils or rock to weathering, which results in the release of additional selenium into the water column. When an anthropogenic activity leads to a greater release of selenium than natural weathering, the state or authorized Tribe should not develop a site-specific criterion using the natural conditions justification. However, if the anthropogenic impacts can be separated from the natural impacts in these situations where both occur, then the state or authorized Tribe could develop a site-specific criterion for the portion of the elevated selenium that is due solely to those natural causes.

When developing a site-specific criterion, the state or authorized Tribe should identify the site boundaries and temporal dynamics to which a natural background (concentration of a parameter due only to non-anthropogenic sources) criterion applies (i.e., it is important that such criteria are developed to maintain and protect the spatial and temporal variation in

[50] USEPA. 2017. Chapter 3: Water Quality Criteria in *Water Quality Standards Handbook*. EPA 823-B-17-001. U.S. Environmental Protection Agency, Office of Water, Washington, DC. https://www.epa.gov/sites/production/files/2014-10/documents/handbook-chapter3.pdf.

NMED Exhibit 60

selenium concentrations under natural conditions[52]). If concentrations vary seasonally, adoption of seasonal criteria may be appropriate. Where concentrations vary spatially, additional waterbody segmentation may be appropriate. In cases where selenium is elevated due to both natural conditions and anthropogenic activities, methods such as modeling (e.g., historical or hydrologic modeling), an examination of past paleolimnological studies, comparison to reference sites with no anthropogenic impacts, or other scientifically defensible techniques may be considered as an option for defining natural conditions.[53] Using these or other tools, a state or authorized Tribe may be able to define what proportion of elevated selenium is due to natural versus anthropogenic impacts. A site-specific criterion could then be derived for the portion of the concentration that is elevated due to natural conditions.

When deriving site-specific fish tissue criterion elements, states and authorized Tribes should consider corresponding changes to the applicable water column criterion elements. If selenium at the site is entirely from natural sources, then the water column criterion element could be set at ambient water column concentrations. However, if some of the selenium is from anthropogenic sources, then the water column concentration should be derived using modeling methods. See section 2.2 for more information on options for adopting site-specific water column criterion elements.

As articulated in the 1997 memorandum *Establishing Site-Specific Aquatic Life Criteria Equal to Natural Background,*[54] the EPA recommends that interested states and authorized Tribes establish site-specific numeric aquatic life criteria by setting the criteria values equal to natural background, where natural background is defined as due *only* to non-anthropogenic sources (i.e., non-human-induced sources). The EPA cautions against using the terminology "ambient" interchangeably with "natural." Ambient conditions refer to current conditions at a site and can include both impacts from anthropogenic and natural sources.

3.2 Water Quality Standards Variances

A state or authorized Tribe could consider a WQS variance if it determines that it is not feasible at present to attain a designated use and an associated criterion, such as a newly adopted

---

[54] Davies, T. USEPA. 1997. Memorandum: Establishing Site Specific Aquatic Life Criteria Equal to Natural Background. Office of Water, Washington DC. https://www.epa.gov/sites/production/files/2014-08/documents/naturalbackground-memo.pdf.

NMED Exhibit 60

selenium criterion, but it may be attainable in the future. A WQS variance may also be considered if there is uncertainty about the feasibility of meeting the designated use and criterion, but progress can be made by implementing known controls and tracking environmental improvements. The WQS regulations at 40 CFR 131.3(o) define a *WQS variance* as "a time-limited designated use and criterion for a specific pollutant(s) or water quality parameter(s) that reflect the highest attainable condition (HAC) during the term of the WQS variance." The WQS variance regulation at 40 CFR 131.14 ensures that incremental progress is made toward attainment of the applicable designated use and associated criterion, while not allowing any lowering of the currently attained ambient water quality. This is accomplished by establishing an HAC, which serves as the basis for deriving less-stringent NPDES permit limits and requirements throughout the term of the WQS variance.[55] Although less stringent than the adopted criterion, the HAC still provides a target for incrementally improving water quality until the applicable designated use and associated criterion become attainable. It is important to note that these permit limits and requirements are applicable only to the discharger(s), pollutant(s)/parameter(s), and waterbody or waterbody segment(s) identified in the WQS variance. All other applicable standards not specifically addressed by the EPA-approved WQS variance would continue to apply for CWA purposes.

A state or authorized Tribe can choose to adopt a WQS variance that is applicable to a single discharger, multiple dischargers, or an entire waterbody/waterbody segment. Because the national CWA section 304(a) recommended selenium criterion is intended to protect aquatic life (CWA section 101(a)(2)), in its WQS variance submission the state or authorized Tribe must provide supporting documentation demonstrating that attaining the designated use and criterion is not feasible throughout the term of the WQS variance due to one of the factors listed at 40 CFR 131.14(b)(2)(i)(A). Such a demonstration, when combined with the other regulatory requirements of 40 CFR 131.14, provides the framework for WQS variances as a water quality improvement tool. The regulations at 40 CFR Part 132 apply to states and authorized Tribes that regulate waters in or contributing to waters of the Great Lakes System. If 40 CFR 131.14 and 40 CFR Part 132 overlap, the more stringent regulation applies. WQS variances are considered new or revised WQS and, therefore, must be reviewed and approved by the EPA in order to be in effect for CWA purposes.

To help states and authorized Tribes in the process of adopting WQS variances, the EPA has developed various resources, including a WQS variances website,[56] the *WQS Variance Building Tool*,[57] *Checklist for Evaluating State Submission of Discharger-Specific Water Quality Standards*

[55] WQS variances with a term greater than five years must be reevaluated at least every five years to determine whether the HAC is more stringent than originally adopted. See 40 CFR 131.14 (b)(1)(v).

NMED Exhibit 60

Variances,[58] and several other resources available on the "Resources" tab of the *WQS Variance Building Tool*. States and authorized Tribes are encouraged to coordinate with the EPA throughout the WQS variance adoption process to develop their WQS variance submissions.

3.3 Revision to Designated Uses

Prior to adopting a revised selenium criterion, a state or authorized Tribe may want to evaluate potential revisions to the relevant designated uses for certain waterbodies as discussed below. The WQS regulation at 40 CFR 131.10(g) provides that states or authorized Tribes may remove a CWA section 101(a)(2) designated use that is *not* an existing use, as defined in 40 CFR 131.3(e), or establish subcategories of such a use that requires less stringent criteria if the state or authorized Tribe can demonstrate that attaining the designated use is not feasible because of one or more of the six factors listed in 40 CFR 131.10(g). Those factors are:

1) Naturally occurring pollutant concentrations prevent the attainment of the use; or

2) Natural, ephemeral, intermittent or low flow conditions or water levels prevent the attainment of the use, unless these conditions may be compensated for by the discharge of sufficient volume of effluent discharges without violating state water conservation requirements to enable uses to be met; or

3) Human caused conditions or sources of pollution prevent the attainment of the use and cannot be remedied or would cause more environmental damage to correct than to leave in place; or

4) Dams, diversions or other types of hydrologic modifications preclude the attainment of the use, and it is not feasible to restore the waterbody to its original condition or to operate such modification in a way that would result in the attainment of the use; or

5) Physical conditions related to the natural features of the waterbody, such as the lack of a proper substrate, cover, flow, depth, pools, riffles, and the like, unrelated to water quality, preclude attainment of aquatic life protection uses; or

6) Controls more stringent than those required by sections 301(b) and 306 of the Act would result in substantial and widespread economic and social impact.

Where required under the EPA's WQS regulations, the state or authorized Tribe must make such a demonstration through a *use attainability analysis* (UAA), which is defined under 40 CFR 131.3(g) as "…a structured scientific assessment of the factors affecting the attainment of the use which may include physical, chemical, biological, and economic factors as described in 40 CFR 131.10(g)." A state or authorized Tribe must conduct a UAA whenever (1) the state or

[58] USEPA. 2016. *Checklist for Evaluating State Submission of Discharger-Specific Water Quality Standards Variances*. U.S. Environmental Protection Agency, Office of Water. Washington, DC. https://www.epa.gov/sites/production/files/2016-03/documents/checklist-evaluating-discharger-specific.pdf.

NMED Exhibit 60

authorized Tribe designates for the first time, or has previously designated for a waterbody, uses that do not include the uses specified in section 101(a)(2) of the CWA; or (2) the state or authorized Tribe wishes to remove a designated use that is specified in section 101(a)(2) of the Act, to remove a subcategory of such a use, or to designate a subcategory of such a use that requires a criterion less stringent than previously applicable (40 CFR 131.10(j)). If a state or authorized Tribe adopts a new or revised WQS based on a required use attainability analysis, the state or authorized Tribe shall also adopt the highest attainable use, as defined in 40 CFR 131.3(m).[59] The WQS regulations also do not allow states and authorized Tribes to remove any uses that are existing uses. In addition, uses cannot be removed if they can be attained by implementing effluent limits required under sections 301(b) and 306 of the Act and by implementing cost-effective and reasonable best management practices for nonpoint source control (40 CFR 131.10(h)).

For selenium, there are at least two potential circumstances where a use change may be appropriate for a waterbody. The first is fishless waters. States or authorized Tribes may want to recognize the difference in aquatic communities in these waters by creating a subcategory of the aquatic life designated use. When doing so, the state or authorized Tribe should be sure that protections for other forms of aquatic life, such as macroinvertebrates, are protected by the revised designated use and associated criterion. If aquatic-dependent wildlife use the waterbody, then the state or authorized Tribe may also want to set a selenium criterion for the protection of these species as well. The second is waterbodies located in areas where the selenium is naturally elevated in the underlying geology and, as a result, are particularly vulnerable to elevated selenium concentrations in the water. Ambient selenium concentrations in these waterbodies can be exacerbated by anthropogenic activities. If the conditions in this circumstance are precluding attainment of the designated use and cannot be remedied, a limited or modified aquatic life use may be more appropriate for these waterbodies. The EPA's regulations at 40 CFR 131.10(g) provide factors related to natural and anthropogenic conditions for states and authorized Tribes to employ in a UAA to justify revising the aquatic life use (see 40 CFR 131.10(j) for when a UAA is required). If the state or authorized Tribe can demonstrate the full aquatic life use is not feasible for a waterbody using at least one of the factors at 40 CFR 131.10(g), then the designated use the state or authorized Tribe must adopt in place of the full aquatic life use must be the highest attainable use for the waterbody, as required by 40 CFR 131.10(g).

[59] 40 CFR 131.3(m) defines "highest attainable use" as the "…modified aquatic life, wildlife, or recreation use that is both closest to the uses specified in section 101(a)(2) of the Act and attainable, based on the evaluation of the factor(s) in §131.10(g) that preclude(s) attainment of the use and any other information or analyses that were used to evaluate attainability."

NMED Exhibit 60

For additional information on use changes and UAAs, see the EPA's *Water Quality Standards Handbook.*[60] Additional information also is available at http://water.epa.gov/scitech/swguidance/standards/uses/uaa/.

3.4 Compliance Schedules

If a state or authorized Tribe's applicable WQS[61] or implementing regulations include a provision authorizing the use of permit compliance schedules, a compliance schedule that is consistent with 40 CFR 122.47 can be included in an NPDES permit with WQBELs for selenium. The NPDES permit regulations at 40 CFR 122.47 allow compliance schedules if (1) the discharger cannot immediately meet the new WQBEL, and requires time to install treatment technology or implement other controls necessary to come into compliance with a new WQBEL; (2) the permitting authority (the state or the EPA) determines that a compliance schedule is *appropriate* in light of all the circumstances; and (3) the discharger can meet its final WQBEL at a date determined to be as-*soon-as-possible*. See section 502(17) of the CWA for a definition of *schedules of compliance* and 40 CFR 122.47 for more information about the schedules. For additional information on compliance schedules, see section 5 in *Frequently Asked Questions: Implementing Water Quality Standards Based on the EPA's 2016 Selenium Criterion in Clean Water Act Section 402 National Pollutant Discharge Elimination System Permits*.[62]

Compliance schedules in NPDES permits can allow additional time to achieve compliance with WQBELs based on WQS adopted after July 1, 1977, if the state or authorized Tribe (i.e., a Tribe with TAS for WQS) has indicated clearly in its WQS or implementing regulations that it intends to allow the use of permit compliance schedules. As defined in the NPDES regulations, "a schedule of compliance" is "a schedule of remedial measures included in a 'permit', including an enforceable sequence of interim requirements (for example, actions, operations, or milestone events) leading to compliance with the CWA and regulations" (40 CFR 122.2). If the schedule is longer than one year, it must include annual interim requirements and dates for their achievement (40 CFR 122.47(a)(3)). Additionally, the permit must include a final WQBEL and a date for its achievement. The decision to include a compliance schedule as well as the dates and interim requirements must be supported by the administrative record. The permit fact sheet should include a justification for the compliance schedule being determined to be *appropriate* and why the chosen time frame was deemed to be *as soon as possible*. For

[61] 40 CFR 131.15 states that: "If a State intends to authorize the use of schedules of compliance for water quality-based effluent limits in NPDES permits, the State must adopt a permit compliance schedule authorizing provision. Such authorizing provision is a water quality standard subject to EPA review and approval under section 303 of the Act and must be consistent with sections 502(17) and 301(b)(1)(C) of the Act."

NOTICES

This document provides information that states and authorized Tribes may consider when establishing water quality standards under the Clean Water Act (CWA) to protect aquatic life from effects of Perfluorooctane sulfonate (PFOS). Under the CWA, states and authorized Tribes establish water quality criteria to protect designated uses. State and Tribal decision makers retain the discretion to adopt approaches that are scientifically defensible that differ from these recommended criteria or benchmarks, including to reflect site-specific conditions. While this document contains the Environmental Protection Agency's (EPA) scientific recommendations regarding ambient concentrations of PFOS that protect aquatic life, the PFOS Criteria Document does not substitute for the Clean Water Act or the EPA's regulations; nor is this document or the values it contains a regulation itself. This document does not establish or affect legal rights or obligations, or impose legally binding requirements on the EPA, states, Tribes, or the regulated community. It cannot be finally determinative of the issues addressed. This document has been approved for publication by the Office of Science and Technology, Office of Water, U.S. Environmental Protection Agency.

Mention of trade names or commercial products does not constitute endorsement or recommendation for use. This document can be downloaded from: https://www.epa.gov/wqc/aquatic-life-criteria-perfluorooctane-sulfonate-pfos.

NMED Exhibit 62

FOREWORD

The Clean Water Act (CWA) Section 304(a)(l) (P.L. 95-217) directs the Administrator of the EPA to develop and publish water quality criteria recommendations that accurately reflect the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare that might be expected from the presence of pollutants in any body of water, including groundwater. This document includes EPA's recommended ambient water quality criteria (AWQC) for the protection of aquatic life based upon consideration of all available information relating to effects of perfluorooctanoic acid on aquatic organisms in freshwaters, as well as an informational acute saltwater benchmark developed under CWA Section 304(a)(2).

Aquatic life benchmarks, developed by the EPA under 304(a)(2) of the CWA, are informational values that EPA generates when there are limited high quality toxicity data available and data gaps exist for several aquatic organism families. EPA develops aquatic life benchmarks to provide information that states and Tribes may consider in their water quality protection programs, including when developing water quality standards. In developing aquatic life benchmarks, data gaps may be filled using new approach methods (NAMs), such as computer-based toxicity estimation tools (e.g., EPA's Web-ICE) or other new approach methods intended to reduce reliance on additional animal testing (https://www.epa.gov/chemical-research/epa-new-approach-methods-work-plan-reducing-use-vertebrate-animals-chemical), including the use of read-across estimates based on other chemicals with similar structures. Like criteria recommendations developed under Section 304(a)(l), the EPA's aquatic life benchmark values are not regulatory, nor do they automatically become part of a state's water quality standards.

NMED Exhibit 62

Under CWA Section 303, states or authorized Tribes adopt water quality standards and submit them to EPA for review and approval. If approved by EPA as water quality standards, they become the CWA water quality standards applicable in ambient waters within that state or authorized Tribe. A state or authorized Tribe may, where appropriate, adopt water quality criteria that have the same numerical values as recommended criteria or benchmarks developed by EPA under CWA Section 304. States and authorized Tribes have discretion to adopt criteria that modify EPA's recommended criteria to reflect site-specific conditions, such as the local water chemistry or ecological conditions, or to develop criteria based on other scientifically defensible methods that are protective of designated uses (40 C.F.R. 131.11[b]). Guidelines to assist the states and authorized Tribes in modifying the criteria presented in this document are contained in the Water Quality Standards Handbook (see Chapter 3 titled "Water Quality Criteria")(U.S. EPA 2023).

Office of Science and Technology

NMED Exhibit 62

EXECUTIVE SUMMARY

The U.S. Environmental Protection Agency (EPA) developed the recommended perfluorooctane sulfonate (PFOS) aquatic life ambient water quality criteria and an acute saltwater benchmark in accordance with the provisions of Section 304(a) of the Clean Water Act. This document provides the EPA's basis for and derivation of the national PFOS ambient water quality criteria recommendations to protect aquatic life. The EPA has derived the recommended PFOS aquatic life criteria and benchmark to be consistent with methods described in the EPA's "*Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses*" (i.e., EPA's 1985 Guidelines; U.S. EPA 1985) and EPA's OCSPP's Ecological Effects Test Guidelines (U.S. EPA 2016b).

PFOS is an organic, human-made perfluorinated compound, consisting of an eight-carbon backbone and a sulfonate functional group. PFOS (and other related chemicals that are perfluoroalkane sulfonic acids) is used in a variety of industrial and commercial products, including surface treatments of soil, surface treatments of textiles, paper, and metals, and in specialized applications such as in firefighting foams. This document provides a critical review of all aquatic toxicity data identified in the EPA's literature search for PFOS, including the anionic form (CAS No. 45298-90-6), the acid form (CAS No. 1763-23-1), potassium salt (CAS No. 2795-39-3), an ammonium salt (CAS No. 56773-42-3), sodium salt (CAS No. 4021-47-0), and a lithium salt (CAS No. 29457-72-5). It also quantifies the toxicity of PFOS to aquatic life and provides criteria to protect aquatic life in freshwater from the acute and chronic toxic effects of PFOS.

The Aquatic Life Ambient Water Quality Criteria for PFOS document includes water column-based acute and a water column-based chronic criteria, as well as chronic tissue-based

NMED Exhibit 62

criteria for freshwaters. Quantitatively-acceptable estuarine/marine toxicity data only fulfilled five of the eight minimum data requirements (MDRs) for deriving acute estuarine/marine criteria and four of the eight MDRs for deriving chronic estuarine/marine criteria per the 1985 Guidelines. The EPA did, however, include an acute aquatic life benchmark for estuarine/marine environments in Appendix L, using available estuarine/marine species toxicity data and the New Approach Methods (NAMs) application of the EPA Office of Research and Development's (ORD) peer-reviewed web-based Interspecies Correlation Estimate tool (Web-ICE; Version 3.3; https://www.epa.gov/webice/) (Raimondo et al. 2010). The estuarine/marine benchmarks are CWA Section 304(a)(2) information provided for states and authorized Tribes to consider in their state/tribal water quality protection programs. However, the acute estuarine/marine benchmark magnitude is less certain than the freshwater criteria as the benchmark was based on both direct laboratory-based and estimated PFOS acute toxicity data (Appendix L).

The freshwater acute water column-based criterion magnitude is 0.071 mg/L, and the chronic water column-based criterion magnitude is 0.00025 mg/L (250 ng/L). The final chronic freshwater criterion also contains tissue-based criteria with magnitudes of 0.201 mg/kg wet weight (ww) for fish whole-body, 0.087 mg/kg ww for fish muscle tissue, and 0.028 mg/kg ww for invertebrate whole-body tissue. All criteria are intended to be equally protective against adverse PFOS effects and are intended to be independently applicable. The three tissue criteria magnitudes (for fish and invertebrate tissues) are translations of the chronic water column criterion for freshwater using bioaccumulation factors (BAFs) derived from a robust national dataset of BAFs (Burkhard 2021). The assessment of the available data for fish, invertebrates, amphibians, and plants indicates these criteria are expected to protect the freshwater aquatic community.

NMED Exhibit 62

Table Ex-1. Recommended Perfluorooctane Sulfonate (PFOS) Ambient Water Quality Criteria for the Protection of Aquatic Life in Freshwaters.

Type/Media	Acute Water Column (CMC)[1,4]	Chronic Water Column (CCC)[1,5]	Chronic Invertebrate Whole-Body[1,2]	Chronic Fish Whole-Body[1,2]	Chronic Fish Muscle[1,2]
Magnitude	0.071 mg/L	0.00025 mg/L	0.028 mg/kg ww	0.201 mg/kg ww	0.087 mg/kg ww
Duration	One-hour average	Four-day average	Instantaneous[3]		
Frequency	Not to be exceeded more than once in three years on average	Not to be exceeded more than once in three years on average	Not to be exceeded[6]		

[1] All five of these water column and tissue criteria are intended to be independently applicable and no one criterion takes primacy. All of the above recommended criteria (acute and chronic water column and tissue criteria) are intended to be protective of aquatic life. These criteria are applicable throughout the year.
[2] Tissue criteria are derived from the chronic water-column criterion magnitude (CCC) with the use of bioaccumulation factors and are expressed as wet weight (ww) concentrations.
[3] Tissue data provide instantaneous point measurements that reflect integrative accumulation of PFOS over time and space in aquatic life population(s) at a given site.
[4] Criterion Maximum Concentration; applicable throughout the water column.
[5] Criterion Continuous Concentration; applicable throughout the water column.
[6] PFOS chronic freshwater tissue-based criteria should not be exceeded, based on measured tissue concentrations representing the central tendency of samples collected at a given site and time.

Table Ex-2. Acute Perfluorooctane Sulfonate (PFOS) Benchmark for the Protection of Aquatic Life in Estuarine/Marine Waters.

Type/Media	Acute Water Column Benchmark
Magnitude	0.55 mg/L
Duration	One hour on average
Frequency	Not to be exceeded more than once in three years on average

NMED Exhibit 62

1 INTRODUCTION AND BACKGROUND

National Recommended Ambient Water Quality Criteria (AWQC) are established by the EPA under the CWA. Section 304(a)(1) states that aquatic life criteria serve as recommendations to states and authorized Tribes by defining ambient water concentrations that are expected to protect against unacceptable adverse ecological effects to aquatic life resulting from exposure to pollutants found in water. States and authorized Tribes may adopt these criteria into their water quality standards (WQS) to protect the designated uses of water bodies. States and authorized Tribes may also modify these criteria before adopting these into standards. After adoption, states/authorized Tribes submit new and revised WQS to EPA for review and approval or disapproval. When approved by EPA, the state's/Tribes WQS become the application WQS for CWA purposes. Such purposes include identification of impaired waters and establishment of Total Maximum Daily Loads (TMDLs) under CWA Section 303(d) and derivation of water quality-based effluent limitations in permits issued under the CWA Section 402 National Pollutant Discharge Eliminations System (NPDES) programs. The EPA recommends the adoption of both the acute and chronic water column criteria as well as the chronic-tissue based criteria to ensure the protection of aquatic life through all exposure pathways, including direct aqueous exposure and bioaccumulation. Aquatic life benchmarks, developed by the EPA under 304(a)(2) of the CWA, are informational values that the EPA generates when there are limited high quality toxicity data available and data gaps exist for several aquatic organism families. The EPA provided an acute estuarine/marine benchmark in Appendix L as additional information on protective values that states and tribes may consider in their water quality programs.

This assessment provides a critical review of all aquatic toxicity data identified in the EPA's literature search for PFOS, including the anionic form (CAS No. 45298-90-6), the acid

NMED Exhibit 62

form (CAS No. 1763-23-1), a potassium salt (CAS No. 2795-39-3), an ammonium salt (CAS No. 56773-42-3), a sodium salt (CAS No. 4021-47-0), and a lithium salt (CAS No. 29457-72-5). It quantifies the toxicity of PFOS to aquatic life and provides criteria to protect aquatic life in freshwater from the acute and chronic toxic effects of PFOS.

The EPA derived the recommended criteria using the best available data to reflect the latest scientific knowledge on the toxicological effects of PFOS to aquatic life. The EPA developed the criteria following the general approach outlined in the EPA's "*Guidelines for Deriving Numerical Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses"* (U.S. EPA 1985). The PFOS freshwater criteria, if adopted and implemented, are expected to be protective of most aquatic organisms, including species listed as threated and endangered, in the community and are derived to be protective of aquatic life designated uses established by states and Tribes for freshwaters. The estuarine/marine benchmarks are also intended to be protective of aquatic life designated uses, but as they are based on fewer empirical PFOS data have greater inherent uncertainty. The criteria recommendations presented herein are the EPA's best estimate of the concentrations of PFOS, with associated frequency and duration specifications, that would protect sensitive aquatic life from unacceptable acute and chronic effects.

1.1 Previously Derived PFOS Toxicity Values and Thresholds

Within the U.S., no states or Tribes have CWA Section 303(c) approved water quality standards for the protection of aquatic life from the exposure to PFOS. However, several states have published draft/interim acute and chronic ecological screening level values/benchmarks for the protection of aquatic life. As such, previously published PFOS acute and chronic criteria, benchmarks, and thresholds developed by states and international regulatory authorities were

NMED Exhibit 62

identified, that included values for both freshwater and marine systems, and are summarized below.

1.1.1 Previously Published Acute Water Protective Values for Direct Aqueous Exposure

Previously published freshwater acute values were available for four states (Florida, Michigan, Minnesota, and Texas) and one geographic region (Europe). These publicly available values for other jurisdictions ranged from 0.021 mg/L in Texas (Giesy et al. 2010; TCEQ 2021) to 0.78 mg/L in Michigan (EGLE 2010). The EPA's freshwater acute PFOS criterion (0.071 mg/L) falls into the middle of the range of state- and European-derived values.

There were two previously derived estuarine/marine acute values, with a benchmark/criterion of 0.0072 mg/L in Europe (RIVM 2010) and 0.21 mg/L in Florida (Stuchal and Roberts 2019) (Table 1-1). These values were derived using safety factors. Consequently, these state values were both lower than the EPA's PFOS acute estuarine/marine benchmark (0.55 mg/L), which used measured and estimated acute toxicity data (Appendix L).

1.1.2 Previously Published Chronic Water Protective Values for Direct Aqueous Exposure

Previously published freshwater chronic values were available for five states (California, Florida, Michigan, Minnesota, and Texas) and three countries or geographic regions (Australia/New Zealand, Canada, and Europe). The publicly available state-derived values ranged from 0.00056 mg/L in California (RWQCB 2020; SERDP 2019; 99% species protection) to 0.14 mg/L in Michigan (EGLE 2010). Overall, the EPA's chronic water column-based PFOS criterion (0.00025 mg/L) is lower than chronic state-derived values because the EPA's chronic PFOS criterion was based on recently published and sensitive insect data.

Internationally, chronic PFOS protective values were 0.000023 mg/L in Europe (RIVM 2010), 0.00013 mg/L in Australia/New Zealand (CRCCare 2017; EPAV 2017) 95% species protection level), and 0.00680 mg/L in Canada (ECCC 2018) (Table 1-1). The EPA's chronic

NMED Exhibit 62

water-column based PFOS criterion (0.00025 mg/L) is in the middle of the range of chronic PFOS values used in different international jurisdictions.

Previously published estuarine/marine chronic values were available for three states (California, Florida, and Texas) and two geographic regions (Australia/New Zealand and Europe). These publicly available values for other jurisdictions ranged from 0.000294 mg/L for Texas (CRCCare 2017; TCEQ 2021) to 0.013 mg/L in Florida (Stuchal and Roberts 2019) and were 0.0000046 mg/L in Europe (RIVM 2010) and 0.00013 mg/L in Australia/New Zealand (95% species protection; CRCCare 2017; EPAV 2017). The EPA did not derive a chronic PFOS criterion or benchmark for estuarine/marine water because of data limitations.

1.1.3 Previously Published Chronic Fish Tissue Criteria

There was a single previously derived fish tissue value for other jurisdictions. This value was a Canadian Federal Fish Tissue Guideline (FFTG) of 9.4 mg/kg whole-body wet weight (ww) (ECCC 2018). This value was derived by multiplying Canada's Federal Water Quality Guideline of 6.8 µg/L by a BAF of 1,378 L/kg. Canada's fish whole-body based Federal Water Quality Guideline (9.4 mg/kg ww) is significantly larger than the EPA's PFOS fish whole-body tissue criterion (0.201 mg/kg ww) because the EPA's value considered more recently published and relatively sensitive toxicity data that were not available at the time Canada's fish whole-body Water Quality Guideline was derived.

NMED Exhibit 62

Table 1-1. Previously Derived PFOS Toxicity Values and Thresholds.

State / Country of Applicability	Aquatic Life Protective Value (mg/L unless otherwise indicated)	Criteria or Benchmark and Calculation Approach	Source
Freshwater Acute			
Some European Countries	0.036	Maximum Acceptable Concentration calculated using the lowest acute (LC50) value of 3.6 mg/L for mysid (*Americamysis bahia)* ÷ by assessment factor of 100. Dataset includes freshwater and marine aquatic species, combined.	RIVM (2010)
Texas	0.021	Acute surface water benchmark calculated using U.S. EPA Great Lakes Initiative (GLI; (U.S. EPA 1995)) Tier I Methodology as reported in (Giesy et al. 2010). This is an acute surface water benchmark and does not represent a CWA Section 303(c) approved water quality standard for PFOS.	Giesy et al. (2010); TCEQ (2021)
Minnesota	0.085	Maximum Criterion (MC) calculated as the acute curve-fitted and extrapolated 10-d EC50 for midge (*Chironomus tentans*) of 170 µg/L, which serves as the Final Acute Value or FAV followed by ÷ 2. This draft value does not represent a CWA Section 303(c) approved water quality standard for PFOS.	STS/MPCA (2007)
Florida	0.53	Secondary Acute Value (SAV) calculated using U.S. EPA Great Lakes Initiative (GLI; U.S. EPA 1995) Tier II Methodology. FAV calculated as the lowest GMAV (unspecified) divided by a safety factor of 6.1. This value was released in a White Paper sponsored by Florida Department of Environmental Protection and is considered a draft eco-based surface water screening level. It is not a CWA Section 303(c) approved water quality standard.	Stuchal and Roberts (2019)

NMED Exhibit 62

State / Country of Applicability	Aquatic Life Protective Value (mg/L unless otherwise indicated)	Criteria or Benchmark and Calculation Approach	Source
Michigan	0.78	FAV of 1,557 µg/L calculated as the lowest Genus Mean Acute Value (GMAV) of 9,500 µg/L for fathead minnow (*Pimephales promelas*) ÷ by a safety factor of 6.1 (following U.S. EPA Great Lakes Initiative [(GLI; U.S. EPA 1995)]. The Acute Maximum Value (AMV) of 0.78 mg/L was then calculated as the FAV ÷ 2. This protective value is a translation of narrative water quality criteria and does not represent a CWA Section 303(c) approved water quality standard for PFOS.	EGLE (2010)
Marine Acute			
Some European Countries	0.0072	Maximum Acceptable Concentration calculated using the lowest acute value (LC_{50}) of 3.6 mg/L for a mysid (*Americamysis bahia*) ÷ by an assessment factor of 500. Dataset includes freshwater and marine aquatic species, combined.	RIVM (2010)
Florida	0.21	Secondary Acute Value (SAV) calculated using U.S. EPA Great Lakes Initiative (GLI; U.S. EPA 1995) Tier II Methodology. FAV calculated as the lowest GMAV (unspecified) divided by a safety factor of 21.9. This value was released in a White Paper sponsored by Florida Department of Environmental Protection and is considered a draft eco-based surface water screening level. It is not a CWA Section 303(c) approved water quality standard.	Stuchal and Roberts (2019)
Freshwater Chronic			
Some European Countries	0.000023	Maximum Permissible Concentration calculated using the lowest value (LOEC) of 0.0023 mg/L for *Chironomus tentans* (MacDonald et al. 2004) ÷ by an assessment factor (100). Dataset includes freshwater and marine aquatic species, combined.	RIVM (2010)

State / Country of Applicability	Aquatic Life Protective Value (mg/L unless otherwise indicated)	Criteria or Benchmark and Calculation Approach	Source
Canada	0.00680	Federal Water Quality Guideline (FWQG) calculated as the fifth percentile value from a Species Sensitivity Distribution (SSD) consisting of 20 species-specific values representing fish (5), amphibians (2), invertebrates (5), and plants and algae (8).	ECCC (2018)
Australia, New Zealand	0.00000023 (99% species protection - high conservation value systems)	Guidelines calculated from Species Sensitivity Distribution (SSD) consisting of 18 species-specific values for fish, amphibians, insects, crustaceans, and algae following the guidance of Warne et al. (2018) and Batley et al. (2014)	CRCCare (2017); EPAV (2017); HEPA (2020)
	0.00013 (95% species protection - slightly to moderately disturbed systems)		
	0.002 (90% species protection - highly disturbed systems)		
	0.031 (80% species protection - highly disturbed systems)		
California	0.00056 (99% species protection)	HC_1 calculated from an acute and chronic NOEC-based SSD as reported in SERDP Project ER18-1614 (SERDP 2019). Acute NOEC values were converted to chronic values using mean acute-to-chronic ratios derived from Giesy et al. (2010). This value represents an "Interim Final Environmental Screening Level" and does not represent a CWA Section 303(c) approved water quality Standard for PFOS.	RWQCB (2020); SERDP (2019)
Texas	0.0051	Acute surface water benchmark calculated using U.S. EPA Great Lakes Initiative (GLI; U.S. EPA 1995) Tier I Methodology as reported in Giesy et al. (2010). This is a chronic surface water benchmark and does not represent a CWA Section 303(c) approved water quality standard for PFOS.	Giesy et al. (2010); TCEQ (2021)

State / Country of Applicability	Aquatic Life Protective Value (mg/L unless otherwise indicated)	Criteria or Benchmark and Calculation Approach	Source
Minnesota	0.019	Chronic Criterion (CC) calculated as the FAV (170 µg/L) ÷ FACR (9.12) per Minnesota Rules Chapter 7050. Two species-specific ACRs and a default ACR were used to calculate the FACR. This draft value does not represent a CWA Section 303(c) approved water quality standard for PFOS.	STS/MPCA (2007)
Florida	0.037	Secondary Chronic Value (SCV) calculated using U.S. EPA Great Lakes Initiative (GLI; U.S. EPA 1995) Tier II Methodology with acute-to-chronic (ACR) of 14.5. SCV = SAV (530 µg/L) ÷ ACR (14.5) = 37 µg/L. This value was released in a White Paper sponsored by Florida Department of Environmental Protection and is considered a draft eco-based surface water screening level. It is not a CWA Section 303(c) approved water quality standard.	Stuchal and Roberts (2019)
Michigan	0.14	Final Chronic Value (FCV) calculated as the FAV (1,557 µg/L) ÷ FACR (11.35) per U.S. EPA Great Lakes Initiative (GLI; U.S. EPA 1995). Two species-specific ACRs and a default ACR were used to calculate the FACR. This protective value is a translation of narrative water quality criteria and does not represent a CWA Section 303(c) approved water quality standard for PFOS.	EGLE (2010)
Marine Chronic			
Australia, New Zealand	0.00000023 (99% species protection - high conservation value systems)	Guidelines calculated from SSD following the guidance of Warne et al. (2018) and Batley et al. (2014) and consisting of nine species-specific values representing fish (2), echinoderms (2), crustaceans (2), mollusc (1), and algae (2). Note: Per HEPA (2020) freshwater values are to be used on an interim basis until final marine guideline values can be set using the nationally agreed process under the Australian and New Zealand Guidelines for Fresh and Marine Water Quality	CRCCare (2017); EPAV (2017); HEPA (2020)
	0.00013 (95% species protection - slightly to moderately disturbed systems)		
	0.002 (90% species protection - highly disturbed systems)		
	0.031 (80% species protection - highly disturbed systems)

Some European Countries	0.0000046	Maximum Permissible Concentration calculated using the lowest value (LOEC) of 0.0023 mg/L for *Chironomus tentans* divided by an assessment factor (500). Dataset includes freshwater and marine aquatic species, combined.	RIVM (2010)
Texas	0.000294	Default guidelines calculated from SSD following the guidance of Warne et al. (2018) and Batley et al. (2014) and consisting of nine of 16 species-specific values as reported in CRCCare (2017). This is a chronic surface water benchmark and does not represent a CWA Section 303(c) approved water quality standard for PFOS.	CRCCare (2017); TCEQ (2021)
California	0.0026 (99% species protection)	HC_1 calculated from an acute and chronic NOEC-based SSD as reported in SERDP Project ER18-1614 (2019). Acute NOEC values were converted to chronic values using mean acute-to-chronic ratios derived from Giesy et al. (2010). This value represents an "Interim Final Environmental Screening Level" and does not represent a CWA Section 303(c) approved water quality Standard for PFOS.	RWQCB (2020); SERDP (2019)
Florida	0.013	Secondary Chronic Value (SCV) calculated using U.S. EPA Great Lakes Initiative (GLI; U.S. EPA 1995) Tier II Methodology with acute-to-chronic (ACR) of 15.6. SCV = SAV (210 µg/L) ÷ ACR (15.6) = 13 µg/L. This value was released in a White Paper sponsored by Florida Department of Environmental Protection and is considered a draft eco-based surface water screening level. It is not a CWA Section 303(c) approved water quality standard.	Stuchal and Roberts (2019)
Fish Tissue			
Canada	9.4 mg/kg whole body ww fish tissue	Federal Fish Tissue Guideline (FFTG) where FFTG of 9.4 mg/kg ww = (FWQG of 6.8 µg/L) * (BAFgeomean of 1378 L/kg)	ECCC (2018)

1.2 Overview of Per- and Polyfluorinated Substances (PFAS)

PFOS, and its salts, belong to the per- and polyfluorinated substances (PFAS) group of chemicals. PFAS are a large group of structurally diverse anthropogenic chemicals that include PFOA, PFOS, and thousands of other fully or partially fluorinated chemicals. There are many families or subclasses of PFAS, and each contains many individual structural homologues and can exist as either branched-chain or straight-chain isomers (Buck et al. 2011; U.S. EPA 2021a). These PFAS families can be divided into two primary categories: non-polymers and polymers. The non-polymer PFAS include perfluoroalkyl and polyfluoroalkyl substances. Polymer PFAS include fluoropolymers, perfluoropolyethers, and side-chain fluorinated polymers (Table 1-2). Several U.S. federal, state, and industry stakeholders as well as European entities have posited various definitions of what constitutes a PFAS. OECD, an international organization comprised of 38 countries, recently published practical guidance regarding the terminology of PFAS (U.S. EPA 2021a). The OECD-led "Reconciling Terminology of the Universe of Per- and Polyfluoroalkyl Substances: Recommendations and Practical Guidance" workgroup provided an updated definition of PFAS, originally posited in part by Buck et al. (2011), as follows: "PFASs are defined as fluorinated substances that contain at least one fully fluorinated methyl or methylene carbon atom (without any H/Cl/Br/I atom attached to it), i.e. with a few noted exceptions, any chemical with at least a perfluorinated methyl group (–CF3) or a perfluorinated methylene group (–CF2–) is a PFAS". It is not within the scope of this framework to compare and contrast the various definitions, or the nuances associated with defining or scoping PFAS; rather the reader of this document is referred to OECD (2021) for review. Generally, the structural definition of PFAS includes chemicals that contain at least one of the following three structures:

NMED Exhibit 62

- R-(CF_2)-CF(R′)R″, where both the CF_2 and CF moieties are saturated carbons, and none of the R groups can be hydrogen (TSCA draft definition);
- R-CF_2OCF_2-R′, where both the CF_2 and CF moieties are saturated carbons, and none of the R groups can be hydrogen; and
- $CF_3C(CF_3)$R′R ″, where both the CF_2 and CF moieties are saturated carbons, and none of the R groups can be hydrogen.

It should also be noted that what defines or constitutes a PFAS may change or evolve over time and under different purviews (e.g., federal, state, international).

Table 1-2. Two Primary Categories of PFAS[1].

PFAS Non-polymers	Structural Elements	Example PFAS Families
Perfluoroalkyl acids	Compounds in which all carbon-hydrogen bonds, except those on the functional group, are replaced with carbon-fluorine bonds	Perfluoroalkyl carboxylic and sulfonic acids (e.g., PFOA, PFOS), perfluoroalkyl phosphonic and phosphinic acids, perfluoroalkylether carboxylic and sulfonic acids
Polyfluoroalkyl acids	Compounds in which all carbon-hydrogen bonds on at least one carbon (but not all) are replaced with carbon-fluorine bonds	polyfluoroalkyl carboxylic acids, polyfluoroalkylether carboxylic and sulfonic acids
PFAS Polymers	**Structural Elements**	**Example PFAS Families**
Fluoropolymers	Carbon-only polymer backbone with fluorines directly attached	polytetrafluoroethylene, polyvinylidene fluoride, fluorinated ethylene propylene, perfluoroalkoxyl polymer
Polymeric perfluoropolyethers	Carbon and oxygen polymer backbone with fluorines directly attached to carbon	F-(CmF2mO-)nCF3, where the CmF2mO represents -CF2O, -CF2CF2O, and/or -CF(CF3)CF2O distributed randomly along polymer backbone
Side-chain fluorinated polymers	Non-fluorinated polymer backbone with fluorinated side chains with variable composition	n:1 or n:2 fluorotelomer-based acrylates, urethanes, oxetanes, or silicones; perfluoroalkanoyl fluorides; perfluoroalkane sulfonyl fluorides

1: Amalgamation of information from Figure 9 of OECD (2021) and Buck et al. (2011).

PFOS belongs to the perfluoroalkyl acids (PFAAs) of the non-polymer perfluoroalkyl substances category of PFAS. PFAAs are among the most researched PFAS (Wang et al. 2017).

NMED Exhibit 62

The PFAA family includes perfluoroalkyl carboxylic, sulfonic, sulfinic, phosphonic, and phosphinic acids (Table 1-3). PFAAs are highly persistent and are frequently found in the environment (Ahrens 2011; Wang et al. 2017). PFAAs may dissociate to their anions in aqueous environmental media, soils, or sediments depending on their acid strength (pK_a value). The protonated and anionic forms may have different physiochemical properties.

NMED Exhibit 62

Table 1-3. Classification and Chemical Structure of Perfluoroalkyl Acids (PFAAs).[1]

Classification	Functional Group	Examples
Perfluoroalkyl carboxylic acids (PFCAs) Or Perfluoroalkyl carboxylates (PFCAs)	-COOH	Perfluorooctanoic acid (PFOA)
	$-COO^-$	Perfluorooctanoate (PFOA)
Perfluoroalkane sulfonic acids (PFSAs) Or Perfluorokane sulfonates (PFSAs)	$-SO_3H$	Perfluorooctane sulfonic acid (PFOS)
	$-SO_3^-$	Perfluorooctane sulfonate (PFOS)[2]
Perfluoroalkyl sulfinic acids (PFSIAs)	$-SO_2H$	Perfluorooctane sulfinic acid (PFOSI)
Perfluoroalkyl phosphonic acids (PFPAs)	$-P(=O)(OH)_2$	Perfluorooctyl phosphonic acid (C8-PFPA)
Perfluoroalkyl phosphinic acids (PFPiAs)	$-P(=O)(OH)(C_mF_{2m+1})$	Bis(perfluorooctyl) phosphinic acid (C8/C8-PFPiA)
Perfluoroalkylether carboxylic acids (PFECAs)	$CF_3(OCF_2)_nCOOH$	Perfluoro (3,5,7-trioxaoctanoic) acid
Perfluoroalkylether sulfonic acids (PFESAs)	$CF_3(OCF_2)_nSO_3H$	6:2 chlorinated polyfluorinated ether sulfonate (6:2 Cl-PFESA)
Perfluoroalkyl dicarboxylic acids (PFdiCAs)	$HOOC-C_nF_{2n}-COOH$	9:3 Fluorotelomer betaine
Perfluoroalkane disulfonic acids (PFdiSAs)	$HO_3S-C_nF_{2n}-SO_3H$	Perfluoro-1,4-disulfonic acid

[1] Modified from Buck et al. (2011); OECD (2021).

[2] The anionic form is most prevalent in the aquatic environment.

Perfluoroalkane (or -alkyl) sulfonic acids (PFSAs), including PFOS, consist of a general chemical structure (of $C_nF_{2n+1}SO_3H$ for PFOS; see Figure 1-1). This chemical structure makes PFOS extremely strong and stable, and resistant to hydrolysis, photolysis, microbial degradation, and metabolism (see Section 2.3) (Ahrens 2011; Beach et al. 2006; Buck et al. 2011). Furthermore, PFOS has been classified as persistent, bioaccumulative, and toxic (Ahrens 2011; Buck et al. 2011; Lindstrom et al. 2011; OECD 2002).

1.2.1 Physical and Chemical Properties of PFOS

Physical and chemical properties along with other reference information for PFOS are provided in Table 1-4. These physical and chemical properties help to define the environmental fate and transport of PFOS in the aquatic environment.

NMED Exhibit 62

Table 1-4. Chemical and Physical Properties of PFOS.

Property	PFOS, acidic form[1]	Source
Chemical Abstracts Service Registry Number (CAS No.)	1763-23-1	
Chemical Abstracts Index Name	1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-heptadecafluoro-1-octanesulfonic acid	
Synonyms	Perfluorooctane sulfonic acid; heptadecafluoro-1-octane sulfonic acid; PFOS acid; perfluorooctane sulfonate	
Chemical Formula	$C_8HF_{17}O_3S$	
Molecular Weight (grams per mole [g/mol])	500.13	Lewis (ed. 2004); HSDB (2012); SRC (2016)
Color/Physical State	White powder (potassium salt)	OECD (2002)
Boiling Point	258–260 °C	SRC (2016)
Melting Point	No data	
Vapor Pressure	2.0×10^{-3} millimeters Mercury (mm Hg) at 25°C (estimate)	HSDB (2012)
Henry's Law Constant	Not measurable; not expected to volatilize from aqueous solution ($< 2.0 \times 10^{-6}$)	ATSDR (2015)
K_{OW}	Not measurable	EFSA (2008); ATSDR (2015)
Organic carbon water partitioning coefficient (K_{OC})	2.57	Higgins and Luthy (2006)
Estimated pKa	3.27 (no empirical measurements available)	Brooke et al. (2004)
Solubility in Water	680 mg/L	OECD (2002)
Half-Life in Water	Stable	UNEP (2006)
Half-Life in Air	Stable	UNEP (2006)

[1] PFOS is commonly produced as a potassium salt (CAS No. 2795-39-3). Properties specific to the salt are not included.

PFOS is moderately water soluble, nonvolatile, and stable (Beach et al. 2006; Young and Mabury 2010). PFOS is solid at room temperature with a low vapor pressure. No direct measurement of the acid dissociation constant (pKa) is available. However, PFOS is considered to have a low pKa, which is based on a calculated pKa of 3.27 provided from Finland in a comment to Brooke et al. (2004). Therefore, PFOS is deemed to be a strong acid (Brooke et al. 2004). PFOS introduced as a salt will dissociate into ionic components when in natural water at a

NMED Exhibit 62

neutral pH and is commonly present as a PFOS anion in solution (Beach et al. 2006; Giesy et al. 2010; Young and Mabury 2010). The PFOS anion forms strong ion pairs with many cations, resulting in less solubility in waters that contain great amounts of dissolved solids. Thus, PFOS solubility in saltwater is approximately 12 mg PFOS/L compared to 589 mg PFOS/L in pure water (Beach et al. 2006). PFOS is reported to have a mean solubility of 56 mg PFOS/L in pure octanol (OECD 2002). These solubility data suggest that any form of PFOS discharged into a water source tends to remain dissolved, unless the PFOS was sorbed to particulate matter or assimilated by organisms (which are both discussed further in Sections 2.2 and 2.5, respectively) (OECD 2002).

Due to the surfactant properties of PFOS, it forms three layers when added to octanol and water in a standard test system used to measure an n-octanol-water partition co-efficient (K_{ow}), thus preventing direct measurement (Giesy et al. 2010; OECD 2002). Although a K_{ow} cannot be directly measured, a K_{ow} for PFOS has been estimated from its individual water and octanol solubilities (Giesy et al. 2010); however, the veracity of such estimates is uncertain (OECD 2002). Lacking a reliable K_{ow} for PFOS precludes application of K_{ow}-based models commonly used to estimate various physiochemical properties for organic compounds, including bioconcentration factors and soil adsorption coefficients. Further, the unusual characteristics of PFOS would bring into question the use of K_{ow} as a predictor of environmental behavior. For example, bioaccumulation of PFOS is thought to be mediated via binding to proteins rather than partitioning into lipids (Giesy et al. 2010; OECD 2002), the latter being the theoretical basis for K_{ow}-based prediction of bioaccumulation.

PFOS is not expected to volatilize from aqueous solution based on its vapor pressure and predicted Henry's law constant < 2.0×10^{-6} (Beach et al. 2006). In 2002, OECD classified PFOS

NMED Exhibit 62

as a type 2, non-volatile chemical that has a very low or possibly negligible volatility (Beach et al. 2006; Giesy et al. 2010; OECD 2002).

2 PROBLEM FORMULATION

A problem formulation provides a strategic framework for water quality criterion development under the CWA by focusing on the most relevant chemical properties and endpoints. In the problem formulation, the purpose of the assessment is stated, the problem is defined, and a plan for analyzing and characterizing risk is developed. The structure of this problem formulation is consistent with the EPA's Guidelines for Ecological Risk Assessment (U.S. EPA 1998).

2.1 Overview of PFOS Sources

2.1.1 Manufacturing of PFOS

PFOS is used in a variety of products including surface treatments for soil and stain resistance, coating of paper as part of a sizing agent formulation, and in specialized applications such as firefighting foams. PFOS is produced through electrochemical fluorination (ECF) in which an organic raw material, such as octane sulfonyl fluoride (OSF; $C_8H_{17}SO_2F$) in the case of PFOS, undergoes electrolysis in anhydrous hydrogen fluoride solution. This electrolysis leads to the replacement of all the hydrogen atoms by fluorine atoms and results in perfluorooctanesulfonyl fluoride (POSF; $C_8F_{17}SO_2F$), which is the major raw material used to manufacture PFOS (Figure 2-1; Buck et al. 2011). The base-catalyzed hydrolysis of POSF results in PFOS and its salts (Lehmler 2005). ECF results in a mixture of linear and branched chain perfluorinated isomers and homologues, with ratios of linear to branched perfluorinated carbon chains of roughly 70 to 80% linear and 20 to 30% branched for PFOS synthesis depending on how the process is controlled (De Voogt 2010). All compounds produced from POSF and other neutral PFAS with sufficient chain length and a sulfur group have the potential to degrade or transform into PFOS, and therefore have been considered to be "PFOS equivalents" and potential sources of PFOS to the aquatic environment (see Section 2.4)(Ahrens

NMED Exhibit 62

2011; Lindstrom et al. 2011). PFOS is used in a variety of products including surface treatments for soil and stain resistance, coating of paper as part of a sizing agent formulation, and in specialized applications such as firefighting foams.

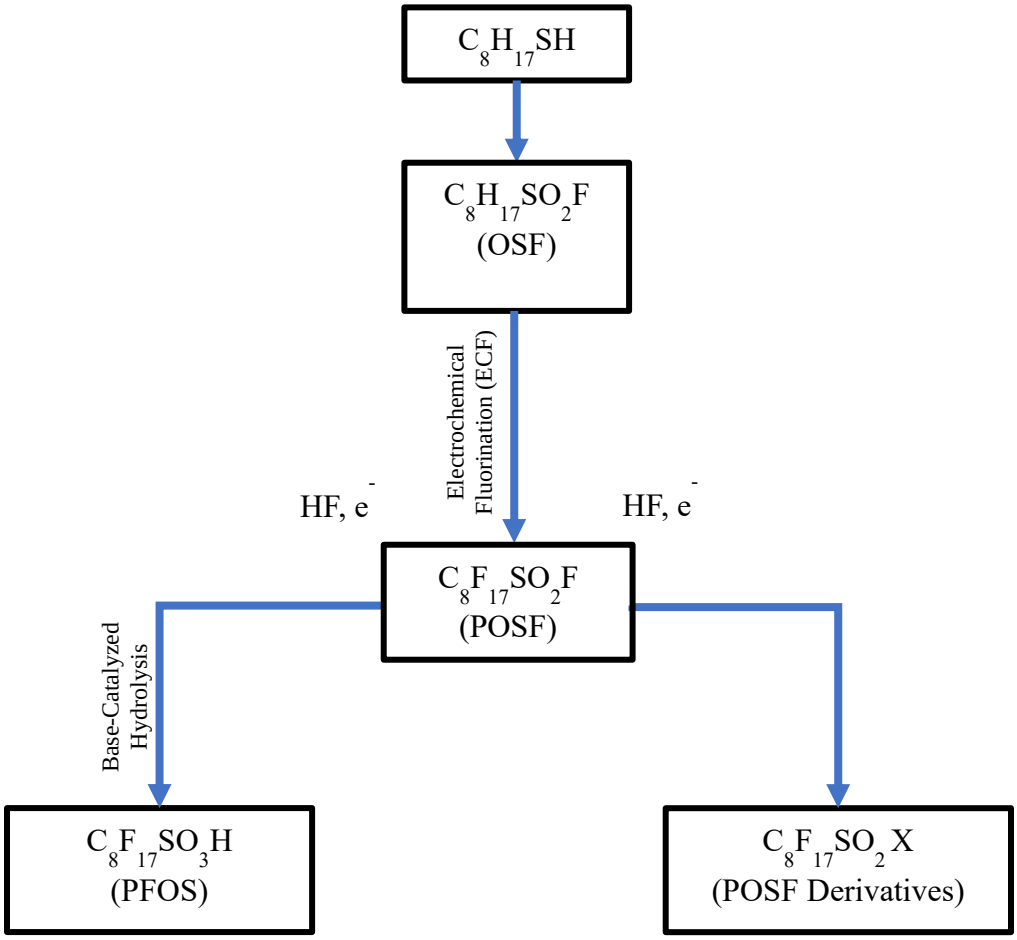

Figure 2-1. Synthesis of PFOS by electrochemical fluorination (ECF).
Modified from Buck et al. (2011).

The manufacture of PFOS started in 1949 with Minnesota Mining and Manufacturing (name changed later to the 3M Company) (3M Company 1999). Prior to 2000, the 3M Company was the major producer of POSF, the raw material used to make PFOS (Figure 2-1), with smaller producers in Europe and Asia (Paul et al. 2009; U.S. EPA 2000a). In 2000, the 3M company manufactured approximately 78% of the estimated global POSF production (approximately

NMED Exhibit 62

3,665 tons of the 4,650 tons produced globally; (approximately 3,665 tons of the 4,650 tons produced globally; OECD 2002). The estimated total cumulative production of POSF is between 44,000 and 96,000 tons (Paul et al. 2009; Prevedouros et al. 2006; Smithwick et al. 2006). Information on previous and current production of POSF from Asia and other production sources is limited (Paul et al. 2009; Prevedouros et al. 2006; Smithwick et al. 2006).

In May 2000, following negotiations between the EPA and 3M, the 3M Company agreed to voluntary phase out and find substitutes for PFOS chemistry used to produce all but a few small applications (i.e., aqueous film-forming foams (AFFF), and hard chrome plating mist suppression) across their range of products by 2002 (Lindstrom et al. 2011; U.S. EPA 2000a). Starting around the same time, a series of Significant New Use Rules (SNUR) were also put into place by the EPA to restrict the production and use of materials that contain PFOS and its precursors in the U.S. (Lindstrom et al. 2011). In 2009, PFOS and related compounds were listed under Annex B of the Stockholm Convention on Persistent Organic Pollutants; restricting global manufacturing and use of PFOS (Ahrens 2011; OECD 2002). Homologues, neutral precursor compounds, and new classes of PFAS continue to be produced and therefore, are potential sources of PFOS (Ahrens 2011). Assuming there was no step-up production of PFOS and its precursors to offset the phase-out by the 3M Company, the production is estimated to be approximately 1,000 tons from 2002 and onward (Paul et al. 2009). However, while industrialized countries, like the U.S., phased-out the use of PFOS and its precursors, producers in other countries, such as China and Brazil, have scaled up their production to fill remaining demand (Wang et al. 2013). Despite the wide use in an array of industrial and consumer products globally, information on the sources, volumes, and emission of PFOS and its precursors are limited (Paul et al. 2009; Zhang et al. 2016).

NMED Exhibit 62

2.1.2 Sources of PFOS to Aquatic Environments

Aquatic environments and soil are thought to serve as a reservoir of PFOS, with 42,000 tons emitted to aquatic environments compared to 235 tons released into to air between 1980 and 2002 (Paul et al. 2009). Unlike other contaminants commonly found in aquatic ecosystems, such as metals for example, PFAS are synthetic compounds with no natural source. Thus, the occurrence of any PFAS in the environment is an indication of anthropogenic sources (Ahrens 2011). The occurrence of PFOS in aquatic environments can be attributed to both point and non-point sources, entering aquatic environments from industrial and consumer products during manufacturing, along supply chains, and during product use and/or disposal (Ahrens 2011; Ahrens and Bundschuh 2014; Kannan 2011; Paul et al. 2009). However, quantitative assessments of PFOS production, point and non-point source discharges, and environmental measurements are limited compared to other persistent, bioaccumulative pollutants (Ahrens and Bundschuh 2014; Zhang et al. 2016).

Potential point sources of PFOS to the aquatic environment include both industrial facilities and municipal wastewater treatment plants (WWTPs). Additional point sources may include surface water runoff from industrial use sites such as metal plating facilities, areas that have received AFFF applications, landfills, and contaminated soils. Of these, industrial facilities, specifically those for fluorochemical manufacturing and other use facilities, are a primary source of PFOS to aquatic systems (Ahrens et al. 2011a; Houtz et al. 2016; Sedlak et al. 2017). Estimated total global releases to water arising from discharge of PFOS during manufacturing from 1970 to 2002 ranged between 230 and 1,450 tons (Paul et al. 2009).

Potential non-point PFOS sources to aquatic environments include: dry and wet atmospheric deposition, runoff from contaminated soils, runoff from metal plating facilities, the runoff or discharge of contaminated groundwater, particularly from the use of fire-fighting

NMED Exhibit 62

foams, and land application of contaminated biosolids (Ahrens 2011; Kannan 2011; OECD 2002; Paul et al. 2009). Identification of non-point PFOS sources and understanding their relative contribution to aquatic ecosystems is difficult due to the lack of sufficient measured environmental data (Ahrens 2011; Paul et al. 2009). Overall, the presence of non-point PFOS sources and their relative contributions are reported to be dependent on the aquatic system, air, groundwater, and soil levels, and nearby land uses. For example, concentrations of PFAS, including PFOS, have been influenced by urban land use (Ahrens 2011; Zhang et al. 2016). Overall, PFOS occurrence in aquatic environments is driven by legacy PFOS sources since PFOS use in the United States was voluntarily phased out by 2002 and SNUR were put into place by the EPA to restrict the production and use of PFOS and its precursors (Lindstrom et al. 2011). However, PFAS concentrations in the environment in general continue to be positively correlated with human population density. For example, PFOS was detected in aquatic systems at elevated concentrations (ranging between 97 and 1,371 ng/L) in densely populated areas of the U.S. and Europe (Zhang et al. (2016) and Loos et al. (2009); respectively), and Paul et al. (2009) estimated the total global PFOS emissions to air and water from 1970 to 2009 resulting from consumer use and disposal to be between 420 and 2,100 tons.

Importantly, PFAS are still produced that can transform or degrade into compounds belonging to the PFSAs family, including PFOS (Ahrens 2011). PFAS precursors such as perfluoroalkyl sulfonamidoacetic acids (FASAAs) and perfluoroalkyl sulfonamidoethanols (FASEs) are known to metabolically transform and degrade to PFOS, respectively (Ahrens and Bundschuh 2014; Benskin et al. 2009; Boulanger et al. 2005b; Buck et al. 2011; Lange 2000; Liu and Mejia Avendano 2013; Plumlee et al. 2008; Rhoads et al. 2008; Wang et al. 2017). However, the understanding of these transformation processes is limited, and additional work is needed to

NMED Exhibit 62

fully understand these processes and their role as sources of PFOS to aquatic environments (Buck et al. 2011; Lau et al. 2007; Liu and Mejia Avendano 2013; Wang et al. 2017). Degradation of precursors represents a potentially significant source of PFOS to the aquatic environment, particularly since PFOS production within the U.S. has not occurred since 2002 (Buck et al. 2011; Liu and Mejia Avendano 2013). Nevertheless, PFOS-treated articles, such as fabrics, paper, and other treated materials, are still being imported into the U.S. and are ultimately, at least in part, released into the environment (Allred et al. 2015; Lang et al. 2016; Liu et al. 2014d). The importation of PFOS treated articles is considered as production under the Toxic Substances Control Act (TSCA) (U.S. EPA 2020).

2.2 Environmental Fate and Transport of PFOS in the Aquatic Environment

2.2.1 Environmental Fate of PFOS in the Aquatic Environment

PFOS has low volatility in ionized form but can adsorb to particles in air where it can be transported globally, including remote locations (Benskin et al. 2012; Butt et al. 2010). PFOS is water soluble and has been found in surface water, ground water, and drinking water. Because of the relatively low K_{oc} of PFOS, it does not easily adsorb to sediments and tends to stay in the water column (Ahrens 2011; Beach et al. 2006; Giesy et al. 2010; Higgins and Luthy 2006).

PFOS can be re-emitted to aquatic environments from PFOS contaminated soil, groundwater, ice, and sediment (see Section 2.3). Sediment may be an important sink of PFOS in the aquatic environment (Ahrens 2011). The movement of PFOS between groundwater, surface water, and sediment depends on the chemical properties of PFOS and site-specific physiochemical characteristics (including pH, temperature, organic carbon content, and salinity) of the aquatic environment. In general, PFOS may sorb to sediments (with a Kd greater than 1 mL/g; (with a Kd greater than 1 mL/g; Giesy et al. 2010). However, this sorption to sediments is limited and PFOS has a K_{oc} of 2.57 indicating that PFOS is relatively mobile in water and the

NMED Exhibit 62

physicochemical characteristics of the sediment ultimately influence the sorption of PFOS (Ahrens 2011; Higgins and Luthy 2006). While the release of PFOS from the transformation of other PFAS and historical products still in use (e.g., consumer goods manufactured, imported and/or obtained before the PFOS discontinuation and regulations) are expected to continue into the future, the re-emissions of PFOS from existing sinks are assumed to be decreasing since the restrictions and regulations of PFOS have gone into place (Ahrens 2011; Ahrens and Bundschuh 2014; Paul et al. 2009; Washington and Jenkins 2015; Washington et al. 2015).

In the water column, and other environmental compartments, PFOS is stable and resistant to hydrolysis, photolysis, volatilization, and biodegradation (see Appendix M)(Beach et al. 2006; OECD 2002). The persistence of PFOS has been attributed to the strong carbon-fluorine (C-F) bond. Additionally, there are limited indications that naturally occurring defluorinating enzymes exist that can break a C-F bond. Consequently, no biodegradation or abiotic degradation processes for PFOS are known. The physiochemical properties discussed in Table 1-4 result in PFOS being highly persistent in the aquatic environment (Ahrens 2011). In aquatic environments, the only dissipation mechanisms for PFOS are physical mechanisms, such as environmental dilution, offsite transport, plant uptake, and sorption.

2.2.2 Environmental Transport of PFOS in the Aquatic Environment

The environmental fate of PFOS, outlined in the previous section (Section 2.2.1) plays a role in the environmental transport of PFOS (Ahrens 2011). PFOS is either distributed in biota (via bioaccumulation discussed in Section 2.5) or abiotic matrices (such as water and sediment). Sediment in particular can act as a sink for PFOS. However, the role of sediment as a sink or source by resuspension is not well understood (Ahrens 2011).

The distribution of PFOS is widespread, including to remote regions despite the limited number of manufacturing facilities and/or small population sizes typically found in these areas

NMED Exhibit 62

(Benskin et al. 2012; Butt et al. 2010). PFOS has been detected in water, sediment, and biota samples from aquatic environments in remote areas (Butt et al. 2010; Giesy and Kannan 2001; Houde et al. 2006b; Yamashita et al. 2008). To date, the dominant transport pathway for PFOS to remote regions has not been conclusively characterized and much of the focus has been on marine systems, with few studies in freshwater environments (Ahrens 2011; Butt et al. 2010; Giesy and Kannan 2002). Additionally, the relative importance of each potential transport pathway is difficult to accurately determine (Butt et al. 2010; Young and Mabury 2010). Many researchers suggest that the dominant mechanism of PFOS transport occurs through water as the anionic form of PFOS, which is the most commonly found form in the aquatic environment, is less volatile (see Section 2.2.1 above) and has a high water solubility. These characteristics make partitioning to and transport through the air less likely (Butt et al. 2010; Giesy and Kannan 2002). However, PFOS transport through water is likely the dominant mechanism on more local scales (e.g., within a waterbody or watershed), and is likely not the prevailing transport pathway of PFOS to remote regions given the considerations of the long distances. Instead, atmospheric transport is likely the main mechanism of PFOS transport to remote regions. Another potential source to remote regions is the indirect formation of PFOS through transformation of other PFAS, particularly volatile precursors (see Section 2.3)(Butt et al. 2010; Wang et al. 2015; Young and Mabury 2010).

Volatile PFOS precursors, which may reach remote locations via atmospheric deposition themselves, may subsequently be metabolized to PFOS in aquatic organisms (Giesy and Kannan 2002). In all likelihood, the continued presence of PFOS in remote areas may be due to multiple exposure pathways, including those caused by direct production and use of PFOS itself as well as degradation and transformation of precursor compounds (Armitage et al. 2009). To better

NMED Exhibit 62

comprehend both environmental transport and exposure to PFOS, the following needs to be better understood: 1) the potential transformation, metabolism, and bioaccumulation of PFOS and its precursors (particularly partitioning behavior, such as tissue distribution and lipophilicity); 2) explicit biotransformation pathways and pharmacokinetics; and 3) atmospheric fate and transport of PFOS and its precursors (Armitage et al. 2009).

2.3 Transformation and Degradation of PFOS Precursors in the Aquatic Environment

Transformation and degradation processes of various PFAS are potential sources of PFOS to the aquatic environment (see Section 2.1.2 above). PFAS are still produced that can transform or degrade into compounds belonging to the PFSAs family of PFAS, including PFOS (Ahrens 2011). Thus, transformation and degradation of PFAS should be considered as an ongoing potential source of PFOS to the aquatic environment. Currently, the understanding of these transformation and degradation processes is limited, particularly for PFOS. There is little understanding of which PFAS and how much of each has been or will be released into the aquatic environment (Liu and Mejia Avendano 2013; Wang et al. 2017). Additional work is needed to fully understand the details of these processes and the occurrence of the compounds to better comprehend their role as a source of PFOS to aquatic environments (Lau et al. 2007).

These transformation and degradation pathways are dependent on environmental conditions, degradation kinetics, and the chemical structures and properties of the individual PFAS precursors and volatile PFAS (Buck et al. 2011; Butt et al. 2014; Liu and Mejia Avendano 2013). Of particular importance is the environmental stability of key chemical linkages (such as esters and ethers) as the stability of these chemical linkages determines the stability of the overall PFAS (Liu and Mejia Avendano 2013). The most well studied PFAS precursors are fluorotelomer-based compounds, which are produced through telomerization technology and are

NMED Exhibit 62

associated with PFOA as the final product (Buck et al. 2011; Liu and Mejia Avendano 2013). In contrast, perfluoroalkane sulfonamido derivatives and other PFAS, such as side-chain-fluorinated polymers, are not as well studied.

It is essential to understand the biodegradation of volatile PFAS, such as perfluroalkane sulfonamido derivatives as their degradation is directly linked with PFOS generation in the environment (Liu and Mejia Avendano 2013). Most published studies on the degradation of perfluoroalkane sulfonamido derivatives focus on those with eight fluorinated carbons since PFOS is a final product (Buck et al. 2011). *N*-ethyl perfluorooctane sulfonamidoethanol (EtFOSE) in particular is the most commonly studied.

2.3.1 Degradation of perfluoroalkane sulfonamido derivatives

Perfluoroalkane sulfonamido derivatives, including perfluoroalkane sulfonamides, sulfonamidoethanols, sulfonamidoethyl acrylates, and sulfonamidoethyl methacrylates, are final products on their own and are important building blocks for further synthesis (Buck et al. 2011). The various derivatives have been found to degrade into PFSAs, such as PFOS when sufficient chain length is present, and are intermediates along the transformation pathway. These derivatives include members of the *N*-ethyl perfluoroalkane sulfonamidoacetic acids (EtFASAAs), *N*-ethyl perfluoroalkane sulfonamides (EtFASAs), perfluoroalkane sulfonamidoacetic acids (FASAAs), perfluoroalkane sulfonamids (FASAs), FASA *N*-glucuronides, and perfluoroalkane sulfinic acids (PFSiAs; Buck et al. 2011). Additionally, in the environment *N*-alkyl perfluoroalkane sulfonamidoethyl acrylates and methacrylates (and polymers based on them) may undergo hydrolysis of the ester linkages to produce *N*-alkyl perfluoroalkane sulfonamidoethanols (FASEs; Buck et al. 2011).

In particular, several studies have demonstrated that EtFOSE, a member of the *N*-alkyl perfluoroalkane sulfonamidoethanols of the perfluoroalkane sulfonamido substances, degrades

NMED Exhibit 62

into PFOS (Benskin et al. 2009; Boulanger et al. 2005b; Hatfield 2001; Lange 2000; Plumlee et al. 2009; Rhoads et al. 2008). EtFOSE was a product of ECF and was a precursor compound for the synthesis of other products such as phosphate esters that were used to manufacture paper protectors (3M Company 1999). Several studies have investigated the degradation of EtFOSE and all found that it is prone to degradation (Benskin et al. 2009; Boulanger et al. 2005b; Hatfield 2001; Lange 2000; Plumlee et al. 2009; Rhoads et al. 2008).

The overall pathway of EtFOSE degradation was determined to be the major difference between these studies (Figure 2-2). Rhoads et al. (2008) determined that EtFOSA could undergo direct dealkylation to form perfluorooctane sulfonamide (FOSA; as shown by the red arrow in Figure 2-2). Lange (2000) suggested that PFOA could be formed as a minor end product through an abiotic one-electron transfer mechanism from perfluorooctane sulfinic acid (PFOSI; demonstrated by the blue arrow in (Figure 2-2). In contrast, the other studies did not find PFOA to be a degradation product (Benskin et al. 2013; Boulanger et al. 2005b; Rhoads et al. 2008). Further, in the aerobic biodegradation studies, the rate limiting step was determined to be the degradation of *N*-ethyl perfluorooctane sulfonamidoacetic acid (EtFOSAA) and consequently EtFOSAA was the major degradation product rather than PFOS (Liu and Mejia Avendano 2013). Nevertheless, the degradation of EtFOSE resulted in the formation of PFOS as one of the final degradation products. In contrast, in the abiotic degradation studies, PFOS and PFOSI were either present at trace concentrations or were not observed (Hatfield 2001; Plumlee et al. 2009). Instead FOSA was considered to be the stable end product (Plumlee et al. 2009). The differences in the degradation pathways observed in the literature can likely be attributed to environmental conditions (Buck et al. 2011; Liu and Mejia Avendano 2013). Nevertheless, these pathways demonstrated that degradation of EtFOSE resulted in the formation of PFOS and should be

NMED Exhibit 62

considered a potential source of PFOS to the aquatic environment. However, currently the relative contribution of this potential source to the aquatic environment cannot be quantified (Buck et al. 2011; Liu and Mejia Avendano 2013).

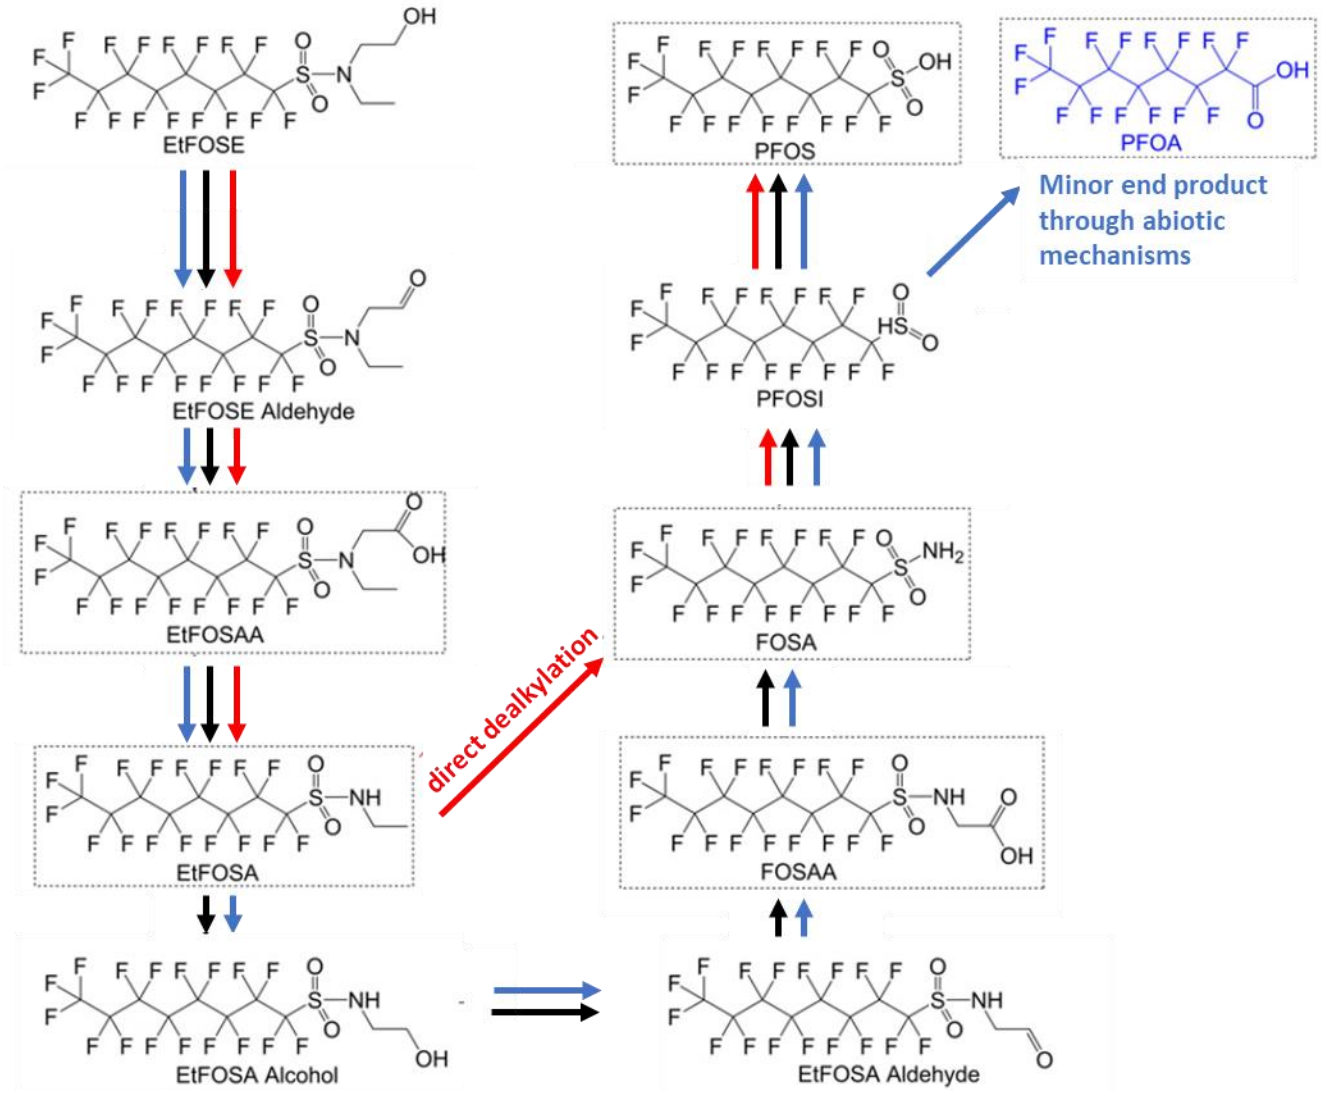

Figure 2-2. Aerobic Biodegradation of EtFOSE in Activated Sludge.
Black arrows show the Aerobic Biodegradation pathway as described by Liu and Mejia Avendano (2013). Blue pathway was observed by Lange (2000). Red pathway was observed by Rhoads et al. (2008). Semi-stable compounds are shown inside boxes.
Modified from: Liu and Mejia Avendano (2013).

2.3.2 Perfluorooctane sulfonamide-based side-chained polymers

In contrast to some other PFAS described in Section 1.2, fluorinated side-chain polymers do not have the per- or polyfluorinated backbone. Instead, fluorinated side-chain polymers consist of a variable composition with per- and polyfluoroalkyl side chains (Buck et al. 2011). The side chains of each of these polymer types may serve to transform into PFAS. Currently, little is known about these transformation processes (Liu and Mejia Avendano 2013). Given the high production volume of perfluorooctane-sulfonamide-based side-chain polymers prior to 2002, these fluorinated side-chain polymers may contribute to the levels of PFAS in the environment. It remains unknown how much these polymers contribute to the PFSAs in the environment (Liu and Mejia Avendano 2013). However, this transformation process is expected to occur over a long period of time (e.g., > 1,000 years) and may be a relatively small contributor of PFAS, including PFOS, in the environment (Buck et al. 2011).

2.3.3 Fluoroalkyl surfactants used in AFFFs

The release of AFFF during firefighting activities has been determined to be a substantial source of PFOS to the aquatic environment (see Section 2.1.2). Since 2002, fluorinated alternatives to PFAAs have been used to manufacture AFFF (Buck et al. 2011; Wang et al. 2013). The ten classes of AFFF chemicals have been identified and show that the new formulations of AFFF include the eight carbon perfluoroalkyl moiety (Place and Field 2012). Some of these fluorinated alternatives may undergo transformation and degradation processes and therefore may contribute to the levels of PFOS occurring in the aquatic environment (Liu and Mejia Avendano 2013). However, additional details about the transformation and degradation processes, including specific transformation pathways, the time to undergo transformation to produce a final product, and the influence of the environmental condition, are lacking at this time (Liu and Mejia Avendano 2013; Wang et al. 2013).

NMED Exhibit 62

2.4 Environmental Monitoring of PFOS in Abiotic Media

PFOS has been detected in a variety of environmental abiotic matrices in aquatic environments around the globe. These abiotic media include surface water, soils, sediments, groundwater, air, and ice caps (Butt et al. 2010; Lau et al. 2007). Water is expected to be the primary environmental medium in which PFOS is found (Lau et al. 2007). Occurrence and detection of PFOS in surface waters is described below and occurrence in other abiotic media is described in Appendix N.

2.4.1 PFOS Occurrence and Detection in Ambient Surface Waters

2.4.1.1 Summary of PFOS occurrence and concentrations across the U.S.

PFOS is one of the dominant PFAS detected in aquatic ecosystems, along with PFOA (Ahrens 2011; Benskin et al. 2012; Dinglasan-Panlilio et al. 2014; Nakayama et al. 2007; Remucal 2019; Zareitalabad et al. 2013). Despite its wide use and persistence in the aquatic environment, current information on the distribution of PFOS in surface waters of the U.S. is relatively limited (Jarvis et al. 2021). Available data are largely collected from freshwater systems in eastern states, with most of the current, published PFOS occurrence data focused on a handful of study areas with known manufacturing or industrial uses of PFAS and among areas of known AFFF use, such as fire-training areas on military bases (Figure 2-3 and Appendix N).

NMED Exhibit 62

/

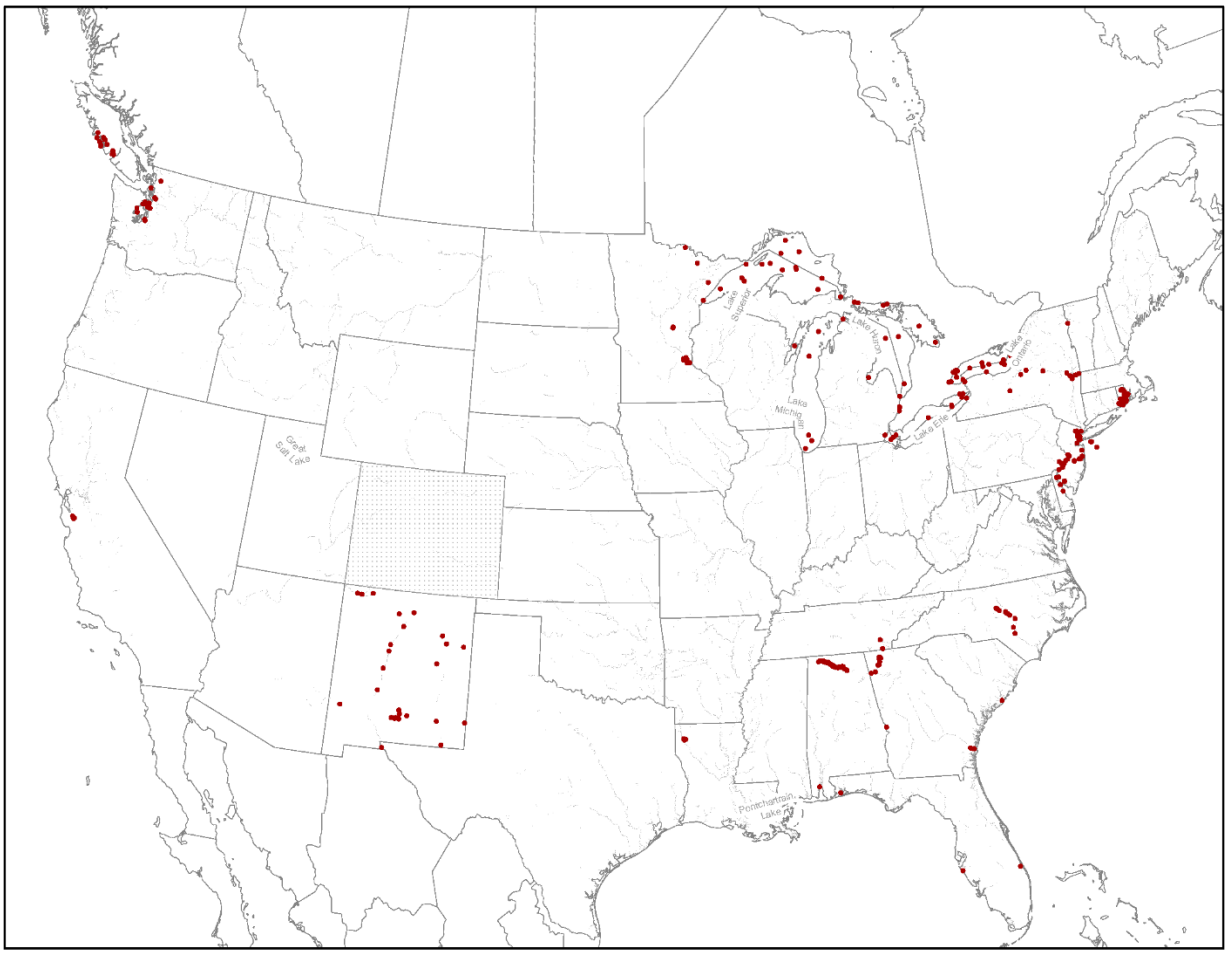

Figure 2-3. Map Indicating Sampling Locations for Perfluorooctane Sulfonate (PFOS) Measured in Surface Waters across the United States (U.S.).

Based on data reported in the current, publicly available literature. Sampling locations for the Colorado data were not available. Therefore, dash marks were used to indicate that measured PFOS surface water concentrations were available for Colorado; however, the exact sampling locations within the state were not publicly available. Detailed information on sampling locations, including references, coordinates (with the exception of Colorado), and sampling site identification numbers and names, are provided in Appendix N.

Modified from: Jarvis et al. (2021).

NMED Exhibit 62

Concentrations of PFOS in surface waters across the U.S. appear to vary widely, with observed concentrations ranging over eight orders of magnitude. PFOS is generally detected in the picogram and nanogram per liter range with reported concentrations in microgram per liter (or part-per-trillion) ranges (Ahrens 2011; Zareitalabad et al. 2013). For the purposes of this overview, all concentrations reported here are in nanogram per liter (ng/L). Measured surface water concentrations of PFOS in peer-reviewed journal articles and publicly available industry and government reports range between 0.074 and 8,970,000 ng/L with an arithmetic mean concentration of 786.77 ng/L and a median concentration of 3.6 ng/L (Figure 2-4) (Jarvis et al. 2021). However, it should be noted that the mean and median concentrations reported in Jarvis et al. (2021) were calculated from the reported concentrations for individual samples and therefore, are not fully representative of all the measured PFOS concentrations in U.S. surface waters. Additionally, as demonstrated by the median concentration of 3.6 ng/L, a majority (roughly 91%) of measured PFOS concentrations were found to fall below 300 ng/L (Jarvis et al. 2021).

NMED Exhibit 62

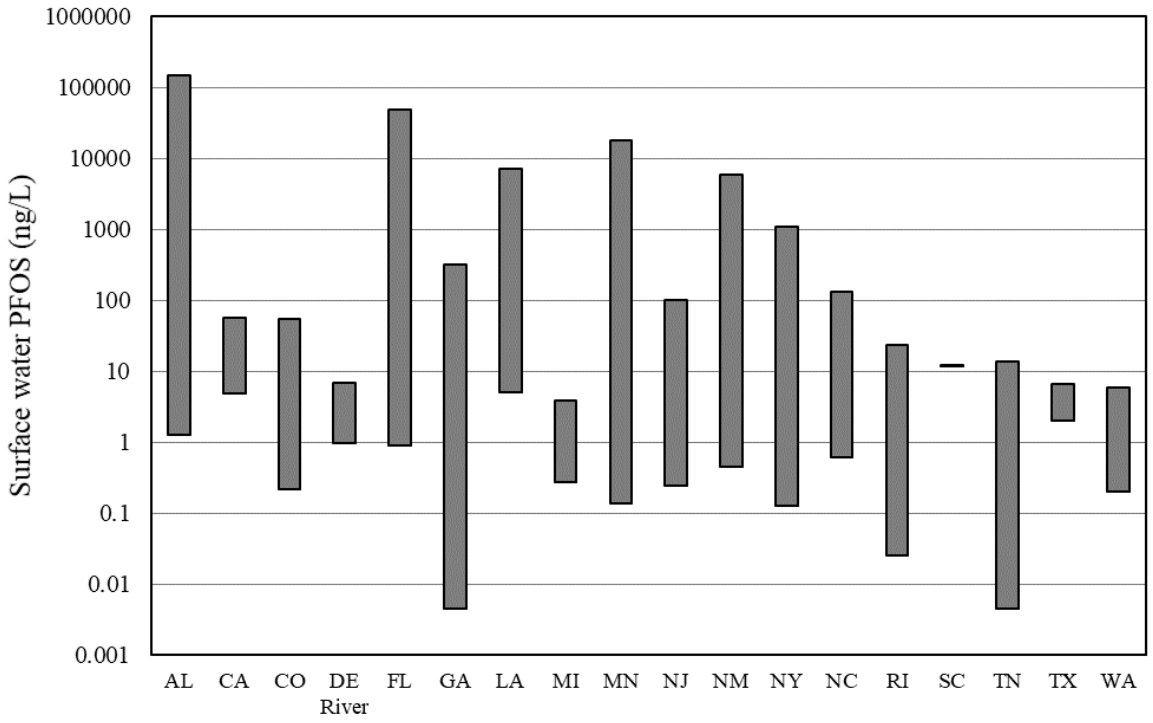

Figure 2-4. Distribution of the Minimum and Maximum Concentrations (ng/L) of Perfluorooctane Sulfonate Measured in Surface Waters for Each State or Waterbody (excluding the Great Lakes) with Reported Data in the Publicly Available Literature.
The distribution is arranged alphabetically by state and waterbody. The measurements in the Delaware River (DE River) could not be contributed to one specific state, and therefore the waterbody is listed.
Modified from: Jarvis et al. (2021).

Numerous available studies report measured PFOS concentrations in surface waters across the U.S. (Appendix N), some of which are summarized in (Jarvis et al. 2021); however, more detailed information on PFOS occurrence in areas not previously sampled and spatial and temporal variability of PFOS remain limited. Prior to the review by Jarvis et al. (2021), there were few analyses of spatial variability of PFOS concentrations in surface water across the U.S (Remucal 2019). Jarvis et al. (2021) indicates that the presence and measured concentrations of PFOS in surface waters are similar between lotic and lentic systems, based on the limited data available (Jarvis et al. 2021)(Appendix N). And as mentioned in the sources of PFOS section above (Section 2.1.2), in contrast with other contaminants commonly found in aquatic ecosystems, PFOS is a synthetic compound with no natural source. Thus, the occurrence of

NMED Exhibit 62

PFOS in water is a result of the presence of an anthropogenic source, a transport pathway (air, surface water, or ground water), and the persistence and mobility of the PFOS in the environment. Therefore, PFOS concentrations in surface water tend to be dependent on the presence of a nearby source and generally increase with levels of urbanization.

Further, there are insufficient data to quantitatively evaluate temporal trends of PFOS in surface waters across the U.S. (Remucal 2019). However, recent studies have suggested that PFOS concentrations in surface waters with limited sampling sites in northeastern states appear to have decreased since the voluntary phase out of PFOS in 2002 (Pan et al. 2018; Zhang et al. 2016). While these studies observed lower measured PFOS concentrations in surface waters compared to those reported in earlier reports (Hansen et al. 2002; Nakayama et al. 2007), few studies have measured PFOS concentrations from the same sampling sites over time (Jarvis et al. 2021). Eight studies (six focused on the Great Lakes and two in New York on the Hudson River) measured PFOS in the same waterbody over time (Appendix N). Thus, the observed lower concentrations reported in recent literature could be due to trends of PFOS concentrations decreasing since the 2002 PFOS phaseout, differences in sampling site locations, and/or advances in analytical methods for detecting PFOS that reduced detection limits (Jarvis et al. 2021).

Despite the wide use and persistence of PFOS in aquatic ecosystems and unlike the extensive sampling of PFOS in drinking water sources[1], groundwater, and fish tissue monitoring[2], current information on the environmental distribution of PFOS in ambient surface

[1] EPA's database for the Unregulated Contaminant Monitoring Rule (UCMR) that includes data for treated surface waters (https://www.epa.gov/dwucmr).
[2] EPA's National Rivers and Streams Assessment (NRSA; https://www.epa.gov/national-aquatic-resource-surveys/ncca) and the Great Lakes Human Health Fish Tissue Study component of the EPA National Coastal Condition Assessment (NCCA/GL).

NMED Exhibit 62

waters across the U.S. remains very limited. More recent sampling efforts indicate that PFOS occurrence may be more widespread. PFOS was detected in almost all collected surface water samples, which can likely be attributed to improvements in analytical methods that lowered the PFOS detection limit compared to older analytical methods (Gewurtz et al. 2013).

Thus, from the currently available data, which were largely collected from freshwater systems in eastern states and in the Upper Midwest with known manufacturing or industrial uses of PFAS or use of AFFF, PFOS concentrations measured in U.S. surface waters appear to vary widely, across eight orders of magnitude (Jarvis et al. 2021). PFOS concentrations in remote areas (i.e., areas with little to no PFAS manufacturing and/or industrial uses) range between 0.074 to 23.23 ng/L (Jarvis et al. 2021). This contrasts with PFOS concentrations measured in areas with known PFAS manufacturing, industrial use, and/or application of AFFF, which vary widely and reach up to the maximum observed concentration of 8,970,000 ng/L at a site impacted by AFFF (Appendix N). While current PFAS occurrence data illustrate the prevalence and quantify concentrations of PFOS in surface waters across the U.S., additional data, particularly in central, southwestern, and western freshwaters as well as saltwater systems, are needed to better understand PFOS occurrence in aquatic ecosystems across the U.S. (Jarvis et al. 2021). See Appendix N for further discussion of PFOS occurrence in surface waters and other abiotic media such as aquatic sediments, groundwater, air, and ice.

2.5 Bioaccumulation and Biomagnification of PFOS in Aquatic Ecosystems

PFAS, including PFOS, are found in aquatic ecosystems around the globe (e.g., Ankley et al. 2020; Giesy and Kannan 2001; Houde et al. 2008). Although they were used predominantly in more populated areas, these compounds are resistant to hydrolysis, photolysis, and biodegradation (see Section 2.2), facilitating their long-range transport to aquatic ecosystems in

NMED Exhibit 62

the remote arctic and mid-oceanic islands (see Section 2.2.2) (Haukas et al. 2007; Houde et al. 2006b). Several physical-chemical properties of PFOS contribute to bioaccumulation within aquatic species once they have entered an ecosystem.

2.5.1 PFOS Bioaccumulation in Aquatic Life

In contrast to many persistent organic pollutants, which tend to partition to fats, PFOS preferentially binds to proteins. Within an organism PFOS tends to bioaccumulate within protein-rich tissues, such as the blood serum proteins, liver, kidney, and gall bladder (De Silva et al. 2009; Jones et al. 2003; Martin et al. 2003a; Martin et al. 2003b). PFOS also binds to ovalbumin, and the transfer of PFOS to such albumin in eggs can be an important mechanism for depuration in female oviparous species, as well as a mechanism for maternal transfer of PFOS to offspring (Jones et al. 2003; Kannan et al. 2005).

The stability of PFOS contributes to its bioaccumulation potential, as it has not been found to undergo biotransformation within the organism (Martin et al. 2003a; Martin et al. 2003b). Within an organism, PFOS undergoes enterohepatic recirculation, in which PFOS is excreted from the liver in bile to the small intestine, then reabsorbed and transported back to the liver (Goecke-Flora and Reo 1996). This process becomes increasingly more efficient the longer the perfluorinated chain length is, resulting in longer biological half-lives for chemicals like PFOS with a relatively long chain length, as they are less readily excreted. PFAS with sulfonate head groups, such as PFOS, are more efficiently resorbed by the small intestine than carboxylate PFAS such as PFOA, resulting in higher bioaccumulation levels (Hassell et al. 2020; Jeon et al. 2010; Martin et al. 2003a).

Sex differences in the elimination rates of PFOS in addition to the transfer of PFOS to albumin in eggs (e.g., Jones et al. 2003; Kannan et al. 2005) have not been well studied. Some research suggests lower PFOS elimination rates in female rats than in male rats (Butenhoff et al.

NMED Exhibit 62

2012; Chang et al. 2012; Pizzurro et al. 2019), suggesting potentially longer retention of PFOS in females. However, this difference was not observed in mice, rabbits, monkeys, or humans (Pizzurro et al. 2019). In contrast to PFOS, PFOA elimination rates are higher in females than in males for both female fathead minnows (Lee and Schultz 2010) and rats (Pizzurro et al. 2019), suggesting potential longer retention of PFOA in males. These data indicate further research across species and genders for PFAS elimination rates may be useful.

The structure of PFOS also affects its bioaccumulation potential, with linear forms being more bioaccumulative than branched forms (Fang et al. 2014; Hassell et al. 2020). The preferential accumulation of linear PFOS occurs because the elimination rate of branched isomers of PFOS is higher, particularly across gill surfaces (Hassell et al. 2020). This pattern has also been observed in the field, as the proportion of branched isomers was higher in water and sediment compared to fish tissue in Taihu Lake, China (Fang et al. 2014) and Lake Ontario (Houde et al. 2008).

2.5.2 Factors Influencing PFOS Bioaccumulation and Biomagnification in Aquatic Ecosystems

Because of their affinity for binding to proteins, PFAS can enter the base of the food web through sorption to organic matter in sediments or biofilms (Higgins and Luthy 2006; Jeon et al. 2010; Penland et al. 2020), or can bind to blood proteins at gill surfaces of aquatic organisms through respiration (De Silva et al. 2009; Hassell et al. 2020; Martin et al. 2003a; Martin et al. 2003b).

PFAS binding to the surface of sediment organic matter and biofilms is influenced by both hydrophobic and electrostatic effects, resulting from the hydrophobicity of the perfluorinated chain and the hydrophilicity of the sulfonate or carboxylate head groups (Higgins and Luthy 2006)(see Section 2.2 for further details on the sorption of PFOS). Overall, these results suggest that sorption to sediments should be an important mechanism for PFOS entry into

NMED Exhibit 62

an aquatic ecosystem, but that subsequent dietary uptake from benthic feeding organisms will be more important for PFOS than PFOA.

The importance of the sediment pathway for PFOS bioaccumulation in aquatic ecosystems has been demonstrated in laboratory studies with *Chironomus riparius* (Bertin et al. 2014), *C. plumosus* (Wen et al. 2016), *Gammarus fossarum* and *G. pulex* (Bertin et al. 2016), and *Lumbriculus variegatus* (Lasier et al. 2011), where PFOS concentrations were positively correlated between sediments and whole-body tissue samples of benthic feeding organisms. The sediment pathway has also been demonstrated in several field studies, where PFOS was measured in sediments and biofilms, and was higher in benthic-feeding invertebrates relative to pelagic-feeding invertebrates (Lescord et al. 2015; Loi et al. 2011; Martin et al. 2004; Penland et al. 2020). In addition, the distribution of PFAS in sediments was more similar to their distribution in the tissues of benthic invertebrates (Lescord et al. 2015) and fish (Thompson et al. 2011) than they were to their distribution in pelagic organisms.

PFAS can also enter aquatic organisms directly from the water column through respiration. Because of its binding affinity to proteins, PFOS can enter the body of gill-breathing organisms by binding to proteins in the blood at gill surfaces (Jones et al. 2003; Martin et al. 2003a; Martin et al. 2003b). The relative distribution of PFOS in tissues is related to the primary route of exposure (dietary or respiratory). In rainbow trout, the rank order of PFOS concentrations following aqueous exposure was blood > kidney > liver (Martin et al. 2003a). In contrast, their rank order following dietary exposure was liver > blood > kidney (Goeritz et al. 2013). Hong et al. (2015) observed the highest concentrations of PFOS in the intestines of green eel goby, soft tissues, shell, and legs of shore crabs; and gills and intestines of oysters, suggesting

NMED Exhibit 62

bioaccumulation through both dietary and aqueous uptake in invertebrates, and primarily dietary uptake in fish.

In addition to being bioaccumulative, PFOS has been shown to biomagnify with increasing trophic level in a variety of freshwater ecosystems (Kannan et al. 2005; Martin et al. 2004; Penland et al. 2020; Xu et al. 2014) and saltwater ecosystems (de Vos et al. 2008; Houde et al. 2006b; Loi et al. 2011; Powley et al. 2008; Tomy et al. 2004) in North America, Europe, and Asia. PFOS is often the most abundant PFAS in aquatic organisms, and this high relative abundance is at least partially explained by the biotransformation of PFOS precursor chemicals into PFOS (see Section 2.3)(Haukas et al. 2007; Kannan et al. 2005; Kelly et al. 2009; Martin et al. 2004; Tomy et al. 2004). Higher trophic level organisms have a greater capacity to metabolize PFOS precursor chemicals, which have been found in lower concentrations in increasing trophic level (Fang et al. 2014; Kannan et al. 2005; Martin et al. 2004). This suggests that in addition to biomagnification, some of the trophic-level increase in PFOS can be explained by the biotransformation of precursor chemicals.

2.5.3 Environmental Monitoring of PFOS in Biotic Media

PFOS is one of the dominant PFAS detected in aquatic ecosystems, along with PFOA (Ahrens 2011; Benskin et al. 2012; Dinglasan-Panlilio et al. 2014; Remucal 2019; Zareitalabad et al. 2013). PFAS were first detected in human serum samples in the late 1960s, and subsequent studies across several continents demonstrated the global distribution of PFAS in humans (Giesy and Kannan 2001; Houde et al. 2006b). Since then, the global distribution of PFAS in tissues of aquatic species has been demonstrated in studies conducted in freshwater and marine environments across every continent, including remote regions far from direct sources, such as the high arctic, Antarctica, and oceanic islands (Giesy and Kannan 2001; Houde et al. 2006b).

NMED Exhibit 62

In lentic surface waters of the U.S., one of the most comprehensive studies of PFOS concentrations included fish muscle tissue data from 157 near shore sites across the Great Lakes selected following a probabilistic design as part of the 2010 National Coastal Condition Assessment (Stahl et al. 2014). In this study, PFOS was measured in fish collected at every site, with a median concentration of 15.2 ng/g ww (Stahl et al. 2014). Lake trout (31% of sampled species), smallmouth bass (14%), and walleye (13%) were the most commonly-sampled species from the Great Lakes samples, and the average PFOS concentrations in lake trout muscle were more than twice as high as PFOS concentrations in muscle of smallmouth bass and walleye (Stahl et al. 2014).

Martin et al. (2004) measured PFOS in whole body samples of invertebrates and fish in Lake Ontario, near the town of Niagara-on-the-Lake. PFOS concentrations were much higher in the benthic amphipod *Diporeia hoya* (280 ng/g ww) than in the more pelagic *Mysis relicta* (13 ng/g ww), suggesting sediments are an important source of PFOS in this area (Martin et al. 2004). Among the four fish species sampled, whole body PFOS concentrations were highest in the slimy sculpin (450 ng/g ww), whose preferred food source is *D. hoya* (Martin et al. 2004). Although adult lake trout occupy the highest trophic level at this site, based on nitrogen stable isotope analysis, their PFOS concentrations were less than half (170 ng/g ww) of those measured in sculpin, as their food web is largely pelagic, and not affected by the high sediment PFOS concentrations. Based on stomach content analysis, 90% of the adult lake trout diet consists of alewife, which feed primarily on the more pelagic *M. relicta*, and have the lowest average PFOS concentration (46 ng/g ww) among all fish species (Martin et al. 2004).

Guo et al. (2012) measured PFOS in lake trout muscle tissues in Canadian waters of Lake Superior, Huron, Erie, and Ontario. Average PFOS concentrations correlated with watershed

NMED Exhibit 62

urbanization, and were 0.85, 8.3, 27, and 46 ng/g ww, respectively (Guo et al. 2012). Delinsky et al. (2010) measured PFOS in bluegill, black crappie, and pumpkinseed muscle tissue in 59 lakes in Minnesota, including four lakes in the Minneapolis-St. Paul metropolitan area. PFOS was detected in muscle tissues of fish collected in 13 of the 59 lakes, and concentrations ranged from 1.08 to 52.4 ng/g ww in lakes where it was detected. In the four lakes in the Minneapolis-St. Paul metropolitan area, PFOS concentrations in fish muscle tissues ranged from 4.39 to 47.3 ng/g ww (Delinsky et al. 2010).

In flowing surface waters of the U.S., one of the most comprehensive fish PFOS monitoring studies included the collection of fish muscle tissue data from 164 urban river sites (5^{th} order or higher) across the conterminous U.S. selected following a probabilistic design. The study was part of the 2008 - 2009 National Rivers and Streams Assessment and the National Coastal Condition Assessment (Stahl et al. 2014). PFOS was detected in 73% of the urban river sites, with a median concentration of 10.7 ng/g ww (Stahl et al. 2014). Largemouth bass (34% of sampled species), smallmouth bass (25%), and channel catfish (11%) were the most commonly sampled species from the urban stream sites, and PFOS concentrations in the muscles of largemouth bass were approximately twice as high as concentrations in the muscles of smallmouth bass (Stahl et al. 2014).

Ye et al. (2008) reported average PFOS concentrations of 83.1, 84.6, and 147 ng/g ww from whole body composite samples of multiple fish species from the Mississippi River, Missouri River, and Ohio River, respectively. Delinsky et al. (2010) sampled PFOS in bluegill, black crappie, and pumpkinseed muscle tissue at several locations along the upper Mississippi River in 2007, and found concentrations ranging from 3.06 ng/g ww at unimpacted sites to 2,000 ng/g ww at Pool 2, a heavily impacted site in the Minneapolis-St. Paul metropolitan area

NMED Exhibit 62

(Delinsky et al. 2010). Malinsky et al. (2011), as reported in Stahl et al. (2014), measured PFOS concentrations ranging from 41.7 to 180 ng/g ww in fish muscle samples collected along the Mississippi River, with the lowest concentration reported for sauger and the highest reported for bluegill.

Kannan et al. (2005) measured PFOS in invertebrates and vertebrates from two rivers in Southern Michigan (Raisin River, St. Claire River), and one in Northern Indiana (Calumet River). PFOS concentrations were similar across sites for the different taxa and suggested trophic biomagnification for PFOS. Among invertebrate taxa, zebra mussel PFOS soft tissue whole body concentrations ranged from below detection to 3.1 ng/g ww, amphipod whole body concentrations ranged from below detection to 2.9 ng/g ww, and crayfish whole body concentrations ranged from 2.4 to 4.3 ng/g ww. Among fish, PFOS concentrations in round goby whole body samples ranged from 6.6 to 21.5 ng/g ww, and smallmouth bass muscle samples ranged from below detection to 41.3 ng/g ww (Kannan et al. 2005).

In a more recent study, Penland et al. (2020) measured PFAS concentrations in invertebrates and vertebrates along the Yadkin – Pee Dee River, in North and South Carolina in 2015. PFOS was measured in whole body tissues of snails (6.47 ng/g ww) but was not detected in whole body tissues of Asian clam, unionid mussels, or crayfish. The highest concentrations in invertebrates were measured in aquatic insect whole body samples (132.8 ng/g ww) and was hypothesized to result from dietary uptake of aquatic biofilms. PFOS was measured in muscle tissue of all 11 sampled fish species and ranged from 11.42 ng/g ww in channel catfish to 37.36 ng/g in whitefin shiner. The highest concentration that Penland et al. (2020) measured was 482.9 ng/g ww, from the eggs of a single robust redhorse sample, underscoring the preferential binding of PFOS to ovalbumin.

NMED Exhibit 62

Houde et al. (2006a) measured whole body PFOS in six fish species in Charleston Harbor, South Carolina, and whole body PFOS in zooplankton and five fish species in Sarasota Bay, Florida. Charleston Harbor was the more developed of the two sites and had higher overall PFOS concentrations. Average PFOS concentrations in Charleston Harbor ranged from 19 ng/g ww in pinfish to 92 ng/g in spot. In Sarasota Bay, PFOS concentrations averaged 0.2 ng/g ww in zooplankton and ranged from 3.1 ng/g ww in pigfish to 8.8 ng/g ww in spotted seatrout, suggesting evidence of trophic biomagnification.

Lescord et al. (2015) measured PFOS in chironomids, zooplankton, and juvenile and adult arctic char in six high arctic lakes in Canada. Two of these lakes had been contaminated by PFAS from a nearby airport while the other lakes were free from point source contamination. PFOS in chironomid whole body samples was high at the two contaminated lakes, ranging from 28 to 445 ng/g ww, compared to 5.3 to 14 ng/g ww at the reference lakes (Lescord et al. 2015). Whole body concentrations in pelagic zooplankton were relatively lower, ranging from 49 to 60 ng/g ww, compared to 0.12 to 2.0 ng/g ww at the reference lakes. The higher concentrations of PFOS in the benthic chironomids indicate the importance of sediments as a route of exposure into the base of the food web. PFOS in whole body samples of juvenile char (181 to 224 ng/g ww) and muscle tissue of adult char (24 to 117 ng/g ww) at the two contaminated lakes were lower than whole body PFOS in chironomids, indicating a lack of trophic biomagnification. Additionally, PFOS in whole body samples of juvenile char (0.001 to 15 ng/g ww) and muscle tissues of adult char (below detection to 2 ng/g ww) at the four reference lakes was also lower than whole body PFOS in chironomids at the four reference lakes.

Tomy et al. (2004) measured PFOS in whole body samples of zooplankton (*Calamus hyperboreus*), shrimp (*Pandalus sp.*), clams (*Nya truncata* and *Serripes groenlandica*), and arctic

NMED Exhibit 62

cod (*Boreogadus saida*); and liver samples of deepwater redfish (*Sebastes mentella*) collected from unimpacted marine locations in the Canadian Arctic. PFOS concentrations were low for all taxa, with the lowest concentrations measured in shrimp (0.3 ng/g ww) and clams (0.04 ng/g ww). PFOS concentrations were similar in zooplankton (1.8 ng/g ww), arctic cod (1.3 ng/g ww), and redfish (1.4 ng/g ww), indicating little, if any biomagnification from invertebrates to fish (Tomy et al. 2004). Haukas et al. (2007) found the average liver PFOS concentration (2.02 ng/g ww) in arctic cod *B. saida* collected in the Barents Sea off the coast of Svalbard in 2004 to be similar to whole body concentrations for this species reported by Tomy et al. (2004). The average whole body PFOS concentration (3.85 ng/g ww) in ice amphipod (*Gammarus wilkitzkii*) samples was higher than the average liver PFOS concentration in in arctic cod, indicating no biomagnification from invertebrates to fish in this ecosystem (Haukas et al. 2007).

Current data indicate that PFOS concentrations measured in aquatic biota vary widely, approximately across four orders of magnitude for both fish (ranging between 0.85 and 2,000 ng/g ww) and aquatic invertebrates (ranging between 0.04 and 445 ng/g ww). Like ambient surface water concentrations, PFOS concentrations in aquatic biota inhabiting remote areas (i.e., areas with little to no PFAS manufacturing and/or industrial uses) appear to be lower than those in areas with known PFAS manufacturing, industrial use, and/or application of AFFF. While current PFAS monitoring data illustrate the prevalence and quantify concentrations of PFOS in aquatic biota across the U.S., additional data are needed to better understand PFOS occurrence and potential bioaccumulation in aquatic ecosystems across the U.S.

2.6 Exposure Pathways of PFOS in Aquatic Environments

There are multiple exposure pathways of PFOS in the aquatic environment, including: 1) direct (dermal and respiratory) aqueous exposure; 2) direct exposure to contaminated sediment

NMED Exhibit 62

(for benthic organisms); 3) dietary and biomagnification; and 4) maternal-transfer (Ankley et al. 2020). Exposure of PFOS through water and sediment occurs through direct contact with the respective media, such as water passing across the gills, or consumption of suspended and deposited sediments (Prosser et al. 2016). Upon entering an organism, PFAS such as PFOS tend to bind to proteins, and concentrate preferentially within the blood and protein rich tissues, such as liver (Haukas et al. 2007; Xia et al. 2013b). The affinity of PFOS to bind to proteins contributes to the bioaccumulation and biomagnification of PFOS (see Section 2.5 above), resulting in increasing concentrations of PFOS in higher trophic level organisms, such as predatory fish and birds (Custer et al. 2019; Haukas et al. 2007; Xu et al. 2014). However, as noted previously in Section 1.2.1, the lack of a meaningful K_{ow} for PFOS due to its binding primarily to protein, not lipids, precludes application of K_{ow}-based models that are commonly used to estimate bioconcentration factors and predict bioaccumulation for many other important, environmental contaminants (e.g., PCBs). Lastly, elevated PFOS concentrations in eggs and young of aquatic life suggests that PFOS may be maternally transferred to offspring. This exposure pathway may be particularly important among egg-laying species because of the preferential binding of PFOS to egg albumin (Kannan et al. 2005). In summary, PFOS exposure has been found to occur through multiple exposure routes, including via water, sediment, diet, and maternal transfer (Jones et al. 2003; Kannan et al. 2005; Sharpe et al. 2010; Wang et al. 2011).

2.7 Effects of PFOS on Biota

The number of PFOS ecotoxicity studies and data are increasing and study designs are evolving to expand the understanding of the effects of PFOS. Currently, PFOS ecotoxicity studies are primarily focused on fish, aquatic invertebrates, plants, and algae. Fewer studies are

NMED Exhibit 62

being conducted on aquatic-dependent birds, reptiles, and mammals. Sections 3 and 4 provide study summaries of individual publicly available high quality aquatic life toxicity studies, and Appendix A through Appendix H summarize current PFOS aquatic life ecotoxicity data, both studies used here and unused studies due to quality issues.

2.7.1 Mode of Action and Toxicity of PFOS

The mechanism(s) underpinning the toxicity of PFOS is not well-understood and is an active area of research. Toxicity literature indicate that PFOS causes a wide range of adverse effects in aquatic organisms, including reproductive effects, developmental toxicity, and estrogen, androgen and thyroid hormone disruption (see Sections 3 and 4 and Appendices A.1 through H.1). However, a great deal of research is still needed from a mechanistic perspective to better understand how the different modes of action elicit specific biological responses. Some potential PFOS modes of action in aquatic life appear to include: 1) oxidative stress (Li et al. 2017; Sant et al. 2018; Shi and Zhou 2010); 2) autophagic cell death or apoptosis (Sant et al. 2018; Shi et al. 2008); 3) endocrine modulation of estrogen and thyroid receptors (Benninghoff et al. 2011; Chen et al. 2018; Du et al. 2013; Kim et al. 2011; Shi et al. 2008); 4) interference at the mitochondrial level through the uncoupling of oxidative phosphorylation (ECCC 2018); 5) interference with the homeostasis of DNA metabolism (Hoff et al. 2003); and 6) activation of the nuclear peroxisome proliferator activated receptor-alpha (PPAR-α) pathways (Arukwe and Mortensen 2011; Cheng et al. 2016; Fang et al. 2013; Fang et al. 2012; Yang et al. 2014).

Following exposure to PFOS, molecular level events can perturb estrogen-, androgen- and thyroid-related endocrine systems, as well as neuronal-, lipid-, and carbohydrate-metabolic systems and lead to cellular- and organ-level disturbances and ultimately result in effects on reproduction, growth, and development at the individual organism-level(see Ankley et al. 2020 and Lee et al. 2020 for the latest reviews on the subject) for the latest reviews on the subject).

NMED Exhibit 62

The mechanisms of PFOS toxicity to fish in particular appear to be related to oxidative stress, apoptosis, thyroid disruption, and alterations of gene expression during development (Lee et al. 2020). Additionally, published research suggested that many of these molecular pathways interact with each other and could be linked. For example, oxidative stress following exposure to PFOS was correlated with effects on egg hatching and larval formation, linking reproductive toxicity, oxidative stress, and developmental toxicity (Lee et al. 2020). The actual mechanism(s) through which PFOS induced oxidative stress operates still requires additional study, but increased ß-oxidation of fatty acids and mitochondrial toxicity are proposed triggers (Ankley et al. 2020; Lee et al. 2020). Thus, the alteration of multiple biological pathways is a plausible explanation for the diversity of observed effects of PFOS reported in the literature (Lee et al. 2020). However, the available data did not allow for a defined adverse outcome pathway-based understanding of the ultimate reductions to survival, growth, and reproduction in the various aquatic taxa in which these effects have been observed or may be expected to occur. Thus, further mechanistic research is warranted.

Notably, PFOS appeared to be related to the disruption of the sex hormone-related endocrine system at the molecular, tissue, and organ levels, resulting in observed adverse reproductive outcomes in freshwater and saltwater fish and invertebrates alike. Further, these effects have been reported after exposure via multiple exposure routes (i.e., waterborne, dietary, maternal; (i.e., waterborne, dietary, maternal; Lee et al. 2020). And these reproductive effects also appeared to be trans-generational, as observed in a multi-generational zebrafish (*Danio rerio*) study by Wang et al. (2011) (see study summary in Appendix Section C.2.5).

PFOS is one of the most studied PFAS in the ecotoxicity literature, with reported adverse effects on survival, growth, and reproduction. However, a great deal of additional research is

NMED Exhibit 62

needed to better understand the modes of action of PFOS. Specifically, additional research from a mechanistic perspective is needed to better understand how the different modes of action elicit specific biological responses in fish, aquatic invertebrates, and amphibians. Potential effects of PFOS involving multiple biological pathways are a research challenge for PFOS and PFAS in general.

2.7.2 Potential for Interactions with Other PFAS

PFAS occur as mixtures in the environment. Occurrence studies document the presence of complex mixtures of PFAS in surface waters in the U.S. and across the globe (see also Section 2.4.1)(Ahrens 2011; Ahrens and Bundschuh 2014; Giesy and Kannan 2002; Houde et al. 2006b; Keiter et al. 2012; Wang et al. 2017). Although the EPA's PFOS recommended aquatic life water quality criteria are based solely on single chemical exposures to aquatic life, it is recognized that PFAS are often introduced into the aquatic environment as end-use formulations comprised of mixtures of PFAS and/or PFAS-precursors. However, the ecological effects of these potential PFAS mixtures are poorly understood (Ankley et al. 2020). It was useful, therefore, to briefly summarize the types of interactions that might be expected based on the few PFAS mixture studies involving PFOS and one or more PFAS to date. It should be noted that for purposes of this document, the reader is referred to Ankley et al. (2020) and elsewhere for more comprehensive reviews of PFAS mixtures in general, and the challenges they are expected to present in ecological risk assessment. Beyond PFOA and PFOS, systematic reviews of chemical mixture studies across various compound classes indicate that departures from dose additivity are uncommon and rarely exceed minor deviations (~2-fold) from predictions based on additivity (Martin et al. 2021).

Findings of the PFAS-specific studies below are as reported by the study authors without any additional interpretation or analysis of uncertainty. At both the organismal and cellular

NMED Exhibit 62

levels, studies on zebrafish (*D. rerio*; Ding et al. 2013), a water flea *(D. magna*; Yang et al. 2019), mosquito (*Aedes aegypti*; Olson 2017), a bioluminescent cyanobacteria (*Anabaena sp*.; Rodea-Palomares et al. 2012), or with cultured hepatocytes of the cyprinid (*Gobiocypris rarus*; Wei et al. 2009), demonstrated that the effects observed from *in vivo* and *in vitro* tests on PFAS mixtures vary and can have unpredictable exposure and species-specific effects. PFAS mixture studies on zebrafish reported interactions for combinations of PFOA and PFOS, but departures from additive models were also minor (Ding et al. 2013). Menger et al. (2020) reported zebrafish behavioral effects from a PFAS mixture that were less than individual PFAS, however evaluation of chemical dose response and comparison to mixture models was not conducted. Yang et al. (2019) exposed the water flea, *D. magna*, to single and binary mixtures of PFOS and PFOA. The authors reported synergism in acute and chronic toxic effects. Conversely, Rodea-Palomares et al. (2012) showed a binary PFOS and PFOA mixture as having an antagonistic interaction across the whole range of effect levels tested using the bioluminescent cyanobacterium, *Anabaena.* Olson (2017) exposed larvae of the mosquito, *A. aegypti,* to PFOS and perfluorohexane sulfonate (PFHxS) separately and as a mixture and reported increased toxicity in a manner greater than would be predicted by additivity.

In tests with cultured hepatocytes of the cyprinid, *G. rarus*, co-exposure of PFOS with a mixture of five other PFAS [PFOA, Perfluorononanoate or Perfluorononanoic acid (PFNA), Perfluorodecanoate or Perfluorodecanoic acid (PFDA), Perfluorododecanoate or Perfluorododecanoic acid (PFDoA), and 8:2 FTOH] resulted in highly complex interactions (Wei et al. 2009). A number of genes differentially expressed in the mixture were not differentially expressed in the exposure to the individual chemicals, potentially indicating different modes of action for the mixture compared to the individual chemicals. In this case, the authors reported no

NMED Exhibit 62

additive responses for the mixture. Consistent with the possible mechanisms of toxicity of PFOS (see Section 2.7.1), the genes identified in the study are involved in multiple biological functions and processes, including fatty acid metabolism and transport, xenobiotic metabolism, immune response, and oxidative stress (Wei et al. 2009). Finally, U.S. EPA (Conley et al. 2022) observed PFOA and PFOS interacting in an additive manner to reduce pup body weight, pup liver weight, and maternal liver weight in the Sprague-Dawley rat.

2.8 Conceptual Model of PFOS in the Aquatic Environment and Effects

A conceptual model depicts the relationship between a chemical stressor and ecological compartments, linking exposure characteristics to ecological endpoints. The conceptual model provided in Figure 2-5 summarizes sources, potential pathways of PFOS exposure for aquatic life and aquatic-dependent wildlife, and possible toxicological effects.

PFOS initially enters the aquatic environment through point sources, including municipal and industrial dischargers and landfill leachate and non-point sources, including land application of contaminated biosolids (see Section 2.1.2). PFOS enters the aquatic environment in dissolved and particle-bound forms and may sorb to surfaces, such as sediment and particulate matter in the water column (see Section 2.2.2), which is depicted in the conceptual model (Figure 2-5). The conceptual model depicted in Figure 2-5 shows exposure pathways for the biological receptors of concern (i.e., aquatic life) and potential effects (e.g., on survival, growth, and reproduction) in those receptors. Both direct (i.e., exposure from the water column which is represented by **) and indirect (i.e., dietary exposure via the food web *) pathways are represented in the conceptual model.

NMED Exhibit 62

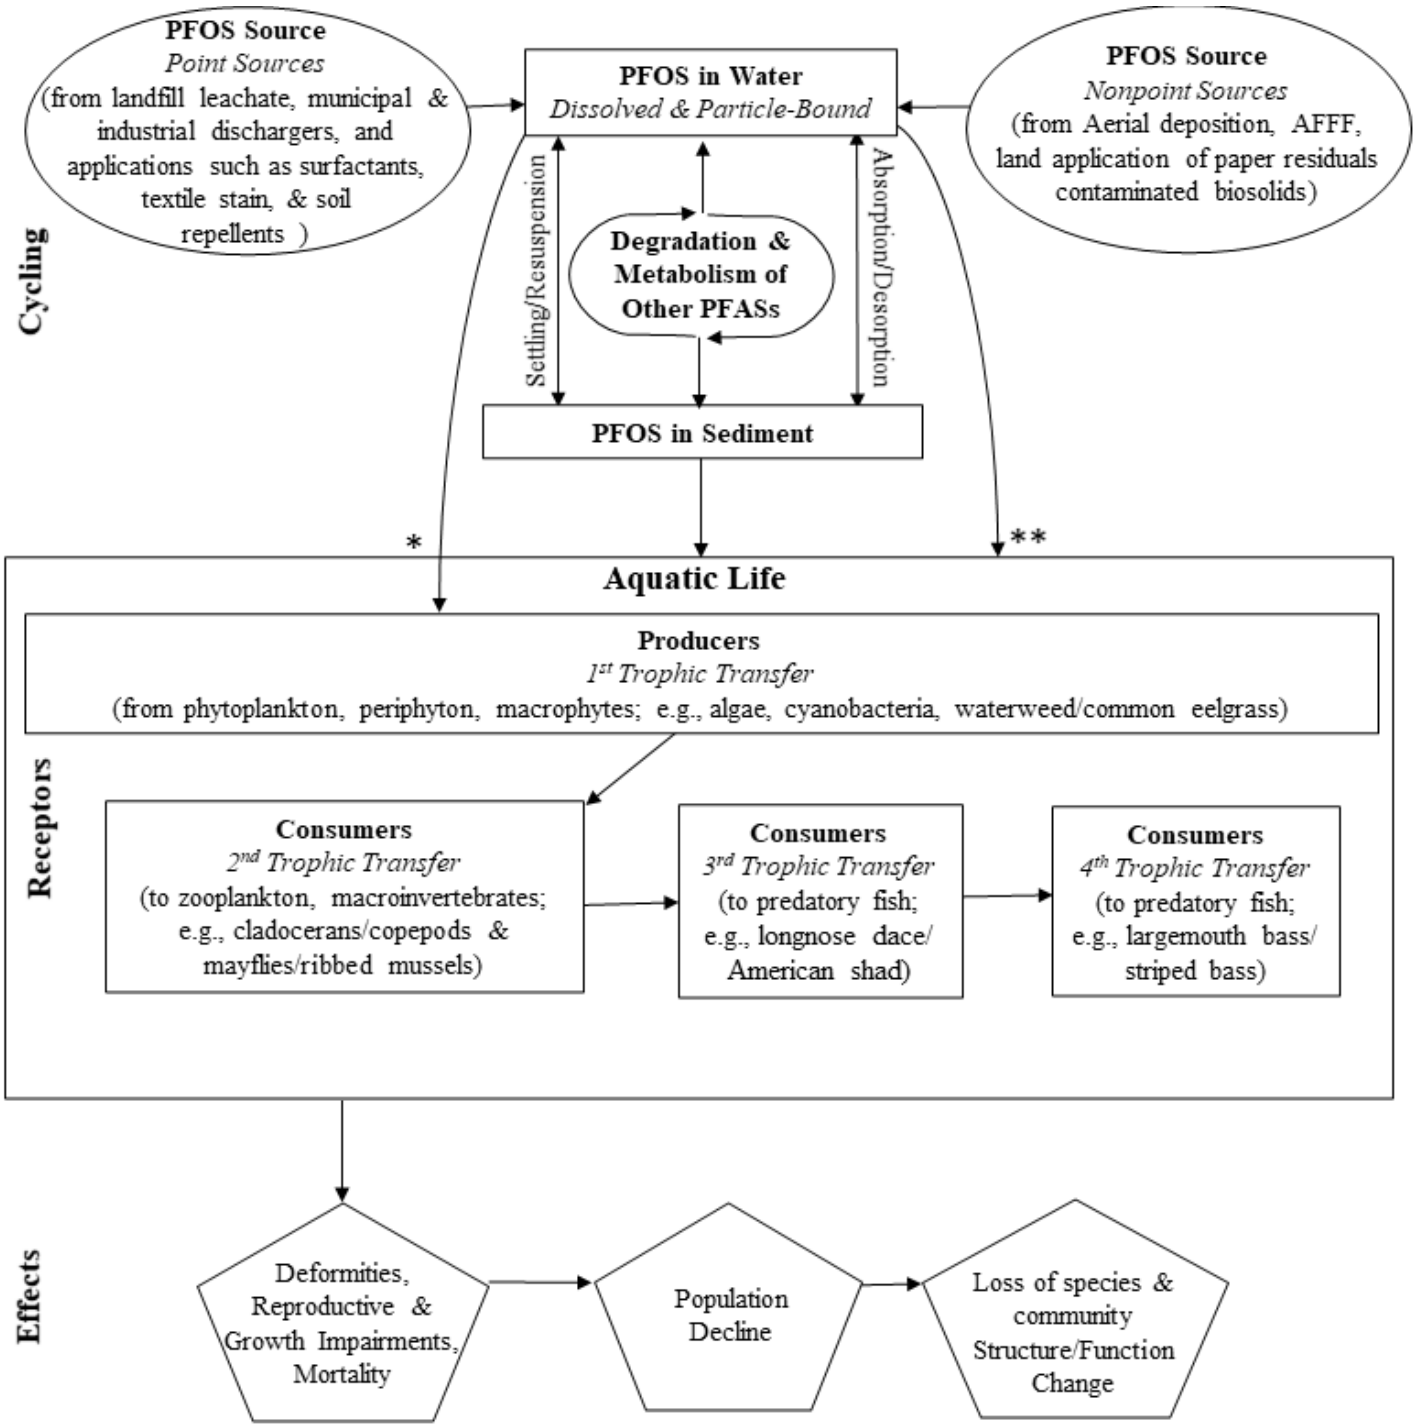

Figure 2-5. Conceptual Model Diagram of Sources, Compartmental Partitioning, and Trophic Transfer Pathways of Perfluorooctane Sulfonate (PFOS) in the Aquatic Environment and its Bioaccumulation and Effects in Aquatic Life.

PFOS sources represented in ovals, compartments within the aquatic ecosystem represented by rectangles, and effects in pentagons. Examples of organisms in each trophic transfer provided as freshwater/marine. Movement of PFOS from water to receptors indicated by two separate pathways: bioconcentration by producers (*) and direct exposure (**) to all trophic levels within box. Relative proportion of PFOS transferred between each trophic level is dependent on life history characteristics of each organism.

NMED Exhibit 62

2.9 Assessment Endpoints

Assessment endpoints are defined as "explicit expressions of the actual environmental value that is to be protected" and are defined by an ecological entity (species, community, or other entity) and its attribute or characteristics (U.S. EPA 1998). Assessment endpoints may be identified at any level of organization (e.g., individual, population, community). In the context of the CWA, aquatic life criteria for toxic pollutants are typically determined based on the results of toxicity tests with aquatic organisms in which unacceptable effects on growth, reproduction, or survival occurred. This information is typically compiled into a sensitivity distribution based on genera and representing the impact on taxa across the aquatic community. Criteria are based on the 5^{th} percentile of genera and are thus intended to be protective of approximately 95 percent of aquatic genera.

The use of laboratory toxicity tests to protect aquatic species was based on the concept that effects occurring to a species in appropriate laboratory tests will generally occur to the same species in comparable field situations. Since aquatic ecosystems are complex and diversified, the 1985 Guidelines recommended acceptable data be available for at least eight genera with a specified taxonomic diversity (the standard eight-family minimum data requirements, or MDRs). The intent of the eight-family MDR was to serve as a surrogate sample community representative of the larger and generally much more diverse natural aquatic community, not necessarily the most sensitive species in a given environment. The 1985 Guidelines note that since aquatic ecosystems can tolerate some stress and occasional adverse effects, protection of all species at all times and places are not deemed necessary (the intent is to protect 95 percent of a group of diverse taxa, and any commercially and recreationally important species; (the intent is to protect 95 percent of a group of diverse taxa, and any commercially and recreationally important species; U.S. EPA 1985).

NMED Exhibit 62

For more details on aquatic life assessment endpoints for PFOS see Section 3.1 below. This criteria derivation for aquatic life was developed using a genus sensitivity distribution (GSD), which represents the potential for impact to the survival, growth, or reproductive effects on taxa across aquatic communities.

2.10 Measurement Endpoints

2.10.1 Overview of Toxicity Data Requirements

To ensure the protection of various components of an aquatic ecosystem, the EPA compiles acute toxicity test data from a minimum of eight diverse taxonomic groups.

- Acute freshwater criterion require data from the following taxonomic groups:
    a. fish in the family Salmonidae in the class Osteichthyes
    b. a second family of fish in the class Osteichthyes, preferably a commercially or recreationally important warmwater species (e.g., bluegill, channel catfish)
    c. a third family in the phylum Chordata (may be in the class Osteichthyes or may be an amphibian)
    d. a planktonic crustacean (e.g., cladoceran, copepod)
    e. a benthic crustacean (e.g., ostracod, isopod, amphipod, crayfish)
    f. an insect (e.g., mayfly, dragonfly, damselfly, stonefly, caddisfly, mosquito, midge)
    g. a family in a phylum other than Arthropoda or Chordata (e.g., Rotifera, Annelida, Mollusca)
    h. a family in any order of insect or any phylum not already represented

- Acute estuarine/marine criterion require data from the following taxonomic groups:
    a. two families in the phylum Chordata
    b. a family in a phylum other than Arthropoda or Chordata
    c. a family from either Mysidae or Penaeidae
    d. three other families not in the phylum Chordata (may include Mysidae or Penaeidae, whichever was not used above)
    e. any other family

Additionally, to ensure the protection of various animal components of the aquatic ecosystem from long term exposures, chronic toxicity test data are recommended from the same eight diverse taxonomic groups that are recommended for acute criteria. If the eight diverse

NMED Exhibit 62

taxonomic groups are not available to support the chronic criterion derivation using a genus distribution approach, the chronic criterion may be derived using an acute-to-chronic ratio (ACR) approach. To apply an ACR approach to derive a chronic criterion, a minimum of three taxa are recommended, with at least one chronic test being from an acutely sensitive species. To calculate ACRs, chronic aquatic life criteria require data from the following taxonomic groups:

a. At least one fish
b. At least one invertebrate
c. At least one acutely sensitive freshwater species, for freshwater chronic criterion (the other two may be saltwater species)
d. At least one acutely sensitive saltwater species for estuarine/marine chronic criterion (the other two may be freshwater species)

The 1985 Guidelines also specified at least one quantitative test with a freshwater alga or vascular plant. If plants are among the most sensitive aquatic organisms, toxicity test data from a plant in another phylum should also be available. Aquatic plant toxicity data were examined to determine whether aquatic plants are likely to be adversely affected by the concentration expected to be protective for other aquatic organisms (see Appendix E for freshwater plant toxicity studies).

2.10.2 Measure of PFOS Exposure Concentrations

This PFOS aquatic life AWQC document provides a critical review of all data identified in the EPA's literature search for PFOS, including all forms of PFOS used in toxicity literature (such as the anionic form and salts) and identified in the ECOTOX database:

- the anionic form (CAS No. 45298-90-6)
- the acid form (CAS No. 1763-23-1)
- potassium salt (CAS No. 2795-39-3)
- an ammonium salt (CAS No. 56773-42-3)
- sodium salt (CAS No. 4021-47-0)
- and a lithium salt (CAS No. 29457-72-5)

NMED Exhibit 62

Typically, studies do not complete an analysis or provide enough information regarding isomer delineation to determine if the PFOS tested was purely linear or branched. However, several PFOS toxicity studies stated that the linear PFOS isomer was used for dosing with fewer studies indicating that the branched isomer was used. Studies reported by researchers that conducted PFOS-only exposures were considered for possible inclusion. For most the EPA aquatic life criteria documents with non-bioaccumulative substances, organisms are exposed to contaminated water but fed a diet grown in uncontaminated media (not spiked with the toxicant prior to introduction into the exposure chambers). Such tests were reviewed, and tests of sufficient quality are included in these PFOS criteria. Toxicity tests conducted with PFOS-spiked diet were also reviewed and considered suitable for deriving a criterion for this bioaccumulative pollutant; however, these toxicity tests were limited in the current PFOS toxicity literature. Consequently, toxicity tests with direct aqueous, dietary, and maternal transfer were included in the EPA's derivation of aquatic life criterion for PFOS (see Section 3). Studies not included in the numeric criteria derivation, including some studies with other PFOS exposures (i.e., *in vitro* studies), were considered qualitatively as supporting information if they were deemed to be of sufficient quality, and are described in the Effects Characterization section below (Section 4.3).

This set of published literature was identified using the ECOTOXicology database (ECOTOX; https://cfpub.epa.gov/ecotox/) as meeting data quality standards. ECOTOX is a source of high-quality toxicity data for aquatic life, terrestrial plants, and wildlife. The database was created and is maintained by the EPA, Office of Research and Development, Center for Computational Toxicology and Exposure. The ECOTOX search generally begins with a comprehensive chemical-specific literature search of the open literature conducted according to ECOTOX Standard Operating Procedures (SOPS; Elonen 2020). The search terms are often

NMED Exhibit 62

comprised of chemical terms, synonyms, degradates and verified Chemical Abstracts Service (CAS) numbers. After developing the literature search strategy, ECOTOX curators conduct a series of searches, identify potentially applicable studies based on title and abstract, acquire potentially applicable studies, and then apply the applicability criteria for inclusion in ECOTOX. Applicability criteria for inclusion into ECOTOX generally include:

a. The toxic effects are related to single chemical exposure (unless the study is being considered as part of a mixture effects assessment)
b. There is a biological effect on live, whole organisms or *in vitro* preparation including gene chips or omics data on adverse outcome pathways potentially of interest
c. Chemical test concentrations are reported
d. There is an explicit duration of exposure
e. Toxicology information that is relevant to EPA Office of Water (OW) is reported for the chemical of concern
f. The paper is published in the English language
g. The paper is available as a full article (not an abstract)
h. The paper is publicly available
i. The paper is the primary source of the data
j. A calculated endpoint is reported or can be calculated using reported or available information
k. Treatment(s) are compared to an acceptable control
l. The location of the study (*e.g.*, laboratory vs. field) is reported
m. The tested species is reported (with recognized nomenclature)

Following inclusion in the ECOTOX database, toxicity studies were subsequently evaluated by EPA OW. All studies were evaluated for data quality as described by U.S. EPA (1985) and in EPA's Office of Chemical Safety and Pollution Prevention (OCSPP)'s Ecological Effects Test Guidelines (U.S. EPA 2016b), and EPA OW's internal data quality SOP, which is consistent with OCSPP's data quality review approach (U.S. EPA 2018). Office of Water completed a Data Evaluation Record (DER) for each species by chemical combination from the PFOS studies identified by ECOTOX. This in-depth review ensured the studies used to derive the criteria resulted in robust scientifically-defensible criteria. Example DERs are shown in

NMED Exhibit 62

Appendix Q with the intent to convey the meticulous level of evaluation, review, and documentation each PFOS study identified by ECOTOX was subject to.

The 1985 Guidelines document indicates that tests used in criteria should be for North American resident species. Due to the EPA's interest in using all available quality data, particularly for data-sparse PFOS (relative to cadmium or ammonia, for example), PFOS toxicity studies were considered for possible inclusion regardless of the test species residential status in North America, as with other published aquatic life criteria. This approach was also based on the relative similarity in sensitivities between resident and non-resident species (see Sections 3 and 4). Moreover, non-North American resident species serve as taxonomically-related surrogate test organisms for the thousands of untested resident species. Supporting analyses to evaluate the influence of including non-resident species on the freshwater criteria magnitudes were conducted by limiting toxicity datasets to North American resident species with established populations in North America (see Section 4.2). These supporting analyses provided an additional line-of-evidence that further suggested it is appropriate to consider non-resident species in PFOS criteria derivation because of their minimal influence of the criteria magnitudes.

Additionally, a substantial number of PFOS toxicity tests reported only nominal, or unmeasured, PFOS concentrations. For PFOS, the EPA has examined the issue of whether nominal (unmeasured) and measured concentrations are in close agreement with each other (Jarvis et al. 2023). While measured PFOS toxicity tests are generally preferred, results of Jarvis et al. (2023) demonstrated that experimental conditions had little influence on observed discrepancies between nominal and measured concentrations for PFOS, with the exception of saltwater tests and freshwater studies that contained substrate. Nominal and measured concentrations in the analysis generally displayed a high degree of linear correlation (>0.95

NMED Exhibit 62

freshwater, >0.84 saltwater) and relatively low median percent differences (Jarvis et al. 2023). In freshwater tests, when tests with substrate were removed, 89% of the 527 PFOA and PFOS measured concentrations were within 20% of their nominal counterparts Conversely, 65.50% of measured PFOS saltwater concentrations differed from corresponding nominal concentrations by >20% (EPA's OCSPP's Ecological Effects Test Guidelines (U.S. EPA 2016b) consider tests acceptable when measured concentrations are within 20% of nominal, and Rewerts et al. (2021) suggested that PFAS-specific toxicity tests may even be acceptable if measured and nominal concentrations do not differ by up to 30%). Potential dosing errors, differences in experimental design, and/or the presence of substrate were hypothesized to be the primary contributor to these discrepancies (Jarvis et al. 2023). Therefore, when available, measured PFOS concentrations were used; however, for several studies measured PFOS concentrations were not reported, and nominal concentrations were utilized, especially if a concentration-response relationship was observed in another medium where PFOS was measured from the same study (e.g., diet, blood, or eggs).

Typically, per the 1985 Guidelines, acute toxicity data from all measured flow-through tests would be used to calculate species mean acute values (SMAV), unless data from a measured flow-through test were unavailable, in which case the acute criterion would be calculated as the geometric mean of all the available acute values (i.e., results of unmeasured flow-through tests and results of measured and unmeasured static and renewal tests). Chronic unmeasured flow-through tests, as well as measured and unmeasured static and renewal tests are not typically considered to calculate chronic values (an exception being for renewal tests with cladocerans where test concentrations were measured). In the case of PFOS, static, renewal, and flow-through experiments were considered for possible inclusion for both species mean acute

NMED Exhibit 62

and chronic values regardless of whether PFOS concentrations were measured because PFOS is a highly stable compound (see Section 1.2.1), resistant to hydrolysis, photolysis, volatilization, and biodegradation (see Section 2.3)(Giesy et al. 2010).

Additionally, chronic values were based on endpoints and durations of exposure that were appropriate to the species. Thus, both life- and partial life-cycle tests were utilized for the derivation of the chronic criteria. However, it should be noted that typically, per the 1985 Guidelines, life-cycle chronic tests would be preferred for invertebrates. The chronic studies used in the derivation of the PFOS criteria followed taxa-specific exposure duration requirements from various test guidelines (i.e., EPA's 1985 Guidelines and EPA's OCSPP's Ecological Effects Test Guidelines, (i.e., EPA's 1985 Guidelines and EPA's OCSPP's Ecological Effects Test Guidelines, U.S. EPA 2016b) when available. For example, the EPA's 1985 Guidelines states that daphnid tests should begin with young < 24 hours old and last for not less than 21 days; and this chronic test duration was applied to the consideration of all chronic daphnid tests. When taxa-specific exposure duration requirements were not available for a particular test organism in the PFOS toxicity literature, both life- and partial life-cycle tests were considered in the derivation of the chronic criteria.

PFOS toxicity in aquatic life can be manifested as effects on survival, growth, and/or reproduction. Measurements of fish tissue, such as whole-body, muscle, and eggs, were most closely linked to the chronic adverse effects of PFOS, since PFOS is highly persistent and bioaccumulative. The following subsection of this problem formulation describes the approaches used to establish PFOS effect concentrations in aquatic life in relation to the various criteria derived, including for water and tissue.

NMED Exhibit 62

2.10.3 Measures of Effect

Each assessment endpoint requires one or more "measures of ecological effect," which are defined as changes in the attributes of an assessment endpoint itself or changes in a surrogate entity or attribute in response to chemical exposure. Ecological effects toxicity test data are used as measures of direct and indirect effects to growth, reproduction, and survival of aquatic organisms.

2.10.3.1 Acute Measures of Effect

The acute measures of effect on aquatic organisms are the lethal concentration (LC_{50}), effect concentration (EC_{50}), or inhibitory concentration (IC_{50}) estimated to produce a specific effect in 50 percent of the test organisms (Table 2-1). LC_{50} is the concentration of a chemical that is estimated to kill 50 percent of the test organisms. EC_{50} is the concentration of a chemical that is estimated to produce a specific effect (e.g., immobilization) in 50 percent of the test organisms. The IC_{50} is the concentration of a chemical that is estimated to inhibit some biological process (e.g., enzyme activity associated with an apical endpoint such as mortality) in 50 percent of the test organisms.

2.10.3.2 Chronic Measures of Effect

The measure of effect for chronic exposures of PFOS was the effect concentration estimated to produce a chronic effect on survival, growth, or reproduction in 10 percent of the test organisms (EC_{10}; Table 2-1). The EPA selected an EC_{10} to estimate a low level of effect that would be both different from controls and not expected to be severe enough to cause severe effects at the population level for a bioaccumulative contaminant, such as PFOS. The use of the EC_{10}, instead of an $EC_{20,}$ is also consistent with the use of this metric for the bioaccumulative pollutant selenium in the recent 2016 Selenium Freshwater Aquatic Life Criteria (U.S. EPA 2016c), and is consistent with the harmonized guidelines from OECD and the generally preferred

NMED Exhibit 62

effect level for other countries such as Canada, Australia and New Zealand (CCME 2007; OECD 2001; Warne et al. 2018).

Regression analysis was used preferentially to characterize a concentration-response (C-R) relationship and to estimate concentrations at which chronic effects are expected to occur. Author-reported No Observed Effect Concentrations (NOECs) and Lowest Observed Effect Concentrations (LOECs) were only used for the derivation of chronic criterion when a robust EC_{10} could not be calculated for the genus. A NOEC is the highest test concentration at which none of the observed effects are statistically different from the control. A LOEC is the lowest test concentration at which the observed effects are statistically different from the control. When LOECs and NOECs are used, a Maximum Acceptable Toxicant Concentration (MATC, geometric mean of the NOEC and LOEC) is calculated. For the calculation of the chronic criteria, point estimates were selected for use as the measure of effect in favor of MATCs, as MATCs are highly dependent on the concentrations tested. Point estimates also provided additional information that is difficult to determine with an MATC, such as a measure of effect level across a range of tested concentrations.

In conformity with the 2013 Ammonia Freshwater Aquatic Life Criteria (U.S. EPA 2013), a decision rule was also applied to the PFOS toxicity data when an author-reported NOEC or LOEC was used. The decision rule was not to use "greater than" values for concentrations of low magnitude or "less than" values for concentrations of high magnitude because they added little significant information to the analyses. Conversely, if data from studies with only low concentrations indicated a significant effect (suggesting the test material was highly toxic) or studies with high concentrations only found an incomplete response for a chronic endpoint (indicating low toxicity of the test material), those data did significantly enhance the

NMED Exhibit 62

understanding of PFOS toxicity. Thus, the decision rule was applied as follows: "greater than" (>) high toxicity values and "less than" (<) low toxicity values were included (U.S. EPA 2013). Data that met the quality objectives and test requirements were utilized quantitatively in deriving these criteria for aquatic life and are presented in Table 3-3 and Table 3-7.

Table 2-1. Summary of Assessment Endpoints and Measures of Effect Used in the Criteria Derivation for PFOS.

Assessment Endpoints for the Aquatic Community	Measures of Effect
Aquatic Life: Survival, growth, and reproduction of freshwater and estuarine/marine aquatic life (i.e., fish, amphibians, aquatic invertebrates)	For effects from acute exposure: 1. LC_{50}, EC_{50}, or IC_{50} concentrations in water For effects from chronic exposure: 1. EC_{10} concentrations in water 2. NOEC and LOEC concentrations in water. *Only used when an EC_{10} could not be calculated for a genus.* *Note: only chronic exposures were considered for derivation of the tissue-based criteria since PFOS is a bioaccumulative chemical. These chronic tissue-based criteria are expected to be protective of acute effects, because acute effects were observed at much greater concentrations than chronic effects.*

LC_{50} = 50% Lethal Concentration
EC_{50} = 50% Effect Concentration
IC_{50} = 50% Inhibitory Concentration
NOEC = No-observed-effect-concentration
LOEC = Lowest-observed-effect-concentration
EC_{10} = 10% Effect Concentration

2.10.3.3 Summary of Independent Calculation of Toxicity Values

Where data were available, toxicity values, including LC_{50} and EC_{10} values, were independently calculated using data from the toxicity studies meeting the inclusion criteria described above, via independent statistical analysis conducted by the EPA. Occasionally, individual replicate-level data or treatment-level data were acquired from the study authors to independently calculate toxicity values. All data were analyzed using the statistical software

NMED Exhibit 62

program R (version 3.6.2) and the associated dose-response curve (drc) package. The R drc package has several models available for modeling a C-R relationship for each toxicity study. The specific model used to calculate toxicity values was selected following the details provided in Appendix K and the models performed well on most or all statistical metrics. The independently-calculated toxicity values used to derive the PFOS aquatic life criteria are included in each quantitative study summary below and were utilized to derive these criteria for aquatic life, where available (for the acute criterion see genus mean values in Table 3-9 and for the chronic criterion, see genus mean values in Table 3-10).

2.11 Analysis Plan

2.11.1 Derivation of Water Column Criteria

During CWA Section 304(a) criteria development, the EPA reviews and considers all relevant toxicity test data. Information available for all relevant species and genera are reviewed to identify: 1) data from acceptable tests that meet data quality standards; and 2) whether the acceptable data meet the minimum data requirements (MDRs) as outlined in the EPA's 1985 Guidelines (U.S. EPA 1985). The MDRs described in Section 2.10.1 were met for acute and chronic freshwater criteria derivation. Acute and chronic MDRs for PFOS estuarine/marine criteria derivation were not met. Consequently, the EPA used the available toxicity data and the EPA's New Approach Methods (NAMs) to generate protective estuarine/marine benchmarks. A minimal number of tests from acceptable studies of aquatic algae and vascular plants were also available. The relative sensitivity of freshwater plants to PFOS exposures indicates plants are less sensitive than aquatic vertebrates and invertebrates so plant criteria were not developed.

NMED Exhibit 62

2.11.2 Consideration for the Derivation of Tissue-Based Criteria following Chronic PFOS Exposures

Chronic toxicity studies (both laboratory and field studies) were further screened to ensure that they contained the relevant chronic PFOS exposure routes for aquatic organisms (i.e., dietary, maternal, or dietary and waterborne PFOS exposure), measurement of chronic effects, and measurement of PFOS in tissue(s). The EPA considered deriving tissue-based criteria using empirical toxicity tests with studies that exposed test organisms to PFOS via water, diet, and/or maternal transfer and reported exposure concentrations based on measured tissue concentrations. This approach generally corresponded with the 2016 Selenium Aquatic Life Freshwater Criterion, which is the only other EPA 304(a) recommended aquatic life criterion with tissue-based criteria (U.S. EPA 2016c). However, currently, the freshwater chronic PFOS toxicity dataset with measured tissue concentrations is somewhat limited. There were 14 total chronic aquatic life studies considered, six quantitative (three fish, one invertebrate, and two amphibian studies) and eight qualitative studies (see Section 4.5). The quantitative studies provided data for three of the eight MDRs. The qualitative studies provided supporting information for only one additional MDR. Therefore, it was concluded that there are currently insufficient data to derive a chronic tissue criterion using a GSD approach from empirical tissue data from toxicity studies. Thus, the EPA used a Bioaccumulation Factor (BAF) approach for chronic tissue criteria development.

2.11.3 Translation of Chronic Water Column Criterion to Tissue Criteria

To enable use of fish tissue measurements of PFOS in protecting designated uses, chronic tissue criteria for PFOS were derived by translating the chronic freshwater water column criterion (summarized in Section 2.11.1 above) into tissue criteria using bioaccumulation factors (BAFs) and the following equation:

NMED Exhibit 62

$$Tissue\ Criteria = Chronic\ Water\ Column\ Criterion\ \times BAF \qquad (Eq.\ 1)$$

The resulting tissue criteria correspond to the tissue type serving as the basis of the BAF used in the equation.

2.11.3.1 Aquatic Life Bioaccumulation Factors (BAFs)

A BAF is determined from field measurements and is calculated using the equation:

$$BAF = \frac{C_{biota}}{C_{water}} \qquad (Eq.\ 2)$$

Where:
C_{biota} = PFOS concentration in organismal tissue(s)
C_{water} = PFOS concentration in water where the organism was collected

Given that a BAF is determined from field measurements [as opposed to controlled experiments designed to measure bioconcentration of PFOS using specific test guidelines; (OECD 2001; U.S. EPA 2016c)], a BAF is an expression of all exposure routes, i.e., dietary, water, maternal transfer, and contact with water and sediments via skin and ingestion. Depending upon the tissue residue measurement, BAFs can be based upon residues in the whole organisms, muscle, liver, or any other tissue.

The literature search for reporting on PFOS bioaccumulation was implemented by developing a series of chemical-based search terms. These terms included chemical names and Chemical Abstracts Service registry numbers (CASRN or CAS[3]), synonyms, tradenames, and other relevant chemical forms (i.e., related compounds). Databases searched were Current Contents, ProQuest CSA, Dissertation Abstracts, Science Direct, Agricola, TOXNET, and UNIFY (database internal to U.S. EPA's ECOTOX database). The literature search yielded numerous citations and the citation list was further refined by excluding citations on analytical

[3] Chemical Abstracts Service registry number (CASRN or CAS) for PFOS is 1763-23-1.

NMED Exhibit 62

methods, human health, terrestrial organisms, bacteria, and where PFOS was not a chemical of study. The citations meeting the search criteria were reviewed for reported BAFs and/or reported concentrations in which BAFs could be calculated. Data from papers with appropriate information were extracted into a PFOS dataset. The studies meeting these inclusion criteria were also screened for data quality.

Four factors were evaluated in the screening of the BAF literature: 1) number of water samples; 2) number of organism samples; 3) water and organism temporal coordination in sample collection; and 4) water and organism spatial coordination in sample collection. Additionally, the general experimental design was evaluated. For further details on BAFs compilation and ranking, see .

Table 2-2 below outlines the screening criteria for study evaluation and ranking. Only BAFs of high and medium quality were used to derive the tissue criteria (Appendix O). For further details on BAFs compilation and ranking, see Burkhard (2021).

Table 2-2. Evaluation Criteria for Screening Bioaccumulation Factors (BAFs) in the Public Literature.

Table modified from Burkhard (2021).

Screening Factor	High Quality	Medium Quality	Low Quality
Number of Water Samples	> 3	2 – 3	1
Number of Organism Samples[1]	> 3	2 – 3	1
Temporal Coordination	Concurrent collection	Within one year	Collection period > 1 year
Spatial Coordination	Co-located collection	Within 1 - 2 km	Significantly different locations (> 2 km)
General Experimental Design			Mixed species tissues samples

[1] Organismal samples from the same species and tissue type.

NMED Exhibit 62

3 EFFECTS ANALYSIS FOR AQUATIC LIFE

3.1 Toxicity to Aquatic Life

All available, reliable studies relating to the acute and chronic toxicological effects of PFOS on aquatic life were considered in the derivation of the national recommended PFOS criteria. Data for possible inclusion in the PFOS criteria were obtained from published literature reporting acute and chronic exposures of PFOS that were associated with mortality, survival, growth, and reproduction. This set of published literature was identified by the EPA's public ECOTOX database (ECOTOX: https://cfpub.epa.gov/ecotox/) as meeting data quality standards. ECOTOX is a source of high-quality toxicity data for aquatic life, terrestrial plants, and wildlife. The database was created and is maintained by the EPA, Office of Research and Development, Center for Computational Toxicology and Exposure. Studies were then further reviewed by the EPA OW to determine test acceptability for use in the criteria derivation. Additional literature searches were also conducted to ensure all available toxicity data were captured. The latest search was conducted through March 2024.

3.1.1 Summary of PFOS Toxicity Studies Used to Derive the Aquatic Life Criteria

Quantitative data for acute PFOS toxicity were available for 29 freshwater species, representing 20 genera and 17 families in five phyla, and six estuarine/marine species, representing six genera and five families in four phyla. Chronic PFOS toxicity data were available for 19 freshwater species, representing 17 genera and 15 families in four phyla, and five estuarine/marine species, representing five genera and five families in three phyla (Table 3-1).

NMED Exhibit 62

Table 3-1. Summary Table of Minimum Data Requirements per the 1985 Guidelines Reflecting the Number of Acute and Chronic Genus and Species Level Mean Values in the Freshwater and Saltwater Toxicity Datasets for PFOS.

MDR	Freshwater			
	GMAV	**SMAV**	**GMCV**	**SMCV**
Family Salmonidae in the class Osteichthyes	1	1	1	1
Second family in the class Osteichthyes, preferably a commercially or recreationally important warmwater species	2	2	2	2
Third family in the phylum Chordata (may be in the class Osteichthyes or may be an amphibian, etc.)	5	10	3	4

Total	**6**	**6**	**5**	**5**

[a] The 1985 Guidelines require that data from a minimum of eight families are needed to calculate an estuarine/marine criterion. Insufficient data exist to fulfill all eight of the taxonomic MDR groups. Consequently, the EPA cannot derive an estuarine/marine acute criterion, based on the 1985 Guidelines. However, the EPA has developed estuarine/marine benchmarks through use of surrogate data to fill in missing MDRs using the EPA's Web-based Inter-species Correlation Estimation (web-ICE) tool. These benchmarks are provided in Appendix L.

Below are the summarized studies that provided key acute and chronic freshwater toxicity data with effect values that were used quantitatively in deriving the acute and chronic freshwater criteria to protect aquatic life from harmful exposure to PFOS. Study summaries are

NMED Exhibit 62

also provided for the estuarine/marine toxicity data that could be used quantitatively to derive acute and chronic estuarine/marine criteria if the MDRs were met.

Study summaries for the most sensitive taxa are grouped by acute or chronic exposure and sorted by sensitivity to PFOS. Study data were summarized in tabular form in Appendix A (freshwater acute studies), Appendix B (estuarine/marine acute studies), Appendix C (freshwater chronic studies), and Appendix D (estuarine/marine chronic studies). Key acute and chronic toxicity studies used qualitatively as supporting information are described in the Effects Characterization (Section 4) below and corresponding data are listed in Appendix E, Appendix F, Appendix G and Appendix H while the remaining, unused studies are listed in Appendix J.

Acute and chronic values were presented as reported by the study authors for each individual study. The EPA independently calculated toxicity values if sufficient raw data were available to conduct statistical analyses. All toxicity values, such as LCs, ECs, NOECs, LOECs, and species- and genus-mean values, were given to four significant figures to prevent round-off error in subsequent calculations, not to reflect the precision of the value. The author-reported toxicity values and the EPA's independently-calculated values (where available) were included for each study throughout the document (in the quantitative data study summaries and appendices as applicable), and the specific value utilized to derive the criteria were identified along with a justification. The EPA's independently-calculated toxicity values were used preferentially, where available.

3.1.1.1 Summary of Acute PFOS Toxicity Studies Used to Derive the Freshwater Aquatic Life Criterion

Acute toxicity data were available for all of the freshwater MDRs. Acceptable data on the acute effects of PFOS in freshwater were available for a total of 29 species representing 20 genera and 17 families in five phyla (Appendix A: Acceptable Freshwater Acute PFOS Toxicity

NMED Exhibit 62

Studies). More specifically, quantitative data for acute PFOS toxicity were available for three freshwater fish species (two of the eight MDRs), 16 freshwater invertebrate species (five of the eight MDRs), and 10 freshwater amphibian species (one of the eight MDRs). Ranked genus mean acute values (GMAVs) for PFOS in freshwater based on acute toxicity were identified in Table 3-2 (4 most sensitive genera) and Table 3-3 (all genera) and plotted in Figure 3-1.

Table 3-2. The Four Most Sensitive Genera Used in Calculating the Acute Freshwater Criterion (Sensitivity Rank 1-4).
Ranked below from most to least sensitive.

Rank	Genus	Species	GMAV (mg/L)
1	*Neocloeon*	Mayfly, *N. triangulifer*	0.07617
2	*Moina*	Cladoceran, *M. microcopa* and *M. micrura*	3.075
3	*Pimephales*	Fathead minnow, *P. promelas*	6.950
4	*Oncorhynchus*	Rainbow trout, *O. mykiss*	7.515

3.1.1.1.1 Most Sensitive Freshwater Genus for Acute Toxicity: Neocloeon (mayfly)

Soucek et al. (2023) conducted a 96-hour acute toxicity test to determine the effects of PFOS-K (PFOS potassium salt, CAS # 2795-39-3, 98% purity) in water on the parthenogenetic mayfly, *Neocloeon triangulifer*. The test was performed under static, nonrenewal conditions beginning with < 24 hour old nymphs. Mayflies were fed live diatom biofilm scraping beginning on day 0. Feeding only occurred on day 0. The authors indicated test organisms required food to survive the entire 96-hour exposure, with previous studies demonstrating greater than 80% mortality at 48 hours with no food (Soucek and Dickinson 2015). Percent survival in the control treatment after 96 hours was 100%. The EPA was able to independently calculate a 96-hour LC_{50} of 0.07617 mg/L (0.06546 - 0.08688 mg/L; 95% CI) for this study. The EPA's independently-

NMED Exhibit 62

calculated LC_{50} is in line with the author-reported LC_{50} of 0.08 mg/L. Therefore, the independently-calculated LC_{50} of 0.07617 mg/L was used quantitatively to derive the freshwater acute water column criterion for PFOS.

3.1.1.1.2 Second Most Sensitive Freshwater Genus for Acute Toxicity: Moina (cladoceran)

Ji et al. (2008) performed a 48-hour static, unmeasured acute test of PFOS (purity unreported) with *Moina macrocopa*. The test followed the EPA's Methods for measuring the acute toxicity of effluents and receiving waters to freshwater and marine organisms [U.S. EPA/600/4-90/027F; (U.S. EPA 2002)]. The test involved four replicates of five neonates each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 6.25, 12.5, 25, 50 and 100 mg/L. Survival of organisms in the negative control was not reported in the paper. However, raw data were obtained by the EPA from the study authors and control survival was 100% in the acute test. The study authors reported a 48-hour EC_{50} value of 17.95 mg/L for *M. macrocopa*. The 48-hour EC_{50} value was independently-calculated by the EPA as 17.20 mg/L. The independently-calculated acute toxicity value was quantitatively used in the derivation of the freshwater acute water column criterion.

Razak et al. (2023) tested the acute toxicity of perfluorooctanesulfonate (PFOS, ≥98% purity) on *Moina micrura* for 48 hours in a measured, static experiment. Testing methods followed OECD 202 (OECD 2004) with nominal testing concentrations of 10, 25, 50, 75, 100, 250, 500, 750, 1,000, 2,500, 5,000, 7,500, and 10,000 µg/L, plus a control, with four replicates per treatment. Test water was filtered lake water. Each replicate consisted of 10 neonates (<48 hours old) in 50 mL of solution in a 100 mL beaker, and organisms were not fed during the study. The lethal effect concentrations (LC) were calculated using Probit analysis, and the 48-

NMED Exhibit 62

hour LC_{50} value of 549.6 µg/L, or 0.5496 mg/L was determined to be acceptable for quantitative use.

The geometric mean of the two SMAVs for *Moina macrocopa* (17.20 mg/L) and *Moina micrura* (0.5496 mg/L) were used to calculate the GMAV of 3.075 mg/L for the genus *Moina*. If the EPA excluded the *M. micrura* SMAV on the basis of it being an overly sensitive outlier (relative to *M. macrocopa* and the overall acute data except for *N. triangulifer*) that would result in the final PFOS acute criterion potentially being underprotective of untested sensitive invertebrate or other taxa, considering that the available data serve as surrogate information for the thousands of untested freshwater species. Conversely, excluding the *M. macrocopa* SMAV on the basis of it being a tolerant outlier (relative to *M. micrura*) would result in the Moina GMAV being highly influenced by a single test/species with an LC_{50} that was relatively sensitive (i.e., *M. micrura* SMAV = 0.5496 mg/L) compared to the overall acute data with the exception of *N. triangulifer*. Averaging the *M. micrura* and *M. moina* SMAVs resulted in a GMAV (3.075 mg/L) that was the second most sensitive GMAV, still in the general range of the data overall.

3.1.1.1.3 Third Most Sensitive Freshwater Genus for Acute Toxicity: Pimephales (fathead minnow)

Drottar and Krueger (2000c) evaluated the acute effects of PFOS-K (PFOS potassium salt, CAS# 2795-39-3, Lot # 217 (T-6295) obtained from the 3M Company, 90.49% purity) on juvenile fathead minnows (*Pimephales promelas*) during a 96-hour measured, static study. Researchers followed protocols from U.S. EPA Series 850, OPPTS 850.1075 and OECD Guideline 203. All fish used in the test were from the same source and year class, and the total length of the longest fish was no more than twice the length of the shortest. The authors reported an LC_{50} of 9.5 mg/L PFOS. The EPA's independently-calculated 96-hour LC_{50} was 9.020 mg/L and was used quantitatively to derive the freshwater acute water column criterion for PFOS. 3M

NMED Exhibit 62

Company (2000) provides the results of a 96-hour static, unmeasured acute toxicity test with the fathead minnow and PFOS-Li (PFOS lithium salt, CAS # 29457-72-5). Fish were 79 days old at test initiation with an average length of 2.1 cm and weight of 0.069 g. No mortality occurred in the control treatment and 100% mortality was observed in the highest treatment (56 mg/L). The study authors reported that the test sample containing 24.5% PFOS-Li exhibited a 96-hour LC_{50} of 19 mg/L, which equates to 4.655 mg/L as PFOS. The independently-calculated 96-hr LC_{50} value was 21.86 mg/L, which equates to 5.356 mg/L as PFOS, and was used quantitatively to derive the freshwater acute water column criterion for PFOS.

The geometric mean of the two acute toxicity values described above for *P. promelas* (9.020 and 5.356 mg/L) were used to calculate an SMAV and GMAV of 6.950 mg/L, which represents the second most sensitive GMAV in the EPA's freshwater acute dataset for PFOS.

3.1.1.1.4 Fourth Most Sensitive Freshwater Genus for Acute Toxicity: Oncorhynchus (trout)

Sharpe et al. (2010) evaluated the acute effects of PFOS-K (potassium salt, CAS # 2795-39-3, 98% purity) to *Oncorhynchus mykiss*, rainbow trout, via a 96-hour renewal exposure with measured concentrations (renewal was not stated in paper, but assumed based on other information provided, including the test Guideline protocol that the authors cited as the protocol that was used). There were limited details in the publication about the test protocol; however, it was noted that the Organization for Economic Co-operation and Development (OECD) Guideline 203 was followed, and the study authors did not identify any deviations from these test guidelines. The EPA obtained clarification from the study authors on the experimental design regarding the biomass loading rate, which was 1 to 1.5 g/L (based on four fish weighing a total of 2 to 3 g per 2 L tank; personal communication with Greg Goss and Rainie Sharpe, March 2021). This biomass loading rate was slightly higher than that stated in OECD Guidelines of 0.8

NMED Exhibit 62

g/L (OECD 1992). The author-reported 96-hour LC_{50} for the study was 2.5 mg/L. The authors do not specify if this concentration was nominal or measured. Given the clarifications regarding the biomass loading, the LC_{50} from this study was used quantitatively to derive the freshwater acute water column criterion for PFOS.

Palmer et al. (2002a) evaluated the acute effects of PFOS-K (potassium salt, identified as FC-95 obtained from 3M Company) to rainbow trout via a 96-hour static exposure with measured concentrations. The study author-reported 96-hour LC_{50} for the study was 22 mg/L. The independently-calculated 96-hour LC_{50} value was 22.59 mg/L. The independently-calculated LC_{50} was used quantitatively to derive the freshwater acute water column criterion for PFOS.

The geometric mean of the two toxicity values described above (2.5 and 22.59 mg/L), was used to calculate the SMAV and GMAV of 7.515 mg/L for rainbow trout, *O. mykiss*. The GMAV of 7.515 mg/L is consistent with the acute rainbow trout studies cited in OECD's 2002 PFOS Hazard Assessment, from which the LC_{50} values for rainbow trout range from 7.8 to 22 mg/L (OECD 2002).

3.1.1.2 Summary of Acute PFOS Toxicity Studies Used to Derive the Estuarine/Marine Aquatic Life Criterion

Quantitative empirical data for acute PFOS toxicity were available for six saltwater species, representing six genera and five families. The data available for saltwater species fulfilled only five of the eight MDRs. In the interest of providing information to states/authorized Tribes on protective values, the EPA developed an estuarine/marine acute benchmark using the

available empirical data supplemented with toxicity values generated through the use of NAMs, specifically through the use of the EPA Office of Research and Development's peer-reviewed publicly-available Web-based Interspecies Correlation Estimation (WebICE) tool (Raimondo et al. 2010). These benchmarks are provided in Appendix L. Table 3-4 below shows the four most sensitive acute estuarine/marine genera that could be used quantitatively to derive acute criteria if the MDRs were met. Ranked GMAVs for saltwater organisms based on acceptable acute toxicity values were identified in Table 3-5 and plotted in Figure 3-2.

Table 3-4. The Four Most Sensitive Acute Estuarine/Marine Genera.
Ranked Below from Most to Least Sensitive.

Rank	Genus	Species	GMAV (mg/L PFOS)
1	*Mytilus*	Mediterranean mussel, *M. galloprovincialis*[1]	1.1

3	*Paracentrotus*	Sea urchin, *P. lividus*[2]	1.795
4	*Americamysis*	Mysid, *A. bahia*	4.914

[1] Not a resident species in North America, but other species in this genus are resident and commercially or ecologically important species.
[2] Not a resident species in North America, but other species in this family (Echinidae) are common ecotoxicity test species that serves as a surrogate for untested urchin species residing in North America.

3.1.1.2.1 Most Sensitive Estuarine/Marine Genus for Acute Toxicity: Mytilus (mussel)

The acute toxicity of perfluorooctane sulfonate (PFOS, purity not provided) on the Mediterranean mussel, *Mytilus galloprovincialis* was evaluated by **Fabbri et al. (2014)**. This species is not resident to North America, but is a surrogate for North American mussel species, including the widespread, commercially and ecologically important blue mussel, *Mytilus edulis.* The test endpoint was the percentage of normal D-larvae in each well, including malformed larvae and pre-D stages, at test termination (48 hours). The acceptability of test results was based

NMED Exhibit 62

on controls for a percentage of normal D-shell stage larvae, > 75% (ASTM 2004b). The percentage of normal D-larva decreased with increasing test concentrations. The NOEC and LOEC reported for the study were 0.00001 and 0.0001 mg/L, respectively. However, the test concentrations failed to elicit a 50% reduction in malformations in the highest test concentration (1 mg/L), and an EC_{50} was not determined. Therefore, the EC_{50} for the study was greater than the highest test concentration (1 mg/L). The 48-hour EC_{50} based on malformation of > 1 mg/L was acceptable for quantitative use.

Hayman et al. (2021) report the results of a 48-hour static, measured test on the effects of PFOS-K (PFOS potassium salt, CAS # 2795-39-3, 98% purity) on *M. galloprovincialis*. Authors noted that tests followed U.S. EPA (1995) and ASTM (2004a) protocols. Larvae were enumerated for total number of larvae that were alive at the end of the test as well as number of normally-developed D-shaped larvae. There were no significant differences between solvent control and filtered seawater, suggesting no adverse effects of methanol. The author-reported 48-hr EC_{50}, based on normal development, was 1.1 mg/L. The EPA was not able to independently calculate a 48-hour EC_{50} value as the curve fitted model did not result in a good fit. Therefore, the author-reported EC_{50} of 1.1 mg/L was considered for quantitative use.

The two EC_{50} values from the two studies both indicated sensitivity of the Mediterranean mussel to acute exposure of PFOS is above 1 mg/L. However, the EC_{50} for *M. galloprovincialis* from **Fabbri et al. (2014)** was unbounded while the EC_{50} from **Hayman et al. (2021)** was definitive, and therefore the latter EC_{50} (1.1 mg/L) serves as the basis for the SMAV and GMAV used to derive the acute estuarine/marine benchmark for PFOS.

NMED Exhibit 62

3.1.1.2.2 Second Most Sensitive Estuarine/Marine Genus for Acute Toxicity: Strongylocentrotus (sea urchin)

The **Hayman et al. (2021)** study also included the results of a 96-hour static, measured test on the effects of PFOS-K (PFOS potassium salt, CAS # 2795-39-3, 98% purity) on the purple sea urchin, *Strongylocentrotus purpuratus*. Authors noted that tests followed U.S. EPA (1995) and ASTM (2004a) protocols. At test termination (96 hours), the first 100 larvae were enumerated and observed for normal development (4-arm pluteus stage). As with the other tests in the study with different species, there were no significant differences between solvent control and filtered seawater, suggesting no adverse effects of methanol. The author-reported 96-hour EC_{50}, based on normal development, was 1.7 mg/L. The EPA was not able to independently calculate a 96-hour EC_{50} value as the curve fitted model did not result in a good fit. Therefore, the author-reported EC_{50} of 1.7 mg/L mg/L was thus applied for quantitative use and was utilized as the SMAV and GMAV to derive the acute estuarine/marine benchmark for PFOS.

3.1.1.2.3 Third Most Sensitive Estuarine/Marine Genus for Acute Toxicity: Paracentrotus (sea urchin)

A 72-hour static, unmeasured PFOS (purity not provided) toxicity test with the sea urchin, *Paracentrotus lividus* (a non-North American species) was conducted by **Gunduz et al. (2013)**. The 72-hour EC_{50} based on normal development to the pluteus stage was 1.795 mg/L PFOS and was acceptable for quantitative use; however, additional consideration needs to be given to the use of this value in benchmark derivation due to the short test duration.

3.1.1.2.4 Fourth Most Sensitive Estuarine/Marine Genus for Acute Toxicity: Americamysis (mysid)

Along with the Mediterranean mussel and purple sea urchin, **Hayman et al. (2021)** conducted a 96-hour static, measured test to determine the effects of PFOS-K on the mysid, *Americamysis bahia*. Authors noted that tests followed U.S. EPA (1995) and ASTM (2004a)

NMED Exhibit 62

protocols. Only two of the sixty organisms (3.3%) were found dead in the controls at test termination. The author-reported 96-hour LC_{50} is 5.1 mg/L PFOS-K. The independently-calculated 96-hr LC_{50} value was 4.914 mg/L and is acceptable for quantitative use in the derivation of the acute estuarine/marine benchmark for PFOS.

Table 3-5. Ranked Estuarine/Marine Water Genus Mean Acute Values.

Rank[1]	GMAV (mg/L PFOS)	MDR Group[3]	Genus	Species	SMAV[2] (mg/L PFOS)
1	1.1	D	*Mytilus*	Mussel, *Mytilus galloprovincialis*	1.1
2	1.7	F	*Strongylocentrotus*	Purple sea urchin, *Strongylocentrotus purpuratus*	1.7
3	1.795	E	*Paracentrotus*	Sea urchin, *Paracentrotus lividus*	1.795
4	4.914	C	*Americamysis*	Mysid, *Americamysis bahia*	4.914
5	6.9	C	*Siriella*	Mysid, *Siriella armata*	6.9
6	>15	A	*Cyprinodon*	Sheepshead minnow, *Cyprinodon variegatus*	>15

NMED Exhibit 62

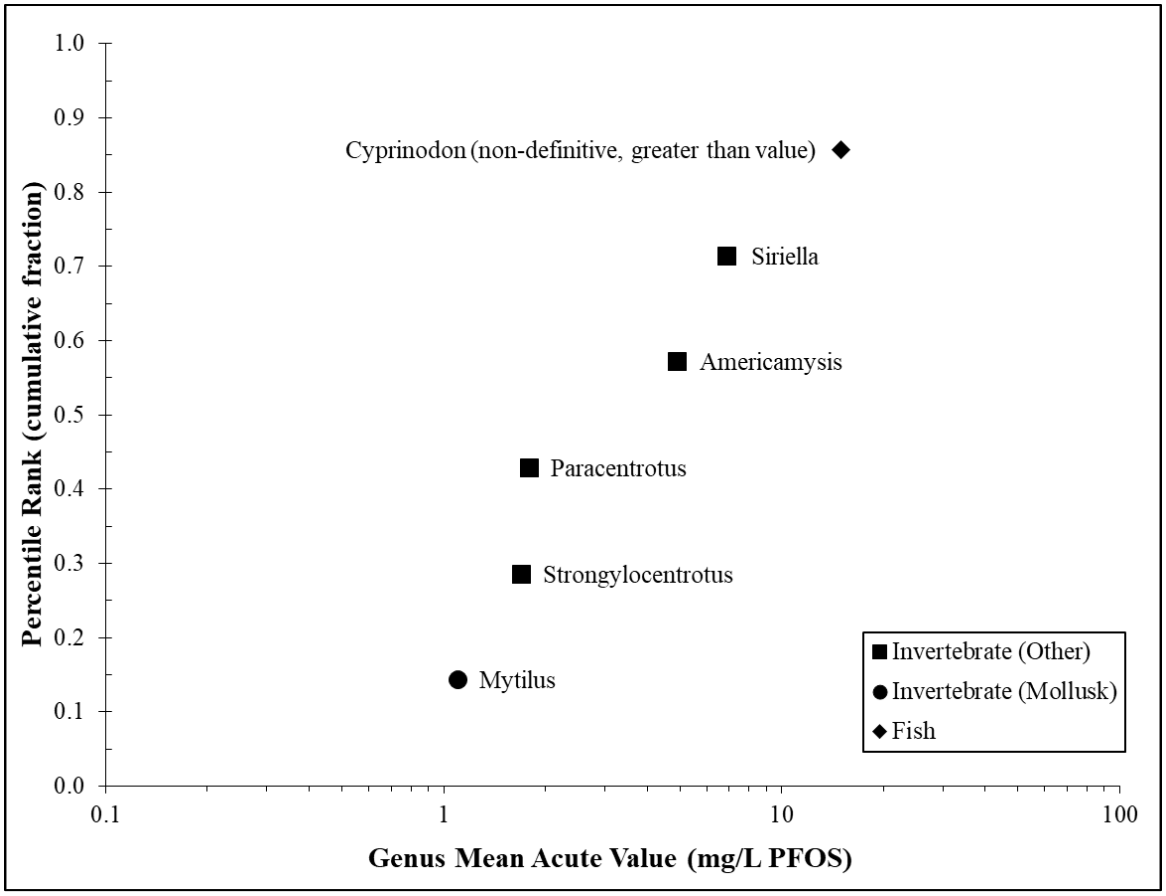

Figure 3-2. Acceptable Estuarine/Marine GMAVs.

3.1.1.3 Summary of Chronic PFOS Toxicity Studies Used to Derive the Freshwater Aquatic Life Criterion

Chronic toxicity data were available for all of the freshwater MDRs. Chronic PFOS toxicity data were available for 19 freshwater species, representing 17 genera and 15 families in four phyla. More specifically, quantitative data for acute PFOS toxicity were available for four freshwater fish species, representing four genera and three families (two of the eight MDRs), 11 freshwater invertebrate species, representing 11 genera and ten families (five of the eight MDRs), and three amphibian species, representing two genera in two families (one of the eight MDRs). Ranked GMCVs for PFOS in freshwater based on chronic toxicity are listed in Table 3-6 (four most sensitive genera) and Table 3-7 (all genera) and plotted in Figure 3-3.

NMED Exhibit 62

Table 3-6. The Four Most Sensitive Genera Used in Calculating the Chronic Freshwater Criterion.

Ranked Below from Most to Least Sensitive.

Rank	Genus	Species	GMCV (mg/L PFOS)[1]
1	*Neocloeon*	Mayfly, *Neocloeon triangulifer*	0.000226
2	*Chironomus*	Midge, *Chironomus dilutus*	0.005198
3	*Lampsilis*	Fatmucket, *Lampsilis siliquoidea*	0.01768
4	*Enallagma*	Blue damselfly, *Enallagma cyathigerum*	0.03162

[1]Other values were used in additional analyses supporting the criterion calculation to examine the effects of less certain toxicity studies and non-resident species on the chronic freshwater criterion. See Section 4.1 below for more details.

3.1.1.3.1 Most Sensitive Freshwater Genus for Chronic Toxicity: Neocloeon (mayfly)

Soucek et al. (2023) conducted a chronic life-cycle test to determine the effects of PFOS-K (PFOS potassium salt, CAS # 2795-39-3, 98% purity) on the parthenogenetic mayfly, *Neocloeon triangulifer*. The test was performed under renewal conditions over 27 days beginning with < 24 hour old nymphs. There were sixteen (with one mayfly per replicate) replicates per test concentration and control. Replicates one through eight were destructively sampled on day 14 and replicates nine through sixteen continued until the end of the test (when all mayflies either molted into imago stage or died). The endpoints that were evaluated included survival for all replicates, 14-d length and calculated dry weight (using a previously published body dry weight equation; Besser et al. 2021) for replicates 1 through 8, and percent survival to pre-emergent nymph (PEN) stage, number of days until PEN stage, percent emergence (to imago stage), and pre-egg laying live weight of imago for replicates 9 through 16. Percent survival in the control after 14 days was 100%. Percent survival of mayflies after 14 days in the remaining seven test concentrations ranged from 79 to 100%. The most sensitive endpoint was 14-day dry weight. The study authors reported three different 14-day dry weight EC_{10} values that were

NMED Exhibit 62

calculated using various point-estimation approaches. The author-reported 14-day dry weight EC_{10} values produced by the various approaches were relatively similar to one another, ranging from 0.000226 (using TRAP [2 parameter, threshold sigmoidal curve]) to 0.000272 mg/L (using log-linear regression, controls excluded). The EPA was not able to fit a reliable model with significant model parameters to the 14-day dry weight C-R dataset and, therefore, relied on the author-reported EC_{10} of 0.000226 mg/L (based on TRAP) as the primary effect concentration. The EPA selected the TRAP-based EC_{10} preferentially over the EC_{10} values based on the two other point estimation approaches (i.e., log-linear regression with and without controls) because the TRAP-based model (1) considered control responses; (2) was more fundamentally consistent with the maximum likelihood regression approaches used by the EPA to assess C-R datasets throughout this PFOS aquatic life AWQC document, and; (3) relied on replicate-level data, which the EPA used preferentially over treatment-mean data in assessing C-R datasets throughout the PFOS aquatic life criteria derivation process. The author-reported EC_{10} of 0.000226 mg/L (TRAP-based) was used quantitatively to derive the freshwater chronic water column criterion for PFOS.

3.1.1.3.2 Second Most Sensitive Freshwater Genus for Chronic Toxicity: Chironomus (midge)

MacDonald et al. (2004) conducted sub-chronic, partial-life cycle tests on larva and chronic life-cycle tests to determine the effects of PFOS-K (PFOS potassium salt, 95% purity) on the midge, *Chironomus dilutus* (formally known as *Chironomus tentans*). The test was performed under renewal conditions over 10 days for the larval test and greater than 50 days for the life-cycle test. The tests followed the general guidance given by EPA-600-R99-064 (U.S. EPA 2000b) and ASTM E 1706-00 (ASTM 2002).

NMED Exhibit 62

The author-reported 10-day growth and survival EC_{10}s for the study were 0.0492 and 0.1079 mg/L, respectively. The study authors also reported NOECs of 0.0491 mg/L, LOECs of 0.0962 mg/L, and MATCs of 0.0687 mg/L for both endpoints. The author-reported 20-day EC_{10}s for growth, survival, and total emergence were 0.0882, 0.0864, and 0.0893 mg/L, respectively. The study authors also reported NOECs of 0.0217 mg/L for growth and survival and < 0.0023 mg/L for emergence, LOECs of 0.0949 mg/L for growth and survival and 0.0271 mg/L for emergence, and MATCs of 0.0454 mg/L for growth and survival and 0.0071 mg/L for emergence. It is noted here that the paper reported contrasting NOECs for 20-day survival. The text in the paper stated that the NOEC was 0.0271 mg/L and Table 2 of the paper provided a value of 0.0949 mg/L. The EPA assumed the NOEC in Table 2 of the paper was not correct and that 0.0217 mg/L was the correct NOEC based on the data presented in Figure 3A of the paper, since the EPA was unable to gain confirmation from the study authors. This assumption was applied to the summary of the study results presented in this PFOS aquatic life AWQC document. The EPA was able to independently calculate an EC_{10} for 10-day growth of 0.05896 mg/L for the study. The independently-calculated 10-day EC_{10} value for growth of the midge was used quantitatively to derive the freshwater chronic water column criterion for PFOS.

McCarthy et al. (2021) conducted two chronic toxicity tests with PFOS (98% purity) on the midge, *C. dilutus*, a 10-day and a 20-day exposure, following standard protocols from U.S. EPA (2000b) and ASTM (2002) with slight modifications. The 10-day exposure was considered a range finding test, with concentrations spaced by ~100x and only mortality measured, whereas the 20-day exposure measured both survival and growth and was termed an "abbreviated full life cycle test" by the study authors. The 20-day exposure is less than the recommended 50 – 65 day full-life cycle method outlined in U.S. EPA (2000b) and used in MacDonald et al. (2004), and

NMED Exhibit 62

since exposures of midges started on day two or four, the actual exposure duration is only 16 or 19 days long. The most sensitive endpoint was survival from the "abbreviated full life cycle test" with an author-reported 16-day EC_{10} of 0.00136 mg/L PFOS. Additionally, the study authors reported EC_{10}s of 0.00162 and 0.00323 mg/L PFOS for growth as mean biomass and mean weight, respectively. The EPA was unable to independently calculate EC_{10}s for survival and mean weight. However, the EPA was able to independently calculate an EC_{10} value for mean biomass of 0.001588 mg/L PFOS. The independently-calculated 16-day EC_{10} for mean biomass was used quantitatively to derive the freshwater chronic water column criterion for PFOS.

Krupa et al. (2022) conducted a partial-life cycle chronic toxicity test with the midge, *C. dilutus*, and PFOS-K (perfluorooctanesulfonate potassium salt, > 98% purity, CAS No. 2795-39-3. The larvae were exposed to PFOS for 16 days. The measured exposure concentrations were < the limit of detection (LOD), 0.001, 0.0025, 0.004, 0.0075, 0.016 and 0.03 mg/L. At test termination, larval survival was assessed, and ash-free dry weight (AFDW) was determined following ASTM (2019). The AFDW of five groups of 12 larvae was measured at test initiation to establish a baseline for growth. The author-reported 16-day growth EC_{10} was 0.0015 mg/L PFOS-K. The EPA was unable to fit a reliable model for any of the chronic endpoints from this test. Therefore, the author-reported EC_{10} value of 0.0015 mg/L for growth presented in the paper was used quantitatively to derive the freshwater chronic water column criterion for PFOS.

The most sensitive endpoints from the two toxicity studies with *C. dilutus* that could be independently-calculated (see details in Appendix C.2.2) were for 10-day growth with an EC_{10} of 0.05896 mg/L (MacDonald et al. 2004) and 16-day mean biomass with an EC_{10} of 0.001588 mg/L (McCarthy et al. 2021). The EPA could not independently calculate the 16-day growth EC_{10} of 0.0015 mg/L (Krupa et al. 2022). Although over an order of magnitude difference exists

NMED Exhibit 62

between MacDonald et al. (2004) and the other two studies, all three EC_{10}s were used quantitatively to derive the chronic aquatic life criterion with a SMCV and GMCV equal to the geometric mean of the three values or 0.005198 mg/L.

As mentioned in the Bots et al. (2010) summary (Section 3.1.1.3.4), the observed effects of PFOS on aquatic insects appeared to be consistent across the available data for chironomids and odonates. However, Bots et al. (2010) did not measure the effects of PFOS on nymph growth and therefore, the observed effects in that study cannot be compared with the results of MacDonald et al. (2004), McCarthy et al. (2021), and Krupa et al. (2022). The remainder of the toxicity values available for aquatic insects were used as supporting information to corroborate the toxicity value used to derive the freshwater chronic criterion and to better understand the effects of PFOS on aquatic insects in general. No other quantitative toxicity values were available for this species or genus.

3.1.1.3.3 Third Most Sensitive Freshwater Genus for Chronic Toxicity: Lampsilis (mussel)

Hazelton (2013); Hazelton et al. (2012) conducted a test of the long-term effects of PFOS (acid form, > 98% purity) on glochidia and juvenile life stages from the mussel *Lampsilis siliquoidea* using a unique experimental design for which standard methods have not been established. The test exposed brooding glochidia (in marsupia) for 36 days followed by a 24-hour exposure of free glochidia in a factorial design. As such, the free glochidia from the control group of the marsupia exposure were divided between a control and the two PFOS treatments and the PFOS treatments were split into control and the same PFOS treatment group as the marsupia exposure. This factorial design allowed for the comparison of PFOS effects in two different life-stages. See Appendix C.2.3 for additional details on the experimental design and considerations for the utilization of this study in the criterion derivation.

NMED Exhibit 62

The data presented in the paper for metamorphosis success were considered for quantitative use in the derivation of the chronic criterion for PFOS (see Appendix C.2.3). The author-reported NOEC was 0.0045 mg/L and LOEC was 0.0695 mg/L. The reduction in metamorphosis success at the LOEC was estimated to be 35.4%. However, this was not a definitive test in that both the study design (which only included two treatment groups) and level of data presented (which are only presented graphically in Figure 2 of the paper) in the publication lack the details needed to fully understand the effects of chronic PFOS exposures to the glochidia and juvenile life stages of *L. siliquoidea.* Additionally, as there were only two PFOS treatment groups and the gap in these exposure concentrations is large (about 15-fold), the EPA was not able to fit a curve to estimate an EC_{10} in a manner similar to the other toxicity studies used to derive this criterion. Instead, both the use of an MATC and an estimated EC_{10} were considered for the chronic value. An EC_{10} was estimated by assuming the 0.0695 mg/L treatment represents an $EC_{35.4}$ and estimating the EC_{10} using the exposure response slope from another PFOS toxicity study focused on another mussel species (*Perna viridis*). Specifically, the chronic exposure of *Perna viridis* reported by Liu et al. (2013), which is summarized in Section 3.1.1.4.1, was used to derive a $EC_{10}/EC_{35.4}$ ratio from that study, which was 0.0033/0.0186, or 0.1770. Applying this ratio to Hazelton et al. (2012) yields an estimated EC_{10} of 0.0123 mg/L. Given the similarity between this EC_{10} and the author-reported MATC for Hazelton et al. (2012), the MATC of 0.01768 mg/L was used to derive the chronic criterion for PFOS. The EPA hopes to further refine the estimated EC_{10} by obtaining the treatment level data from the study authors and exploring additional exposure response slopes from the PFOS dataset. No other quantitative chronic toxicity values were available for this species or genus; therefore, the

NMED Exhibit 62

MATC of 0.01768 mg/L was used quantitatively to derive the freshwater chronic water column criterion for PFOS.

3.1.1.3.4 Fourth Most Sensitive Freshwater Genus for Chronic Toxicity: Enallagma (damselfly)

Bots et al. (2010) conducted a 320-day partial life-cycle study under renewal test conditions to examine the effects of PFOS (tetraethylammonium salt, 98% purity) on the damselfly *Enallagma cyathigerum.* Approximately 40% of the nymphs in the control treatment died during the first 60 days and similar mortality levels were observed in the other treatments. However, it appeared that control survival plateaued between 60 and 200 days, with 82.57% of the remaining nymphs in the control treatment surviving during this time, indicating that survival settled out during this phase of the experiment. The initial drop in nymph survival could likely be attributed to the handling of the test organisms between the various phases of the experiment. This would explain the observed plateau between 60 and 200 days, as the nymphs were not handled during this time. The observed control survival in this test was consistent with other odonate tests and excessive mortality of nymphs is typically expected within the first 200 days given the difficulty in maintaining odonates in a lab setting (Abbott and Svensson 2007; Rice 2008). Therefore, the observed control survival for this study was considered within the acceptable range for this species up to the 200-day exposure duration. Further, the control survival observed in this study was largely consistent with the toxicity testing guidelines for chironomids (requiring 70% control survival: ASTM 2002; U.S. EPA 2000b), which are currently the only test guidelines for an emergent aquatic insect as there currently is no test guideline for odonates. Therefore, considerations regarding the use of these data for chronic criterion derivation were based on best scientific judgement and were restricted to the first 200 days of the experiment.

NMED Exhibit 62

The observed effects of PFOS on *E. cyathigerum* reported in the paper by the study authors include decreased survival over the exposure duration and decreased metamorphosis success. The MATC based on metamorphic success was less sensitive than for survival. As such, the MATC author-reported value of 0.03162 mg/L for nymph survival was considered quantitatively in the derivation of the aquatic life criteria. The remainder of the toxicity values were used as supporting information to corroborate the toxicity value used to derive the freshwater chronic criterion and to better understand the effects of PFOS on aquatic insects. As no other quantitative toxicity values were available for this species or genus, the author-reported MATC of 0.03162 mg/L served directly as the SMCV/GMCV. Additionally, the EPA ran additional analyses with some of the other toxicity values for *E. cyathigerum* to understand the influence of this study on the overall chronic criterion (see Section 4.1 below).

Table 3-7. Ranked Freshwater Genus Mean Chronic Values.

Rank[a]	GMCV (mg/L PFOS)	MDR Group[c]	Genus	Species	SMCV[b] (mg/L PFOS)

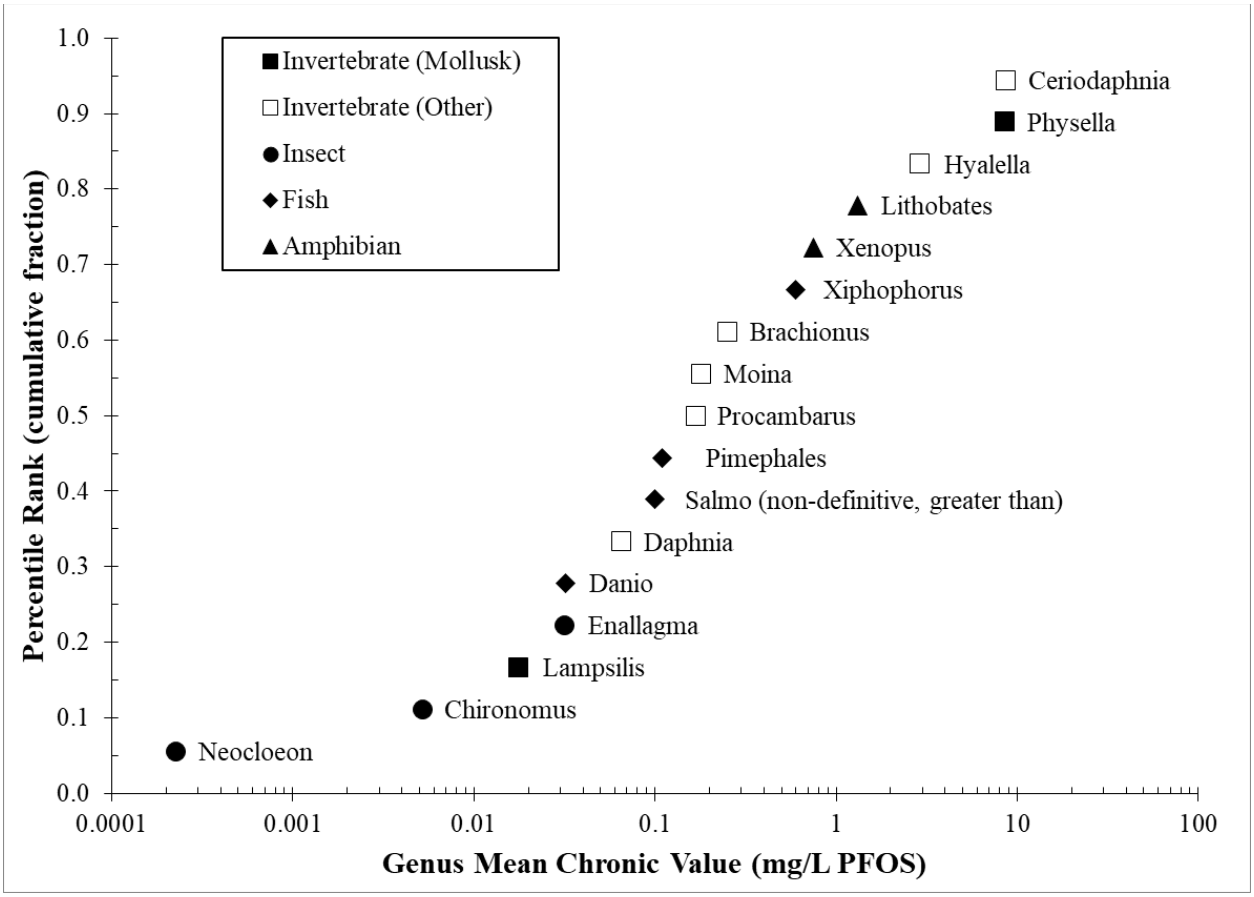

Figure 3-3. Ranked Freshwater Chronic PFOS Used Quantitatively to Derive the Criterion.

3.1.1.4 Summary of Chronic PFOS Toxicity Studies Used to Derive the Saltwater Aquatic Life Criterion

Data for chronic PFOS toxicity were available for five saltwater invertebrate species, representing five genera and five families. The data available for saltwater fish fulfilled only five of the eight MDRs.

NMED Exhibit 62

Table 3-8. The Four Ranked Estuarine/Marine Genus Mean Chronic Values.
Ranked Below from Most to Least Sensitive.

Rank	Genus	Species	GMCV (mg/L PFOS)	Comments
1	*Perna*	Asian green mussel, *Perna viridis*	0.0033	Not a resident species in North America
2	*Austrochiltonia*	Amphipod, *Austrochiltonia subtenuis*	0.01118	Not a resident species in North America, but other species in this Order (Amphipoda) are common ecotoxicity test species that serves as a surrogate for untested amphipod species residing in North America.
3	*Americamysis*	Mysid, *Americamysis bahia*	0.3708	North American resident species
4	*Tigriopus*	Copepod, *Tigriopus japonicus*	0.7071	Not a resident species in North America, but other species in this genus (*Tigriopus*) are common ecotoxicity test species that serves as a surrogate for untested copepod species residing in North America.

3.1.1.4.1 Most Sensitive Estuarine/Marine Genus: Perna (mussel)

Liu et al. (2013) evaluated the chronic effects of PFOS-K (PFOS potassium salt, CAS# 2795-39-3, 98% purity) on green mussels, *Perna viridis*, via a 7-day measured, static-renewal study. Mussels were exposed at a salinity of 25 ppt (artificial seawater) and a temperature of 25°C. PFOS concentrations were verified through water and muscle tissue samples via liquid chromatography-tandem mass spectrometry. Weights and lengths were determined on days zero and seven. An author-reported NOEC of 0.0096 mg/L and a LOEC of 0.106 mg/L was determined for the growth condition index. The EPA's independently-calculated EC_{10} for growth condition index is 0.0033 mg/L. This EC_{10} is used quantitatively to represent the chronic sensitivity of this species to PFOS exposure in the marine/estuarine aquatic life dataset.

NMED Exhibit 62

3.1.1.4.2 Second Most Sensitive Estuarine/Marine Genus: Austrochiltonia (amphipod)

Sinclair et al. (2022) tested perfluorooctane sulfonic acid (PFOS, purity not reported) on amphipods (*Austrochiltonia subtenuis*) in a 7-day unmeasured, static experiment. The 7-day experiment consisted of five controls, one solvent control (methanol 0.25 mL/L), and five nominal PFOS concentrations (0.04, 0.2, 1.0, 5.0, 25 µg/L). Test vessels were 600 mL beakers with 400 mL of test material and a 2x2 cm gauze substrate. Each test vessel included 20 amphipods, and all test material was dissolved in modified standard artificial media. The NOEC and LOEC for 7-day survival were 0.005 mg/L and 0.025 mg/L, respectively, and the resulting MATC of 0.01118 mg/L was determined to be acceptable for quantitative use.

3.1.1.4.3 Third Most Sensitive Estuarine/Marine Genus: Americamysis (mysid)

Drottar and Krueger (2000h) reported the results of a 35-day flow-through, measured life-cycle test of PFOS-K (potassium salt, 90.49% purity) with *Americamysis bahia* (formerly *Mysidopsis bahia*). The 35-day NOEC (reproduction and growth) was 0.25 mg/L, and the corresponding 35-day LOEC was 0.55 mg/L. An independently-calculated EC_{10} could not be defined at this time given the level of data that was presented in the paper (Appendix D). The calculated MATC for the test was 0.3708 mg/L. This chronic value was considered acceptable for quantitative use despite the control survival of 78% because it was only slightly below the 80% survival threshold, and because there were no other deficiencies in the study design.

3.1.1.4.4 Fourth Most Sensitive Estuarine/Marine Genus: Tigriopus (copepod)

A 20-day renewal, unmeasured full life-cycle test with PFOS (analytical grade) was conducted on the copepod, *Tigriopus japonicus* (non-North American species) by **Han et al. (2015)**. The development of the copepod's growth from nauplii to copepodite and from nauplii to adults was determined daily based on morphological characteristics. Results were presented as

NMED Exhibit 62

the number of days needed to reach the normal development stages. The highest test concentration (1 mg/L PFOS) significantly increased the amount of time it took the copepods to reach the development stage. Additionally, the authors assessed the reproduction of the copepods by counting the nauplii produced by eight ovigerous females for 10 days in each well exposed to PFOS. However, it was unclear if this was a subsampling of the organisms used in the 20-day developmental test or if an independent assay with adult females was run. Results are presented graphically as daily nauplii production/individual. There was a statistically significant decrease in production (daily nauplii production/individual) in the 0.25, 0.5 and 1.0 mg/L PFOS concentrations compared to the control. Production was decreased by approximately 50% in the highest concentration (1 mg/L). The 20-day MATC based on time to reach development stage was 0.7071 mg/L and was acceptable for quantitative use in the marine/estuarine chronic aquatic life dataset.

NMED Exhibit 62

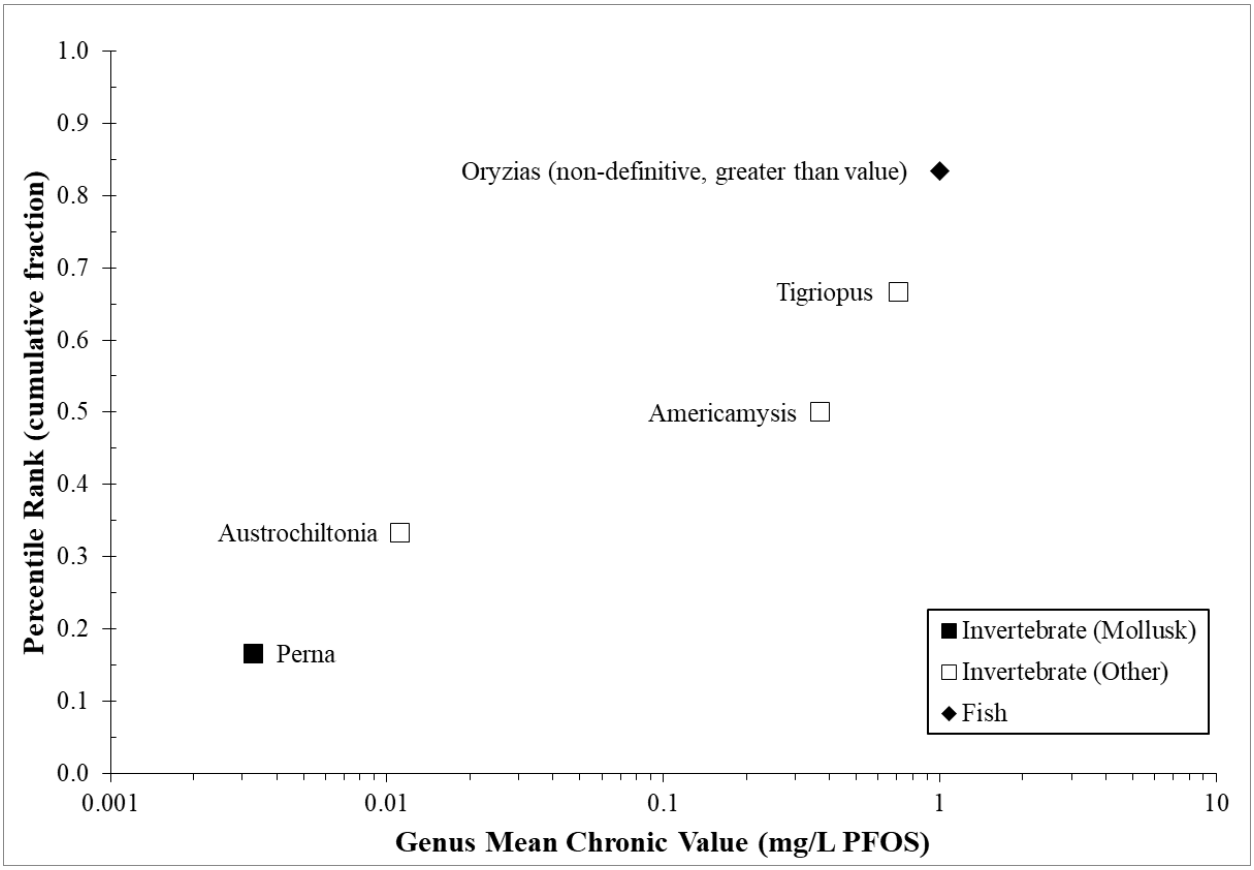

Figure 3-4. Acceptable Estuarine/Marine GMCVs.

3.2 Derivation of the PFOS Aquatic Life Criteria

3.2.1 Derivation of Water Column Criteria for Direct Aqueous Exposure

3.2.1.1 Derivation of Acute Water Column Criterion for Freshwater

The PFOS acute dataset for freshwater based on direct aqueous exposures contained 20 genera representing all eight MDRs. GMAVs for the 20 freshwater genera are provided in Table 3-3, and the four most sensitive genera were within a factor of ~100 of each other. The lowest acute value for the mayfly, *Neocloeon triangulifer*, is 40 times lower than the second most sensitive genus (Figure 3-5). The freshwater FAV, the 5th percentile of the genus sensitivity distribution, for PFOS was 0.1413 mg/L, and was calculated using the procedures described in the 1985 Guidelines (U.S. EPA 1985). The FAV was lower than all of the GMAVs of the tested species, except the mayfly, *Neocloeon triangulifer*. The FAV was then divided by two to obtain a

NMED Exhibit 62

concentration yielding minimal effects (see Section 2.9). The FAV/2, which is the acute freshwater criterion (or criterion maximum concentration, CMC), was 0.071 mg/L PFOS (rounded to two significant figures), and is expected to be protective of approximately 95% of freshwater genera potentially exposed to PFOS via direct aqueous exposure, under short-term duration conditions of one-hour, when the criterion magnitude is not exceeded more than once in three years on average (Table 3-9).

Table 3-9. Freshwater Final Acute Value and Criterion Maximum Concentration.

Calculated Freshwater FAV based on 4 lowest values: Total Number of GMAVs in Dataset = 20						
Rank	**Genus**	**GMAV (mg/L)**	**ln(GMAV)**	**ln(GMAV)^2**	**P=R/(N+1)**	**sqrt(P)**
1	*Neocloeon*	0.07617	-2.57	6.63	0.048	0.218
2	*Moina*	3.075	1.12	1.26	0.095	0.309

4	*Oncorhynchus*	7.515	2.02	4.07	0.190	0.436
		Σ (Sum):	**2.50**	**15.72**	**0.48**	**1.34**

S^2 = 534.58 **S = slope**
L = -7.127 **L = X-axis intercept**
A = -1.957 **A = lnFAV**
FAV = 0.1413 **P = cumulative probability**
CMC = 0.071 mg/L PFOS (rounded to two significant figures)

NMED Exhibit 62

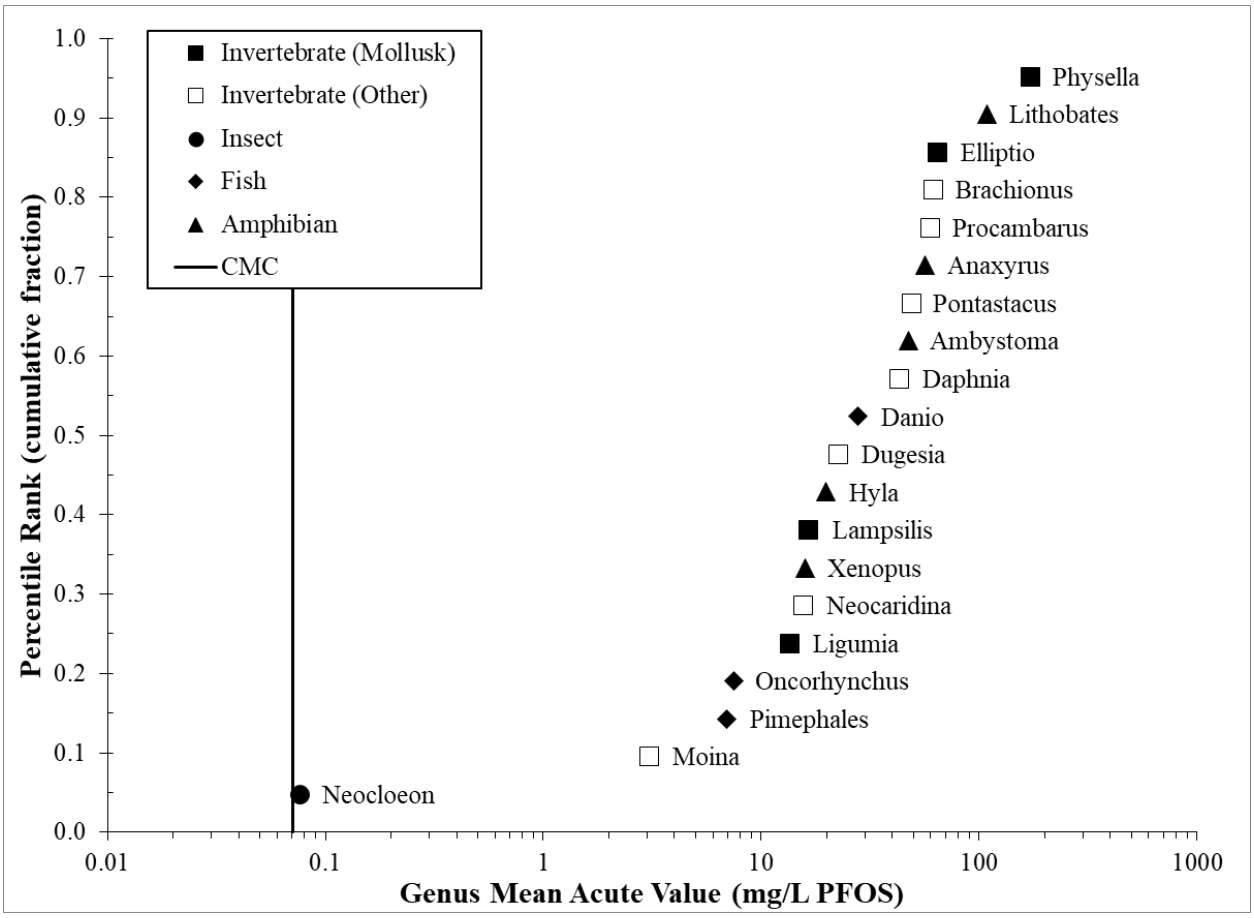

Figure 3-5. Ranked Freshwater Acute PFOS GMAVs Used Quantitatively to Derive the Criterion.

3.2.1.2 Derivation of Acute Water Column Criterion for Estuarine/Marine Water

The estuarine/marine acute dataset for PFOS contained six genera (Table 3-5 and Appendix B) representing only five of the eight taxonomic MDR groups. The missing MDR groups included one family in the phylum Chordata, a family in a phylum other than Chordata, and another family not already represented. The GMAVs of the four most sensitive definitive estuarine/marine genera were within a factor of 4.5 of each other (Table 3-5).

Because data were available for only five of eight MDRs, the EPA developed an estuarine/marine acute benchmark using the available empirical data supplemented with toxicity values generated through the use of NAMs, specifically through the use of the EPA Office of

NMED Exhibit 62

Research and Development's peer-reviewed publicly-available web-ICE tool (Raimondo et al. 2010). This benchmark is provided in Appendix L.

3.2.1.3 Derivation of Chronic Water Column Criterion for Freshwater

The PFOS chronic dataset based on direct aqueous exposures contained data for all eight MDRs, thus the Final Chronic Value (FCV) can be calculated directly without the use of an ACR. There were GMCVs for 17 freshwater genera (Table 3-7). The four most sensitive genera were within a factor of 140 of each other. The lowest chronic value for the mayfly, *Neocloeon triangulifer*, is over an order of magnitude lower than the second most sensitive genus (Figure 3-6). The freshwater FCV for PFOS of 0.0002491 mg/L was calculated using the procedures described in the 1985 Guidelines (U.S. EPA 1985). The FCV is the 5th percentile of the genus sensitivity distribution and is intended to be protective of 95 percent of the genera. The FCV was lower than all of the GMCVs of the tested species, except the mayfly, *Neocloeon triangulifer*. Unlike the FAV, the FCV was not divided by two, as it already represents a low effect level, and was equal to the water column chronic criterion (or criterion continuous concentration, CCC; Table 3-10). The freshwater CCC had a magnitude 0.00025 mg/L PFOS (rounded to two significant figures), or 0.25 µg/L, and is expected to be protective of 95% of freshwater genera potentially exposed to PFOS through direct aqueous exposure under long term conditions of four days, if not exceeded more than once every three years on average (Table 3-10).

NMED Exhibit 62

Table 3-10. Freshwater Final Chronic Value and Criterion Continuous Concentration.

Calculated Freshwater FCV based on 4 lowest values: Total Number of GMCVs in Dataset = 17						
Rank	**Genus**	**GMCV (mg/L)**	**ln(GMCV)**	**ln(GMCV)^2**	**P=R/(N+1)**	**sqrt(P)**

CCC = 0.00025 mg/L PFOS (rounded to two significant figures)

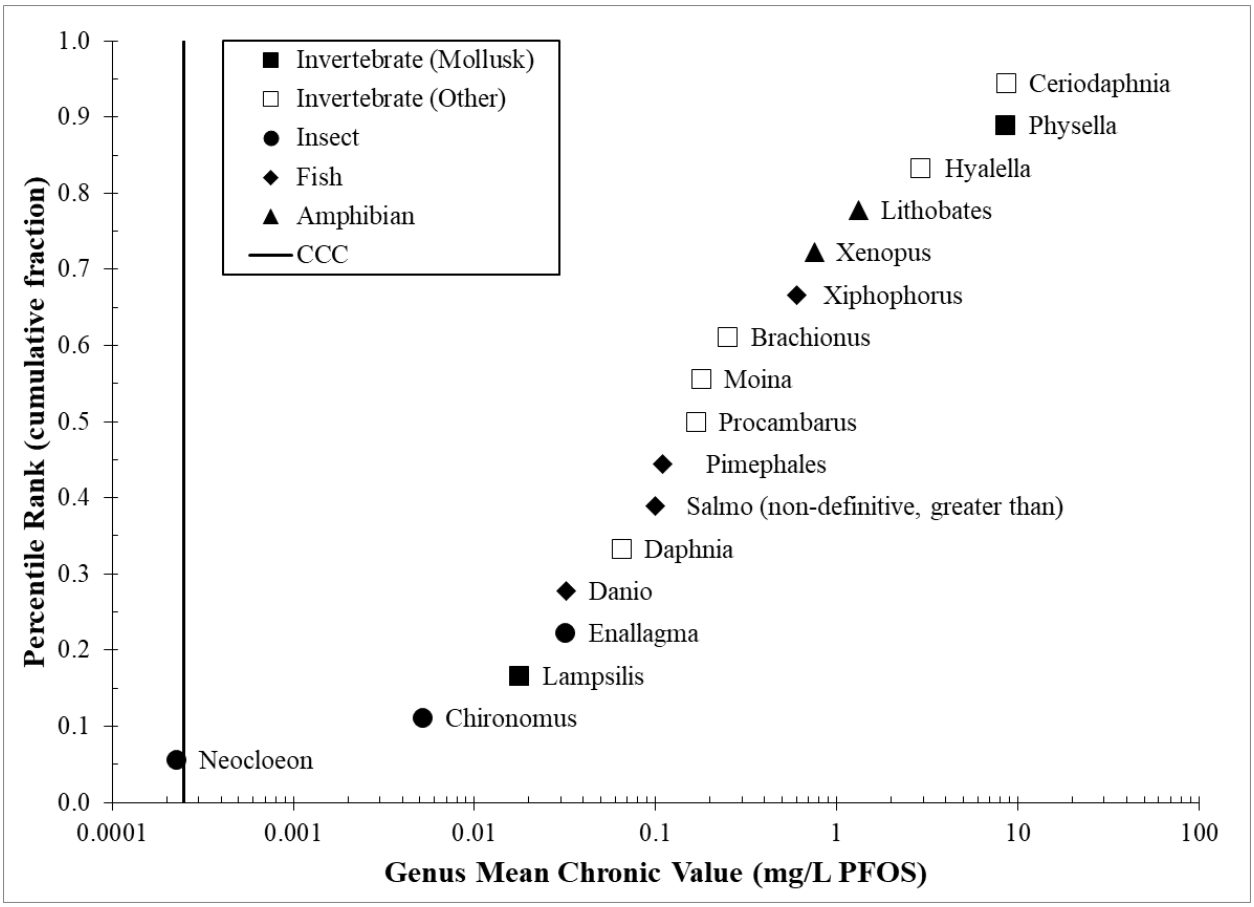

Figure 3-6. Ranked Freshwater Chronic PFOS GMCVs Used Quantitatively to Derive the Criterion.

3.2.1.4 Deriving A Protective Duration Component of the Chronic Water Column-Based Criterion

Effects to sensitive life stages was a primary reason why the 1985 Guidelines (U.S. EPA 1985) recommended a 4-day duration for most water column-based criteria. U.S. EPA (1985) states, "*An averaging period of four days seems appropriate for use with the CCC for two reasons. With one of the two reasons specify being, "for some species it appears that the results of chronic tests are due to the existence of a sensitive life stage at some time during the test*."

The SMCV for *C. dilutus*, representing the *Chironomus* GMCV (second most sensitive genus) is based on the EPA's independently-calculated EC_{10} of 0.05896 mg/L for a 10-day larval growth endpoint by MacDonald et al. (2004), an EC_{10} of 0.001588 mg/L for a 16-day larval mean biomass endpoint by McCarthy et al. (2021), and an EC_{10} of 0.0015 mg/L for a 14-day larval growth endpoint by Krupa et al. (2022). The EC_{10} for a 10-day larval growth by MacDonald et al. (2004) is slightly higher than the author-reported EC_{10} for this effect in the study. The author-reported EC_{10}s for the 20-day test by MacDonald et al. (2004) were higher than those for the 10-day test, which is an atypical outcome, and were not used for criteria derivation. Consequently, there was no clear influence of exposure time on the effects of PFOS on this species.

The SMCV for *L. siliquoidea,* representing the *Lampsilis* GMCV (third most sensitive genus) is based on a 36-day study by Hazelton (2013); Hazelton et al. (2012) using glochidia and juvenile life stages. The test exposed brooding glochidia (in marsupia) for 36 days followed by a 24-hour exposure of free glochidia. The 24-hour free glochidia exposure consisted of a factorial design, such that free glochidia from the control group of the marsupia exposure were divided between a control and the two PFOS treatments and the PFOS treatments were split into control

NMED Exhibit 62

and the same PFOS treatment group as the marsupia exposure. This factorial design allowed for the comparison of PFOS effects in two different life-stages.

Given the limitations of time points that could be discerned by the test, it appeared that for reduced viability and or metamorphosis success of free glochidia to occur at concentrations near the chronic value for the test (0.01768 mg/L), the test's 36-day exposure period would also be needed. For example, the study authors determined that the *in-marsupia* (36-day) exposure held the greatest weight of evidence and explained 78% of the variability in the glochidia viability (AIC = 22843, wi = 0.78) and 83% of the metamorphosis success (AIC = 21955, wi = 0.83). As a result, this species appears to be protected by the chronic 4-day duration component of the water column criterion. It should also be noted, brief PFOS exposures at elevated concentrations consistent with the magnitude and four-day duration of the chronic criterion are not expected to cause effects to free swimming glochidia based on the 24-hour acute toxicity data for glochidia.

The SMCV for *Enallagma cyathigerum*, representing the *Enallagma* GMCV (fourth most sensitive genus) are based on a 320-day partial life-cycle test by Bots et al. (2010). Only a single treatment, 0.1 mg/L, showed partial effects. The treatment 10X higher (i.e., 1 mg/L) yielded 100% mortality within 20 days. The treatment 10X lower (0.01 mg/L) showed no effects over the entire test. The authors provided the time course of mortality throughout the entire test. At 0.1 mg/L a marked reduction in survival began at 130 days, and reached zero survival at 250 days, suggesting a relatively long time-to-effect. Because 0.1 mg/L is more than 3-fold higher than the estimated chronic value for the test, 0.03162 mg/L, it is postulated that the time course of mortality observed at 0.1 mg/L would be substantially faster than what would be expected to occur at 0.03162 mg/L. Given the relatively slow manifestation of chronic effects observed in

NMED Exhibit 62

this study, this species appears to be protected by the chronic 4-day duration component of the water column criterion.

No chronic PFOS toxicity tests specifically evaluated time-to-effect, reported effect data at time intervals at a high enough resolution to model the speed of toxic action, assessed time variable PFOS exposures, or provided insight into the potential for latent toxicity. However, chronic tests, including life-cycle tests with relatively sensitive species, suggested chronic effects may occur at durations shorter than those of standard chronic toxicity tests (e.g., 28-day ELS tests) and a chronic 4-day duration component of the water column criterion was considered protective for these species/genera. Therefore, the EPA has set the duration component of the PFOS chronic water column criterion at four days to reflect the chronic criterion duration recommended in the 1985 Guidelines. This 4-day duration component of the chronic water column is also consistent with U.S. EPA (1991), which considered the default 4-day chronic averaging period as "*the shortest duration in which chronic effects are sometimes observed for certain species and toxicants*", and concludes that 4-day averaging "*should be fully protective even for the fastest acting toxicants*."

3.2.1.5 Derivation of Chronic Water Column Criterion for Estuarine/Marine Water

The estuarine/marine chronic dataset for PFOS contained GMCVs for five genera. GMCVs for five estuarine/marine genera are summarized in Section 3.1.1.4 and shown in Figure 3-4. The eight-family taxonomic (MDR) requirement was not met by the chronic dataset, as acceptable chronic studies for species representing three MDR groups are not available (one family in the phylum Chordata, a family in a phylum other than Arthropoda or Chordata, and another family not already represented). The 1985 Guidelines allow the use of a Final Acute-Chronic Ratio (FACR) to convert a FAV to an FCV (i.e., FAV/FACR = FCV), which is equivalent to a CCC. However, since an FAV could not be calculated with the available data, an

NMED Exhibit 62

FCV also could not be calculated. Consequently, the EPA could not derive estuarine/marine chronic criteria for PFOS (see Appendix L for derivation of acute estuarine/marine benchmarks).

3.2.2 Derivation of Freshwater Chronic Tissue criteria for PFOS

Currently, the freshwater chronic PFOS toxicity data with measured tissue concentrations were somewhat limited. There are 14 total freshwater aquatic life studies considered for either quantitative (six studies – three fish, one invertebrate, and two amphibian studies) or qualitative (eight studies) use in this aquatic life criterion. The quantitative studies only comprised data for three of the eight MDRs. The qualitative studies provided supporting information for only one additional MDR. Therefore, it was concluded that there is currently insufficient data to derive a chronic tissue criterion using a GSD approach from empirical tissue data from toxicity studies. However, these studies provided context to the translation of tissue criteria as described in Section 3.2.3 below. This comparison is provided in the Effects Characterization (Section 4.5).

3.2.3 Translation of Chronic Water Column Criterion to Tissue Criteria

As described in Section 3.2.2 above, there are currently insufficient freshwater chronic toxicity data with measured tissue concentrations to derive a chronic PFOS tissue criterion using a GSD approach. Therefore, the chronic tissue criteria for PFOS were derived by translating the chronic freshwater water column criterion (see Section 3.2.1.3) into tissue criteria using bioaccumulation factors (summarized in Section 3.2.3.1 below) and the following equation:

$$Tissue\ Criteria = Chronic\ Water\ Column\ Criterion\ \times BAF \qquad (Eq.\ 1)$$

The resulting tissue criteria corresponded to the tissue type associated with the BAF used in the equation.

3.2.3.1 PFOS Bioaccumulation Factors (BAFs)

Section 2.11.3.1 above summarizes the literature search, calculation, and evaluation of the PFOS BAFs for aquatic life. These BAFs were compiled by and can be found in Burkhard

NMED Exhibit 62

(2021). BAFs used in the derivation of the PFOS tissue criteria consisted of two or more water and organism samples each and were collected within one year and 2 km distance of one another. In order to derive more protective tissue criteria and to limit the effects of site-specific differences in BAFs, the distributions of BAFs used to derive tissue criteria were based on the lowest species-level BAF reported at a site. When more than one BAF was available for the same species within the same waterbody, the species-level BAF was calculated as the geometric mean of all BAFs for that species at that site. Summary statistics for the PFOS BAFs used in the criteria derivation are presented in Table 3-11 and individual BAFs are provided in Appendix O.

Table 3-11. Summary Statistics for PFOS BAFs in Fish and Invertebrates[1].

Category	n	Geometric Mean BAF (L/kg-ww)	Median BAF (L/kg-ww)	20th Centile BAF (L/kg-ww)	Minimum (L/kg-ww)	Maximum (L/kg-ww)
Invertebrates	28	771.6	924	111.5	2.69	100,000
Fish (Whole-Body)	28	3,739	5,905	803.9	4.79	46,098
Fish (Muscle)	21	1,069	1,048	346.4	8.72	50,234

[1] Based on the lowest species-level BAF measured at a site (i.e., when two or more BAFs were available for the same species at the same site, the species-level geometric mean BAF was calculated, and the lowest species-level BAF was used).

The fish tissue criteria were developed for muscle and whole-body to accommodate the most commonly sampled tissue types in monitoring programs. Additional tissue values for various other tissue types (e.g., liver and blood) were also calculated and can be found in Appendix P.

3.2.3.2 Deriving Protective Tissue Concentrations from the Chronic Water-Column Criterion

Invertebrate whole-body and fish muscle and whole-body tissue criteria were derived separately by multiplying the freshwater chronic water-column criterion (see Section 3.2.1.3) by the respective 20th centile of the distribution of BAFs using Equation (Eq. 1) from Section 3.2.3. The 20th centile BAF was used to derive tissue-based criteria as a relatively conservative BAF

NMED Exhibit 62

estimate in order to protect species across taxa and across water bodies with variable bioaccumulation conditions. That is, use of the 20th centile BAF protects species and conditions where the bioaccumulation of PFOS and resultant tissue-based exposures is relatively low as well as those conditions with the bioaccumulation potential of PFOS is relatively high.

The invertebrate whole-body tissue criterion was calculated by multiplying the 20th centile BAF of 111.5 L/kg ww by the PFOS freshwater chronic water criterion of 0.00025 mg/L, resulting in an invertebrate whole-body tissue criterion of 0.028 mg/kg ww. The fish whole-body tissue criterion was calculated by multiplying the 20th centile BAF of 803.9 L/kg ww by the PFOS freshwater chronic water criterion of 0.00025 mg/L, resulting in a fish whole-body tissue criterion of 0.201 mg/kg ww. The fish muscle tissue criterion was calculated by multiplying the 20th centile BAF of 346.4 L/kg ww by the PFOS freshwater chronic water criterion of 0.00025 mg/L, resulting in a fish muscle tissue criterion of 0.087 mg/kg ww. The chronic tissue-based criteria are expected to be protective of 95% of freshwater genera potentially exposed to PFOS under long-term exposures if the tissue-based criteria are not exceeded. The duration component of the tissue-based criteria is expressed as an instantaneous duration because the tissue-based criteria are protective of long-term conditions and represent an integrated measure of bioaccumulated PFOS concentrations over time.

The EPA acknowledges that there is uncertainty in deriving protective tissue criteria magnitudes by transforming the chronic water column criterion (which was based on tests that only added PFOS to the water column) into tissue concentrations through field-measured bioaccumulation data of paired water and tissue concentrations in waterbodies. Nevertheless, the chronic water column criterion is based on chronic toxicity tests where test organisms were fed. In these tests, PFOS can directly affect species based on direct water column exposure and/or

NMED Exhibit 62

sorb to added food that is consumed by test organisms before eliciting chronic effects from dietary exposure. Therefore, the chronic water column criterion magnitude accounts for water column-based and, to a possible lesser extent, dietary-based effects, while the field-based BAFs account for water column- and dietary-based PFOS exposure and subsequent accumulation in tissues. The chronic tissue criteria will allow states, Tribes, and stakeholders monitoring PFOS in freshwater lentic and lotic systems to evaluate potential effects to aquatic organisms based on the aquatic tissue monitoring data collected. Quantitatively acceptable data on the effects of dietary exposures to aquatic species were relatively limited, thus the EPA chose to develop protective values for freshwater aquatic organisms based on the observed relationship between water column concentrations and tissue concentrations and observed PFOS toxicity in chronic tests where PFOS was only added directly to the water column.

3.2.3.3 Deriving A Protective Duration and Exceedance Frequency for the Tissue-based Chronic Criteria

3.2.3.3.1 Duration: Chronic Tissue-Based Criteria

PFOS concentrations in tissues are generally expected to change only gradually over time in response to environmental fluctuations. The chronic tissue-based criteria averaging period, or duration, was therefore specified as instantaneous, because tissue data provide point, or instantaneous, measurements that reflect integrative accumulation of PFOS over time and space in population(s) at a given site.

3.2.3.3.2 Frequency: Chronic Tissue-Based Criteria

The PFOS tissue-based criteria frequencies are set as “not to be exceeded” to ensure protection of freshwater aquatic organisms. The “not to exceed” condition for frequency is meant to account for the many variables influencing ecological recovery and uncertainty due to the complete lack of PFAS-specific ecological recovery case studies available to inform recovery

NMED Exhibit 62

rates following elevated PFOS concentrations in aquatic biota. Ecological recovery times following chemical disturbances in general are situational-specific, being largely dependent on: (1) biological variables such as the presence of nearby source populations or generational time of taxa affected; (2) physical variables such as lentic and lotic habitat considerations where recovery rates in lentic systems may be slower than lotic systems where the pollutant may be quickly flushed downstream, and; (3) chemical variables such as the persistence of the chemical and potential for residual effects.

PFOS-specific case studies are unavailable to directly inform rates of ecological recovery following elevated concentrations in fish and aquatic invertebrates. Metals and other chemical pollutants may be retained in the sediment and biota, where they can result in residual effects over time that further delay recovery. Few studies are available concerning PFOS elimination or depuration half-life in aquatic animals, however the data that exist indicate a short half-life. For example, the elimination half-life for PFOS in adult rainbow trout exposed to PFOS for 28 days via the diet followed by 28 days depuration was estimated to be 8.4 days in muscle tissue (Falk et al. 2015), while the terminal half-life in rainbow trout receiving a one-time intra-arterial injection of PFOS was 86.8 days (Consoer 2017). Additionally, the depuration half-life in northern leopard frog tadpoles via a 40-day aqueous exposure to 0.01 mg/L PFOS was estimated to be 2.2 days (Hoover et al. 2017). It's unclear whether PFOS half-life in aquatic organism tissues is the mechanistic result of rapid depuration or an artifact of these measurements taken during relatively short testing times (e.g., 28 days) where steady state between PFOS and water and tissues has not occurred. Long-term uptake and subsequent excretion rates of PFOS has been extensively studied in humans relative to aquatic life. Li et al. (2018) reported a median PFOS half-life of 3.4 years in human serum following exposure to PFOS in drinking water, which the

NMED Exhibit 62

authors stated was in the range of previously published estimates. Due to chemical retention in tissues, ecosystems impacted by discharges of bioaccumulative pollutants (such as selenium) generally recover from chemical disturbances at relatively slow rates. For example, Lemly (1997) concluded that although water quality in Belews Lake in North Carolina (a freshwater reservoir) had recovered significantly in the decade since selenium discharges were halted in 1985, the threat to fish had not been eliminated. The selenium discharges that led to severe reproductive failure and deformities in fish were still measurable (as fish deformities) in 1992 (seven years later) and in 1996 (ten years later). Lemly (1997) estimated based on these data that "*the timeframe necessary for complete recovery from selenium contamination from freshwater reservoirs can be on the order of decades.*"

Beyond bioaccumulation, chemical-specific considerations such as degradation versus persistence may also provide a mechanism influencing ecological recovery rates. The persistence of PFOS in the environment has been attributed to the strong C-F bond, with no known biodegradation or abiotic degradation processes for PFOS (refer to Section 2.3). Somewhat similarly to PFOS, metals do not degrade and may persist in aquatic systems following elevated discharge. The persistence of metals may explain why metals had the second longest median recovery time of any disturbance described in a systematic review of aquatic ecosystem recovery (Gergs et al. 2016). Gergs et al. (2016) showed recovery times following metal disturbances ranged from roughly six months to eight years (median recovery time = 1 year; 75^{th} centile ~ 3 years; n = 20). Unlike metals, however, PFOS is not naturally occurring, and aquatic organisms possess no evolved detoxification mechanisms to aid in recovery at the individual level. Furthermore, the degradation of other PFAS into PFOS may represent an additional source of PFOS in aquatic systems that further delays recovery.

NMED Exhibit 62

The persistence and bioaccumulative/human-made nature of PFOS in aquatic systems, in combination with the documented recovery times of pollutants with similar chemical attributes (Gergs et al. 2016; Lemly 1997; Mebane 2022), suggests aquatic systems may recover from PFOS tissue criteria exceedances on the order of 5 to 10 years, if sources were eliminated. However, recovery times could be longer, if the sources of PFOS and other PFAS that degrade into PFOS have not been removed. Specifying a time interval associated with ecological recovery from exceedances of PFOS tissue criteria, then, is highly uncertain given the lack of PFOS-specific examples of ecological recovery and the many situational-specific factors influencing recovery (Mebane 2022). For example, the lack of PFOS degradation in the environment, and the fact that other PFAS in the environment can degrade into PFOS could act as ongoing PFOS sources that further delay recovery. Given these uncertainties, the PFOS tissue-based criteria frequencies are set as "not to be exceeded" to ensure protection of aquatic life populations. Moreover, if tissue-based criteria were exceeded, then PFOS has likely built up through the food web and PFOS source reservoirs are likely to exist, representing a broad level of PFOS contamination throughout the aquatic ecosystem.

The "not to exceed" frequency components of the tissue-based criteria do not suggest aquatic ecosystems could never recover from an exceedance of the PFOS tissue-based criteria under the right conditions. Ecological recovery from such an exceedance could begin once PFOS source reservoirs existing within the ecosystem are eliminated or decreased, including other PFAS that degrade into PFOS; became permanently isolated from possible uptake by the ecosystem (e.g., long-term burial with no benthic disturbances under certain environmental conditions); and, unaffected organisms were able to repopulate the system through immigration and/or reproductive events that yield generations that are no longer exposed to PFOS.

NMED Exhibit 62

Evaluation of PFOS concentrations in tissues would likely include evaluating the central tendency of samples for a given species, collected at a specific site and time. Considering a measure of central tendency to assess tissue-based exposures in the field relative to the criteria is appropriate because the criteria are intended to protect aquatic life populations.

3.3 Summary of the PFOS Freshwater Aquatic Life Criteria and Acute Estuarine/Marine Benchmark

The PFOS aquatic life criteria were developed to protect freshwater aquatic life against adverse effects, such as mortality, altered growth, and reproductive impairments, associated with acute and chronic exposure to PFOS. The nationally recommended criteria include water column based acute and chronic criteria for fresh waters. The freshwater acute water column-based criterion magnitude is 0.071 mg/L, and the chronic water column-based criterion magnitude is 0.00025 mg/L (Table 3-12). The chronic freshwater tissue-based criteria magnitudes are 0.201 mg/kg wet weight (ww) for fish whole-body, 0.087 mg/kg ww for fish muscle tissue and 0.028 mg/kg ww for invertebrate whole-body tissue. These PFOS aquatic life criteria are expected to be protective of aquatic life on a national basis (Table 3-12). All of these water column and tissue criteria are intended to be independently applicable and no one criterion takes primacy. All of the recommended criteria (acute and chronic water column and tissue criteria) are intended to be protective of aquatic life. Acute and chronic water column criteria for estuarine/marine waters could not be derived at this time due to data limitations; however, an estuarine/marine acute benchmark protective of aquatic life is provided in Appendix L.

The freshwater chronic water-column criterion is more strongly supported than the chronic tissue-based criteria because the water column-based chronic criterion was derived directly from the results of empirical toxicity tests. The chronic tissue-based criteria are relatively less certain because they were derived by transforming the chronic water-column

NMED Exhibit 62

criterion into tissue concentrations through BAFs, with any uncertainty and variability in the underlying BAFs then propagating into the resultant tissue-based criteria magnitudes.

Table 3-12. Recommended Perfluorooctane Sulfonate (PFOS) Ambient Water Quality Criteria for the Protection of Aquatic Life in Freshwaters.

Type/Media	Acute Water Column (CMC)[1,4]	Chronic Water Column (CCC)[1,5]	Chronic Invertebrate Whole-Body[1,2]	Chronic Fish Whole-Body[1,2]	Chronic Fish Muscle[1,2]
Magnitude	0.071 mg/L	0.00025 mg/L	0.028 mg/kg ww	0.201 mg/kg ww	0.087 mg/kg ww
Duration	One-hour average	Four-day average	Instantaneous[3]		
Frequency	Not to be exceeded more than once in three years on average	Not to be exceeded more than once in three years on average	Not to be exceeded[6]		

[1] All five of these water column and tissue criteria are intended to be independently applicable and no one criterion takes primacy. All of the above recommended criteria (acute and chronic water column and tissue criteria) are intended to be protective of aquatic life. These criteria are applicable throughout the year.
[2] Tissue criteria are derived from the chronic water-column criterion magnitude (CCC) with the use of bioaccumulation factors and are expressed as wet weight (ww) concentrations.
[3] Tissue data provide instantaneous point measurements that reflect integrative accumulation of PFOS over time and space in aquatic life population(s) at a given site.
[4] Criterion Maximum Concentration; applicable throughout the water column.
[5] Criterion Continuous Concentration; applicable throughout the water column.
[6] PFOS chronic freshwater tissue-based criteria should not be exceeded, based on measured tissue concentrations representing the central tendency of samples collected at a given site and time.

This Aquatic Life Ambient Water Quality Criteria and Acute Saltwater Benchmark for PFOS document includes a water column based acute benchmark for estuarine/marine waters. The derivation of this benchmark is described in detail in Appendix L. The saltwater acute benchmark 0.55 mg/L (magnitude component), expressed as a one-hour average (duration component), that is not to be exceeded more than once in three years on average (Table 3-13).

Aquatic life benchmarks, developed under 304(a)(2) of the CWA, are informational values that the EPA generates when there are limited high quality toxicity data available and data gaps exist for several aquatic organism families. The EPA develops aquatic life benchmarks to provide information that states and Tribes may consider in their water quality protection

NMED Exhibit 62

programs. In developing aquatic life benchmarks, data gaps may be filled using new approach methods (NAMs), such as computer-based toxicity estimation tools (e.g., EPA's Web-ICE) or other new approach methods intended to reduce reliance on additional animal testing (https://www.epa.gov/chemical-research/epa-new-approach-methods-work-plan-reducing-use-vertebrate-animals-chemical), including the use of read-across estimates based on other chemicals with similar structures. The EPA's aquatic life benchmark values are not regulatory, nor do they automatically become part of a state's water quality standards.

Table 3-13. Acute Perfluorooctane Sulfonate (PFOS) Benchmark for the Protection of Aquatic Life in Estuarine/Marine Waters.

Type/Media	Acute Water Column Benchmark
Magnitude	0.55 mg/L
Duration	One hour on average
Frequency	Not to be exceeded more than once in three years on average

NMED Exhibit 62

4 EFFECTS CHARACTERIZATION FOR AQUATIC LIFE

The purpose of this section was to describe the supporting information for the derivation of the PFOS aquatic life AWQC that contributed to the weight-of-evidence for the derivation. This section includes: (1) additional analyses supporting the criteria that were used as part of the lines-of-evidence discussion to better understand the influence of using less certain toxicity data (Section 4.1); (2) an assessment of the influence of including non-North American resident species in water column criteria derivation (i.e., species not resident to North America removed from dataset; Section 4.2); (3) summaries of the toxicity studies with apical endpoints (e.g., effects on survival, growth, or reproduction) that were not used directly to derive the water column criteria, but were used qualitatively to support them (Section 4.3); (4) a discussion of acute to chronic ratios (Section 4.4); (5) a comparison of empirical tissue concentrations to translated tissue criteria (Section 4.5); (6) a discussion of the effects of PFOS on aquatic plants (Section 4.6); and (7) a discussion of the effects of PFOS on threatened and endangered species (Section 4.7). The EPA derived the final national recommended PFOS aquatic life AWQC described in the Effects Analysis Section (see Section 3 above). The additional analyses presented here are solely intended to support the PFOS criteria through a weight-of-evidence approach that evaluated the influence of data variation and uncertainties on the PFOS criteria.

4.1 Additional Analyses Supporting the Derivation of the Chronic Water Column Criterion for Freshwater

In addition to the EPA's recommended freshwater chronic water column criterion of 0.00025 mg/L PFOS described above in Section 3.2.1.3, eight additional analyses supporting the derivation of the chronic criterion were examined as part of a line-of-evidence evaluation to consider the effect of including less certain toxicity data (i.e., the chronic toxicity values for damselfly, fatmucket, and mayfly) on the magnitude of the freshwater chronic water column

NMED Exhibit 62

criterion. The data considered to be less certain generally centered around two specific areas: (1) the difficultly in reliably estimating a chronic toxicity value given the wide spacing (up to 15-fold difference) of the treatment concentrations (e.g., for fatmucket in Hazelton et al. (2012) and damselfly in Bots et al. (2010) (see Section 3.1.1.3.3 and 3.1.1.3.4, respectively) and (2) the uncertainty in the chronic toxicity values given the level of data presented in the papers associated with the mayfly (*N. triangulifer*), fatmucket (*L. siliquoidea*), and damselfly (*E. cyathigerum*) – see study summaries in Appendices C.2.1, C.2.3, and C.2.4, respectively).

The eight additional analyses presented below involved either changing or excluding toxicity values from the three toxicity studies (Table 4-1). The additional analyses presented here are solely intended to support the PFOS chronic criterion through a weight-of-evidence approach that evaluated the influence of data variation on the criterion derivation process. Based on these additional analyses, the EPA decided to retain the mayfly, fatmucket, and damselfly values as presented in Section 3.1.1.3, to ensure protection of these sensitive taxa as well as the many untested species for which these species may serve as representative taxonomic surrogate species. The availability of additional toxicity data for these particular taxa would reduce the uncertainty in the analysis. The criteria presented in Section 3.3 are the EPA's best estimate of the maximum concentrations of PFOS that will support protection of sensitive aquatic life from unacceptable chronic exposures.

NMED Exhibit 62

Table 4-1. Additional Analyses Supporting the Derivation of the Freshwater Chronic Water Column Criterion.

*Presented in the order that is summarized in the text below.**

Order of Additional Analyses	Purpose of Additional Analysis	Details of Additional Analysis	Chronic Water Column Concentration for Additional Analysis (mg/L)	Study
1	To explore the impact of using the various author reported toxicity values for damselfly	Used 10-day MATC of 0.3162 mg/L for damselfly instead of 150-day MATC of 0.03162 mg/L	0.00025	Bots et al. (2010)
2		Used 60-day NOEC of 0.1 mg/L for damselfly instead of 150-day MATC of 0.03162 mg/L	0.00025	
3		Used 320-day NOEC of 0.01 mg/L for damselfly instead of 150-day MATC of 0.03162 mg/L	0.00027	
4	To explore the impact of using the MATC for fatmucket	Removed MATC of 0.01768 mg/L for fatmucket	0.00021	Hazelton et al. (2012)
5	To explore the impact of using both the EC_{10} for fatmucket and the 150-day MATC for damselfly	Removed both MATC of 0.01768 mg/L for fatmucket and 150-day MATC of 0.03162 mg/L for damselfly	0.00016	Hazelton et al. (2012) and Bots et al. (2010), respectively
6	To explore the impact of using the EC_{10} for fatmucket	Use estimated EC_{10} of 0.0123 mg/L for fatmucket instead of MATC of 0.01768 mg/L	0.00025	Hazelton et al. (2012)
7	To explore the impact of using the various author-reported toxicity values for mayfly	Use EC_{10} of 0.000272 mg/L for mayfly calculated with linear regression without control	0.00029	Soucek et al. (2023)
8		Use EC_{10} of 0.000232 mg/L for mayfly calculated with linear regression without control	0.00026	

*Final derived freshwater chronic water column criterion was 0.00025 mg/L PFOS.

In the first additional analysis, instead of using the 150-day MATC of 0.03162 mg/L for *Enallagma cyathigerum* as described in the calculation of the final freshwater chronic water column criterion described above in Section 3.2.1.3, the 10-day MATC of 0.3162 mg/L was used (Table 4-2) (Bots et al. 2010), yielding a freshwater FCV for PFOS of 0.0002486 mg/L. This chronic water column concentration of 0.00025 mg/L (rounded to two significant figures) is the same as the final chronic value of 0.00025 mg/L derived above. This first additional analysis indicated that there is little difference in the calculated chronic criterion based either on the 150-

NMED Exhibit 62

day or 10-day MATC for *E. cyathigerum.* However, as the 150-day MATC was more comparable to the other aquatic insect data and more representative of life-cycle effects than the 10-day MATC, the EPA has concluded that the 150-day MATC should be used quantitatively to derive the freshwater chronic criterion.

In the second analysis, instead of using the 150-day MATC of 0.03162 mg/L for *E. cyathigerum*, the 60-day NOEC of 0.1 mg/L from the same test was used (Table 4-2) (Bots et al. 2010), also yielding an FCV of 0.0002486 mg/L. Similar to the first analysis, there is no difference in the calculated chronic criterion based either on the 150-day or 60-day NOEC for *E. cyathigerum.* However, since the 150-day MATC was more comparable to the other aquatic insect data and representative of life-cycle effects than the 10-day MATC, the EPA has concluded that the 150-day MATC should be used quantitatively to derive the freshwater chronic criterion.

In the third analysis, instead of using the 150-day MATC of 0.03162 mg/L for *E. cyathigerum*, the 320-day NOEC of 0.01 mg/L from the same test was used (Table 4-2) (Bots et al. 2010), yielding an FCV of 0.0002661 mg/L, or 0.00027 mg/L (rounded to two significant figures). This analysis indicated that there is a slightly higher FCV (less stringent) in the calculated chronic criterion if the 320-day NOEC for *E. cyathigerum* is used. However, as there were concerns with the control survival of test organisms (reported as roughly 60% in the first 60 days), the EPA has determined that the 150-day MATC should be used quantitatively to derive the freshwater chronic water column criterion since this toxicity value still represents a life-cycle effect and control survival of test organisms was determined to be acceptable at this time point in the test.

NMED Exhibit 62

In the fourth analysis, the MATC for fatmucket (*L. siliquoidea)* of 0.01768 mg/L was removed from the chronic dataset to understand the influence of this toxicity value on the criterion magnitude (Table 4-2). This additional analysis placed the GMCV of 0.03217 mg/L for *Danio* among the four most sensitive genera, and yielded an FCV of 0.0002097 mg/L or 0.00021 mg/L (rounded to two significant figures) (Section 3.2.1.3; U.S. EPA 1985). The removal of the chronic toxicity value for *L. siliquoidea* has only a modest influence on the calculated chronic criterion magnitude (criteria became more stringent) but would eliminate mollusks from the chronic PFOS dataset. The EPA decided to retain the fatmucket value to ensure representation and protection of this sensitive taxon.

In the fifth analysis, the 150-day MATC of 0.03162 mg/L for damselfly (*E. cyathigerum*) and MATC for fatmucket (*L. siliquoidea*) of 0.01768 mg/L were removed since these values are less certain compared to other quantitative studies in the chronic criterion dataset (Table 4-2). As noted above, these toxicity values were considered to be less certain due to (1) the difficultly in reliably estimating a chronic toxicity value given the wide spacing (15-fold difference in Hazelton et al. (2012) for *L. siliquoidea* and 10-fold difference in Bots et al. (2010) for *E. cyathigerum*) of the treatment concentrations, and (2) the uncertainty in the chronic toxicity values given the level of data presented in the papers. This fifth analysis yielded a freshwater FCV for PFOS of 0.0001621 mg/L, or 0.00016 mg/L (rounded to two significant figures). The calculated chronic criterion magnitude was reduced 1.6-fold. The EPA decided to retain the damselfly and fatmucket values as presented in Section 3.1.1.3 in the criterion derivation to ensure representation and protection of these sensitive taxa.

In the sixth analysis, the estimated EC_{10} for fatmucket of 0.0123 mg/L was used in the chronic dataset to understand the influence of this estimated toxicity value on the criterion

NMED Exhibit 62

derivation (Table 4-2), particularly since the EPA was not able to fit a curve to estimate an EC_{10} given that there were only two PFOS treatment groups and the gap in these exposure concentrations is large (about 15-fold). This additional analysis yielded an FCV of 0.0002476 mg/L, or 0.00025 mg/L. This additional analysis indicated that the estimated toxicity value from *L. siliquoidea* has no influence on the calculated chronic criterion. Since the estimated toxicity value had no influence on the recommended CCC value, the author-reported MATC was used instead.

In the seventh analysis, another author-reported EC_{10} for mayfly of 0.000272 mg/L (based on log-linear regression without controls) was used in the chronic dataset to understand the influence of this alternate toxicity value on the criterion derivation (Table 4-2). This additional analysis yielded a FCV was 0.0002938 mg/L, or 0.00029 mg/L, indicating that this other toxicity value for *N. triangulifer* has little influence on the final calculated chronic criterion. Since this other toxicity value had limited influence on the recommended CCC value, the author-reported EC_{10} (0.000226 mg/L, two parameter, threshold sigmoidal curve) described in Section 3.1.1.3.1 in the criterion derivation was used instead.

Lastly, in the eighth analysis, a second author-reported EC_{10} for mayfly of 0.000232 mg/L (based on log-linear regression with controls) was used in the chronic dataset to understand the influence of this third toxicity value on the chronic criterion derivation (Table 4-2). This additional analysis yielded a FCV was 0.0002550 mg/L, or 0.00026 mg/L, indicating that this third possible toxicity value for *N. triangulifer* has limited influence on the calculated chronic criterion. Since this alternate toxicity value had limited influence on the recommended CCC value, the author-reported EC_{10} (0.000226 mg/L, two parameter, threshold sigmoidal curve) described in Section 3.1.1.3.1 in the criterion derivation was used instead.

4.2 Influence of Using Non-North American Resident Species on PFOS Criteria

The EPA conducted two additional analyses of the freshwater criteria by analyzing the effect of reducing the limited toxicity datasets to only organisms that are resident to, or have been introduced and have established populations in the conterminous U.S. These analyses were conducted for illustrative purposes, to indicate the effects on the criteria magnitude of the inclusion of data for taxa that are not resident species to North America but serve as surrogates for other sensitive organisms. This analysis was conducted for both the acute and chronic freshwater datasets only, since the estuarine/marine datasets are limited even when all species are included.

4.2.1 Freshwater Acute Water Column Criterion with Native and Established Organisms (Species Not Resident to North America removed from dataset)

For the purpose of illustrating the effect of including non-resident species in the acute criterion calculation, additional analyses were made. For this illustrative analysis, four species were removed from the freshwater acute water column criterion calculation to ensure that only native, reproducing, or established organism in the conterminous U.S. were included: Japanese swamp shrimp (*Neocaridina denticulata*), planarian (*Dugesia japonica*), crayfish (*Pontastacus leptodactylus*) and cladoceran (*Daphnia carinata*). Removal of these species truncated the freshwater acute dataset to 25 species (Table 4-3). None of the non-resident species were among the four most sensitive, with the cladoceran (*Daphnia carinata*), being the most sensitive SMAV of the four (Table 3-3). The acute water column concentration was 0.048 mg/L PFOS (Table 4-4) when using the reduced dataset which was slightly lower than the recommended CMC of 0.071 mg/L. This value is lower than all of the GMAVs in Table 3-3. The EPA decided to retain the full acute dataset and associated acute criterion for PFOS of 0.071 mg/L in order to have the

NMED Exhibit 62

largest, high-quality dataset to serve as surrogate species for the broad range of the thousands of untested species present in the freshwater environment in the U.S.

Acute Water Column Concentration = 0.048 mg/L PFOS (rounded to two significant figures)

4.2.2 Freshwater Chronic Water Criterion with Native and Established Organisms (Species Not Resident to North America removed from dataset)

For the purpose of illustrating the effect of including non-resident species in the chronic criterion calculation, additional analyses were made. For this illustrative analysis, two species were removed from the chronic freshwater dataset that are not native or established organism in the conterminous U.S.: the cladoceran (*Daphnia carinata*) and the clawed frog (*Xenopus tropicalis*). Removal of these species truncated the freshwater chronic dataset to 17 species representing 17 genera (Table 4-5). The revised freshwater chronic dataset consisted of all eight MDRs. The cladoceran and clawed frog GMCVs were not among the four most chronically sensitive species. Removal of the species that are not resident to North America had no effect on the chronic water column concentration (Table 4-6) because other species were available from the same genera and neither of the non-resident species were from the four most chronically sensitive genera. The chronic water column concentration was 0.0002491 mg/L PFOS when using the reduced dataset, which was the same as the recommended chronic criterion of 0.00025 mg/L. Therefore, the EPA decided to retain the full chronic dataset and associated chronic water column criterion for PFOS of 0.00025 mg/L in order to have the largest, high quality dataset to serve as surrogate species for the broad range of the thousands of untested species present in the freshwater environment in the U.S.

4.3 Qualitatively Acceptable Water Column-Based Toxicity Data

Several studies were identified as either not meeting the EPA's data quality guidelines for inclusion in the criteria derivation or did not have data available to support the independent calculation of a toxicity value (e.g., LC_{50} and/or EC_{10}). However, these studies were used qualitatively as supporting information to the PFOS criterion derived to protect aquatic life and provide additional evidence of the observed toxicity and effects of PFOS, including the relative sensitivities of surrogate, untested species. The key studies with apical endpoints (e.g., effects on survival, growth, or reproduction) that were used qualitatively in the derivation of the PFOS water column criteria are summarized below, grouped as either acute or chronic exposures and sorted by relative sensitivity of genera following the previous study summaries included in the Effects Analysis (Section 3). Qualitative study summaries within a factor of two of the final acute and chronic values were also included and arranged according to taxonomic relatedness. NOEC and LOEC values were provided in several of the study summaries for comparison to the toxicity values summarized in the Effects Analysis section. The toxicity values summarized

NMED Exhibit 62

below as part of this Effects Characterization were not used quantitatively to derive the acute or chronic PFOS freshwater criteria. Results of each individual study (as well as the rationale why a study was not quantitatively acceptable) were considered relative to the corresponding freshwater acute or chronic criterion magnitude to ensure the water column-based PFOS criteria were not underproductive and to provide additional supporting evidence of the potential toxicity of PFOS to aquatic organisms. Tabulated data for the studies summarized below, as well as additional qualitative studies of less sensitive taxa, were listed in Appendix G.

4.3.1 Consideration of Qualitatively-Acceptable Acute Data

4.3.1.1 Qualitatively Acceptable Acute Data for Species Among the Four Most Sensitive Genera Used to Derive the Acute Water Column Criterion

4.3.1.1.1 Most acutely sensitive genus, Neocloeon

There were no qualitatively-acceptable acute tests with the genus, *Neocloeon*.

4.3.1.1.2 Second most acutely sensitive genus, Moina

There were no qualitatively-acceptable acute tests with the genus, *Moina*.

4.3.1.1.3 Third most acutely sensitive genus, Pimephales

There were no qualitatively-acceptable acute tests with the genus, *Pimephales*.

4.3.1.1.4 Fourth most acutely sensitive genus, Oncorhynchus

Raine et al. (2021) exposed unfertilized rainbow trout (*Oncorhynchus mykiss*) oocytes for three hours to PFOS (perfluorooctanesulfonic acid, > 97% pure, CAS No. 1763-23-1, obtained from SynQuest Laboratories). The authors reported a residue accumulation NOEC of 0.87 mg/L and LOEC of 7.47 mg/L PFOS. This test is considered for qualitative use since the exposure duration was too short for both acute and chronic test exposure according to the test guidelines. Also, no apical endpoints were reported.

NMED Exhibit 62

4.3.1.2 Consideration of Relatively Sensitive Tests with Freshwater Species based on Qualitatively-Acceptable Acute Data

4.3.1.2.1 Genus: Danio (zebrafish)

Cormier et al. (2019) evaluated the acute effects of (1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-heptadecafluorooctane-1-sulfonic acid (PFOS, purity ≥ 98%, CAS No. 2785-37-3, purchased from Sigma-Aldrich in St. Louis, MO) on zebrafish (*Danio rerio*) via a 96-hour measured, static-renewal study. Zebrafish embryos were collected and tested according to OECD TG 236. The authors reported a 96 hour NOEC value of 700 ng/L PFOS (or 0.0007 mg/L) for hatching success, embryo mortality, and developmental deformations. Since the value represents a greater than low value (see description of decision rule in Section 2.10.3.2) (U.S. EPA 2013), the study is only used qualitatively in the acute criterion.

Haimbaugh et al. (2022) evaluated the acute toxic effects of low-level (≤2,400 ng/L) PFOS on zebrafish from zero to five days post fertilization. Unmeasured test concentrations (24, 240, or 2,400 ng/L PFOA) were renewed daily. At test termination, the highest test concentration (2,400 ng/L or 0.0024 mg/L) had no effects on mortality or abnormal development. This test was not used quantitatively and retained for qualitative use only because the exposure durations were too long for an acute test and too short for a chronic test with no effects observed. This study also represents a greater than low value.

The noted toxicity values provided above (>0.0007 mg/L and >0.0024 mg/L), indicated that this genus might be more sensitive to acute exposures of PFOS than the quantitative data for the genus (with a GMAV of 27.86 mg/L). However, this non-definitive qualitative value does not provide any clarity on true sensitivity. All eight of the quantitatively-acceptable acute tests for this species reported LC_{50} values (range = 3.502 – 71.12 mg/L; geometric mean = 27.86

NMED Exhibit 62

mg/L; n = 8) that were more than an order of magnitude greater than the FAV, leading the EPA to conclude that *D. rerio* is not a sensitive species to acute PFOS exposures.

4.3.2 Consideration of Qualitatively-Acceptable Chronic Data

4.3.2.1 Qualitatively Acceptable Chronic Data for Species Among the Four Most Sensitive Genera Used to Derive the Chronic Water Column Criterion

4.3.2.1.1 Most chronically sensitive genus, Neocloeon

There were no qualitatively-acceptable chronic tests with the genus, *Neocloeon*.

4.3.2.1.2 Second most chronically sensitive genus, Chironomus

Zhai et al. (2016) exposed *Chironomus plumosus* larvae to PFOS (perfluorooctane sulfonate, obtained from Tokyo Chemical Industries, Tokyo, Japan, 98% pure) spiked in sediment for 10.3 days. The sediment was collected from the upstream region of the Yongding River in Beijing, China. Spiking involved adding 1 mL of PFOS methanol solution (20 mg/L) to the sediment to obtain a concentration of 100 ng/g PFOS and thoroughly mixing in a fume hood. The midge larvae used in this study were collected from the uncontaminated upstream area of the Yangliuqing River in the outer suburbs of Tianjin, China. At the end of the experiment, the surviving larvae were counted. The 10-day mortality NOEC was 0.00985 mg/L PFOS, the only concentration tested. This study was considered for qualitative use for the following reasons: (1) the exposure duration was relatively short when comparing to the test guidelines for aquatic invertebrates and considered a sub-chronic exposure, (2) the sediment and test organisms used appear to have been previously exposed to low levels of PFAS (albeit low exposures) based on the measured concentrations reported in the paper, and (3) the apical endpoint for mortality results in a > NOEC that is a low value, which provides little information to the relative sensitivity of midge and was not used to derive the chronic PFOS criterion based on the data use rules established for these criteria (see Section 2.10.3.2).

NMED Exhibit 62

Stefani et al. (2014) conducted a chronic (10 generation) test of PFOS (form and purity not reported) with the midge, *Chironomus riparius*. The NOEC and LOEC were 0.0035 and > 0.0035 mg/L (as time-weighted average) as there were no effects on emergence, reproduction, or sex ratio at this concentration. The results from this study were not acceptable for quantitative use because only a single test concentration was used, the chronic value is a greater than low value and not informative for criterion development, and there was a lack of details pertaining to the characteristics of the sediment used in the exposure, including details regarding any differences in measured concentrations over the duration of the exposure. Since this study was focused on the chronic effects of PFOS to a relatively sensitive species, however, consideration of the greater than chronic value from this study (> 0.0035 mg/L) in the context of other values for the midge was prudent. The EC_{10}s for *Chironomus dilutus* of 0.05896 mg/L, 0.001588 mg/L, and 0.0015 mg/L from MacDonald et al. (2004), McCarthy et al. (2021), and Krupa et al. (2022), respectively, that were used quantitatively in the chronic criterion derivation are more robust values than the toxicity value reported in Stefani et al. (2014), and likely a better estimation of the sensitivity of *C. riparius*. The chronic value reported by Stefani et al. (2014), although slightly lower than the *Chironomus* GMCV, is higher than the final recommended chronic criterion, and was expressed as a NOEC, as no effects were observed at 0.0035 mg/L (as time-weighted average).

In a companion paper to Stefani et al. (2014), Marziali et al. (2019) similarly conducted a chronic (10 generation) test of PFOS (form and purity not reported) with *C. riparius*. The LOEC based on F1 developmental time and F1 adult weight was < 0.004 mg/L (time-weighted average). The were no effects on F1 exuvia length at this concentration. The results from this study were not considered for quantitative use because only a single test concentration was used,

NMED Exhibit 62

there was a lack of consistent observed effects in both the control and the treatment groups across the generations, and details pertaining to the characteristics of the sediment used in the exposure were lacking, including details regarding any differences in measured concentrations over the duration of the exposure. Again, it is prudent to consider the less than chronic value from this study (< 0.004 mg/L) in the context of the more robust and definitive values for midge. Similar to the determination above, the chronic values established for the related midge, *C. dilutus*, from MacDonald et al. (2004) and McCarthy et al. (2021) are deemed more reliable and definitive values representing the sensitivity of the genus in the freshwater chronic water column criterion dataset.

4.3.2.1.3 Third most chronically sensitive genus, Lampsilis

There were no qualitatively-acceptable chronic tests with the genus, *Lampsilis*.

4.3.2.1.4 Fourth most chronically sensitive genus, Enallagma

Van Gossum et al. (2009) conducted a chronic, approximately 4-month renewal test of PFOS (tetraethylammonium salt, 98% purity) with damselfly, *Enallagma cyathigerum.* The test organisms were larvae that had reached the F2 instar stage. Dilution water was dechlorinated tap water. Photoperiod was 16 hours light and 8 hours dark. Light intensity was not reported. A primary stock solution was prepared and proportionally diluted with dilution water to prepare the test concentrations. Exposure vessels were plastic containers (15 cm x 10 cm x 11 cm) with a 2 cm depth of test solution. The test employed 19-20 larvae each in two test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 0.01, 0.1, 1, and 10 mg/L. All larvae were housed (and presumably tested) in temperature-controlled rooms at 21±1.3°C. No other water quality parameters were reported as having been measured in test solutions. Negative control mortality was said to be much lower than the 100% mortality that occurred at 1

NMED Exhibit 62

and 10 mg/L but was not reported. The 4-month NOEC (behavioral – including general activity, swimming performance, foraging success) was 0.010 mg/L. The 4-month LOEC was 0.100 mg/L. The calculated MATC was 0.03163 mg/L. The chronic value was acceptable for qualitative use because only non-apical endpoints were reported.

4.3.2.2 Consideration of Relatively Sensitive Tests with Freshwater Species based on Qualitatively-Acceptable Chronic Data

4.3.2.2.1 Genus: Lithobates (leopard frog)

Flynn et al. (2021) evaluated the chronic effects of perfluorooctane sulfonic acid (PFOS, CAS# 1763-23-1, ≥ 96% purity, purchased from Sigma-Aldrich) on Northern Leopard frogs, *Lithobates pipiens* (formerly, *Rana pipiens*), via a 30-day sediment-spiked measured, static mesocosm study. The study authors reported a 30-day NOEC of 0.016 mg/L for weight, snout-vent length and mortality and a 30-day LOEC of 0.00006 mg/L for developmental stage (measured as Gosner stage). Independently-calculated EC_{10}s could not be calculated as the EPA was unable to fit a model with significant parameters. Therefore, given this was an outdoor mesocosm with spiked sediment that included the addition of algal and zooplankton communities, and the EPA was unable to independently calculate toxicity values based on the replicate level data provided by the study authors, this study was used qualitatively to derive the final recommended chronic water column criterion.

Hoskins et al. (2022) evaluated the chronic effects of PFOS alone and in mixture with PFHxS on northern leopard frogs (*Lithobates pipiens*) from Gosner Stage 25 tadpoles through metamorphosis (Gosner Stage 46) in a static-renewal measured exposure. No effects were observed on survival, mass index and snout-vent length at 0.000934 mg/L PFOS (the highest test concentration at test termination (day 120). The test results in a greater than NOECs (>0.000934 mg/L) and provides little information to the relative sensitivity of the species. Therefore, this

NMED Exhibit 62

study was not used to derive the chronic PFOS criterion based on prior data use rules (U.S. EPA 2013).

4.4 Acute-to-Chronic Ratios

The 1985 Guidelines allow the use of a final acute-to-chronic ratio (FACR) to convert the FAV to the FCV as an alternative approach to derive the chronic criterion instead of the direct calculation to determine the FCV (as described in Section 2.10.1) when the eight MDRs are not met (U.S. EPA 1985). While this alternative approach was not needed for the derivation of the chronic PFOS criterion, which was derived from empirical chronic data with all of the eight MDRs met, the possibility of calculating a scientifically-defensible FACR is as follows, for illustrative purposes only. Seventeen ACRs for eight invertebrate species and two fish species can be calculated from the quantitative acute and chronic toxicity data (Appendix A and Appendix C). Appendix I includes the ACRs for freshwater aquatic species with quantitative chronic values for which comparable quantitative acute values were reported from the same study or same investigator and laboratory combination. For each species where more than a single ACR was calculated, species mean acute-to-chronic ratios (SMACRs) were also calculated as the geometric mean value of individual ACRs for a species. In the case of a single ACR within a species, that ACR was the SMACR.

The ACRs ranged from 4.110 to 12,877 across all tests (a factor of 3,133), which occurs within the *Daphnia magna* SMACR. There was little explanation for the extreme range in ACRs among paired tests with *D. magna*. However, the ACR of 12,877 from paired tests conducted by Lu et al. (2015) appears to be an outlier. Excluding the 12,877 outlier ACR from the paired tests with *D. magna* reported by Lu et al. (2015) and from the paired test with *Daphnia carinata* (Logeshwaran et al. 2021) produced an SMACR range of 16.32 to 1,030. This range was greater

NMED Exhibit 62

than a factor of 10 with no relationship between SMACR and SMAV apparent. The 1985 Guidelines do not provide for calculation of a FACR under these circumstances.

4.5 Comparison of Empirical Tissue Concentrations to Translated Tissue Criteria

Measured PFOS tissue data were reported in 14 publications focused on freshwater species, six of which were quantitatively acceptable and eight of which were qualitatively acceptable (Table 4-7). The six quantitatively acceptable studies included data for one invertebrate, two fish, and one amphibian species, and the eight qualitatively acceptable studies included data for two invertebrate and four fish species. Results of these studies are summarized in Section 4.5.1 and Section 4.5.2, below.

Tissue concentration data from these toxicity studies were compared to the translated tissue criteria (fish whole body, fish muscle, invertebrate whole body) and supplemental fish tissue values (blood, liver, reproductive tissue) to better understand the protectiveness of the chronic aquatic life tissue criteria. Although tissue concentrations from the toxicity literature were limited, translated tissue criteria and supplemental fish tissue values were lower than tissue-based PFOS concentrations from chronic toxicity studies where toxic effects were observed, suggesting that the tissue criteria (and supplemental fish tissue values) are protective. Finally, while no amphibian tissue criteria are available, tissue concentrations from two amphibian toxicity tests suggest that the fish tissue criteria are protective of amphibians.

NMED Exhibit 62

Table 4-7. Comparison of Empirical Tissue Concentrations to Chronic Tissue Criteria and Additional Tissue Values.

Species	Endpoint	Percent Effect Observed	Measured Tissue Concentration (mg/kg ww)[1]	Calculated Chronic Tissue Values[2] (mg/kg ww)	Tissue Type	Reference
Quantitative Studies						
Fatmucket (*Lampsilis siliquoidea*)	Probability of successful metamorphosis of glochidia	33.5%	LOEC: 0.248	0.028	Invertebrate Whole-body (adult)	Hazelton et al. (2012)
Zebrafish (*Danio rerio)*	F1 survival	21%	LOEC: 4.8	0.201	Whole-body (adult female)	Wang et al. (2011)
			LOEC: 6.0	0.201	Whole-body (adult male)	
Fathead minnows (*Pimephales promelas*)	Fecundity	49% (LOEC)	NOEC: 7.1 – LOEC 19.4	0.616	Liver concentrations (adult male)[3]	Ankley et al. (2005)
			NOEC: 31.8 – LOEC 82.9	0.616	Liver concentrations (adult female)	
			NOEC: 8.8 – LOEC 19.9	1.29[3]	Gonad concentrations (adult male)[3]	
			NOEC: 33.1 – LOEC 81.6	1.29	Gonad concentrations (adult female)	
	Growth (weight in F1)	18%	LOEC: 37.9	1.29[3]	Gonad concentrations (adult F0 male)[3]	Suski et al. (2021)
			LOEC: 37.4	1.29	Gonad concentrations (adult F0 female)	
			LOEC: 84.5	0.616	Liver (adult F0 male)	
			LOEC: 68.2	0.616	Liver (adult F0 female)	
Northern leopard frog (*Lithobates pipiens*)	Length at metamorphosis (GS 42[4])	17%	LOEC: 66.6	None Available	Whole-body (before metamorphosis, day 54)	Ankley et al. (2004)
	Gosner stage after 40 days	5%	LOEC: 14.36		Whole-body	Hoover et al. (2017)

NMED Exhibit 62

Species	Endpoint	Percent Effect Observed	Measured Tissue Concentration (mg/kg ww)[1]	Calculated Chronic Tissue Values[2] (mg/kg ww)	Tissue Type	Reference
Qualitative Studies						
Red worms (*Limnodrilus hoffmeisteri*)	Reduction in superoxide dismutase[5]	13%	LOEC: 1,757 (dw)	0.028	Invertebrate Whole-body	Liu et al. (2016)
Great pond snails (*Lymnaea stagnalis*)	Survival	31%	LOEC: 2,877	0.028	Invertebrate Whole-body	Olson (2017)
European eels (*Anguilla anguilla*)	Survival	0%	NOEC: > 5.037	0.616	Liver	Roland et al. (2014)
Goldfish (*Carassius auratus*)	Survival	0%	NOEC: > 39.91 (dw)	0.087	Muscle	Feng et al. (2015)
Common carp (*Cyprinus carpio*)	Condition factor	3%	LOEC: 168.4	0.616	Liver	Hagenaars et al. (2008)
Zebrafish (*Danio rerio*)	Swimming distance[5]	18%	LOEC: 21.6	0.201	Whole-body	Spulber et al. (2014)

[1] Measured tissue concentrations are author-reported values. The EPA did not independently calculate toxicity values for tissue concentrations.

[2] Chronic tissue value concentrations represent chronic tissue criteria (invertebrates, fish muscle, fish whole body) or additional tissue values (fish blood, fish liver, fish reproductive tissue) calculated from BAFs for a given tissue type. See Section 3.2.3 and Appendix P for details.

[3] Fish reproductive tissue value based on female reproductive tissue.

[4] Gosner stage (GS) associated with this endpoint is not specifically reported by the study authors. However, the authors define complete metamorphosis as emergence of the forelimbs, which is GS 42 according to Taylor and Kollros (1946).

[5] Non-apical endpoint.

NMED Exhibit 62

4.5.1 Comparison of Quantitative Studies and Tissue-Based Criteria

Tissue concentration data from these toxicity studies were compared to the translated tissue values for invertebrates and fish to better understand the protectiveness of the aquatic life tissue criteria. Hazelton et al. (2012) exposed adult fatmucket (*Lampsilis siliquoidea*) to aqueous PFOS for 36 days. Measured PFOS water concentrations in the control and exposure treatments averaged 0.0021, 0.0045, and 0.0695 mg/L, respectively. Corresponding tissue concentrations were 0.009, 0.015 and 0.248 mg/kg wet weight. A statistically significant decrease in the probability of successful metamorphosis of glochidia to the juvenile stage was observed in the highest PFOS exposure concentration.

Wang et al. (2011) exposed larval (8 hpf) zebrafish (*Danio rerio*) to aqueous PFOS for five months. Fish were exposed to three nominal PFOS concentrations (0.005, 0.05, and 0.25 mg/L, respectively). Whole-body PFOS tissue concentrations measured after five months in the two highest exposure concentrations averaged 6.0 and 11.2 mg/kg wet weight, respectively, in males, and 4.8 and 7.8 mg/kg wet weight, respectively, in females. PFOS was also measured in embryos produced from exposed parents and averaged 5.69 and 11.35 ng/embryo wet weight in the two highest exposure concentrations. Weights of embryos were not reported by the study authors, so concentrations could not be calculated to compare embryo tissue concentrations to the translated tissue criteria. However, given the study design included tissue measurements in the parental (F0) generation and the exposure to the offspring generation (F1) was via maternal transfer, the tissue concentration in the F0 generation associated with the F1 survival LOEC of 0.05 mg/L was a whole-body tissue concentration of 6.2 and 4.0 mg/kg wet weight (ww) in male and females, respectively.

Ankley et al. (2005) exposed sexually mature adult fathead minnows (*Pimephales promelas*) to aqueous PFOS for 21 days during which time they were allowed to reproduce, and

NMED Exhibit 62

then the resulting offspring were held for an additional 24 days in the same exposure concentrations. Aqueous measured PFOS concentrations in the control and exposure treatments averaged <0.001, 0.0276, 0.101, 0.281, and 0.818 mg/L, respectively. PFOS was measured in the plasma, livers, and gonads of adult males and females after 21 days, in embryos, and in whole-body larval samples after 12 and 24 days. Tissue measurements were not made in organisms from the highest exposure concentration, where exposed adults were either dead or listless after 14 days. Plasma PFOS concentrations in adult organisms exposed to 0.0276, 0.101, and 0.281 mg/L PFOS averaged 26.9, 135, and 354 mg/L in males, and 47.1, 177, and 471 mg/L in females. Liver PFOS concentrations in adults averaged 7.1, 19.4, and 109 mg/kg wet weight in males, and 31.8, 82.9, and 261 mg/kg wet weight in females, respectively. Similarly, gonad PFOS concentrations averaged 8.8, 19.9, and 108 mg/kg wet weight in males, and 33.1, 81.6, and 263 mg/kg wet weight in females. PFOS concentrations in embryos from parents exposed to 0.0276, 0.101, and 0.281 mg/L PFOS were 9.3, 11.5, and 28.6 mg/kg, respectively. Larval PFOS concentrations measured after 12 and 24 days of exposure were similar, with whole-body concentrations corresponding to the 0.0276, 0.101, and 0.281 mg/L exposures were 19.8, 48.0, and 57.5 mg/kg wet weight after 12 days, and 17.8, 49.0, and 83.5 mg/kg wet weight after 24 days. The most sensitive apical endpoint was fecundity, with an aqueous EC_{10} of 0.051 mg/L. No corresponding tissue-based EC_{10} was calculated, but the corresponding liver concentrations would be expected to fall between 7.1 and 19.4 mg/kg in males and 31.8 and 82.9 mg/kg in females, and the corresponding gonad concentrations would be expected to fall between 8.8 and 19.9 mg/kg in males and 33.1 and 81.6 mg/kg in females. No muscle or whole-body measurements in adults are available to perform a direct comparison to the tissue criteria.

NMED Exhibit 62

Suski et al. (2021) reported the chronic toxicity of PFOS-K (PFOS potassium salt, CAS# 2795-39-3, ≥ 98%,) on the fathead minnow, *Pimephales promelas*. Measured PFOS concentrations in water were 0.00014 (control), 0.044, 0.088, 0.14, and 0.231 mg/L. The most sensitive endpoint from the study was a significant decrease in the mean mass of individuals in the larval F1 generation with the author-reported NOEC and LOEC, based on growth in the F1 generation, being 0.044 (6% reduction in growth compared to controls) and 0.088 mg/L PFOS (associated with an 18% reduction in growth), respectively. The calculated MATC based on mean mass of individuals in the larval F1 generation is 0.06222 mg/L. The F1 larval LOEC was associated with measured gonad and liver concentrations in F0 male and females of 37.9, 37.4, 84.5, and 68.2 mg/kg ww, respectively. No corresponding tissue-based EC_{10} was calculated, but the corresponding gonad and liver EC_{10} concentrations would be expected to be greater than the translated reproductive tissue concentration of 1.29 mg/kg ww and the translated liver tissue concentration of 0.616 mg/kg ww. No muscle or whole-body measurements in adults are available to perform a direct comparison to the fish tissue criteria.

Ankley et al. (2004) exposed Northern leopard frogs (*Lithobates pipiens*) to PFOS from Gosner stage 8/9 embryos through metamorphosis. The time to metamorphosis ranged from 60-112 days. All frogs in the highest exposure concentration died before metamorphosis. The most sensitive apical endpoint was length at metamorphosis, which was significantly lower ($p < 0.05$) in the second highest exposure relative to the control. The measured aqueous PFOS concentrations in the NOEC and LOEC exposure concentrations averaged 0.957 and 3.42 mg/L over the full exposure duration. PFOS in whole body tissue was analyzed as dry weight but reported by the authors as wet weight normalized. Corresponding whole-body tissue NOEC and LOEC concentrations measured in tadpoles exposed for 54 days (before metamorphosis) were

NMED Exhibit 62

16.9 and 66.6 mg/kg wet weight normalized. Whole body concentrations were also measured after 35 days and were higher than the 54-day measurements at the 0.957 mg/L exposure (22.1 mg/kg wet weight normalized) and 3.42 mg/L exposures (117.0 mg/kg wet weight normalized). Tadpole moisture content was not reported.

In a separate study with *L. pipiens*, Hoover et al. (2017), exposed juvenile (Gosner stage 26) northern leopard frogs to three PFOS concentrations (0.008, 0.078, and 0.884 mg/L measured PFOS, respectively) for 40 days. Survival, growth (snout-vent length), and developmental time (Gosner stage after 40 days) were measured, and the most sensitive apical endpoint was developmental time (Gosner stage after 40 days), with a NOEC of 0.008 mg/L and a LOEC of 0.078 mg/L. Whole body PFOS concentrations in frogs exposed to 0.008 mg/L PFOS in solution averaged 10.45 mg/kg dry weight after 40 days, and concentrations in frogs exposed to 0.078 mg/L averaged 51.46 mg/kg dry weight after 40 days. Tadpole moisture content was not reported in this study. In order to convert the reported dry weight concentrations to wet weight concentrations, so that they would be more directly comparable to the whole-body fish tissue criteria, a whole-body moisture content of 72.1% was applied, calculated as the average for all fish collected as part of the USGS National Contaminant Biomonitoring Program (NCBP Fish Database (usgs.gov)). Corresponding 40-day NOEC and LOEC wet weight PFOS tissue concentrations were 2.92 and 14.36 mg/kg wet weight, respectively.

In all of the studies described above, the translated tissue criteria and supplemental fish tissue concentrations were lower than the measured tissue concentrations where toxicity was observed, suggesting that the tissue criteria are protective. As noted above, tissue concentrations associated with the LOEC in both Ankley et al. (2004) and Hoover et al. (2017) are higher than

NMED Exhibit 62

the fish whole-body tissue criterion, suggesting that the fish tissue criteria is protective of amphibians.

4.5.2 Comparison of Qualitative Studies and Tissue-Based Criteria

Like the comparison with the quantitative studies, tissue concentration data from these qualitative toxicity studies were compared to the translated tissue values for invertebrates and fish to better understand the protectiveness of the aquatic life tissue criteria. Liu et al. (2016) exposed 4-5 cm body length red worms (*Limnodrilus hoffmeisteri*) to two aqueous concentrations of PFOS for 10 days at pH 8.0 and measured oxidative stress biomarker activity. Measured exposure concentrations were 0.567 and 5.494 mg/L PFOS, and corresponding whole-body tissue PFOS concentrations were 89.5 and 1,757 mg/kg dry weight. Moisture content was not reported. A significant ($P < 0.05$) reduction in superoxide dismutase was observed in the highest treatment concentration after 10 days. Apical endpoints were not reported for this exposure. In a separate study with *L. hoffmeisteri*, Qu et al. (2016) calculated 48-hour EC_{50}s in response to PFOS at three pH values (6.2, 7.0, 8.0). PFOS was not measured in water. However, whole body tissue concentrations were measured after 48-hours in the control, 0.2 mg/L, and 2.0 mg/L nominal PFOS exposures. Whole-body tissue concentrations in the 2.0 mg/L exposure were 23.41 mg/kg dry weight at pH 6.2 and 12.61 mg/kg dry weight at pH 8.0. After 48 hours, a significant ($P < 0.05$) increase in superoxide dismutase was observed in both the 0.2 mg/L and 2.0 mg/L PFOS treatments; however, no significant differences were observed at pH 8.0 for either treatment level.

Olson (2017) exposed adult great pond snails (*Lymnaea stagnalis*) to PFOS for 21 days. The most sensitive apical endpoint was survival, with a NOEC of 3 mg/L PFOS nominal, and a LOEC of 6 mg/L PFOS nominal. Whole-body PFOS tissue concentrations at the NOEC and LOEC after 21 days were 8,969 mg/kg dry weight and 9,820 mg/kg dry weight, respectively.

NMED Exhibit 62

Percent moisture was not reported by the study authors, so dry weights were converted to wet weights using the average whole soft body % moisture content of 70.7% for the snail species *Achatina achatina* (Achaglinkame et al. 2020) in order to more directly compare *L. stagnalis* tissue concentrations from this study to the invertebrate chronic whole body tissue criterion. Resulting wet weight PFOS concentrations at the NOEC and LOEC were 2,628 and 2,877 mg/kg, respectively.

Roland et al. (2014) exposed juvenile European eels (*Anguilla anguilla*) to PFOS for 28 days. Measured PFOS water concentrations were 0.00001 mg/L in the control and 0.00081 and 0.011 mg/L in the two aqueous exposure concentrations. Corresponding liver tissue PFOS concentrations after 28 days were 0.0338 and 5.037 mg/kg wet weight, respectively. The study authors noted that during the study, there was no mortality, and no significant differences in growth across either PFOS treatment. Significant ($p < 0.05$) changes in protein expression were reported for both exposure concentrations.

Feng et al. (2015) conducted a 96-hour study with juvenile goldfish (*Carassius auratus*) and measured the effects of PFOS on mortality or antioxidant enzyme activity. Measured PFOS in the two exposure concentrations were 1.04 µmol/L (0.520 mg/L) and 10.18 µmol/L (5.09 mg/L). Liver, gill, and muscle PFOS concentrations were 32.81, 42.13, and 33.08 mg/L dry weight, respectively, at the lower exposure level, and 58.37, 69.02, and 39.91 mg/L dry weight, respectively, at the higher exposure level. No mortality occurred during the test. Among the antioxidant enzyme activity endpoints, glutathione peroxidase activity was significantly ($p < 0.05$) lower in the highest exposure concentration than the control.

Hagenaars et al. (2008) exposed juvenile common carp (*Cyprinus carpio*) to three exposure concentrations of PFOS plus a control for 14 days and measured relative condition

NMED Exhibit 62

factor and several non-apical endpoints related to liver function. Nominal PFOS exposure concentrations were control, 0.1, 0.5, and 1 mg/L. Corresponding liver PFOS concentrations after the 14-day exposure were 0.97, 35.97, 168.4, and 283.0 mg/kg wet weight. The most sensitive endpoint was condition factor, which was significantly ($p < 0.0001$) lower than controls at the 0.5 mg/L nominal aqueous exposure concentration. Hepatosomatic index was also significantly ($P < 0.05$) lower at the 0.5 mg/L concentration compared to the control. The corresponding liver tissue PFOS concentration at this effect concentration (LOEC) was 168.4 mg/kg wet weight.

Spulber et al. (2014) exposed *Danio rerio* embryos (2 hpf) to 0.1 mg/L and 1.0 mg/L nominal PFOS concentrations for seven days. Corresponding whole-body PFOS concentrations in 7-day-old larvae were 21.6 and 213.5 mg/kg wet weight, respectively. Spulber et al. (2014) reported no effects of PFOS on viability, time to hatch, or deformities. The most sensitive endpoint was swimming distance, where fish exposed to the 0.1 and 1.0 mg/L PFOS treatments exhibited lower levels of activity ($p < 0.05$) in response to a pulse of darkness.

The translated tissue criteria and supplemental fish tissue concentrations were lower than the measured tissue concentrations where toxicity was observed for all of the qualitative studies. Although tissue concentrations from the toxicity literature were limited, available data suggest that the tissue criteria are protective.

4.6 Effects on Aquatic Plants

Available data for aquatic plants and algae were reviewed to determine if aquatic plants were likely to be more sensitive than aquatic animals to aqueous PFOS exposure (see Appendix E). Toxicity values for freshwater plants were well above the freshwater chronic water column criterion. Effect concentrations for freshwater plants and algae ranged from 0.19 to 252 mg/L

NMED Exhibit 62

compared to the range in animal chronic values of 0.000226 to 16.35 mg/L (Appendix C: Acceptable Freshwater Chronic PFOS Toxicity Studies). Therefore, it was not necessary to develop a criterion based on the toxicity of PFOS to aquatic plants. The PFOS freshwater acute and chronic criteria are expected to be protective of freshwater plants.

4.7 Protection of Threatened and Endangered Species

The PFOS acute and chronic datasets are include some data representing species that are listed as threatened or endangered by the U.S. Fish and Wildlife Service and/or National Oceanic and Atmospheric Administration (NOAA) Fisheries. Summaries are provided here describing the available PFOS toxicity data for listed species indicating that the 2024 PFOS criteria are protective of these listed species, based on available scientific data.

4.7.1 Quantitatively Acceptable Acute Toxicity Data for Listed Species

Quantitatively acceptable acute toxicity test data evaluating the effects of PFOS on threatened and endangered freshwater species were available for rainbow trout (*Oncorhynchus mykiss*) with a SMAV of 7.515 mg/L PFOS (Palmer et al. 2002a; Sharpe et al. 2010). The SMAV is over 100 times higher than the recommended acute criterion (CMC) of 0.071 mg/L, indicating the acute criterion is protective of rainbow trout and is expected to be protective of other listed salmonid species.

Quantitatively acceptable acute data were also available for the Eastern tiger salamander (*A. tigrinum*). While the species is not considered to be a federally listed species, it is considered endangered in Delaware, Maryland, New Jersey, New York, and Virginia (Smith 2003), threatened in North Carolina (Smith 2003), and critically imperiled in Louisiana (2024). The Eastern tiger salamander is also closely related to the endangered California tiger salamander (U.S. FWS 2016a; U.S. FWS 2016b; U.S. FWS 2017). The *A. tigrinum* SMAV of 68.63 (Tornabene et al. 2021) is almost an order of magnitude above the recommended acute criterion

NMED Exhibit 62

(CMC) of 0.071 mg/L, indicating the acute criterion is protective of the Eastern tiger salamander and the federally-listed California tiger salamander. There were no acceptable acute toxicity data for endangered or threatened estuarine/marine aquatic species.

4.7.2 Quantitatively Acceptable Chronic Toxicity Data for Listed Species

Quantitatively acceptable chronic toxicity test data evaluating the effects of PFOS on threatened and endangered freshwater species were available for the listed Atlantic salmon (*Salmo salar*) with a SMCV of >0.1 mg/L PFOS (Spachmo and Arukwe 2012). The SMCV is 400 times higher than the recommended chronic criterion (CCC) of 0.00025 mg/L, indicating the acute criterion is protective of Atlantic salmon and other listed salmonid species. There were no acceptable chronic toxicity data for endangered or threatened estuarine/marine aquatic species.

4.7.3 Qualitatively Acceptable Toxicity Data for Listed Species

Focusing on qualitatively acceptable tests with apical endpoints and water column exposures, there were toxicity data available for two fish species, rainbow trout and Atlantic salmon. For rainbow trout, the NOEC for mortality was 1 mg/L in a 12-day microcosm exposure and 3 mg/L in a 14-day early life stage static laboratory test (Oakes et al. 2005). For Atlantic salmon (*Salmo salar*), no adverse effects for growth were observed at the highest treatment concentration (0.1 mg/L PFOS) following a 49-day exposure (Arukwe et al. 2013). For both species, the qualitative NOECs were orders of magnitude greater than the recommended acute criterion (CCC) of 0.00025 mg/L, which further indicates that the chronic criteria are protective of listed salmonid species. There were no qualitative acute or chronic toxicity data for endangered or threatened estuarine/marine aquatic species.

NMED Exhibit 62

4.8 Summary of the PFOS Aquatic Life Criterion and the Supporting Information

The PFOS aquatic life AWQC were developed to protect aquatic life against adverse effects, such as mortality, altered growth, and reproductive impairments, associated with acute and chronic exposure to PFOS. The national recommended criteria include water column-based acute and chronic criteria for fresh waters. The freshwater acute water column-based criterion magnitude is 0.071 mg/L, and the chronic water column-based criterion magnitude is 0.00025 mg/L (0.25 µg/L). The chronic freshwater criterion also contains tissue-based criteria expressed as 0.201 mg/kg wet weight (ww) for fish whole-body, 0.087 mg/kg ww for fish muscle tissue, and 0.028 mg/kg ww for invertebrate whole-body tissue. These PFOS aquatic life criteria are expected to be protective of all freshwater aquatic life on a national basis. Although empirical PFOS toxicity data for estuarine/marine species were not available to fulfill the eight MDRs directly, the EPA included an acute aquatic life benchmark for estuarine/marine environments using available estuarine/marine species toxicity data and a NAMs application of the EPA ORD's peer-reviewed web-ICE tool (see Appendix L). The estuarine/marine acute water column-based benchmark magnitude is 0.55 mg/L and is expected to protect estuarine/marine aquatic life from acute aqueous PFOS exposures. The EPA conducted additional analyses supporting the derivation of the water column criteria for PFOS (as summarized above in Sections 4.1 and 4.2) and confirmed that the criteria and benchmark calculations presented in this document accurately reflect the latest and best available scientific knowledge.

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

[b] Chemical concentrations made in a side-test representative of exposure and verified stability of concentrations of PFOS in the range of concentrations tested under similar conditions. Daily renewal of test solutions.

[c] Reported in moles converted to milligram based on a molecular weight of 500.13 mg/mmol or 538.22 mg/mmol PFOS-K.

[d] Not used in SMAV calculation; only the most sensitive life-stage used.

[e] Values in bold used the in the SMAV calculation.

[f] Author-reported LC_{50} of 19 mg/L x 24.5% PFOS = 4.655 mg/L PFOS; EPA-calculated LC_{50} of 21.86 mg/L x 24.5% PFOS = 5.356 mg/L PFOS.

[g] Author pooled tests or life-stages.

NMED Exhibit 62

A.2 Detailed PFOS Acute Freshwater Toxicity Study Summaries and Corresponding Concentration-Response Curves (when calculated for the most sensitive genera)

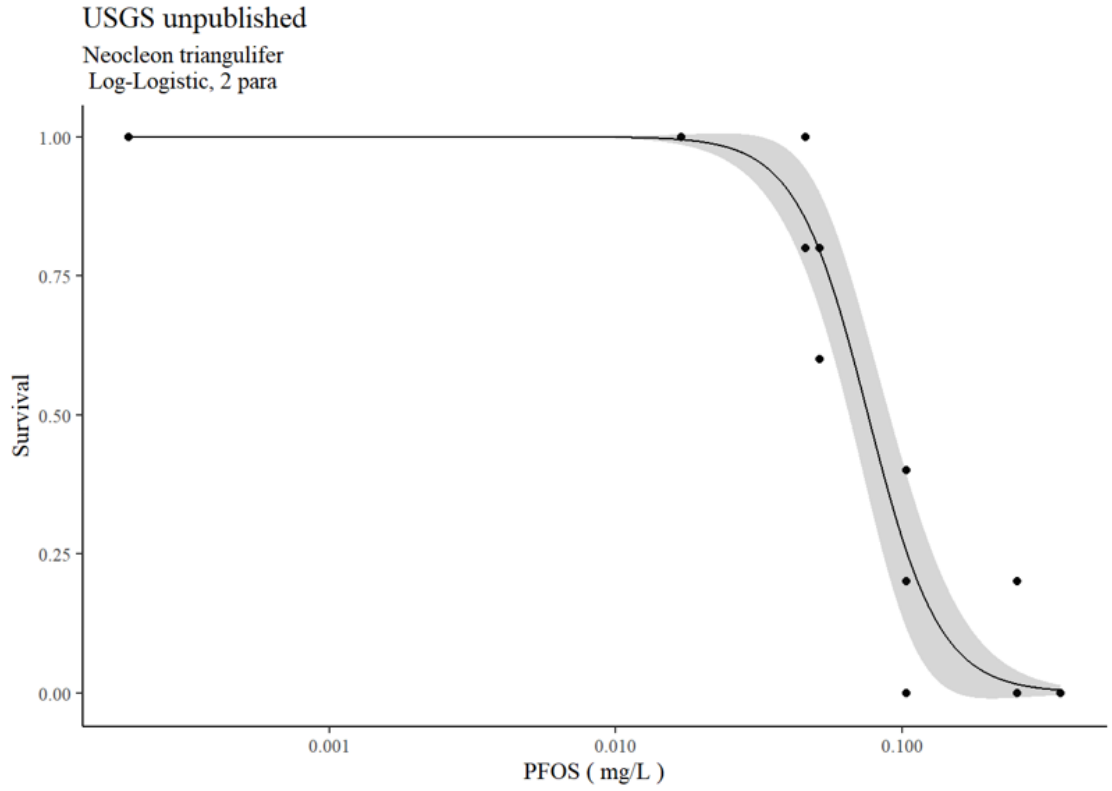
The purpose of this section was to present detailed study summaries for tests that were considered quantitatively acceptable for criteria derivation, with summaries grouped and ordered by genus sensitivity. Concentration-response (C-R) models developed by the EPA that were used to determine acute toxicity values used for water column criterion derivation are also presented for the most sensitive genera when available. C-R models included here with study summaries were those for the five most sensitive genera (consistent with Section 3.1.1.1). When required, the EPA also included models for non-resident species that were more sensitive than the fourth most sensitive North American resident genus. In many cases, authors did not report C-R data in the publication/supplemental materials and/or did not provide C-R data upon the EPA request. In such cases, the EPA did not independently calculate a toxicity value and the author-reported effect concentrations were used in the derivation of the criterion.

A.2.1 Most Sensitive Freshwater Genus for Acute Toxicity: *Neocloeon* (mayfly)

Soucek et al. (2023) conducted a 96-hour acute toxicity test to determine the effects of PFOS-K (PFOS potassium salt, CAS # 2795-39-3, 98% purity) on the parthenogenetic mayfly, *Neocloeon triangulifer*. The test was performed under static, nonrenewal conditions beginning with < 24-hour old nymphs. Exposures consisted of five mayfly nymphs per 30 mL polypropylene cup filled with 20 mL test solution. The control and each of six PFOS test concentrations were replicated five times for a total of 25 test organisms per treatment. Nominal test concentrations were 0 (control), 0.0156, 0.0313, 0.0625, 0.125, 0.250, and 0.500 mg/L PFOS. Mean measured PFOS concentrations (EPA Analytical Method 1633; LC-MC/MS) were 0.0002 (control), 0.017, 0.046, 0.052, 0.103, 0.253, and 0.358 mg/L PFOS, respectively. Animals were exposed at 23 ± 1°C under a 16:8 hour light (˜110 – 300 lux):dark cycle and fed live diatom

NMED Exhibit 62

biofilm scraping beginning on Day 0. Percent survival in the control treatment after 96 hours was 100%. A uniform C-R pattern for percent survival was observed decreasing from 100 and 96% in the lowest treatments to 4 and 0% in the highest test treatments. The EPA was able to independently calculate a 96-hour LC_{50} of 0.07617 mg/L (0.06546 – 0.08688 mg/L; 95% CI) for this study. The EPA's independently-calculated LC_{50} is in line with the author-reported LC_{50} of 0.08 mg/L. Therefore, the independently-calculated LC_{50} of 0.07617 mg/L was acceptable for quantitative use in the derivation of the freshwater acute water column criterion for PFOS.



NMED Exhibit 62

A.2.1.1 Soucek et al. (2023) Concentration Response Curve – Neocloeon (mayfly)

Publication: Soucek et al. (2023)
Species: Mayfly, *Neocloeon triangulifer*
Genus: *Neocloeon*
EPA-Calculated LC_{50}: 0.07617 (0.06546 – 0.08688) mg/L
Concentration-Response Model Estimates:

Concentration-Response Model Fit:

A.2.2 Second Most Sensitive Freshwater Genus for Acute Toxicity: *Moina* (cladoceran)

Ji et al. (2008) performed a 48-hour static, unmeasured acute test of PFOS (acid form, CAS # 1763-23-1, purity unreported) with *Moina macrocopa*. The test followed the EPA's Methods for measuring the acute toxicity of effluents and receiving waters to freshwater and marine organisms [U.S. EPA/600/4-90/027F; (U.S. EPA 2002)]. *M. macrocopa* used for testing were obtained from brood stock cultured at the Environmental Toxicology Laboratory at Seoul

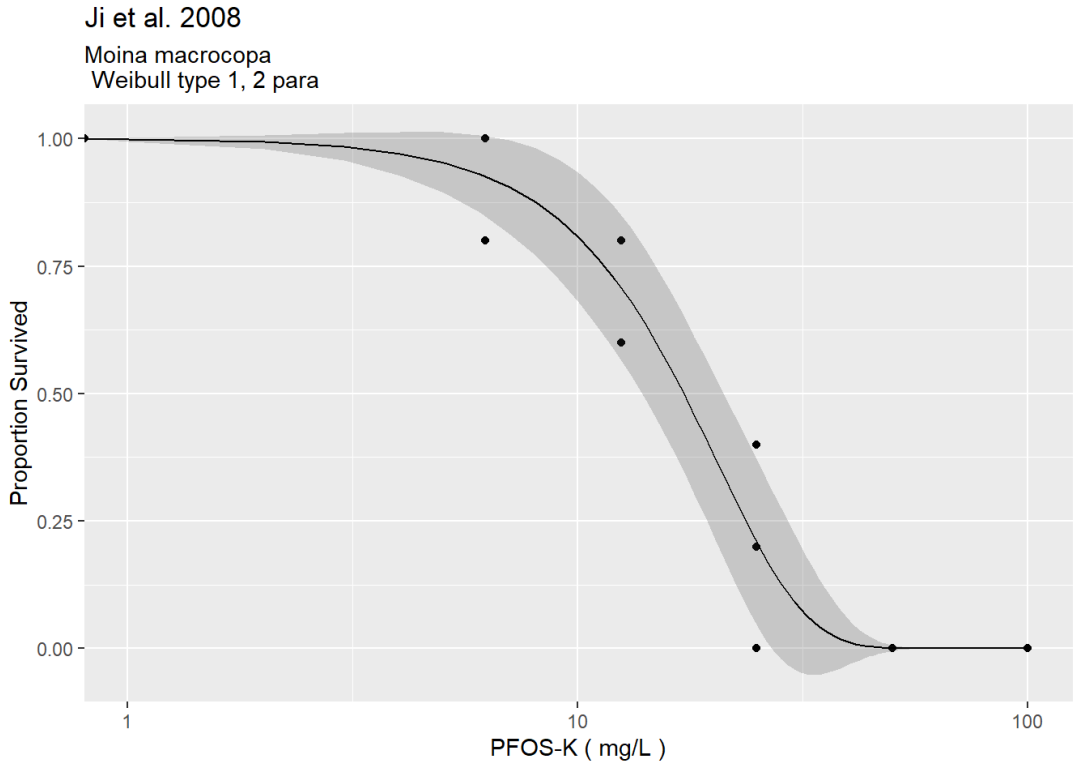
NMED Exhibit 62

National University (South Korea). Test organisms were less than 24 hours old at test initiation. Dilution water was moderately hard reconstituted water (hardness typically 80-100 mg/L as $CaCO_3$). Experiments were conducted in glass jars of unspecified size and fill volume. The photoperiod for the test was assumed by the reviewers to have been 16:8-hours light:dark, as was used for daphnid culture in tests by the same authors. Preparation of test solutions was not described. The test involved four replicates of five neonates each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 6.25, 12.5, 25, 50 and 100 mg/L. Test temperature was maintained at 25 ± 1°C. Authors note water quality parameters (pH, temperature, conductivity, and D.O.) were measured 48 hours after exposure, but the information was not reported. Survival of organisms in the negative control was not reported in the paper. However, raw data were obtained by the EPA from the study authors and control survival was 100% in the acute test, meeting the EPA/600/4-90/027F requirement of at least 90% survival for test acceptability. The study authors reported a 48-hour EC_{50} value of 17.95 mg/L (C.I. 14.72 - 21.18) for *M. macrocopa*. The 48-hour EC_{50} value was independently-calculated by the EPA as 17.20 (13.73 – 20.66) mg/L. The independently-calculated acute toxicity value was quantitatively used in the derivation of the freshwater acute water column criterion.

Razak et al. (2023) tested the acute toxicity of perfluorooctanesulfonate (PFOS) on *Moina micrura* for 48 hours in a measured, static experiment. PFOS (≥98% purity) analytical standards were purchased from Dr. Ehrenstorfer GmbH (Augsburg, Germany), and PFOA and solvents for making test solutions were purchased from Fisher Scientific (New Jersey, USA). Organisms were obtained from the Aquatic Animal Health and Therapeutics Laboratory (Aquahealth) at the Institute of Bioscience, Universiti Putra Malaysia. Culturing procedures

NMED Exhibit 62

followed International Organisation for Standardization (ISO) procedure 6341:2012. Cultures were kept under a 12:12 light:dark cycle at 27±1°C. Culture water was renewed every two weeks, and culture organisms were fed green algae (*Chlorella vulgaris*) three times weekly. Both culture and test water was filtered (0.2 µm) surface lake water. A stock solution of 100 mg/L PFOS with filtered surface lake water was made just before testing began. Testing methods followed OECD 202 (OECD 2004) with nominal testing concentrations of 10, 25, 50, 75, 100, 250, 500, 750, 1,000, 2,500, 5,000, 7,500, and 10,000 µg/L, plus a control, with four replicates per treatment. Each replicate consisted of 10 neonates (<48 hours old) in 50 mL of solution in a 100 mL beaker, and organisms were not fed during the study. Nonparametric Kruskal-Wallace tests followed by post-hoc tests were used to calculate significant ($P<0.05$) differences between controls and treatment concentrations for all endpoints. The lethal effect concentrations (LC_{10}, LC_{50}, LC_{75}, LC_{90}) were calculated using Probit analysis, and the 48-hour LC_{50} value of 549.6 µg/L, or 0.5496 mg/L was determined to be acceptable for quantitative use. C-R data could not be obtained for this test (beyond the visual presentation in the Razak et al. (2023), so the EPA was unable to perform independent C-R analysis.



A.2.2.1 Ji et al. (2008) Concentration Response Curve – Moina (cladoceran)

Publication: Ji et al. (2008)
Species: Cladoceran, *Moina macrocropa*
Genus: *Moina*
EPA-Calculated LC_{50}: 17.20 (13.73 – 20.66) mg/L
Concentration-Response Model Estimates:

Parameter	Estimate	Std. Error	t-stat	p-value
b	2.18	0.47	4.60	$4.16\ e^{-06}$
e	20.34	2.06	9.87	$<2.2\ e^{-16}$

NMED Exhibit 62

Concentration-Response Model Fit:

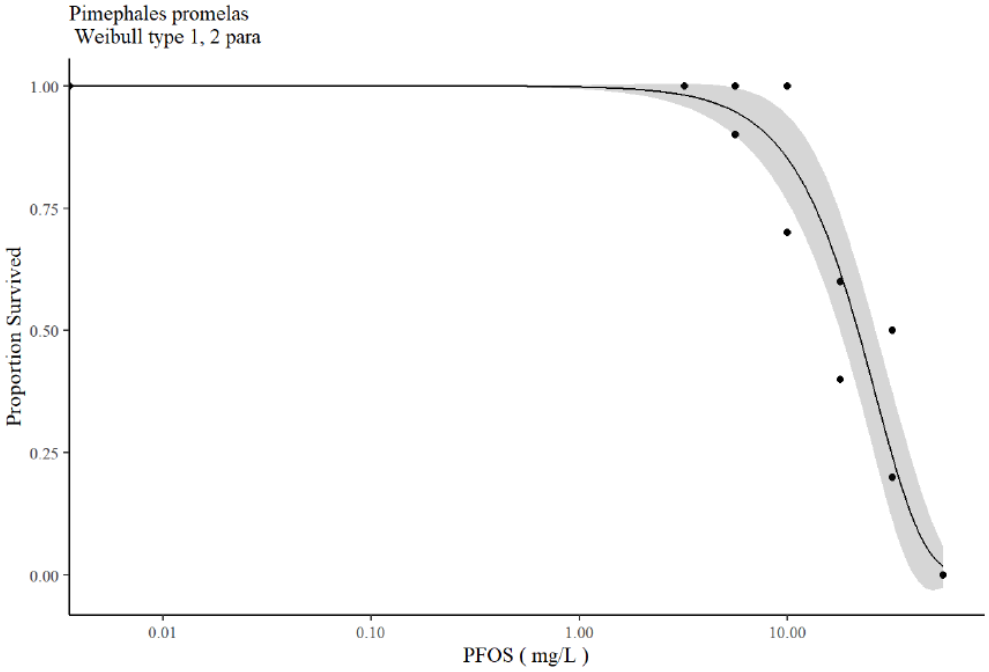
A.2.3 Third Most Sensitive Freshwater Genus for Acute Toxicity: *Pimephales* (fathead minnow)

3M Company (2000) provides the results of a 96-hour static, unmeasured acute toxicity test with the fathead minnow, *Pimephales promelas*, and PFOS-Li (perfluorooctanesulfonate lithium salt, CAS # 29457-72-5). A stock solution was made with carbon-filtered well water at a test sample concentration of 400 mg/L and where the test sample was reported as a mixture of PFOS-Li (24.5%) in water (75.5%). Fish were obtained from a commercial supplier (Aquatic Biosystems, Fort Collins, CO) and were 79 days old at test initiation with an average length of 2.1 cm and weight of 0.069 g. Exposure vessels were 2 L glass beakers containing 1 L of solution and 10 fish per beaker (0.69 g fish/L). Each test treatment was replicated twice with nominal test concentrations (control, 3.2, 5.6, 10.0, 18.0, 32.0 and 56.0 mg/L test sample). Throughout the experiment the dissolved oxygen (D.O.) ranged from 4.8 - 7.9 mg/L, pH 8.0 - 8.4 and a test temperature of 19.2 - 19.5°C. The low D.O. of 4.8 mg/L was only observed in one

replicate of the highest test concentration at 96 hours; D.O. was ≥6.0 mg/L for all other treatments and replicates. No mortality occurred in the control treatment and 100% was observed in the highest treatment (56 mg/L). The study authors reported that the test sample containing 24.5% PFOS-Li exhibited a 96-hour LC_{50} of 19 mg/L, which equates to 4.655 mg/L as PFOS. The independently-calculated 96-hour LC_{50} value was 21.86 (17.63 – 26.08) mg/L, which equates to 5.356 mg/L as PFOS and is acceptable for quantitative use in the derivation of the acute freshwater criterion for PFOS.

Drottar and Krueger (2000c) evaluated the acute effects of PFOS-K (CAS# 2795-39-3, Lot # 217 (T-6295) obtained from the 3M Company, 90.49% purity, stored at ambient room temperature) on juvenile fathead minnows (*Pimephales promelas*) during a 96-hour measured, static study. Researchers stated they followed protocols by U.S. EPA Series 850 (OPPTS 850.1075), OECD Guideline 203, and ASTM E729-88a. A primary stock solution was prepared at 27 mg/L and mixed with an electric mixer for 22 hours prior to use in testing to ensure solubilization of the test substance. After mixing, the primary stock solution was proportionally diluted with dilution water to prepare the four additional test concentrations. Test fish were obtained from cultures at Wildlife International Ltd. in Easton, Maryland. The minnows were held for approximately 126 days prior to testing and were acclimated to test conditions for 48 hours prior to test initiation. Fish were fed a commercially-prepared diet prior to the 48-hour acclimation period. All fish used in the test were from the same source and year class, and the total length of the longest fish was no more than twice the length of the shortest. Fathead minnows were randomly distributed among mean measured test concentrations of 0 (control), 3.3, 5.6, 9.5, 17 and 28 mg/L, with 10 fish per 25-L polyethylene aquarium provided in duplicate. Aquaria were filled with 15 L of test solution with an observed D.O. of 7.7 - 8.4 mg/L,

NMED Exhibit 62



temperature of 22 ± 2ºC, pH of 8.2 - 8.5, and a total hardness of 131 mg/L as $CaCO_3$. Fathead minnows were subjected to a 16:8-hour light:dark photoperiod at 391 lux. Sand and 0.45 um filtered well water from a 40 m deep well on site served as both the culture water and the testing media. The authors reported an LC_{50} of 9.5 mg/L PFOS. The EPA's independently-calculated 96-hour LC_{50} was 9.020 (7.146 - 10.89) mg/L, rounded to four significant figures, and was used quantitatively to derive the freshwater acute water column criterion.

A.2.3.1 3M Company (2000) Concentration Response Curve – Pimephales (fathead minnow)

Concentration-Response Model Fit:

A.2.4 Fourth Most Sensitive Freshwater Genus for Acute Toxicity: *Oncorhynchus* (trout)

Sharpe et al. (2010) evaluated the acute effects of perfluorooctane sulfonate (PFOS, potassium salt, CAS #2795-39-3, 98% purity) to *Oncorhynchus mykiss*, rainbow trout, via a 96-hour renewal measured exposure (renewal not stated in paper, but assumed based on other information provided, including the test Guideline protocol). Limited details about the test protocol were provided in the publication, but the authors noted they followed OECD Guideline 203, and did not identify any deviations from these test guidelines. Trout eggs were obtained

NMED Exhibit 62

from Raven Trout Hatchery, transported immediately postfertilization to the University of Alberta aquatics facility, and kept in dechlorinated City of Edmonton water. The eggs were reared until hatching in Heath trays in a recirculating, temperature-controlled system at 10°C with a 12:12-hour light:dark photoperiod (the same conditions are assumed for the toxicity test). The rainbow trout used in the study were parr (2-3 g, the fourth stage of the salmon life cycle) at test initiation. The dilution water was dechlorinated City of Edmonton water, and dissolved oxygen content and temperature were monitored daily, but physico-chemical results were not reported. PFOS was dissolved in MeOH, and all vehicle controls received a volume of MeOH equal to that present in the highest PFOS dose of that experiment (final MeOH content 0.2% v/v). The concentration of PFOS in any experiment was always well below its reported solubility in water (≈500 mg/L). Trout toxicity tests were performed using food-grade 2 L plastic tanks with four fish per tank, and two tanks per dose. The EPA obtained clarification from the study authors regarding the experimental set-up pertaining to the biomass loading rate, which was 1 to 1.5 g/L (based on four fish weighing a total of 2 to 3 g per 2 L tank (personal communication with Greg Goss and Rainie Sharpe, March 2021). This biomass loading rate was nearly two-fold higher than that stated in OECD Guidelines of 0.8 g/L (OECD 1992). The trout were randomly assigned to doses defined as control (0 mg/L PFOS); vehicle control (0 mg/L PFOS, 0.2% MeOH v/v); and 0.78, 1.56, 3.12, 6.25, and 12.5 mg/L PFOS. The authors indicated that measured PFOS concentrations averaged 88% of nominal but did not indicate whether LC_{50}s were based on measured or nominal concentrations. Given the clarifications regarding the biomass loading, this study was considered for quantitative use in the derivation of the acute PFOS freshwater criterion. The author-reported 96-hour LC_{50} for the study of 2.5 mg/L (authors did not specify if this concentration was nominal or measured) was acceptable for quantitative

NMED Exhibit 62

use and was among other toxicity values used for this species to calculate the SMAV/GMAV (see further details at the end of the study summaries in this section) that was utilized to derive the freshwater acute water column criterion.

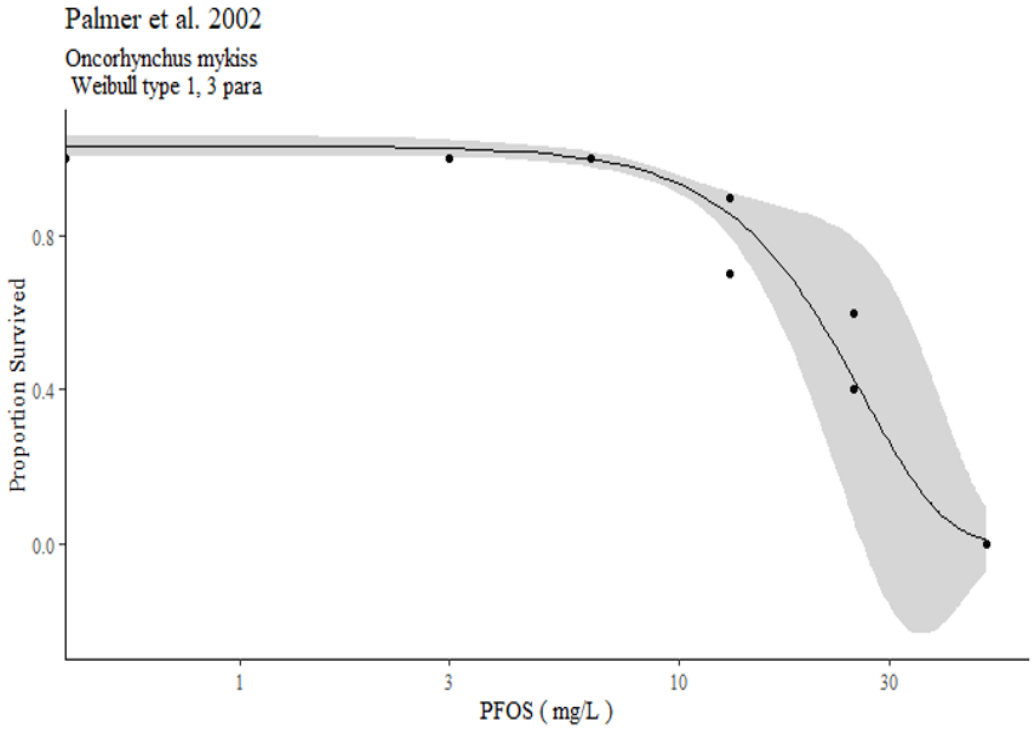
Palmer et al. (2002a) evaluated the acute effects of PFOS (PFOS, potassium salt, identified as FC-95 obtained from 3M Company) to *Oncorhynchus mykiss*, rainbow trout, via a 96-hour static exposure with measured concentrations. The test organisms were obtained from Thomas Fish Company in Anderson, California and were reported as juveniles with a mean weight of 0.34 g and mean total length of 3.6 cm. All test organisms were from the same source and year class, and the length of the longest fish was no more than twice the length of the shortest. The fish were held for approximately five weeks prior to the initiation of the test. This acclimation was done in water from the same source and at the same temperature as the test. During the acclimatation period, no mortalities or signs of disease were observed. Test organisms were only fed a commercially-prepared diet (reported from Zeigler Brothers Inc.) during a 14-day holding period after which point fish were no longer fed through the acclimation period (at least 48 hours prior to the test) or during the test. The test water was obtained from a well located near the testing facility and was characterized as moderately-hard water. The target test temperature was 12 ± 1°C and a 16:8-hour light:dark photoperiod was maintained through the holding, acclimatation, and testing periods. Dissolved oxygen and pH measurements were made on water samples collected at test initiation followed by 24-hour intervals for each replicate test chamber of each treatment and control. Test chambers were 25-L polyethylene aquaria containing 15 L of test solution. At the initiation of the test, rainbow trout were indiscriminately moved from the acclimation tank and distributed two at a time to the test chambers until each contained ten fish. The resulting biomass loading rate was 0.23 g fish/L of

NMED Exhibit 62

test water. A 40-L stock solution was prepared in dilution water at a concentration of 150 mg PFOS/L. Nominal concentrations were 3.1, 6.3, 13, 25, and 50 mg/L. Two replicates of each test solution were prepared at nominal concentrations by adding the appropriate volume of stock solution to dilution water in the test aquaria to achieve the final volume of 15 L. Measured test concentrations at the end of the test ranged from 97 to 100% of nominal with concentrations of 3.0, 6.3, 13, 25, and 50 mg/L. Results from this study were based on measured concentrations. Mortality and other signs of toxicity were observed daily. Trout in the control group appeared normal and healthy throughout the test period. Additionally, test organisms in the lowest treatment groups (3.0 and 6.3 mg/L) appeared healthy with no mortalities or other signs of toxicity. After 96-hours of exposure, mortality in the 13, 25, and 50 mg/L treatment groups was 20, 50, and 100%, respectively. The author-reported 96-hour LC_{50} for the study was 22 mg/L. This study was considered acceptable for quantitative use in the derivation of the acute PFOS freshwater water column criterion. The independently-calculated 96-hour LC_{50} value was 22.59 mg/L.

NMED Exhibit 62

A.2.4.1 Sharpe et al. (2010) Concentration Response Curve - Oncorhynchus (trout)



Publication: Sharpe et al. (2010)

b	2.3775	0.5634	4.2189	$2.455\ e^{-5}$
d	1.0339	0.0140	73.6910	$< 2.2\ e^{-16}$
e	26.3557	5.7449	4.5877	$4.482\ e^{-6}$

Concentration-Response Model Fit:

A.2.5 Fifth Most Sensitive Freshwater Genus for Acute Toxicity: *Ligumia* (mussel)

Hazelton (2013); Hazelton et al. (2012) evaluated the acute effects of PFOS (acid form, > 98% purity) on two freshwater mussels*: Ligumia recta* and *Lampsilis siliquoidea.* The tests yielded the 4th and 7th most sensitive genera values (respectively) in the PFOS freshwater acute criterion dataset (the *L. siliquoidea* results are reported below). Acute toxicity was observed under either static or renewal conditions over a 24-hour period (< 24-hour old glochidia; static exposure) or a 96-hour period (4–6-week-old juveniles; renewal exposure). The tests followed the (ASTM 2006) test method. Dilution water was hard reconstituted water (total hardness typically 160-180 mg/L as $CaCO_3$). Photoperiod and light intensity were not reported. No details were provided regarding primary stock solution and test solution preparation. Experiments were conducted in 3.8 L glass jars of unspecified fill volume. The test employed three replicates of 150 glochidia or seven juvenile mussels each in six measured test concentrations plus a negative control (10 juveniles for the control treatment). Nominal concentrations were 0 (negative control), 0.005, 0.05, 0.5, 5, 50, and 500 mg/L; respective measured concentrations were < limit of quantitation (LOQ; specifics not provided), 0.0054, 0.0514, 0.456, 4.68, 47.2, and 490 mg/L. Recovery of PFOS standards ranged from 85.3-123% over all experiments. For all acute tests, alkalinity ranged from 97 to 110 mg $CaCO_3$/L with a mean of 104.4 mg $CaCO_3$/L; total hardness ranged from 132 to 162 mg $CaCO_3$/L with a mean of 149.6 mg $CaCO_3$/L; conductivity ranged from 514 to 643 µS/cm with a mean of 556.5 µs/cm; pH ranged from 8.05 to 8.56 with a mean of 8.46; and D.O. ranged from 8.16 to 9.46 mg/L with a mean of 8.62 mg/L (n = 12 for alkalinity and total hardness, n = 55 for all other parameters). Exposures were conducted in environmental chambers set at a temperature of 20°C (glochidia tests), or in dilution water maintained at 20°C (juvenile tests). Survival of mussels in the negative control was > 90% in all exposures. The 24-hour EC_{50} reported by the study authors for glochidia of *L. recta* was 13.5 mg/L (C.I. 5.7-31.8).

NMED Exhibit 62

The 96-hour LC_{50} reported by the study authors for juvenile *L. recta* was 141.7 mg/L (C.I. 80.4-249.6). The 24-hour EC_{50} for *L. recta* glochidia represented an acute value acceptable for quantitative use. The juvenile life stage was less sensitive, such that its LC_{50} is not used quantitatively in the SMAV for the species. An independently-calculated toxicity value could not be calculated at this time given the lack of data presented in the paper. The study author reported values are currently used quantitatively to derive the freshwater acute water column criterion.

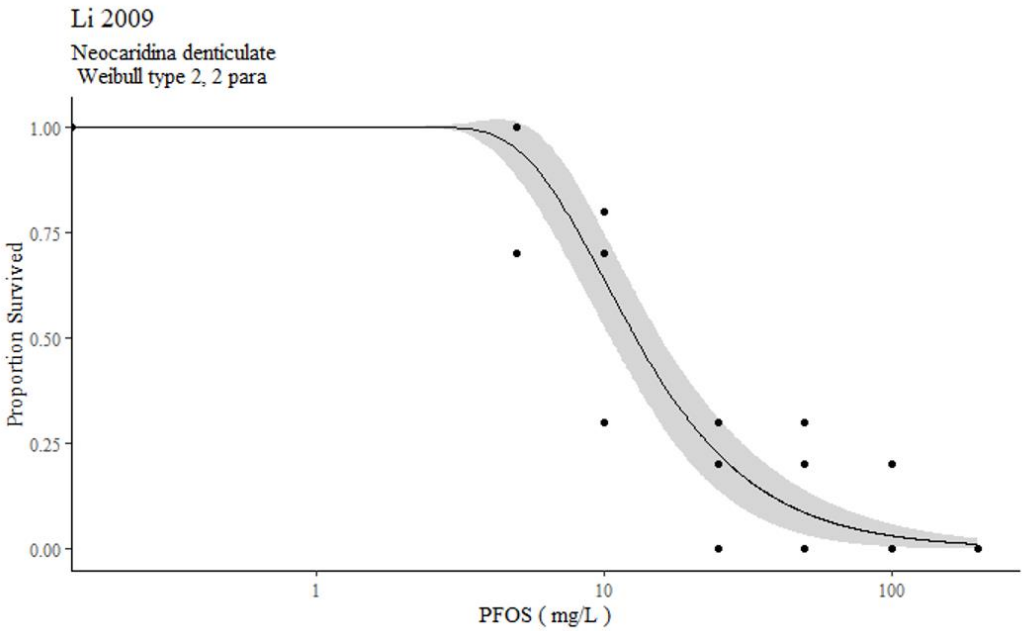
A.2.5.1 Hazelton et al. (2012) Concentration Response Curve – Ligumia (mussel)

Publication: Hazelton et al. (2012)
Species: Black sandshell, *Ligumia recta*
Genus: *Ligumia*
EPA-Calculated LC_{50}: Not calculable, concentration-response data not available

A.2.6 Sixth Most Sensitive Freshwater Genus for Acute Toxicity: *Neocaridina* (shrimp)

Li (2009) conducted three independent repeats of a 96-hour static test on PFOS (potassium salt, >98% purity) with the freshwater shrimp species, *Neocaridina denticulata* (a non-North American species). Test organisms were obtained from an unspecified local supplier and acclimated in the laboratory for at least seven days prior to the experiments. *N. denticulata* of unspecified age were used at test initiation. Dilution water was dechlorinated tap water. The photoperiod consisted of 12 hours of illumination at an unreported light intensity. A primary stock solution was prepared in dilution water. Exposure vessels were polypropylene beakers of unreported dimensions and 1 L fill volume. The test employed five replicates of six shrimp each in at least five test concentrations (the first repeated experiment had one additional PFOS treatment group at 10 mg/L compared to the other two experimental repeats) plus a negative control. Each treatment was tested three independent times. Nominal test concentrations were in the range of 5-200 mg/L PFOS. The test temperature was maintained at 25±2°C. Water quality parameters including pH, conductivity, and D.O. were reported as having been measured at the

NMED Exhibit 62



beginning and end of each test, but the information was not reported. Survival of negative control animals was 90%. The study reported 96-hour LC_{50} was 10 mg/L (C.I. 9-12). The toxicity test was acceptable for quantitative use. The independently-calculated LC_{50} values for the three independent experimental repeats were 12.91 (10.29 – 15.53), 28.55 (15.05 – 42.05), 10.32 (7.788 – 12.85) mg/L, respectively. These independently-calculated LC_{50} values were used to calculate the SMAV/GMAV value (as the geometric mean of the three LC_{50} values previously mentioned) of 15.61 mg/L and was used to derive the freshwater acute water column criterion.

A.2.6.1 Li (2009) Concentration Response Curve – Neocaridina (shrimp)

Publication: Li (2009)
Species: Japanese Swamp Shrimp, *Neocaridina denticulata*
Genus: *Neocaridina*
EPA-Calculated LC_{50}s: 12.91 (95% C.I. 10.29 – 15.53), 28.55 (95% C.I. 15.05 – 42.05), 10.32 (95% C.I. 7.788 – 12.85) mg/L

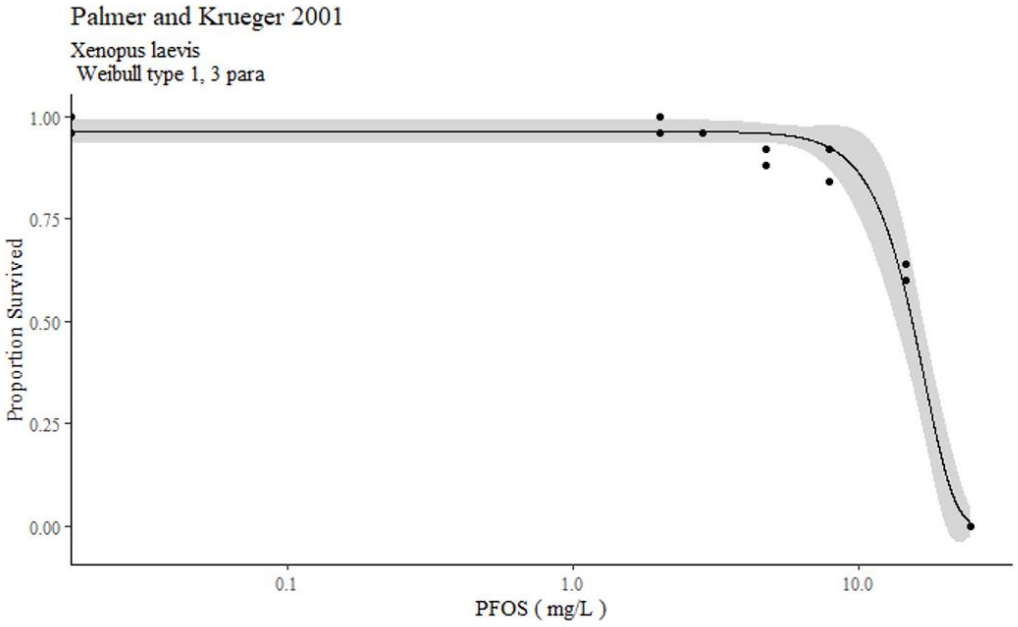
A.2.7 Seventh Most Sensitive Freshwater Genus for Acute Toxicity: *Xenopus* (frog)

Palmer and Krueger (2001), associated with Wildlife International, conducted three good laboratory practice (GLP) renewal definitive assays with the potassium salt of PFOS (86.9% purity) using the frog embryo teratogenesis assay - *Xenopus* (FETAX) with *Xenopus laevis.* A primary PFOS stock solution was prepared in FETAX solution at a concentration of 48 mg/L, and subsequently diluted with FETAX solution to prepare the six nominal test concentrations (1.82, 3.07, 5.19, 8.64, 14.4 and 24.0 mg PFOS/L). Eggs were obtained from breeding colonies of *X. laevis* at the University of Maryland Wye Research and Education Center. Adults were held in flow-through polyethylene aquaria with 10 cm of dechlorinated tap water (23.5±0.5°C) and a maximum of 10 adults/chamber and photoperiod of 16:8-hours light:dark. They were bred in the dark following injection of human chorionic gonadotropin to

NMED Exhibit 62

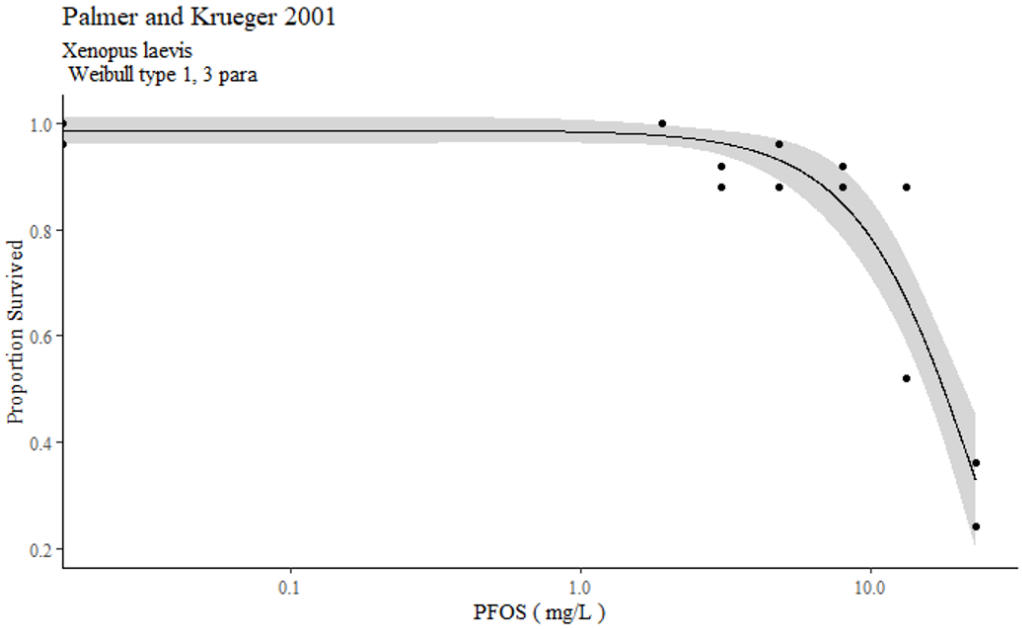
dorsal lymph sac of males and females. During each assay, *X. laevis* embryos (between NF stages 8-11) were exposed to PFOS for 96 hours. Two replicate test chambers were maintained in each treatment group and four replicates were maintained in each control group from the three separate assays. Each test chamber contained 25 embryos for a total of 50 embryos per treatment group and 100 embryos per control group. Tests were conducted at 24°C, pH of 7.26-7.30, estimated total hardness of 75 mg/L as $CaCO_3$, D.O. of 7.8-8.1 mg/L and a 12:12-hour light:dark photoperiod (60-85 foot candles). PFOS concentrations were measured at the initiation and termination of all three assays. The authors reported 96-hour LC_{50} values for mortality of 13.8, 17.6 and 15.3 mg/L PFOS, teratogenesis EC_{50}s of 12.1, 17.6 and 16.8 mg/L PFOS, and minimum concentration to inhibit growth values (effectively a LOEC) of >14.7, 7.97 and 8.26 mg/L for the same three tests, respectively. Independently-calculated 96-hour LC_{50} values for mortality were 15.53 (13.86 – 17.21), 18.04 (15.33 – 20.74), and 14.60 (12.65 – 16.55) mg/L for the three assays, respectively. No additional quantitative, acute toxicity data were available for this species. Therefore, these independently-calculated LC_{50} values were used to calculate the SMAV/GMAV value (as the geometric mean of the three LC_{50} values) of 15.99 mg/L that was used to derive the freshwater acute water column criterion.



NMED Exhibit 62

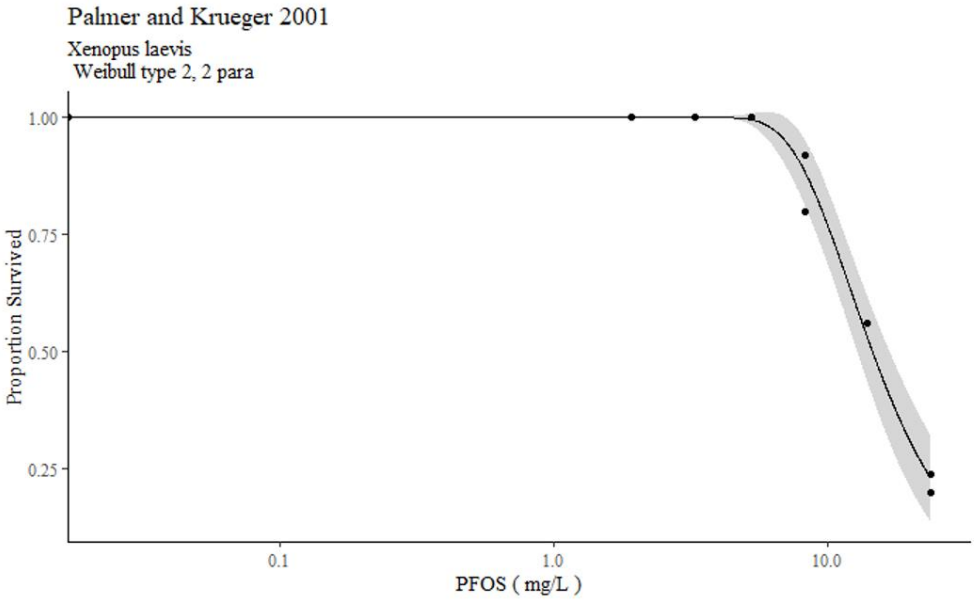
A.2.7.1 Palmer and Krueger (2001) Concentration Response Curve – Xenopus (frog)

Publication: Palmer and Krueger (2001)
Species: Frog, *Xenopus laevis*
Genus: *Xenopus*
EPA-Calculated LC_{50}: 15.53 (95% C.I. 13.86 – 17.21), 18.04 (95% C.I. 15.33 – 20.74), 14.60 (95% C.I. 12.65 – 16.55) mg/L
Concentration-Response Model Estimates:



Parameter	Estimate	Std. Error	t-stat	p-value
b	4.1306	1.0464	3.9475	$7.897\ e^{-5}$
d	0.9633	0.0149	64.7242	$< 2.2\ e^{-16}$
e	16.9770	0.7991	21.2452	$< 2.2\ e^{-16}$

Concentration-Response Model Fit: *In order of LC_{50}s listed immediately above*



Concentration-Response Model Estimates:

Parameter	Estimate	Std. Error	t-stat	p-value
b	1.8800	0.3458	5.4366	$5.431\ e^{-8}$
d	0.9868	0.0127	77.7694	$< 2.2\ e^{-16}$
e	21.9190	1.9259	11.3812	$< 2.2\ e^{-16}$

Concentration-Response Model Estimates:

Parameter	Estimate	Std. Error	t-stat	p-value
b	-1.9934	0.2667	-7.4757	$7.681\ e^{-14}$
e	12.1461	0.7197	16.8763	$< 2.2\ e^{-16}$

A.2.8 Eighth Most Sensitive Freshwater Genus for Acute Toxicity: *Lampsilis* (mussel)

Hazelton (2013); Hazelton et al. (2012) evaluated the acute effects of PFOS (acid form, > 98% purity) on two freshwater mussels, as noted above*: Lampsilis siliquoidea* and *Ligumia recta.* The *L. siliquoidea* studies yielded the 7th most sensitive genus value in the PFOS freshwater acute criterion dataset. Hazelton et al.'s experimental design and study conditions for *L. siliquoidea* were reported above under the description of the fourth most sensitive taxa, *Ligumia*. The 24-hour EC_{50} reported by the study authors for glochidia of *L. siliquoidea* was 16.5 mg/L (C.I. 8.0-33.9). The 96-hour LC_{50} reported by the study authors for juvenile *L. siliquoidea* was 158.1 mg/L (C.I. not calculable). The 24-hour EC_{50} for *L. siliquoidea* glochidia represented an acute value acceptable for quantitative use for the mussel species. Because the juvenile life stage was less sensitive, only the glochidia LC_{50} was used to calculate the SMAV. An

NMED Exhibit 62

independently-calculated toxicity value could not be calculated at this time given the data presented in the paper. The study author reported value was used quantitatively to derive the freshwater acute water column criterion.

A.2.9 Ninth most Sensitive Freshwater Genus for Acute Toxicity: *Hyla* (frog)

Tornabene et al. (2021) conducted acute toxicity tests with the gray treefrog, *Hyla versicolor*, and PFOS (purchased from Sigma Aldrich, Catalog # 77282-10G; purity not provided). The acute tests followed standard 96-hour acute toxicity test guidance (ASTM 2017; U.S. EPA 2002). The frog was collected from the field in the wetlands of Indiana near the campus of Purdue University. Collected egg masses were raised outdoors in 200 L polyethylene tanks filled with well water. Experiments began when frogs reached Gosner stage 26, defined as when larvae are free swimming and feeding. An additional acute test with Gosner stage (GS) 40 was run to determine if toxicity varied between life stages. Before test initiation larvae were acclimated to test conditions (21°C and 12:12-hour light:dark photoperiod) for 24 hours. A stock solution of PFOS (500 mg/L) was made in UV-filtered well water and diluted with well water to reach test concentrations (ranged from 0 - 500 mg/L PFOS). Test concentrations were not measured in test solutions, based on previous research that demonstrated limited degradation under similar conditions. Larva were transferred individually to 250 mL plastic cups with 200 mL of test solutions and were not fed during the exposure period. The number of replicates varied by life stage and treatment; 10 replicates for each treatment for GS 26 larva, and five to six replicates for each treatment for GS 40 frogs. No mortality occurred in the controls of the GS 26 test and two of the six frogs died in the controls of the GS 40 test. The author reported 96-hour LC_{50}s were 79 and 24 mg/L PFOS for GS 26 and 40, respectively. The independently-calculated 96-hr LC_{50} values were 78.33 and 19.88 mg/L and are acceptable for quantitative use.

NMED Exhibit 62

Given that GS 40 frogs appear to be a more sensitive life-stage the LC_{50} of 19.88 (13.80 – 25.95) mg/L was utilized in the derivation of the freshwater acute water column criterion.

A.2.10 Tenth Most Sensitive Freshwater Genus for Acute Toxicity: *Dugesia* (planarian)

Li (2008) conducted three independent repeats of a 96-hour static, unmeasured acute toxicity test on the potassium salt of PFOS (CAS # 2795-39-3, > 98% purity) with the planarian, *Dugesia japonica* (a non-North American species). The test organisms were originally collected from Nan-shi stream located in Wu-lai, Taipei County, Taiwan in 2004 and maintained in the laboratory in dechlorinated tap water. The planarians had a body length of 0.9 ±0.1 cm at test initiation. Dilution water was dechlorinated tap water. The photoperiod consisted of 12 hours of illumination at an unreported intensity. A primary stock solution was prepared in dilution water. Exposure vessels were polypropylene beakers of unreported dimensions and 50 mL fill volume. The test employed five replicates of five planarians each in at least five test concentrations plus a negative control. Nominal test concentrations were in the range of 10-200 mg/L PFOS. The test temperature was maintained at 25 ±1°C. No other water quality parameters were reported for test solutions. Survival of negative control animals was not reported. The author-reported 96-hour LC_{50} was 17 mg/L (C.I. 16-18). The toxicity value could not be independently calculated at this time given the level of data that was presented in the paper. The author-reported value was used quantitatively to derive the freshwater acute water column criterion.

Li (2009) conducted three independent repeats of a second 96-hour static, unmeasured acute test of PFOS (potassium salt, > 98% purity) with *Dugesia japonica.* The tested individuals were also originally collected from Nan-shi stream located in Wu-lai, Taipei County, Taiwan in 2004 and maintained in the laboratory in dechlorinated tap water. The planarians had a body length of 0.9±0.1 cm at test initiation. Dilution water was dechlorinated tap water. The photoperiod consisted of 12 hours of illumination at an unreported intensity. A primary stock

NMED Exhibit 62

solution was prepared in dilution water. Exposure vessels were polypropylene beakers of unreported dimensions and 50 mL fill volume. Each of the three independent repeats employed three replicates of 10 planarians each in at least five test concentrations plus a negative control. Nominal test concentrations were in the range of 5-200 mg/L PFOS. The test temperature was maintained at 25±1°C. Water quality parameters including pH, conductivity, and D.O. were reported as having been measured at the beginning and end of each test, but the information is not reported. Survival of negative control animals was also not reported. The author-reported 96-hour LC_{50} was 23 mg/L (C.I. 20-25). An independently-calculated LC_{50} could not be estimated for the first and second independent tests (as EPA was unable to fit a model with significant parameters), but was estimated for the third independent test as 22.68 (18.27 – 27.10) mg/L. This acute value was acceptable for quantitative use and was used to derive the freshwater acute water column criterion.

Yuan et al. (2014) also conducted a 96-hour unmeasured acute test on PFOS (potassium salt, > 99% purity) with *Dugesia japonica*, under daily renewal conditions. *D. japonica* used for testing were originally collected from a fountain in Quan HetouBoshan, China, and cultivated in the laboratory for an unspecified time period before use. The planarians had a body length of 10-12 mm at test initiation. Dilution water was aerated tap water. No details were provided regarding photoperiod or light intensity. A primary stock solution was prepared by dissolving the salt in DMSO. The control and exposed planarians received 0.005% DMSO (v/v). Exposure vessels were beakers of unreported material type and dimensions with 50 mL fill volume. The test employed three replicates of 10 planarians each in six test concentrations plus a solvent control. Nominal test concentrations were 0 (solvent control), 10, 30, 35, 37.5, 40 and 45 mg/L PFOS. The test temperature was reported as 20°C. No other water quality parameters were

NMED Exhibit 62

reported. Survival of solvent control animals was not reported. The author-reported 96-hour LC_{50} was 29.46 mg/L (C.I. 25.80 - 33.12). An independently-calculated toxicity value could not be calculated at this time given the level of data that was presented in the paper. The author-reported value was used quantitatively to derive the freshwater acute water column criterion.

The noted toxicity values provided in each study summary above (17.00, 22.68, and 29.46 mg/L), comprising of both author-reported and independently-calculated LC_{50} values, were used to calculate the SMAV/GMAV value (as the geometric mean of the three LC_{50} values previously mentioned) of 22.48 mg/L, which was used to derive the freshwater acute aquatic life criterion.

A.2.11 Eleventh Most Sensitive Freshwater Genus for Acute Toxicity: *Danio* (zebrafish)

Ye et al. (2007) evaluated the acute effects of perfluorooctanesulfonic acid (PFOS, purity not reported) to *Danio rerio* via a 96-hour static-renewal unmeasured exposure. The PFOS stock solution of 480 mg/L was maintained at a pH of 8.2 with phosphate buffer and test substances were agitated in the reconstituted water by ultrasonification. The solutions were stored at 4 ± 1°C. Each test solution, at the selected concentration, was prepared by diluting the stock solution with reconstituted water. No added solvents were used. The fish (AB strain) used in this experiment were obtained from the School of Life Sciences at Fandan University, Shanghai, China. Breeding fish (1.5 years old) were fed live brine shrimp twice daily and kept with a 14:10-hour light:dark period in aquaria containing aerated natural water. The pH ranged from 7 to 8.5 and water temperature was maintained at 26 ± 1°C. Embryos were obtained from spawning adults, usually 5 male and 3 female. For each toxicant concentration, 48 embryos were randomly distributed into each well of 24-well polystyrene multi-well plates, with four eggs per well. Each well was filled with 2.5 mL test solution which were completely renewed daily by transferring embryos into newly cleaned wells. Nominal exposure concentrations were 0

NMED Exhibit 62

(control), 10, 85, 100, 110, 160, 200 and 240 mg/L PFOS. The multi-well plates were kept at 26 ± 1°C, with a photoperiod of 16:8-hour light:dark. The observations of embryos were made at distinct stages, which represent important steps of zebrafish development. The author-reported 96-hour LC_{50} was 71 mg/L PFOS. The EPA was unable to independently calculate a 96-hour LC_{50} value based on the level of data provided by the study authors in the paper. Therefore, the author-reported LC_{50} value was used quantitatively to derive the freshwater acute water column criterion.

Hagenaars et al. (2011b) exposed *D. rerio* embryos to the potassium salt of PFOS (CAS # 2795-39-3, purity ≥97%) under static unmeasured conditions for 96 hours. The PFOS was dissolved in medium-hard reconstituted laboratory water, which was aerated and kept at 26°C until use (no solvent). Adult wild-type zebrafish (breeding stock) were obtained from a commercial supplier (Aqua hobby, Heist-op-den-berg, Belgium) and kept in aerated and biologically filtered medium-hard reconstituted freshwater. Four males and four females were used for egg production. Fertilized eggs were collected in egg traps within 30 minutes of spawning. Eggs were transferred to the test solutions (nominal PFOS concentrations of 0.1, 0.5, 1, 5, 10 mg/L in the definitive ELS test and 1, 5, 10, 25, 50 and 100 mg/L in the 96-hour range-finding test) within 60 minutes after spawning. Eggs with anomalies or damaged membranes were discarded and fertilized eggs were separated from the non-fertilized eggs using a stereomicroscope. Twenty normally shaped fertilized eggs per exposure concentration were divided over a 24-well plastic plate and each egg was placed individually in 2 mL of the test solution. The remaining four wells were filled with clean water and used for the control eggs. Two replicate plates were used for each exposure concentration resulting in 40 embryos per treatment at the beginning of the experiment. The 24-well plates were covered with a self-

NMED Exhibit 62

adhesive foil, placed in an incubation chamber at 26 ± 0.3°C and subjected to a 14:10-hour light:dark cycle. A test was considered valid if more than 90% of the controls successfully hatched and showed neither sublethal nor lethal effects. The authors reported a 96-hour LC_{50} of 58.47 mg/L PFOS, based on the results of the range-finding test. The author-reported value was used quantitatively to derive the freshwater acute water column criterion.

Sharpe et al. (2010) examined the toxicity of PFOS-K (potassium salt, CAS # 2795-39-3, 98% purity) and bioaccumulation of PFOS and its isomers on *Danio rerio* through three different tests, a 96-hour renewal toxicity test on adults, a 48-hour renewal toxicity test on embryos, and a chronic exposure test that evaluated maternal transfer and fecundity of PFOS isomers. The 96-hour test is described in this appendix, as these results were used quantitatively to derive the freshwater acute water column criterion. The 48-hour and chronic toxicity tests were used qualitatively (Appendix G). The authors provided little detail about the test protocol, other than following OECD Guideline 203. Adult zebrafish were obtained from a local pet store. They were acclimated and held in 70 L glass aquaria in an environmental chamber set to 26°C under a 14:10-hour light:dark photoperiod for six to 10 months prior to use in experiments. Conditioned zebrafish water (ZF water) was obtained from the Biological Sciences Zebrafish Facility at the University of Alberta, where an automated reverse osmosis system regulated both the salinity and hardness (160 mg/L total hardness and 20 mg/L calcium carbonate hardness) of the water. A stock solution of 25 mg/ml PFOS in MeOH was used for dosing in all experiments. All vehicle controls received a volume of MeOH equal to that present in the highest PFOS treatment of that experiment (final MeOH content 0.65% v/v). The concentration of PFOS in any experiment was always well below its reported solubility in water (approximately 500 mg/L). Zebrafish toxicity tests were performed using food grade 2 L plastic tanks with four fish per

NMED Exhibit 62

tank, and two tanks per concentration. Fish were randomly assigned to nominal concentrations defined as control (0 mg/L PFOS); vehicle control (0 mg/L PFOS, 0.4% MeOH v/v); and 6.25, 12.5, 2, 50 and 100 mg/L PFOS. Authors indicated that measured PFOS concentrations averaged 88% of nominal but did not indicate whether the LC_{50} was measured or nominal. The adult 96-hour acute test followed OECD 203 protocol and was acceptable for quantitative use. The author-reported LC_{50} was 22.2 ± 4.6 mg/L for PFOS. The author-reported value was used quantitatively to derive the freshwater acute water column criterion.

Evaluated the acute effects of perfluorooctane sulfonate, potassium salt (PFOS-K, CAS# 2795-39-3 purchased from Wellington Laboratories Inc., Ontario, Canada) on zebrafish (*Danio rerio*) during a 96-hour unmeasured, static-renewal study. Zebrafish were purchased from a local market at approximately three months in age and 2.2 cm in length. Fish were allowed to acclimate for seven days and were fed three times per week until 24 hours before the test was started. Water used for the testing was aerated for 48 hours before testing began, and testing followed OECD Guideline 203. Observed exposure water characteristics were total hardness of 180-220 mg/L as $CaCO_3$, temperature of 23 ± 1ºC, D.O. of 7.0 – 8.6 mg/L and a photoperiod of 12:12-hours light:dark. Each 2-L beaker was filled with 1,500 mL of test solution at nominal concentrations of 0 (control), 2.87, 5, 8.7, 15.14, 26.34, 45.83 and 79.74 mg/L PFOS. There were three replicates per concentration, and seven fish per beaker. Test solutions were renewed at 48 hours. The author-reported 96-hour LC_{50} was 17.0 mg/L PFOS based on a sigmoidal three-parameter regression. The EPA was unable to independently calculate a 96-hour LC_{50} value based on the level data provided in the paper. Therefore, the author-reported LC_{50} value of 17.0 mg/L PFOS was used quantitatively to derive the freshwater acute water column criterion.

NMED Exhibit 62

Li et al. (2015) evaluated the acute effects of PFOS (CAS # 2795-39-3, 98% purity) to *Danio rerio* via a 96-hour static unmeasured exposure. Solutions for waterborne exposure were formulated with medium used to rear embryos (reconstituted laboratory water). Adult, wild-type zebrafish were obtained from the Institute of Hydrobiology, at the Chinese Academy of Sciences (Wuhan, China), and kept in treated tap water at 26 – 29°C. Fish were reared with a female/male ratio of 1:2 under 14:10-hour light:dark photoperiod, with 1/3 of the water exchanged daily. Spawning and fertilization took place within 30 minutes after the lights were turned on in the morning, with fertilized embryos collected and cleaned with embryo rearing water. Immediately after fertilization, embryos were examined, and damaged or unfertilized embryos were discarded. Zebrafish embryos were exposed in 24-well cell culture plates (assume plastic) to a series of PFOS concentrations (6.25, 12.5, 25.0, 50.0, 100.0 and 200.0 mg/L). Twenty, normally shaped, fertilized embryos were assigned to each treatment (three replicates) and 2 mL of test solution per well; the four remaining wells were assigned with control embryos. Embryos were exposed in an incubator at 28.5°C, pH of 8.3 and a 14:10-hour light:dark photoperiod. Toxicological endpoints included whether embryos were clear or opaque, exhibited edema at 4, 8, 24, 48, 72, or 96 hpf, or developed structural malformations at 72 or 96 hpf until hatching. Coagulated embryos before hatching are opaque, milky white, and appear dark under the microscope. Coagulation of embryos was recorded and used for the calculation of an LC_{50} value. The author reported 96-hour LC_{50} was 68.0 mg/L PFOS. The independently-calculated LC_{50} value was 71.12 (56.82 – 85.42) mg/L PFOS. This toxicity value is acceptable for quantitative use and was used to derive the freshwater acute water column criterion.

Du et al. (2017); Du et al. (2016b) exposed *Danio rerio* to heptadecafluorooctanesulfonic acid (PFOS, potassium salt, CAS# 2795-39-3, 98% purity) using

NMED Exhibit 62

static unmeasured procedures. Although the study focused on the protective effects of zinc nanoparticles (ZnO-NPs) on PFOS toxicity (development and damage to DNA), data were also reported for PFOS-only exposures. Adult AB strain zebrafish were purchased from State Key Laboratory of Freshwater Ecology and Biotechnology, Chinese Academy of Sciences (Wuhan, China). Fish were maintained and tested at 28°C under a 14:10-hour light:dark cycle. Male and female fish were paired in spawning boxes overnight in rearing water and spawning was completed at the beginning of the light cycle. Eggs were collected from the spawn traps and transferred to clean rearing water prior to testing. The embryos were exposed to PFOS (1, 2, 4, 8 and 16 mg/L in a preliminary test to determine the LC_{50}, and at 0.4, 0.8 and 1.6 mg/L in a later test with ZnO-NPs solutions to evaluate mortality (at 96 hours), body length (at 96 hours), hatch rate (at 72 hours), heart rate (at 48 hours), and malformation rate (at 96 hours). Embryos were kept in 24-well multi-plates at two embryos/well, in which 20 wells contained 2 mL reconstituted water test solution and four wells contained 2 mL of culture medium as the control. Each plate contained 40 embryos for exposure testing and eight embryos as internal water controls. For each concentration and water control, three 24-well plates (replicates) were included. The study authors reported a 96-hour LC_{50} of 3.502 mg/L for PFOS. The EPA was unable to independently calculate a 96-hour LC_{50} value based on the level data provided in the paper. Therefore, the author-reported LC_{50} value of 3.502 mg/L PFOS was used quantitatively to derive the freshwater acute water column criterion.

Stengel et al. (2017b) exposed 1 hpf *Danio rerio* embryos to PFOS for 96 hours using renewal unmeasured procedures as specified in (OECD 2013) guidelines. PFOS stock and exposure solutions were prepared in reconstituted laboratory water. All adult zebrafish used for breeding were wild-type descendants of the “Westaquarium” strain and obtained from the

NMED Exhibit 62

Aquatic Ecology and Toxicology breeding facilities at the University of Heidelberg. Details of zebrafish maintenance, egg production and embryo rearing were as described previously (Kimmel et al. 1995; Kimmel et al. 1988; Nagel 2002; Spence et al. 2006; Wixon 2000) but included updates for the purpose of the zebrafish embryo toxicity test by Lammer et al. (2009). Embryos no older than 1 hpf were exposed in glass vessels, which had been preincubated (saturated) for at least 24 hours, to a series of PFOS dilutions (0, 3.125, 6.25, 12.5, 25, 50 mg/L). After confirmation of fertilization success, embryos were individually transferred to the wells of 24-well plates, which had been pre-incubated with 2 mL of the test solutions per well for 24 hours prior to the test start and kept in an incubator at 26.0 ±1.0°C under a 14:10-hour light:dark regime. In order to prevent evaporation or cross-contamination between the wells, the plates were sealed with self-adhesive foil. Embryo tests were classified as valid if the mortality in the negative control was ≤ 10%, and if the positive control (3,4-dichloroaniline) showed mortalities between 20 and 80%. All fish embryo tests were run in three independent replicates. Both lethal and sublethal effects were used for the determination of EC values. The author-reported 96-hour LC_{50} and EC_{50} (combination of lethal and sublethal effects) values were 34.2 and 21.4 mg/L PFOS, respectively. The independently-calculated LC_{50} was 38.82 (36.67 – 40.98) mg/L PFOS. The independently-calculated LC_{50} was considered quantitative and used to derive the freshwater acute water column criterion.

Nilén et al. (2022) evaluated the acute effects of perfluorooctanesulfonate, potassium salt (PFOS-K, CAS No. 2795-39-3, ≥ 98% purity, purchased from Sigma-Aldrich, Stockholm, Sweden) on zebrafish (*Danio rerio*) during a 96-hour measured, static-renewal test. PFOS stock solutions (464 mM) were prepared in DMSO. Adult zebrafish (AB strain) were purchased from Karolinska Institute (Stockholm, Sweden). Fish were kept at a 14:10-hour light:dark cycle in a

NMED Exhibit 62

recirculating system. Fish embryo toxicity tests were performed following the OECD Technical Guideline No. 236 (OECD 2013). Prior to testing, 96-well plates were pre-incubated for 24 hours with the chemical solutions to limit sorption to the well plates. On the day of exposure, five different exposure concentrations were prepared in glass beakers through a serial dilution (1:2) using ISO water. The DMSO content was adjusted to 0.09% (v/v) in all solutions and all tests included three control groups: negative control (ISO-water), solvent control (0.09 % DMSO in ISO-water) and positive control (4 mg/L DCA). Test concentrations were selected based on previous studies about lethality and sub-lethality. One embryo (64-cell stage) with 250 µL of test solution was added to each well on a 96-well plate. For each concentration, 24 embryos were used, and each test contained a total of 192 embryos. The plates were covered with self-adhesive film and incubated at 26 ± 1°C in a 14:10-hour light:dark cycle. An experiment was considered valid by the study authors if the mortality in the negative control and the solvent control was less than 10%. In addition, the mortality of the positive control had to be ≥ 30%. Each experiment was repeated three to five times representing independent replicates and the embryos were exposed for 96 hpf. The exposure solutions were sampled before the start and at the end of the exposure period. Nominal exposure concentrations were 0 (control), 0 (solvent control), 7, 14, 28, 56 and 111.5 µM PFOS-K. Equivalent PFOS concentrations were 3.768, 7.535, 15.07, 30.14 and 60.01 mg/L PFOS-K, respectively, based on a molecular weight of 538.22 g/mol PFOS-K. Measured concentrations were between 1.3 and 23% of nominal at 96 hours. The author-reported 96-hour LC_{50} was 44.57 µM PFOS-K, or 23.99 mg/L PFOS-K (based on a molecular weight of 538.22 g/mol; 44.57 x 538.22 ÷ 1,000). The EPA was unable to independently calculate a 96-hour LC_{50} value based on the level of data provided in the paper by the study authors. Therefore,

NMED Exhibit 62

the author-reported LC_{50} value of 23.99 mg/L PFOS was used quantitatively to derive the freshwater acute water column criterion.

A.2.12 Twelfth Most Sensitive Freshwater Genus for Acute Toxicity: *Daphnia* (cladoceran)

Logeshwaran et al. (2021) conducted acute and chronic toxicity tests with the cladoceran, *Daphnia carinata*, and PFOS-K (perfluorooctanesulfonate potassium salt, ≥ 98% purity, purchased from Sigma-Aldrich Australia). In-house cultures of daphnids were maintained in 2 L glass bottles with 30% natural spring water in deionized water, 21℃ and a 16:8-hour light:dark photoperiod. The acute test protocol followed OECD (2000) with slight modifications. A PFOS stock solution (20 mg/mL) was prepared in dimethylformamide and diluted with deionized water to achieve a concentration of 200 mg/L PFOS. Cladoceran culture medium was used to prepare the PFOS stock and test solutions. Ten daphnids (6-12 hours old) were transferred to polypropylene containers containing one of 14 nominal test concentrations (0, 0.5, 1, 2.5, 5, 10, 15, 20, 25, 30, 35, 40, 45 and 50 mg/L PFOS). Each test treatment was replicated three times and held under the same conditions as culturing. At test termination (48 hours) immobility was determined after 15 seconds of gentle stirring. No mortality occurred in the controls. The author-reported 48-hour EC_{50} was 8.8 mg/L PFOS. The independently-calculated 48-hour EC_{50} value was 11.56 (10.06 – 13.07) mg/L and is acceptable for quantitative use in the derivation of the freshwater acute water column criterion.

Drottar and Krueger (2000g) reported the results of a 48-hour static, measured acute toxicity test on PFOS (potassium salt, CAS # 2795-39-3, 90.49% purity) with *Daphnia magna*. The GLP test was conducted at Wildlife International, Ltd. In Easton, MD in February, 1999. The test followed OECD (2004); (U.S. EPA 1996d). The test organisms were less than 24 hours old at test initiation. Dilution water was 0.45 µm filtered well water [hardness: 132 (128-136) mg/L as $CaCO_3$; alkalinity: 178 (176-178) mg/L as $CaCO_3$; pH: 8.3 (8.2-8.3); TOC: < 1.0 mg/L;

NMED Exhibit 62

conductivity: 313 (310-315) µmhos/cm]. Photoperiod was 16:8-hours light:dark with a 30 minute transition period. Light was provided at an intensity of approximately 359 lux. A primary stock solution was prepared in dilution water at 91 mg/L. It was mixed for ~19.5 hours prior to use. After mixing, the primary stock was proportionally diluted with dilution water to prepare the four additional test concentrations. Exposure vessels were 250 mL plastic beakers containing 240 mL of test solution. The test employed two replicates of 10 daphnids each in five measured test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 12, 20, 33, 55, 91 mg/L. Mean measured concentrations were <LOQ (4.58 mg/L), 11, 20, 33, 56 and 91 mg/L. Analyses of test solutions were performed at Wildlife International Ltd. Using HPLC/MS. The mean percent recovery of matrix fortifications analyzed concurrently during sample analysis was 96.2%. Samples collected at test initiation had measured values from 85.5 to 112% of nominal. Measured values for samples taken at 24 hours ranged from 92.2 to 115% of nominal, and at 48 hours from 91.6 to 106% of nominal. Dissolved oxygen in control and highest test concentration (91 mg/L) ranged from 8.6-8.9 mg/L and 8.6-9.1 mg/L; pH ranged from 8.2-8.5 and 8.5-8.6, respectively. Test temperature ranged from 19.5-20.2°C and 19.3-20.1°C, respectively. At 24 hours, daphnids in the negative control, and the 11, 20 and 33 mg/L treatments appeared healthy and normal with no mortality, immobility, or overt clinical signs of toxicity. However, five percent mortality was observed at 48 hours in the negative control. The author-reported 48-hour EC_{50} was 61 mg/L (C.I. 33-91). The independently-calculated toxicity value was 58.51 (53.59 – 63.43) mg/L and was used quantitatively to derive the freshwater acute water column criterion.

Boudreau (2002); Boudreau et al. (2003a) performed a 48-hour static test on PFOS (potassium salt, CAS # 2795-39-3, 95% purity) with *Daphnia magna* and *Daphnia pulicaria* as

NMED Exhibit 62

part of a Master's thesis at the University of Guelph, Ontario, Canada. The results were subsequently published in the open literature (Boudreau et al. 2003a). The test followed ASTM (1999a). Daphnids used for testing were less than 24 hours old at test initiation. *D. magna* were obtained from a brood stock (Dm99- 23) at ESG International (Guelph, ON, Canada). *D. pulicaria* were acquired from a brood stock maintained in the Department of Zoology at the University of Guelph. Dilution water was clean well water obtained from ESG International. Hardness was softened by addition of distilled deionized water to achieve a range of 200-225 mg/L of $CaCO_3$. Photoperiod was 16:8-hours light:dark under cool-white fluorescent light between 380 and 480 lux. Laboratory-grade distilled water was used for all solutions with maximum concentrations derived from stock solutions no greater than 450 mg/L. Test vessels consisted of 225 mL polypropylene disposable containers filled with 150 mL of test solution. All toxicity testing involved four replicates of 10 daphnids each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 31, 63, 125, 250 and 450 mg/L. Experiments were conducted in environmental chambers at a test temperature of 21 ±1°C. Authors note temperature and pH were measured at beginning and end of study, but the information was not reported. Survival of daphnids in the negative control was also not reported, although ASTM E729-96 requires at least 90% survival for test acceptability. The author-reported 48-hour EC_{50} for *D. magna* was 67.2 mg/L (C.I. 31.3-88.5). The author-reported 48-hour EC_{50} for *D. pulicaria* was 134 mg/L (C.I. 103-175). Independently-calculated toxicity values could not be calculated given the level of data that was presented in the paper. The study author reported values were used quantitatively to derive the freshwater acute water column criterion.

NMED Exhibit 62

Ji et al. (2008) performed a 48-hour static, unmeasured acute test of PFOS (acid form, CAS # 1763-23-1, purity unreported) with *Daphnia magna*. The test followed the EPA's Methods for measuring the acute toxicity of effluents and receiving waters to freshwater and marine organisms (U.S. EPA 2002). *D. magna* used for testing were obtained from brood stock cultured at the Environmental Toxicology Laboratory at Seoul National University (South Korea). Test organisms were less than 24 hours old at test initiation. Dilution water was moderately hard reconstituted water (hardness typically 80-100 mg/L as $CaCO_3$). Experiments were conducted in glass jars of unspecified size and fill volume. Photoperiod was assumed by the reviewers to have been 16:8-hours light:dark. Preparation of test solutions was not described. The test involved four replicates of five daphnids each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 6.25, 12.5, 25, 50 and 100 mg/L. Test temperature was maintained at 21 ± 1°C. Authors note water quality parameters (pH, temperature, conductivity, and D.O.) were measured 48 hours after exposure, but the information is not reported. Survival of daphnids in the negative control was not reported in the paper. However, raw data were obtained by the EPA from the study authors and control survival was 100% and therefore meets the EPA/600/4-90/027F requirement of at least 90% survival for test acceptability. The author-reported 48-hour EC_{50} value for the study was 37.36 mg/L (C.I. 30.72-43.99) for *D. magna*. The 48-hour EC_{50} value was independently-calculated as 35.46 (28.26 – 42.66) mg/L. The independently-calculated acute toxicity value was included in the derivation of the freshwater acute water column criterion.

Li (2009) conducted three independent repeats of a 48-hour static acute test on PFOS (potassium salt, > 98% purity) with *Daphnia magna*. The test followed OECD (1984). *D. magna* used for the test were less than 24 hours old at test initiation. Dilution water was dechlorinated

NMED Exhibit 62

tap water. The photoperiod consisted of 12 hours of illumination at an unreported light intensity. A primary stock solution was prepared in dilution water and did not exceed 400 mg/L. Exposure vessels were polypropylene of unreported dimensions and 50 mL fill volume. The test employed five replicates of six daphnids each in at least five test concentrations plus a negative control. Each treatment was tested three independent times. Based on water solubility of test chemicals and preliminary toxicity results, nominal test concentrations were in the range of 10 - 400 mg/L for PFOS. Water quality parameters including water pH, conductivity and D.O. were measured at the beginning and at the end of each test. Initial values of pH were 7.82±0.12 and 7.91±0.03 after 48 hours. At the start of the bioassays, D.O. and specific conductivity were 67.7±6.8% and 101.8±6.8 µS/cm. After the 48-hour testing period, D.O. and specific conductivity were 55.6±1.26% and 109.1±3.5 µS/cm. The D.O. after 48-hours of testing was lower than the test guideline recommendation of >60% (ASTM 2002; U.S. EPA 2016a; U.S. EPA 2016b); however, it was not low enough to change the use of the study. The test was conducted in a temperature incubator at 25 ±2°C. None of the control animals became immobile at the end of the test. The author-reported 48-hour EC_{50} was 63 mg/L (C.I. 58-69) which was an average LC_{50} of the three tests. The independently-calculated LC_{50} values for the three independent experimental repeats were 55.40 (45.97), 72.70 (61.63 – 83.77) and 64.60 (49.53 – 79.66) mg/L, respectively. The three independently-calculated LC_{50} values were used to calculate the SMAV for *D. magna* and derive the freshwater acute water column criterion.

Yang et al. (2014) conducted a 48-hour static acute test of PFOS (potassium salt, CAS # 2795-39-3, 99% purity) with *Daphnia magna,* following ASTM (1993). *D. magna* used for the test were donated by the Chinese Research Academy of Environmental Sciences. The daphnids were less than 24 hours old at test initiation. Dilution water was dechlorinated tap water (pH,

NMED Exhibit 62

7.0±0.5; D.O., 7.0±0.5 mg/L; total organic carbon, 0.02 mg/L; and hardness, 190.0±0.1 mg/L as $CaCO_3$). Photoperiod was 12:12-hours light:dark at an unreported light intensity. A primary stock solution was prepared by dissolving PFOS in deionized water and cosolvent DMSO. The primary stock was proportionally diluted (0.56x) with dilution water to prepare the test concentrations. Exposure vessels were 200 mL beakers of unreported material type containing 200 mL of test solution. The test employed three replicates of 10 daphnids each in six test concentrations (measured in low and high treatments) plus a negative and solvent control. Nominal concentrations were 0 (negative and solvent controls), 20.00, 36.00, 64.80, 116.64, 209.95 and 377.91 mg/L. Mean measured concentrations before and after renewal were respectively 18.43 and 19.80 and mg/L (lowest concentration) and 341.74 and 372.35 mg/L (highest concentration). Analyses of test solutions were performed using HPLC/MS and negative electrospray ionization. The concentration of PFOS was calculated from standard curves (linear in the concentration range of 1-800 ng/mL), and the average extraction efficiency was in the range of 70-83%. The concentrations and chromatographic peak areas exhibited a significant positive correlation ($r = 0.9987$, $p < 0.01$), and the water sample-spiked recovery was 105%. The temperature, D.O., and pH were reported has having been measured every day during the acute test, but results are not reported. Negative control survival was > 96%. Solvent control survival was 100%. The author reported 48-hour LC_{50} was 78.09 mg/L (C.I. 54.38-112.13) and was used quantitatively to derive the freshwater acute water column criterion.

Lu et al. (2015) conducted a 48-hour static test on PFOS (purity 98%) with *Daphnia magna*, following OECD (2004). *D. magna* used for the test were originally obtained from the Chinese Center for Disease Control and Prevention (Beijing, China) and cultured in the laboratory according to the International Organization for Standardization (ISO 1996). Daphnids

NMED Exhibit 62

were less than 24 hours old at test initiation. Dilution water was the same used for daphnid culture and was reconstituted according to OECD (2004) with a hardness of 250 mg/L as $CaCO_3$, as calculated based on the recipe provided, and pH ranging from 7.7 to 8.4. Photoperiod was 16:8-hours light:dark at an unreported light intensity. The test solution was prepared immediately prior to use by diluting the stock solution with a daphnia culture medium. Exposure vessels were 100 mL glass beakers containing 45 mL of test solution. The test employed three replicates of 10 daphnids each in six nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 1, 3, 10, 30, 100 and 300 mg/L. Exposure water quality was checked daily and maintained at a temperature of 20 ± 1°C, pH of 7.2 ± 0.3, and D.O. of 6.5 ± 0.5 mg/L. One hundred percent survival was observed at 48 hours in the negative control. The author-reported 48-hour EC_{50} was 23.41 mg/L (LC_{50} = 49.27) and used quantitatively to derive the freshwater acute water column criterion.

Liang et al. (2017) conducted a 48-hour static test on PFOS (potassium salt, CAS # 2795-39-3, ≥ 98% purity) with *Daphnia magna*. The test followed OECD (2004). *D. magna* used for the test were originally obtained from State Key Laboratory of Environmental Aquatic Chemistry (Eco-Environmental Sciences of Chinese Academy of Sciences, Beijing) and cultured in the laboratory according to Revel et al. (2015). Daphnids were less than 24 hours old at test initiation. Dilution water was artificial medium (M4) at 20°C and pH 7 (Revel et al. 2015). Photoperiod was 16:8-hours light:dark at an unreported light intensity. The test solution was prepared immediately prior to use by diluting the stock solution with M4 medium. Exposure vessels were 80 mL beakers of unreported material type containing an unspecified volume of test solution. The test employed five replicates of five daphnids each in six nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 30, 44,

NMED Exhibit 62

66, 100 and 150 mg/L. No mention was made of water quality being checked during the exposure. 100% survival was observed at 48 hours in the negative control. The author reported 48-hour EC_{50} was 79.35 mg/L. The independently-calculated toxicity value was 94.58 (94.20 – 94.96) mg/L and was used quantitatively to derive the freshwater acute water column criterion.

Yang et al. (2019) evaluated the acute effects of perfluorooctane sulfonate, potassium salt (PFOS-K, CAS# 2795-39-3, 98% purity, purchased from Sigma-Aldrich in St. Louis, MO) on *Daphnia magna* via a 48-hour unmeasured, static mortality test. *D. magna* cultures were obtained from the Institute of Hydrobiology of Chinese Academy of Science in Wuhan, China. Organisms were cultured in Daphnia Culture Medium according to the parameters laid out in OECD Guideline 202, and all testing followed the guideline. Cultures were fed green algae daily and were acclimated for two to three weeks before testing. Acute test concentrations included 0 (control), 0.0000156, 0.0000234, 0.0000349, 0.0000788 and 0.000118 mol/L (or 0 (control), 8.396, 12.59, 18.78, 28.31, 42.41, and 63.51 mg/L given the molecular weight of the form of PFOS used in the study, CAS # 2795-39-3, of 538.22 g/mol). Five neonates (12-24 hours old) were placed randomly in 100 mL glass beakers filled with 60 mL test solution, with four replicates per concentration. Organisms were observed for mortality at 48 hours, and the authors reported a LC_{50} of 22.77 mg/L. The EPA's independently-calculated 48-hour LC_{50} was 22.43 (15.74 – 29.12) mg/L PFOS and was used quantitatively to derive the freshwater acute water column criterion.

A.2.13 Thirteenth Most Sensitive Freshwater Genus for Acute Toxicity: *Ambystoma* (salamander)

Tornabene et al. (2021) conducted acute toxicity tests with three species of salamanders in the genus *Ambystoma* and PFOS (purchased from Sigma Aldrich, Catalog # 77282-10G; purity not provided). Acute tests followed standard 96-hour acute toxicity test guidance (ASTM

NMED Exhibit 62

2017; U.S. EPA 2002). The three test species (Jefferson salamander, *Ambystoma jeffersonianum*; small-mouthed salamander, *A. texanum*; eastern tiger salamander, *A. tigrinum*) were collected from a field in the wetlands of Indiana near the campus of Purdue University. Collected egg masses were raised outdoors in 200 L polyethylene tanks filled with well water. Experiments began when salamanders reached Harrison stage 40, defined as when larvae are free swimming and feeding. Before test initiation larvae were acclimated to test conditions (21°C and 12:12-hour light:dark photoperiod) for 24 hours. An additional acute test with Harrison stage 46 small-mouthed salamanders was run to determine if toxicity varied between life stages. A stock solution of PFOS (500 mg/L) was made in UV-filtered well water and diluted with well water to reach test concentrations (ranged from 0-500 mg/L PFOS). Test concentrations were not measured in test solutions, based on previous research that demonstrated limited degradation under similar conditions. Larva were transferred individually to 250 mL plastic cups with 200 mL of test solutions and were not fed during the exposure period. The number of replicates varied by species, life stage and treatment; five replicates per treatment for Jefferson salamander and Harrison stage 46 small-mouthed salamander, seven replicates per treatment for Harrison stage 40 small-mouthed salamander, and 20 replicates in the control and 10 replicates in each treatment for eastern tiger salamander. No mortality occurred in any of the control groups. Author-reported 96-hour LC_{50}s were 64, 41 and 73 mg/L PFOS for the Jefferson salamander, small-mouthed salamander and eastern tiger salamander, respectively. The authors did not find a significant difference between the life stages of small-mouthed salamander so results of the two tests were pooled. The independently-calculated 96-hour LC_{50} values were 51.71 (40.84 – 62.58) for Jefferson salamander; 46.71 (34.33 – 59.09) and 30.00 (27.14 – 32.86) for small-mouthed salamander, Harrison stage 40 and 46; and 68.63 (61.90 – 75.37) mg/L for eastern tiger

NMED Exhibit 62

salamander, respectively. In general, the independently-calculated toxicity values were acceptable for quantitative use and used to derive the freshwater acute water column criterion for PFOS. However, only the LC_{50} value of 30.00 mg/L for Harrison stage 46 small-mouthed salamander was used for this species as this life stage was determined to be the most sensitive.

A.2.14 Fourteenth Most Sensitive Freshwater Genus for Acute Toxicity: *Pontastacus* (crayfish)

Belek et al. (2022) tested heptadecafluorooctanesulfonic acid potassium salt (PFOS-K) on narrow-clawed crayfish (*Pontastacus leptodactylus*; formerly, *Astacus leptodactylus*) for 96 hours in an unmeasured, static experiment. Heptadecafluorooctanesulfonic acid potassium salt (≥98% purity) was obtained from Sigma-Aldrich (USA). Crayfish were obtained from a local breeder in Lake Egirdir, Turkey during the inter-molt stage, and averaged 29.1±0.39 g weight and 10.27±0.05 cm length. Crayfish were acclimated in the laboratory at the Biology Department of Gazi University for two weeks in glass aquariums filled with aerated, dechlorinated tap water for two weeks at a temperature of 21°C, and were fed a daily ration of raw trout. Testing parameters followed animal care guidance from NRC (1996). A 96-hour acute test was conducted to determine the LC_{50}, and a subsequent 21-day chronic test was conducted with a water only control, a DMSO solvent control, and two treatments set to 0.5 and 5 mg/L, which approximated 1% and 10% of the acute LC_{50}. The chronic test measured biochemical and enzymatic responses to PFOS. Mean water quality parameters for test water were as follows: 21±1°C temperature, 6.79±0.31 pH, 117.38±17.20 µS/cm specific conductivity, 0.01±0.001 mg/L total ammonia nitrogen, and 6.72±0.05 mg/L dissolved oxygen. Organisms were kept under a 16:8 light:dark cycle in 15 L of aerated, dechlorinated tap water during testing. The LC_{50} was calculated using Probit analysis using the U.S. EPA LC_{50} Software Program version 1.00. The author reported 96-hour LC_{50} value of 48.81 mg/L was determined to be acceptable for quantitative use.

NMED Exhibit 62

A.2.15 Fifteenth Most Sensitive Freshwater Genus for Acute Toxicity: *Anaxyrus* (toad)

Tornabene et al. (2021) conducted acute toxicity tests with the American toad, *Anaxyrus americanus*, and PFOS (purchased from Sigma Aldrich, Catalog # 77282-10G; purity not provided). The acute tests followed standard 96-hour acute toxicity test guidance (ASTM 2017; U.S. EPA 2002). The frog was collected from a field in the wetlands of Indiana near the campus of Purdue University. Collected egg masses were raised outdoors in 200 L polyethylene tanks filled with well water. Experiments began when toads reached Gosner stage (GS) 26, defined as when larvae are free swimming and feeding. An additional acute test with GS 41 was run to determine if toxicity varied between life stages. Before test initiation larvae were acclimated to test conditions (21°C and 12:12-hour light:dark photoperiod) for 24 hours. A stock solution of PFOS (500 mg/L) was made in UV-filtered well water and diluted with well water to achieve test concentrations ranging from 0 – 500 mg/L PFOS. Test concentrations were not measured in test solutions, based on previous research that demonstrated limited degradation under similar conditions. Larva were transferred individually to 250 mL plastic cups with 200 mL of test solutions and were not fed during the exposure period. The number of replicates varied by life stage, and treatment; 10 replicates for each treatment for GS 26 toads, and six to 10 replicates for each treatment for GS 41 toads. No mortality occurred in any of the control groups. The author-reported 96-hour LC_{50} was 62 mg/L PFOS. The authors did not find a significant difference between the life stages of the American toad, so results of the two tests were pooled. The independently-calculated 96-hour LC_{50} values were 63.41 (62.32 – 64.51) mg/L for the GS 26 toads and 56.49 (49.10 – 63.90) mg/L for GS 41 toads. Given that the GS 41 toads appear to be a more sensitive life-stage the LC_{50} of 56.49 mg/L was considered acceptable for quantitative use and used in the derivation of the freshwater acute water column criterion.

NMED Exhibit 62

A.2.16 Sixteenth Most Sensitive Freshwater Genus for Acute Toxicity: *Procambarus* (crayfish)

Funkhouser (2014) conducted a 7-day static acute test on PFOS (potassium salt, ≥98% purity) with the crayfish species, *Procambarus fallax* (f. *virginalis*), as part of a Master's thesis at the Texas Tech University, Lubbock, TX. Juvenile *P. fallax* (2-week old, 0.041 g) used for the test were originally purchased from a private collector. The crayfish reproduced for several generations before being used for experiments. Based on an average reproductive age of 141-255 days, an interclutch period of 50-85 days, and a brooding time of 22-42 days, the author estimated the experimental animals to be stage F4-F6 (Seitz et al. 2005). Dilution water was moderately hard reconstituted laboratory water (3.0 g $CaSO_4$, 3.0 g $MgSO_4$, 0.2 g KCl, and 4.9 g $NaHCO_3$ added to 50 L deionized water). Photoperiod was 14:10-hours light:dark at an unreported light intensity. PFOS was dissolved in dilution water to prepare the test concentrations. Exposure vessels were 1 L polypropylene containers containing 500 mL of test solution. The test employed two replicates of three snails each in five test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 40, 80, 120, 160, and 200 mg/L. Exposure concentrations were reportedly measured, but concentrations were not reported. Analyses of test solutions were performed using LC-MS/MS. Standards were used as part of the analytical method, but details were not reported. The reporting limit was 0.010 mg/L. Experiments were conducted in an incubator at 25 ±1°C and covered with plastic opaque sheeting to limit evaporation. No other water quality parameters were reported as having been measured in test solutions. Negative control survival was 100% after seven days. The author reported 96-hour LC_{50} was reported as 59.87 mg/L. For comparison, the 7-day LC_{50} was 39.71 mg/L. The independently-calculated 96-hour LC_{50} value was also 59.87 mg/L (C.I. 54.29-65.45). This independently-calculated LC_{50} value of 59.7 mg/L was used quantitatively to derive the freshwater acute water column criterion.

NMED Exhibit 62

A.2.17 Seventeenth Most Sensitive Freshwater Genus for Acute Toxicity: *Brachionus* (rotifer)

Zhang et al. (2013) performed a 24-hour static test of PFOS (potassium salt, CAS # 2795-39-3, ≥98% purity) with *Brachionus calyciflorus*. Organisms were less than two hours old at test initiation. All animals were parthenogenetically-produced offspring of one individual from a single resting egg collected from a natural lake in Houhai Park (Beijing, China). The rotifers were cultured in an artificial inorganic medium at 20°C (16:8-hours light:dark; 3,000 lux) for more than six months before toxicity testing to acclimate to the experimental conditions. All toxicity tests were carried out in the same medium and under the same conditions as during culture (i.e., pH, temperature, illumination). Solvent-free stock solutions of PFOS (1,000 mg/L) were prepared by dissolving the solid in deionized water via sonication. After mixing, the primary stock was proportionally diluted with dilution water to prepare the test concentrations. Exposures were in 15 mL, 6-well cell culture plates (assumed plastic) each containing at total of 10 mL of test solution. The test employed seven measured test concentrations plus a negative control. Each treatment consisted of one replicate plate of 10 rotifers each in individual cells and repeated six times. Nominal concentrations were 0 (negative control), 40, 50, 60, 70, 80, 90, and 100 mg/L. PFOS concentrations were not measured in the rotifer exposures, but rather, in a side experiment using HPLC/MS. The side experiment showed that the concentration of PFOS measured every eight hours over a 24-hour period in rotifer medium with green algae incurs minimal change in the concentration range 0.25 to 2.0 mg/L. The acute test was conducted without green algae added to the exposure medium. One hundred percent survival was observed at 24 hours in the negative control. The author-reported 24-hour LC_{50} was 61.8 mg/L. The author-reported value was used quantitatively to derive the freshwater acute water column criterion.

NMED Exhibit 62

A.2.18 Eighteenth Most Sensitive Freshwater Genus for Acute Toxicity: *Elliptio* (mussel)

Drottar and Krueger (2000f) reported the results of a 96-hour renewal, measured test on the effects of PFOS (potassium salt, CAS # 2795-39-3, 90.49% purity) on *Elliptio complanata* (formerly known as *Unio complanatus)*. The good laboratory practice (GLP) test was conducted at Wildlife International, Ltd. In Easton, MD in August, 1999, using a protocol based on procedures outlined in U.S. EPA (1996b). *E. complanata* (76.5 g and 48.7 mm) used for the test were purchased from Carolina Biological Supply Company in Burlington, NC, after being caught in the wild. They were of an unspecified age at test initiation. Dilution water was 0.45 µm filtered well water [total hardness: 126 (120-132) mg/L as $CaCO_3$; alkalinity: 174 (170-178) mg/L as $CaCO_3$; pH: 8.3 (8.1-8.5); TOC: < 1.0 mg/L; conductivity: 21 (310-330) µmhos/cm]. Photoperiod was 16:8-hours light:dark with a 30-minute transition period. Light was provided at an intensity of approximately 369 lux. A primary stock solution was prepared in dilution water at 91 mg/L. It was mixed for ~24 hours prior to use. After mixing, the primary stock was proportionally diluted with dilution water to prepare the four additional test concentrations. Exposure vessels were 25 L polyethylene aquaria containing 20 L of test solution. The test employed two replicates of 10 mussels each in five measured test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 5.7, 11, 23, 46, and 91 mg/L. Mean measured concentrations were less < 0.115 mg/L, 5.3, 12, 20, 41, and 79 mg/L, respectively. Analyses of test solutions were performed at Wildlife International, Ltd. using high performance liquid chromatography with mass spectrometric detection (HPLC/MS). The mean percent recovery of matrix fortifications analyzed concurrently during sample analysis was 94.7%. Concentrations measured at test initiation averaged 86% of nominal. Concentrations measured prior to renewal at 48 hours averaged 89% of nominal. Concentrations measured at 96 hours averaged 100% of nominal. Dissolved oxygen in control and the high-test concentration (79

NMED Exhibit 62

mg/L) respectively ranged from 5.8-8.5 mg/L and 5.0-8.6 mg/L; pH ranged from 8.0-8.4 and 7.9-8.5. Test temperature ranged from 21.4-21.8°C and 21.8-23.7°C. Mussels in the negative control, the 5.3, 12, and 20 mg/L treatments appeared healthy and normal throughout the test with no mortality, immobility or overt clinical signs of toxicity. The author-reported 96-hour LC_{50} was 59 mg/L (C.I. 51-68). The independently-calculated LC_{50} value was 64.35 (56.22 – 72.48) mg/L and used to derive the freshwater acute water column criterion.

A.2.19 Nineteenth Most Sensitive Freshwater Genus for Acute Toxicity: *Lithobates* (frog)

Flynn et al. (2019) evaluated the acute effects of perfluorooctanesulfonic acid (PFOS, CAS# 1763-23-1, purchased from Sigma-Aldrich) on the American bullfrog (*Lithobates catesbeiana*, formerly, *Rana catesbeiana*) during a 96-hour unmeasured, static study. Testing followed Purdue University's Institutional Animal Care and Use Committee Guidelines Protocol #16010013551. American bullfrog eggs were taken from a permanent pond in the Martell Forest outside of West Lafayette, Indiana. The eggs from a single egg mass were acclimated in 100-L outdoor tanks filled with 70 L of aged well water and covered with a 70% shade cloth. Once hatched, tadpoles were fed rabbit chow and TetraMin® *ad libitum* and were acclimated to laboratory conditions for 24 hours before testing. A 500 mg/L PFOS stock solution was prepared with RO water to create nominal test concentrations of 0 (control), 10, 25, 50, 75, 100, 150, 300 and 500 mg/L. Each treatment contained 10 replicates with one Gosner Stage 25 tadpole in each 250 mL plastic tub maintained at 21ºC and a 12:12-hour light:dark photoperiod. Mortality was monitored twice daily. The author-reported LC_{50} value was 144 mg/L PFOS. The EPA's independently-calculated 96-hour LC_{50} was 154.8 (108.7 – 200.9) mg/L PFOS and used quantitatively to derive the freshwater acute water column criterion. However, this value was not used in the SMAV calculation because a more sensitive life stage was available for the species.

NMED Exhibit 62

Tornabene et al. (2021) conducted acute toxicity tests with four species of frogs in the genus *Lithobates* (formerly, *Rana*) and PFOS (purchased from Sigma Aldrich, Catalog # 77282-10G; purity not provided). Acute tests followed standard 96-hour guidance (ASTM 2017; U.S. EPA 2002). The four test species (American bullfrog, *Lithobates catesbaeiana*; green frog, *L. clamitans*; northern leopard frog, *L. pipiens*; wood frog, *L. sylvatica*) were collected from a field in the wetlands of Indiana near the campus of Purdue University. Collected egg masses were raised outdoors in 200 L polyethylene tanks filled with well water. Experiments began when frogs reached Gosner stage 26, defined as when larvae are free swimming and feeding. Before test initiation larvae were acclimated to test conditions (21℃ and 12:12-hour light:dark photoperiod) for 24 hours. A stock solution of PFOS (500 mg/L) was made in UV-filtered well water and diluted with well water to reach test concentrations ranging from 0 – 500 mg/L PFOS. Test concentrations were not measured in test solutions, based on previous research that demonstrated limited degradation under similar conditions. Larva were transferred individually to 250 mL plastic cups with 200 mL of test solutions and were not fed during the exposure period. The number of replicates varied by species, and treatment; 20 replicates in the control and five to 10 replicates in each treatment for American bullfrog, 10 replicates for each treatment for green frog, northern leopard frog and wood frog. No mortality occurred in any of the control groups. Author-reported 96-hour LC_{50}s were 163, 113, 73 and 130 mg/L PFOS for the American bullfrog, green frog, northern leopard frog, and wood frog, respectively. The independently-calculated 96-hr LC_{50} values for American bullfrog and northern leopard frog were 133.23 (95.75 – 170.8), and 72.72 (63.88 – 81.55) mg/L, respectively. The EPA was unable to independently calculate LC_{50} values for green frog and wood frog as a curve could not be fit with significant parameters. Therefore, the independently-calculated LC_{50} values for American

NMED Exhibit 62

bullfrog (133.3 mg/L) and northern leopard frog (72.72 mg/L) were used quantitatively to derive the freshwater acute water column criterion for PFOS, while the author-reported LC_{50} values for green frog (113 mg/L) and wood frog (130 mg/L) were used. The author-reported toxicity values were consistent with the independently-calculated LC_{50} values for other species included in the study.

A.2.20 Twentieth Most Sensitive Freshwater Genus for Acute Toxicity: *Physella* (snail)

Li (2009) conducted three independent repeats of a 96-hour static acute test on PFOS (potassium salt, > 98% purity) with the bladder snail species, *Physella acuta* (Note: formerly known as *Physa acuta*). The test organisms were collected from a ditch located in Shilin of Taipei City in June 2005. Snails were fed with lettuce and half of the culture medium was changed with dechlorinated water every two weeks, implying a holding time of greater than two weeks. *P. acuta* of mixed ages were used at test initiation. Dilution water was dechlorinated tap water. The photoperiod consisted of 12 hours of illumination at an unreported light intensity. A primary stock solution was prepared in dilution water. Exposure vessels were polypropylene beakers of unreported dimensions and 1 L fill volume. The test employed 5-6 replicates of six snails each in at least five test concentrations plus a negative control. Each treatment was tested three independent times. Nominal test concentrations were in the range of 25-300 mg/L PFOS. The test temperature was maintained at 25±2°C. Water quality parameters including pH, conductivity, and D.O. were reported as having been measured at the beginning and end of each test, but the information was not reported. Survival of negative control animals was also not reported. The author-reported 96-hour LC_{50} was 178 mg/L (C.I. 167-189) and represented an average of the LC_{50}s for each test. Only one of three independent experiments could be fitted. The independently-calculated LC_{50} value was 183.0 (161.4 – 204.7) mg/L and was used quantitatively to derive the freshwater acute water column criterion.

NMED Exhibit 62

Funkhouser (2014) conducted a 96-hour static test on PFOS (potassium salt, ≥98% purity) with the physid snail, *Physella heterostropha pomilia* (Note: formerly known as *Physa pomilia*), as part of a Master's thesis at the Texas Tech University, Lubbock, TX. Adult *P. pomilia* (4 month old) used for the test were field collected from two different collections from the North Fork of the Double Mountain Fork of the Brazos River near Lubbock, TX. Offspring from both collections were reared in 12, 10-gallon aquaria with lab water for several generations prior to use in the test. Dilution water was moderately hard reconstituted laboratory water (3.0 g $CaSO_4$, 3.0 g $MgSO_4$, 0.2 g KCl, and 4.9 g $NaHCO_3$ added to 50 L deionized water). Photoperiod was 12:12-hours light:dark at an unreported light intensity. PFOS was dissolved in dilution water to prepare the test concentrations. Exposure vessels were 400 mL polypropylene containers containing 200 mL of test solution. The test employed two replicates of four snails each in six test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 100, 150, 200, 250, 300, and 375 mg/L. Exposure concentrations were reportedly measured, but concentrations were not reported. Analyses of test solutions were performed using liquid chromatography/ tandem mass spectrometry (LC-MS/MS). Standards were used as part of the analytical method, but details were not reported. The reporting limit was 0.010 mg/L. Experiments were conducted in incubators set to 25°C, which did not vary more than 1°C during the course of the test. No other water quality parameters were reported as having been measured in test solutions. Negative control survival was not reported specifically for the test but was reported to be 85-100% across all experiments. The author-reported 96-hour LC_{50} was reported as 161.77 mg/L. An independently-calculated toxicity value could not be calculated given the level of data that was presented in the paper. The study author reported value was used quantitatively to derive the freshwater acute water column criterion.

NMED Exhibit 62

Appendix B Acceptable Estuarine/Marine Acute PFOS Toxicity Studies

B.1 Summary Table of Acceptable Quantitative Estuarine/Marine Acute PFOS Toxicity Studies

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp (°C)	Salinity (ppt)	Effect	Author Reported Effect Conc. (mg/L)	EPA Calculated Effect Conc. (mg/L)	Final Effect Conc. (mg/L)[b]	Species Mean Acute Value (mg/L)	Reference

[c] Not used in SMAV calculations, because a definitive value is available

NMED Exhibit 62

B.2 Detailed PFOS Acute Saltwater Toxicity Study Summaries and Corresponding Concentration-Response Curves (when calculated for the most sensitive genera)

The purpose of this section was to present detailed study summaries for acute saltwater tests that were considered quantitatively acceptable for criterion derivation, with summaries grouped and ordered by genus sensitivity. The data available for saltwater invertebrates fulfilled three of the eight MDRs. The EPA could not, therefore, develop acute estuarine/marine criteria following the 1985 Guidelines methods. In the interest of providing informations to states/Tribes on protective values, the EPA developed an estuarine/marine acute benchmark using the available empirical data supplemented with toxicity values generated through the use of New Approach Methods (NAMs), specifically through the use of the EPA Office of Research and Development's peer-reviewed publicly-available web-ICE tool (Raimondo et al. 2010). These benchmarks are provided in Appendix L.

B.2.1 Most Sensitive Estuarine/Marine Genus for Acute Toxicity: *Mytilus* (mussel)

The acute toxicity of perfluorooctane sulfonate (PFOS, purity not provided) on the Mediterranean mussel, *Mytilus galloprovincialis* was evaluated by **Fabbri et al. (2014)**. This species is not resident to North America, but is a surrogate for North American mussel species, including the widespread, commercially and ecologically important blue mussel, *Mytilus edulis.* Sexually mature mussels were purchased from an aquaculture farm in the Ligurian Sea (La Spezia, Italy) and held for two days for gamete collection. Gametes were held in artificial sea water (ASW) made of analytical grade salts and at a constant temperature of 16 ±1°C. It was assumed that the gametes were held at the same environmental conditions as the adults, so test salinity was assumed to be 36 ppt with a pH of 7.9-8.1. Embryos were transferred to 96-well microplates with a minimum of 40 embryos/well. Each treatment had six replicates. Embryos were incubated with a 16:8-hour light:dark photoperiod for 48 hours and exposed to one of six

NMED Exhibit 62

nominal PFOS concentrations (0.00001, 0.0001, 0.001, 0.01, 0.1, and 1 mg/L) or control (ASW) water. The PFOS stock was made with ethanol, and ASW control samples run in parallel included ethanol at the maximal final ethanol concentration of 0.01%. Each experiment was repeated four times. At test termination (48 hours), the endpoint was the percentage of normal D-larvae in each well, including malformed larvae and pre-D stages. The acceptability of test results was based on the control group exhibiting >75% of normal D-shell stage larvae (ASTM 2004b). Authors noted that controls had ≥80% normal D-larvae across all tests. PFOS was only measured once in one treatment which was similar to the nominal concentration; that is, 0.000085 mg/L versus the nominal concentration of 0.0001 mg/L. PFOS was below the limit of detection (LOD) in the control ASW (0.06 ng/L or 0.00000006 mg/L). The percentage of normal D-larva decreased with increasing test concentrations. The NOEC and LOEC reported for the study were 0.00001 and 0.0001 mg/L, respectively. However, the test concentrations failed to elicit a 50% reduction in malformations in the highest test concentration, and an EC_{50} was not determined. Therefore, the EC_{50} for the study was greater than the highest test concentration (1 mg/L). The 48-hour EC_{50} based on malformation of >1 mg/L was acceptable for quantitative use.

Hayman et al. (2021) report the results of a 48-hour static, measured test on the effects of PFOS-K (potassium salt, CAS # 2795-39-3, 98% purity, purchased from Sigma-Aldrich, St. Louis, MO) on the Mediterranean mussel, *Mytilus galloprovincialis*. Authors note tests followed U.S. EPA (1995) and ASTM (2004b) protocols. Mussels were collected in the field (San Diego Bay, CA) and conditioned in a flow-through system at 15°C. Mussels were induced to spawn by heat-shock and approximately 250 embryos (2-cell stage) were added to 20 mL borosilicate glass scintillation vials with 10 mL of test solution. There were five replicates per test concentration. Test conditions were 30 ppt, 15°C and a 16:8-hour light:dark photoperiod. Six test solutions were

NMED Exhibit 62

made in 0.45 µm filtered seawater (North San Diego Bay, CA) with PFOS-K dissolved in methanol. The highest concentration of methanol was 0.1% (v/v). Measured test concentrations ranged from 0.52 – 2.50 mg/L. Control mussel embryos were exposed to 100% filtered seawater and the acute test also included a solvent control. At test termination (48 hours), larvae were enumerated for total number of larvae that were alive at the end of the test (normally or abnormally developed), as well as number of normally-developed (in the prodissoconch "D-shaped" stage) larvae. There were no significant differences between solvent and negative (100% filtered seawater) control groups, suggesting no adverse effects of methanol. The author-reported 48-hr EC_{50}, based on normal development, was 1.1 mg/L PFOS. The EPA was not able to independently calculate a 48-hour EC_{50} value as the curve fitted model did not result in a good fit. Therefore, the author-reported EC_{50} of 1.1 mg/L mg/L was considered for quantitative use.

B.2.2 Second Most Sensitive Estuarine/Marine Genus for Acute Toxicity: *Strongylocentrotus* (sea urchin)

Hayman et al. (2021) report the results of a 96-hour static, measured test on the effects of PFOS-K (potassium salt, CAS # 2795-39-3, 98% purity, purchased from Sigma-Aldrich, St. Louis, MO) on the purple sea urchin, *Strongylocentrotus purpuratus*. Authors note that tests followed U.S. EPA (1995) and ASTM (2004b) protocols. Sea urchins were collected in the field (San Diego Bay, CA) and conditioned in flow-through system at 15°C. They were induced to spawn by KCl injection and approximately 250 embryos (2-cell stage) were added to 20 mL borosilicate glass scintillation vials with 10 mL of test solution. There were five replicates per test concentration. Test conditions were 30 ppt, 15°C and a 16:8-hour light:dark photoperiod. Seven test solutions were made in 0.45 µm filtered seawater (North San Diego Bay, CA) with PFOS dissolved in methanol. The highest concentration of methanol was 0.1% (v/v). Measured test concentrations ranged from 0.52 – 10.0 mg/L. Control urchin embryos were exposed to

NMED Exhibit 62

100% filtered seawater and the acute test also included a solvent control. At test termination (96 hours), the first 100 larvae were enumerated and observed for normal development (4-arm pluteus stage). There were no significant differences between solvent and negative (100% filtered seawater) control groups, suggesting no adverse effects of methanol. The author-reported 96-hour EC_{50}, based on normal development, was 1.7 mg/L PFOS. The EPA was not able to independently calculate a 96-hour EC_{50} value as the curve fitted model did not result in a good fit. Therefore, the author-reported EC_{50} of 1.7 mg/L mg/L was considered for quantitative use.

B.2.3 Third Most Sensitive Estuarine/Marine Genus for Acute Toxicity: *Paracentrotus* (sea urchin)

A 72-hour static, unmeasured PFOS (purity not provided) toxicity test with the sea urchin, *Paracentrotus lividus* (a non-North American species) was conducted by **Gunduz et al. (2013)**. Adult sea urchins were collected from the Aegean coast of Turkey, in an area the authors noted as clean and lacking domestic and industrial wastewater inputs. Filtered natural seawater from the same area was used as the dilution water. Adult sea urchins were cultivated in the same filtered natural sea water with a salinity of 35 ppt and 18°C. Zygote suspensions (1 mL) were added to the controls or 9 mL of the various PFOS treatments. This ensured that there were about 30 fertilized embryos/mL or approximately 300 embryos per treatment. The experiments were conducted in six-well TPP culture plates with six replicates per treatment. PFOS stock solutions were made with dimethyl sulfoxide (DMSO) and diluted with seawater to obtain five nominal treatments (0.5, 1.0, 3.0, 5.0 and 10 mg/L PFOS). In addition to a natural seawater control, experiments also included a DMSO solvent control equal to the amount in the highest test concentration. The embryos were incubated in a growth chamber at 18 ±2°C from 10 minutes after fertilization to up to the 72-hour pluteus larval stage. At test termination, 100 individuals were selected randomly from each treatment and evaluated for normal plutei, retarded plutei,

NMED Exhibit 62

pathologic malformed plutei, pathologic embryos unable to differentiate up to the pluteus larval stages, and dead embryos/larvae. There was 97.75% and 91% frequency of normal larvae in the control and solvent control, respectively with no deaths reported in the controls or any PFOS treatments. The 72-hour EC_{50} based on normal development to the pluteus stage was 1.795 mg/L PFOS and is acceptable for quantitative use; however, additional consideration needs to be given to the short test duration.

B.2.4 Fourth Most Sensitive Estuarine/Marine Genus for Acute Toxicity: *Americamysis* (mysid)

Hayman et al. (2021) report the results of a 96-hour static, measured test on the effects of PFOS (potassium salt, CAS # 2795-39-3, 98% purity, purchased from Sigma-Aldrich, St. Louis, MO) on the mysid, *Americamysis bahia*. Authors note that tests followed U.S. EPA (1995); U.S. EPA (2002); and ASTM (2004b) protocols. Mysids were purchased from a commercial supplier (Aquatic Research Organisms, Hampton, NH) and acclimated to test conditions (30 ppt, 20°C and a 16:8-hour light:dark photoperiod). Five test solutions were made in 0.45 µm filtered seawater (North San Diego Bay, CA) with PFOS-K dissolved in methanol. The highest concentration of methanol was 0.1% (v/v). Measured test concentrations ranged from 0.95 – 16 mg/L. Control mysids were exposed to 100% filtered seawater and the acute test also included a solvent control. Five mysids (3 days old, which is older than the typical age of < 24 hours at test initiation) were added to 120 mL polypropylene cups and 100 mL of test solutions with six replicates per treatment. Living mysids were counted and dead organisms were removed daily. There were no significant differences between solvent and negative (100% filtered seawater) control groups, suggesting no adverse effects of methanol. Only two organisms were found dead in the controls at test termination. The author-reported 96-hour LC_{50} was 5.1

NMED Exhibit 62

mg/L PFOS. The independently-calculated 96-hr LC_{50} value was 4.914 (3.578 – 6.250) mg/L and is acceptable for quantitative use.

B.2.5 Fifth Most Sensitive Estuarine/Marine Genus for Acute Toxicity: *Siriella* (mysid)

Mhadhbi et al. (2012) performed a 96-hour static, unmeasured acute test with PFOS (98% purity) and the mysid, *Siriella armata*. Mysids were collected from the same source as the dilution water [filtered sea water from the Ria of Vigo (Iberian Peninsula)] and quarantined before use in 100 L plastic tanks with circulating sand-filtered seawater. The adult stock was fed daily and maintained at laboratory conditions (17-18°C, salinity between 34.4-35.9 ppt, and D.O. 6 mg/L). A stock solution of PFOS was made either with filtered sea water from the Ria of Vigo for low exposure concentrations, or with DMSO for high PFOS concentrations (a final maximum DMSO concentration of 0.01% (v/v) in the test medium). However, the authors did not indicate what was considered a high-test concentration. If DMSO was used, a solvent control was also included. Twenty neonates (<24 hours old) were used per each treatment. Mysids were exposed to one of five nominal PFOS treatments (1.25, 2.5, 5, 10 and 20 mg/L). To prevent cannibalism, a single individual was added to each glass vial with 2-4 mL of test solution. Vials were incubated at 20°C with a 16-hour light period. Neonates were fed 10-15 *Artemia salina* nauplii daily and mortality was recorded after 96 hours. The 96-hour LC_{50} was 6.9 mg/L PFOS and was acceptable for quantitative use.

B.2.6 Sixth Most Sensitive Estuarine/Marine Genus for Acute Toxicity: *Cyprinodon* (sheepshead minnow)

Palmer et al. (2002b) conducted a 96-hour static-renewal measured acute test with PFOS-K (perfluorooctanesulfonate potassium salt, 86.9% purity from the 3M Company) on the sheepshead minnow, *Cyprinodon variegatus*. The test followed standard guidance for acute toxicity tests outlined in U.S. EPA (1985) and ASTM (1994). Sheepshead minnows were purchased from a commercial supplier (Aquatic Biosystems, Fort Collins, CO) and held for

NMED Exhibit 62

several weeks prior to testing. Fifty-one hours before testing fish were acclimated to test conditions (16:8-hour light:dark photoperiod, salinity of 20 ppt and 22°C). Natural seawater (Indian River Inlet, Delaware) was filtered and diluted with well water to 20 ppt and was used for culturing and testing. A nominal PFOS stock solution (40 mg/L) was made by dissolving PFOS in methanol and diluting it with seawater to achieve the nominal test concentration (20 mg/L). A solvent control (0.5 mL/L methanol) and a sea water control were also included. Ten minnows (3.0 cm, 0.44 g) were added to 25 L polyethylene aquaria with 15 L of test solution (loading was 0.30 g fish/L of test water). Test treatments were replicated three times. PFOS concentrations were measured daily at test solution renewal with averaged measured concentrations in the control and solvent control less than the LOQ (5 mg/L) and PFOS-spiked seawater, 15 mg/L. At test termination (96 hours) none of the minnows died in the controls or single PFOS test treatment, therefore the author-reported LC_{50} was >15 mg/L. The EPA was unable to independently calculate the LC_{50} value as this test only consisted of one treatment group. The author-reported LC_{50} >15 mg/L is being used quantitatively for the acute saltwater benchmark because it is a greater than high value which adds value to the assessment of potential sensitivity of this species to acute PFOS exposure (see Section 2.10.3.2).

NMED Exhibit 62

Appendix C Acceptable Freshwater Chronic PFOS Toxicity Studies

C.1 Summary Table of Acceptable Quantitative Freshwater Chronic PFOS Toxicity Studies

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Chronic Value Endpoint	Author Reported Chronic Value (mg/L)	EPA Calculated Chronic Value (mg/L)	Final Chronic Value (mg/L)[c]	Species Mean Chronic Value (mg/L)	Reference

C.2 Detailed PFOS Chronic Freshwater Toxicity Study Summaries and Corresponding Concentration-Response Curves (when calculated for the most sensitive genera)

The purpose of this section was to present detailed study summaries for tests that were considered quantitatively acceptable for freshwater chronic water column criterion derivation, with summaries grouped and ordered by genus sensitivity. C-R models developed by the EPA that were used to determine chronic toxicity values used for criterion derivation are also presented for the most sensitive genera when available. The C-R models included with the study summaries were those for the four most sensitive genera (consistent with Section 3.1.1.3). When required, the EPA also included models for non-resident species that were more sensitive than the fourth most sensitive North American resident genus. In many cases, authors did not report C-R data in the publication/supplemental materials and/or did not provide C-R data upon the EPA request. In such cases, the EPA did not independently calculate a toxicity value and the author-reported effect concentrations were used in the derivation of the criterion.

C.2.1 Most Sensitive Freshwater Genus for Chronic Toxicity: *Neocloeon* (mayfly)

Soucek et al. (2023) conducted a chronic life-cycle test to determine the effects of PFOS-K (PFOS potassium salt, CAS # 2795-39-3, 98% purity) on the parthenogenetic mayfly, *Neocloeon triangulifer*. The test was performed under renewal conditions over 27 days beginning with < 24 hour old nymphs. Single mayfly exposures were static without renewal for the first four days due to the small size of starting organisms and then water was renewed three times per week thereafter by transferring organisms to new exposure chambers. From Day 0 to 14, mayflies were exposed in 30 mL polypropylene cups with 20 mL exposure water. Organisms were transferred after 14 days into 250 mL glass beakers with 100 or 150 mL of test water (or control water) and to 300 mL tall form glass beakers for emergence. There were sixteen replicates (with one mayfly per replicate) per test concentration and control. Replicates one

NMED Exhibit 62

through eight were destructively sampled on day 14 and replicates nine through sixteen continued until the end of the test (when all mayflies either molted into imago stage or died). The endpoints that were evaluated included survival for all replicates, 14-d length and calculated dry weight (using a previously published body length dry weight equation; Besser et al. 2021) for replicates 1 through 8, and percent survival to pre-emergent nymph (PEN) stage, number of days until PEN stage, percent emergence (to imago stage), and pre-egg laying live weight of imago for replicates 9 through 16. Nominal test concentrations were 0 (control), 0.00016, 0.00031, 0.00063, 0.00125, 0.0025, 0.005, and 0.010 mg/L PFOS. Mean measured PFOS concentrations (EPA Analytical Method 1633; LC-MC/MS) were 0.000056 (control), 0.000205, 0.000418, 0.000764, 0.001143, 0.002057, 0.003892, and 0.006789 mg/L PFOS, respectively. Mayflies were exposed at 23 ± 1°C under a 16:8-hour light:dark cycle and fed 0.2 mL diatom slurry plus small scraping on test Days 0 and 4 followed by live diatom biofilm scraping after Day 4 on solution renewal days. Percent survival in the control after 14 days was 100%. Percent survival of mayflies after 14 days in the remaining seven test concentrations ranged from 79 to 100%. The most sensitive endpoint was 14-day dry weight. The study authors reported three different 14-day dry weight EC_{10} values that were calculated using various point-estimation approaches. The author-reported 14-day dry weight EC_{10} values produced by the various approaches were relatively similar to one another, ranging from 0.000226 (using TRAP [2 parameter, threshold sigmoidal curve]) to 0.000272 mg/L (using log-linear regression, controls excluded). The EPA was not able to fit a reliable model with significant model parameters to the 14-day dry weight C-R dataset and, therefore, relied on the author-reported EC_{10} of 0.000226 mg/L (based on TRAP) as the primary effect concentration. The EPA selected the TRAP-based EC_{10} preferentially over the EC_{10} values based on the two other point estimation approaches (i.e., log-

NMED Exhibit 62

linear regression with and without controls) because the TRAP-based model (1) considered control responses; (2) was more fundamentally consistent with the maximum likelihood regression approaches used by the EPA to assess the C-R datasets evaluated in this document, and; (3) relied on replicate-level data, which the EPA used preferentially over treatment-mean data in assessing the C-R datasets. The author-reported EC_{10} of 0.000226 mg/L (TRAP-based) was used in the derivation of the freshwater PFOS chronic water column criterion.

Current toxicity literature indicates that aquatic insects, specifically mayfly, midge, and odonates, are sensitive to PFOS exposures. Further, given that recent research has led to the development of successful culturing methods for mayflies that are now being used in laboratory-based toxicity studies (Soucek and Dickinson 2015; Soucek et al. 2023), new toxicity studies indicate that mayflies (*Neocloeon triangulifer*) are the most sensitive taxa to acute and chronic PFOS exposures. This finding is consistent with other chemical exposures, including major geochemical ions, pesticides, and heavy metals (Johnson et al. 2015; Kim et al. 2012; Raby et al. 2018; Soucek and Dickinson 2015; Soucek et al. 2020; Soucek et al. 2023; Wesner et al. 2014). The high sensitivity of mayflies to contaminant exposures has also been observed in mesocosm-based experiments (Mebane et al. 2020) and field-based surveys (Cormier et al. 2018; U.S. EPA 2011). Many of these laboratory-based toxicity tests used mayflies capable of adapting to laboratory settings, therefore it is hypothesized that mayfly species unable to survive in laboratory settings may also be even more sensitive to contaminant exposures than the relatively hardy mayfly species (e.g., *N. triangulifer*) now commonly being used to toxicity testing. Thus, inclusion of the mayfly toxicity data (Soucek et al. 2023) is important to ensuring the protectiveness of the PFOS aquatic life AWQC.

NMED Exhibit 62

Publication: Soucek et al (2023)
Species: Mayfly, *Neocloeon triangulifer*
Genus: *Neocloeon*
EPA-Calculated EC_{10}: unable to fit a reliable model with significant model parameters; author-reported TRAP-based EC_{10} used

C.2.2 Second Most Sensitive Freshwater Genus for Chronic Toxicity: *Chironomus* (midge)

MacDonald et al. (2004) conducted larval sub-chronic partial-life cycle and chronic life-cycle tests to determine the effects of PFOS (potassium salt, 95% purity) on the midge, *Chironomus dilutus* (formally known as *Chironomus tentans*). The test was performed under renewal conditions over 10 days for the larval sub-chronic partial-life cycle test and 60 days for the chronic life-cycle test, with four of the twelve replicates terminated following 20 days of exposure to evaluate survival and growth. The tests followed the general guidance given by EPA-600-R99-064 (U.S. EPA 2000b) and ASTM E 1706-00 (ASTM 2002). These methods are for measuring the toxicity and bioaccumulation of sediment-associated contaminants with freshwater invertebrates and have different exposure durations than those typically considered for invertebrate aqueous exposures, as well as different control survival requirements and recommendations. *C. dilutus* used for the tests were 10-day old larvae for the 10-day exposure (larval sub -chronic partial-life cycle test) and newly-hatched larvae at test initiation for the chronic life-cycle test (both 60-d and 20-day exposures). Dilution water was reconstituted hard water consistent with ASTM (2002) with unspecified total hardness, but typically 160-180 mg/L as $CaCO_3$ (based on ASTM 2002), with alkalinity 110-120 mg/L as $CaCO_3$, and pH 7.6-8.0. The photoperiod was 16:8-hours light:dark. Light intensity was not reported. A primary stock solution was proportionally diluted with dilution water to prepare the test concentrations. Exposure vessels were 250 mL polypropylene beakers containing 240 mL of test solution and a sediment substrate. The 10-day exposure test employed at least two replicates with 10

NMED Exhibit 62

individuals all of which were obtained from four large C-shaped egg cases that were distributed among seven test solutions plus a negative control. The life-cycle test (60-day exposure) employed 12 replicates of 12 midges each in five measured test solutions plus a negative control. From these 12 replicates, four were randomly terminated following a 20-day exposure to measured survival and growth endpoints (thereby referred to as the 20-day exposure henceforth) The remaining eight replicates were monitored over the test duration for emergence and reproduction. Nominal test concentrations for the 10-day test were 0 (negative control), 0.001, 0.005, 0.010, 0.020, 0.040, 0.080, and 0.150 mg/L. The nominal test concentrations for the 20-day exposure were 0 (negative control), 0.001, 0.005, 0.010, 0.050, and 0.100 mg/L. Mean measured concentrations for the 10-day test were 0 (LOQ not reported), 0.0008, 0.00460, 0.0115, 0.241, 0.0491, 0.0962, and 0.1501 mg/L, respectively. Mean measured concentrations for the 20-day exposure were 0 (LOQ not reported), 0.0023, 0.0144, 0.0217, 0.0949, and 0.149 mg/L, respectively. Analyses of test solutions were performed using LC-MS. The mean percent recovery and detection limits were not reported. Measured values of test concentrations in the 20-day exposure were 2 to 2.5-fold higher than nominal concentrations. Temperature and D.O. concentrations were measured in at least two replicates per treatment on a daily basis for the 10-day test and up to day 20 in the life-cycle test. Afterwards they were measured every other day (on alternate days from test solution renewal) from days 21 to 60 for the life-cycle test. The frequency of monitoring was reduced during this period, because both parameters consistently remained within acceptable ranges (21.0-23.0°C; D.O. >5.0 mg/L). Survival of negative control animals was >75%, which was considered acceptable for a full life-cycle exposure per ASTM (2002). The study authors reported EC_{10}s and NOECs; however, specific details pertaining to the

NMED Exhibit 62

curve fitting process (including statistical output from the models and the curves) were not provided in the paper and therefore, limit independent interpretation of the toxicity values.

The observed effects of PFOS on *C. dilutus* reported in the paper by the study authors include survival and growth as weight (measured as mg of ash-free dry mass per individual) for both the 10-day and 20-day exposure durations and emergence and reproduction over the 60-day exposure duration. Significant reductions in larval weight were observed after 10 days of exposure to PFOS in the 0.0962 and 0.1501 mg/L treatment groups (roughly 0.38 and 0.19 mg, respectively) compared to the control group (roughly 0.88 mg). These differences resulted in roughly a 56.8 and 78.4% decline in midge weight in these treatment groups compared to those observed in the control. In contrast, there were no significant differences reported for survival between any of the PFOS treatments (with percent survival ranging between roughly 69.7% in the highest treatment group and 100% in the lowest) and the control (with roughly 100% survival). However, the authors noted that there was a 30% decline of midge survival in the highest PFOS treatment group with a measured concentration 0.1501 mg/L. The author-reported 10-day growth and survival EC_{10}s for the study were 0.0492 and 0.1079 mg/L, respectively. The study authors also reported NOECs of 0.0491 mg/L, LOECs of 0.0962 mg/L, and MATCs of 0.0687 mg/L for both endpoints.

Similar to the 10-day exposure results summarized above, there was a general decline in growth (as ash-free dry mass per individual) across the PFOS treatment groups (ranging roughly between 29.2 and 47.2% reduction compared to controls) in the 20-day exposure (chronic life-cycle test). However, only the decline in the 0.0949 mg/L treatment group was significantly different (roughly 0.29 mg) compared to the control (roughly 0.89 mg) and there was not a C-R relationship across the PFOS treatment groups. Additionally, midge survival was reduced after

NMED Exhibit 62

20 days of exposure to PFOS in the 0.0949 and 0.149 mg/L treatment groups (29.2 and 0% survival, respectively) compared to the control (75% survival). Survival was determined to be not significantly different across the rest of the PFOS treatment groups (ranging roughly between 56.5 and 75% survival) compared to the control. However, it should be noted that there was a 25% decline in survival in the 0.0217 mg/L PFOS treatment group compared to the control that was determined not to be significantly different. The author-reported 20-day EC_{10}s for growth, survival, and total emergence were 0.0882, 0.0864, and 0.0893 mg/L, respectively, and the study authors also reported NOECs of 0.0217 mg/L for growth and survival and < 0.0023 mg/L for emergence, LOECs of 0.0949 mg/L for growth and survival and 0.0217 mg/L for emergence, and MATCs of 0.0454 mg/L for growth and survival and 0.0071 mg/L for emergence. Also, it should be noted, the paper reports contrasting NOECs for 20-day survival. The text in the paper stated that the NOEC was 0.0217 mg/L for growth and survival and Table 2 of the paper stated 0.0949 mg/L. The EPA assumed the NOEC in Table 2 of the paper was not correct and that 0.0217 mg/L was the correct NOEC based on the data presented in Figure 3A of the paper. This assumption was applied to the summary of the study results presented in this document.

Independent statistical analyses were conducted for both the 10-day (larval sub-chronic partial-life cycle test) and 60- and 20-day (chronic life-cycle test) exposure durations using data that were estimated (using Web plot digitizer) from the figures presented in the paper. The EPA could not fit a curve to independently verify the 10-day survival (due to a lack of a specific sample size for this endpoint as the number of replicates was not stated in the paper; however, the number of replicates was between two and four and the EPA sought to obtain clarification and treatment level data from the study authors) or the 20-day growth toxicity values (due to a lack of an observed C-R for this endpoint). However, the EPA-calculated 10-day EC_{10} for

NMED Exhibit 62

growth was 0.05896 mg/L, which was slightly higher than the growth-based EC_{10} of 0.0492 mg/L reported in the paper. The chronic life-cycle EC_{10}s for larval survival (following 20 days of exposure) and emergence (with 60 days of exposure) were 0.0171 and 0.0102 mg/L, respectively. These chronic life-cycle EC_{10}s were much lower than those reported in the paper of 0.0864 and 0.0893 mg/L, respectively. The EC_{10}s for survival and emergence endpoints from the chronic life-cycle test were not considered to be reliable endpoints at this time given the disparities in the calculated EC_{10}s and the level of data that was presented in the paper, which made independent verification of the toxicity values less accurate. Specifically, for the 20-day survival endpoint, there appeared to be overdispersion (i.e., observed data display a larger variability than would be expected given an assumed statistical distribution about the mean response) in the data as it was presented in the paper (in Figure 3A of the paper), which adds uncertainty around the independently-calculated EC_{10} of 0.0171 mg/L and may explain the disparity between the reported EC_{10} and the EPA's independently-calculated value. As for the 60-day emergence endpoint, there was a lack of a C-R relationship and there were very similar levels of observed effects (which ranged between 42.6 and 50.1%) despite the more than nine-fold increase in the mid-range treatment concentrations (0.0023, 0.0144, 0.0217 mg/L, respectively). Lastly, the toxicity values from the observed effects from the chronic life-cycle exposure were considered to be less certain given the relatively large difference between the nominal and measured concentrations for this test. The dosing of the chronic life-cycle test (20- and 60-day exposure) was more of a concern than the larval sub-chronic partial-life cycle test (10-day exposure), which had measured concentrations that were much more in line with the expected nominal concentrations. Thus, the survival and emergence endpoints from the chronic life-cycle test were not considered for quantitative use in the derivation of the freshwater chronic

NMED Exhibit 62

water column criterion. Instead, these endpoints were considered as supporting information until detailed replicate level data can be obtained from the study authors.

The most sensitive endpoint from the remaining toxicity values that could be independently calculated was for 10-day growth with an EC_{10} of 0.05896 mg/L. As mentioned in the Bots et al. (2010) summary in Section C.2.4 below, the observed effects of PFOS on aquatic insects appears to be consistent across the available data for chironomids and odonates. However, Bots et al. (2010) did not measure the effects of PFOS on nymph growth and therefore, the observed effects in MacDonald et al. (2004) on larval weight cannot be compared across the two studies. The EC_{10} of 0.05896 (0.05769 – 0.06023) mg/L for 10-day growth was used quantitatively to derive the freshwater chronic water column criterion. The remainder of the toxicity values were used as supporting information to corroborate the toxicity value used and to better understand the effects of PFOS on aquatic insects.

McCarthy et al. (2021) conducted a 10-day range-finding toxicity test and a separate 20-day (note, based on age of starting organisms, this test was actually 16 or 19 days of exposure) "abbreviated partial-life cycle" toxicity test with PFOS (98% purity, purchased from Sigma-Aldrich) on the midge, *Chironomus dilutus*. PFOS stock solution was dissolved in reconstituted moderately hard water without the use of a solvent and stored in polyethylene at room temperature until use. Two chronic exposures with PFOS were run, a 10-day and a 20-day exposure, following standard protocols (U.S. EPA 2000b) with slight modifications. The 10-day exposure was considered a range-finding test, with concentrations spaced by ~100x and only mortality measured, whereas the 20-day exposure measured both survival and growth. The 20-day exposure is less than the recommended 65-day full-life cycle method outlined in U.S. EPA (2000b) and since exposures of midges started on day two or four the actual exposure duration is

NMED Exhibit 62

only 16 or 19 days long; therefore, the study authors referred to this test as an "abbreviated partial-life cycle test". Exposure vessels for both experiments were 1 L high-density polyethylene beakers containing natural-field collected sediment. The 10-day exposure had 60 mL of sediment and 105 mL of test solution and the 20-day exposure had 100 mL of sediment and 175 mL of test solution. PFOS in test solutions was added via pipette to the beakers with the tip just above the sediment substrate. Nominal test concentrations for the 10-day and 20-day exposure were 0, 0.0004086, 0.33, 33, 100 and 350 mg/L PFOS and 0, 0.001, 0.005, 0.01, 0.05 and 0.1 mg/L PFOS, respectively. Egg cases were obtained from outside suppliers (Aquatic Biosystems or USGS Columbia Environmental Research Center) and held for 10 days in the 10-day test or held for four days before testing in the 20-day exposure (in test vessels). In the 20-day exposure the test organism age (four-day old larvae) was greater than the protocol recommendation (< 24 hour) because earlier experiments had control survival issues (< 70%). In both tests each beaker held 12 organisms with five replicates per exposure treatment. Solutions were renewed every 48 – 72 hours in the 10-day exposure and daily for the 20-day exposure. Water samples of test concentrations were measured on day one and day 10 in the 10-day exposure and day 10, 15 and 20 in the 20-day exposure. In the 10-day exposure measured test concentrations ranged from 7 – 62% of nominal. In the 10-day exposure, the author-reported LOEC, based on mortality, of 0.4086 µg/L (0.0004086 mg/L PFOS) is reported as a nominal concentration. Mean PFOS concentrations in the 20-day exposure were 0 (control), 0.000447, 0.00209, 0.0042, 0.0231 and 0.0463 mg/L PFOS. Results of the *C. tetans* 16- to 19-day "abbreviated full life cycle test" were used preferentially over the results of the 10-day range-finding test to inform the chronic sensitivity of *C. tetans* because: (1) the 10-day range-finding test only measured survival, (2) the 10-day range-finding test had exposure concentrations that

NMED Exhibit 62

differed by up to a factor of 100, which make C-R modeling more difficult than the dilution series in the16- to 19-day test, and (3) the 16- to 19-day test was a longer exposure duration that was more akin to a full life-cycle test. Consequently, the results of the 10-day range finding test were not used quantitatively to derive the freshwater chronic water column criterion, but they were retained for qualitative use.

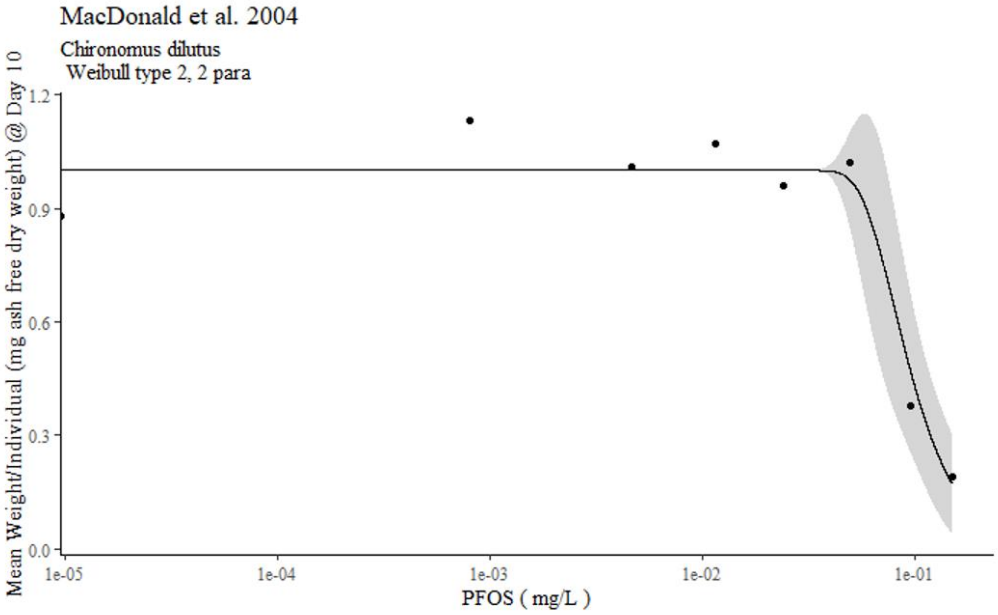
From the 16- to 19-day "abbreviated full life cycle test" percent survival in the control and lowest test concentration were 77% with no survivors reported in the highest two test concentrations. The most sensitive endpoint appeared to be survival with an author-reported 16-day reported EC_{10} of 1.36 µg/L (0.00136 mg/L PFOS). Additionally, the authors reported EC_{10}s of 1.62 µg/L (0.00162 mg/L PFOS) and 3.23 µg/L (0.00323 mg/L PFOS) for growth as mean biomass and mean weight, respectively. The EPA was unable to independently calculate EC_{10}s for survival and mean weight. However, the 16- to 19-day independently-calculated EC_{10} value for mean biomass was 0.001588 (0.00118 – 0.00200) mg/L PFOS. This independently-calculated EC_{10} was acceptable for quantitative use and was used in the derivation of the freshwater chronic water column criterion.

Krupa et al. (2022) conducted a partial-life cycle chronic toxicity test with the midge, *Chironomus dilutus*, and PFOS-K (perfluorooctanesulfonate potassium salt, > 98% purity, CAS No. 2795-39-3, purchased from Sigma-Aldrich). *C. dilutus* egg masses obtained from Aquatic Biosystems (Fort Collins, Colorado, USA) were placed in 12-inch glass culture bowls (2 – 3 egg mases per dish) containing carbon-filtered municipal tap water and examined daily for viability and hatch. Hatching began after 2 days and larvae typically left the egg case 24-hours after the first hatch. The larvae were fed daily finely ground TetraMin® fish food flakes (~150 mg/dish as a slurry) with partial water changes as necessary until the larvae were the appropriate age for

NMED Exhibit 62

initiating the test (4-days old). The larvae were exposed to PFOS for 16 days. A 100 mg/L PFOS-K stock solution was prepared by dissolving PFOS-K salt into ultrapure water using a stir bar and stir plate for >20-hours. Controls and PFOS solutions were then prepared using carbon filtered dechlorinated tap water. Each test concentration was individually spiked rather than serially diluted to reduce PFOS waste generated. All test solutions for water renewals were prepared the day before test initiation. The measured exposure concentrations were < LOD, 0.001, 0.0025, 0.004, 0.0075, 0.016 and 0.03 mg/L, with 5 replicates of 12 animals per replicate for each concentration. Tests were conducted in 300 mL polycarbonate beakers containing approximately 200 mL of exposure solution under a 16:8-hour light:dark cycle in an environmental chamber maintained at 22.5 ± 1°C. Each beaker received 50 mL of clean silica sand (250 – 500 µm) as substrate. Aeration was provided and larvae were fed finely ground TetraMin® (6 mg/day, added as a slurry in dechlorinated water). Partial water renewals (150 mL of solution was exchanged) were conducted three times per week, after 48 or 72-hour periods. At test termination, larval survival was assessed, and ash-free dry weight (AFDW) was determined following ASTM (2019). The AFDW of five groups of 12 larvae was measured at test initiation to establish a baseline for growth. The temperature, D.O., pH, and total hardness test values ranged from 22.0 - 22.9°C, 7.29 - 8.05 mg/L, 7.28 - 7.75 SU and 52 - 62 mg/L as $CaCO_3$, respectively. Water samples for verification of PFOS concentrations were collected at test initiation (day 0) and termination (day 16), in addition to before (out-water) and after (in-water) every renewal of test solution. Water samples from days 0, 6, 10, and 16 were analyzed to verify PFOS concentrations. The author-reported 16-day growth EC_{10} was 0.0015 mg/L PFOS-K. The EPA was unable to fit a reliable model for any of the chronic endpoints from this test. Therefore,

NMED Exhibit 62



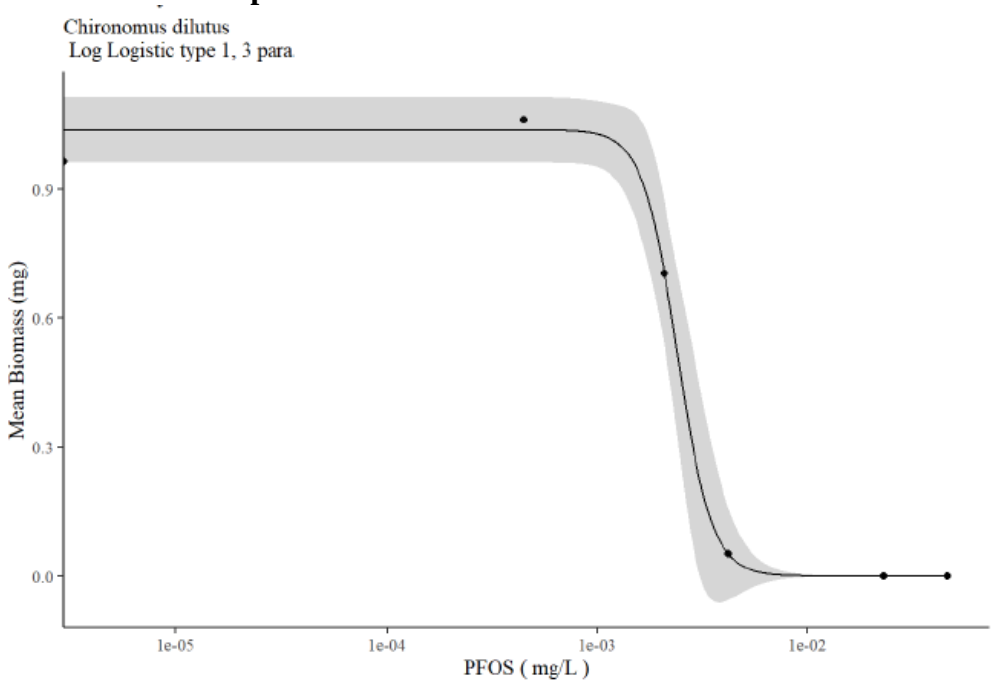
the author-reported EC_{10} value of 0.0015 mg/L for growth was used to derive the freshwater chronic water column criterion.

C.2.2.1 MacDonald et al. (2004) Concentration Response Curve – Chironomus (midge)

Publication: MacDonald et al. (2004)
Species: Midge (*Chironomus dilutus*)
Genus: *Chironomus*
EPA-Calculated EC_{10}: 0.05896 (95% C.I. 0.05769 – 0.06023) mg/L
Concentration-Response Model Estimates:

Parameter	Estimate	Std. Error	t-stat	p-value
b	-2.6770	0.6384	-4.1933	0.0057
e	0.0805	0.0090	8.9243	0.0001

Concentration-Response Model Fit:



C.2.2.2 McCarthy et al. (2021) Concentration Response Curve – Chironomus (midge)

Publication: McCarthy et al. (2021)
Species: Midge *Chironomus dilutus*
Genus: *Chironomus*
EPA-Calculated EC_{10}: 0.001588 (95% C.I. 0.00118 – 0.00200) mg/L
Concentration-Response Model Estimates:

Parameter	Estimate	Std. Error	t-stat	p-value
b	5.2881	1.0432	5.0693	0.0148
d	1.0372	0.0238	43.4942	$2.675\ e^{-5}$
e	0.0024	0.0001	21.9936	0.0002

Concentration-Response Model Fit:

C.2.2.3 Krupa et al. (2022) Concentration Response Curve – Chironomus (midge)

Publication: Krupa et al. (2022)
Species: Midge, *Chironomus dilutus*
Genus: *Chironomu*
EPA-Calculated EC_{10}: unable to fit a reliable model with significant model parameters; author-reported EC_{10} used

C.2.3 Third Most Sensitive Freshwater Genus for Chronic Toxicity: *Lampsilis* (mussel)

Hazelton (2013); Hazelton et al. (2012) conducted a test of the long-term effects of PFOS (acid form, > 98% purity) on glochidia and juvenile life stages from the mussel *Lampsilis siliquoidea*. To initiate the PFOS partial life-cycle test, brooding females were collected from Perche Creek, Missouri and shipped over night to the test laboratory. The length of time between collection from Perche Creek and shipment was not reported, and authors were unable to recall such details (R. Bringolf, personal comm.); however, the EPA did not believe storage, shipping, and handling compromised test results since study authors only relied on those mussels with >70% glochidia viability. Dilution water was dechlorinated tap water. Mean total hardness (47.5 ± 9.2 mg $CaCO_3$/L) and alkalinity (34.8 ± 4.1 mg $CaCO_3$/L) were measured by titration twice weekly (n = 8) prior to water changes. Replicates used for water quality measurements were changed daily to allow measurements from all four replicates every four days. For all treatments, water temperature ranged from 14.6 to 16.1°C, D.O. ranged from 6.1 to 7.3 mg/L, and pH ranged from 7.6 to 8.5, but did not differ across treatments. Photoperiod and light intensity were not reported. No details were provided regarding primary stock solution and test solution preparation. The test exposed brooding glochidia (in marsupia) for 36 days followed by a 24-hour exposure of free glochidia. Experiments were conducted in 3.8 L glass jars of unspecified fill volume. The 36-day *in marsupia* exposure test employed four replicates individually containing single brooding females for each of the two PFOS treatment groups plus the control. The *in marsupia* exposure was followed by a 24-hour free glochidia exposure consisting of a factorial design, such that free glochidia from the control group of the *in marsupia* exposure were divided between a control and the two PFOS treatments and the PFOS treatments were split into control and the same PFOS treatment group as the *in marsupia* exposure. This factorial design allowed for the comparison of PFOS effects in two different life stages. However, it

NMED Exhibit 62

should be noted that glochidia were pooled from females within each *in marsupia* treatment group, and thus the influence of parental effects could be a confounding factor that cannot be separated from the PFOS effects. Nevertheless, the influence of the potential parental confounding factor was likely to be minimal compared to the effects of the PFOS exposures.

Nominal concentrations throughout the exposures were 0 (negative control), 0.001 and 0.100 mg/L. Mean measured concentrations were 0.00211 (negative control), 0.00452 and 0.0695 mg/L. Analyses of test solutions were performed at the U.S. EPA National Exposure Research Laboratory in Research Triangle Park, NC using HPLC/MS. Two standard curves were used to quantify PFOS water concentrations during the experiment: low range (0.00005, 0.00025, 0.0005, 0.00075, 0.001, 0.0025, 0.005 mg/L) and high range (0.001, 0.005, 0.010, 0.025, 0.050, 0.100, 0.150 mg/L). Two replicate samples were measured at each standard concentration. Accuracy (recovery) of PFOS in the low-range standard curve ranged from 89.5 to 123% (n = 7) and for the high-range standard curve accuracy was 85.3 to 123% (n = 7). Adult mussel and glochidia survival in the negative control was 100% and > 90%, respectively. The study authors determined that the *in marsupia* exposure held the greatest weight of evidence and explained 78% of the variability in the glochidia viability (AIC = 22843, w_i = 0.78) and 83% of the metamorphosis success (AIC = 21955, w_i = 0.83), and therefore it appeared that the data presented in the study are in terms of the *in marsupia* exposure alone and there are no data presented in terms of the factorial design during the 24-hour free glochidia exposure. Additionally, the specific treatment groups of the data presented in the paper are unclear in terms of the factorial design during the 24-hour free glochidia exposure (e.g., it is unclear if the data presented in Figure 2 of the paper are lumped according to marsupial exposure, reducing seven

NMED Exhibit 62

treatments to three, or if only the data in which the *in marsupia* and free glochidia exposures were the same are presented).

The test resulted in an author-reported NOEC of 0.0695 mg/L, which was associated with a 38% reduction in the viability of free glochidia at 24 hours post removal from females, a point when control viability of free glochidia was > 80% (author reported LOEC and MATC > 0.0695 mg/L). While a 38% reduction was observed at the NOEC (0.0695 mg/L) treatment group compared to controls, the authors reported this reduction was not statistically different from the control. Over time, the study authors reported significant reductions in free glochidia survival between three- and seven-days post removal from females, indicating a potential LOEC < 0.0045 mg/L. However, it should be noted that the observed level of effect between the two PFOS treatment groups (0.0045 and 0.0695 mg/L) were extremely similar despite the 15-fold difference between treatment groups. Additionally, in accordance with the decision rule described in Section 2.10.3.2 and a study by Bringolf et al. (2013), only glochidia toxicity data within 24 hours and with survival of at least 80% in the control treatment would be considered (U.S. EPA 2013). These specific data requirements ensured that the related effects of PFOS exposure to the viability of glochidia were consistent with environmental exposures during this short life stage and also take the unique life cycle of mussels into account. Therefore, the chronic toxicity value for viability of free glochidia at 24 hours following removal from females resulted in a NOEC of >0.0695 mg/L, which is an uncertain value and indicated that viability of free glochidia at 24 hours was a less sensitive endpoint.

In contrast, the data presented in the paper for metamorphosis success suggest a NOEC of 0.0045 mg/L and a LOEC of 0.0695 mg/L, or MATC = 0.01768 mg/L. The reduction in metamorphosis success at the LOEC was estimated to be 35.4%. However, as there were only

NMED Exhibit 62

two PFOS treatment groups and the gap in these exposure concentrations is large (about 15-fold), the EPA was not able to fit a curve to estimate an EC_{10} in a manner similar to the other toxicity studies used to derive the freshwater chronic water column criterion. Instead, both the use of an MATC and an estimated EC_{10} were considered for the chronic value. An EC_{10} was estimated by assuming the 0.0695 mg/L treatment represents an $EC_{35.4}$ and estimating the EC_{10} using the exposure response slope from another chronic PFOS toxicity study focused on another mussel species (*Perna viridis*). Specifically, the chronic exposure of *Perna viridis* reported by Liu et al. (2013), which is summarized in Section 3.1.1.4.1 and D.2.1, was used to derive a ratio of $EC_{10}/EC_{35.4}$ values from that study equal to: $EC_{10}/EC_{35.4} = 0.0033/0.0186 = 0.1774$. Applying this ratio to Hazelton et al. (2012) yields an estimated EC_{10} of 0.0123 mg/L. Given the similarity between this EC_{10} and the author-reported MATC for metamorphosis success of 0.01768 mg/L, the latter was used to derive the freshwater chronic water column criterion. While this MATC is currently used quantitatively to derive the chronic water column criterion, the EPA hopes to further refine this estimated EC_{10} by obtaining the treatment level data from the study authors and exploring additional exposure response slopes from the study-specific dataset.

C.2.3.1 Hazelton et al. (2012) Concentration Response Curve – Lampsilis (mussel)

Publication: Hazelton et al. (2012)
Species: Fatmucket, *Lampsilis siliquoidea*
Genus: *Lampsilis*
EPA-Calculated EC_{10}: 0.0123 mg/L
Concentration-Response Model Fit: Concentration-response data not available
Value used Quantitatively in Criterion: Author-reported MATC of 0.01768 mg/L

C.2.4 Fourth Most Sensitive Freshwater Genus for Chronic Toxicity: *Enallagma* (damselfly)

Bots et al. (2010) conducted a 320-day partial life-cycle study under renewal test conditions to assess the effects of PFOS (tetraethylammonium salt, 98% purity) on the damselfly

NMED Exhibit 62

Enallagma cyathigerum. Test organisms were obtained by collecting mature female *E. cyathigerum* all from the same location near the edge of a fen (a groundwater fed wetland) in northern Belgium. After collection, females were transported to the laboratory in small cages and housed in oviposition chambers for 24 hours before eggs were collected. *E. cyathigerum* used for the test were newly-hatched nymphs at test initiation. Dilution water was dechlorinated tap water that contained only a negligible concentration of PFOS (2.64 ng/L) and no other water quality parameters from the tap water were provided other than pH ≥7.5. Photoperiod was 16:8-hours light:dark in a climate room. Light intensity was not reported. Test solutions were prepared taking purity into account. To start the test, a total of 18,552 eggs were distributed amongst 150 exposure chambers (i.e., petri dishes of unreported size and material type). The distribution of the total number of eggs consisted of the entire clutch from each of the 30 females being divided into five subsamples, which were then randomly allotted to the various test treatments; thereby ensuring that each treatment group consisted of an even distribution of test organisms from the 30 females. After hatching, a total of 7,938 nymphs continued to be exposed (10 individuals per cup of unreported size and material type). After 10 days, seven nymphs for every female and treatment were monitored (resulting in a total of 741 nymphs). Nominal concentrations were 0 (negative control), 0.01, 0.1, 1.0, and 10 mg/L. Actual test concentrations were not measured. All nymphs were housed (and presumably tested) in a climate room at 21°C. Water quality (pH, carbonate and total water hardness, O_2, NO_2, and NO_3 levels) was checked weekly using standard aquarium tests, but values are not reported. Approximately 40% of the nymphs in the control treatment died during the first 60 days and similar mortality levels were observed in the other treatments. Additionally, it appears that control survival plateaued between 60 and 200 days, with 82.57% of the remaining nymphs in the control treatment surviving during this time,

NMED Exhibit 62

indicating that survival settled out during this phase of the experiment. The initial drop in nymph survival can likely be attributed to the handling of the test organisms between the various phases of the experiment. This would explain the observed plateau between 60 and 200 days, as the nymphs were not handled during this time. The observed control mortality in this test was consistent with other odonate tests and excessive mortality of nymphs is typically expected within the first 200 days given the difficulty in maintaining odonates in a lab setting (Abbott and Svensson 2007; Rice 2008). Therefore, the observed control survival for this study was considered within the acceptable range for this species up to the 200-day exposure duration. Further, the control survival observed in this study was largely consistent with the toxicity testing guidelines for chironomids (requiring 70% control survival)(ASTM 2002; U.S. EPA 2002), which represent the only test guidelines for an emergent aquatic insect species as similar test guidelines for odonates are not available. Therefore, considerations regarding the use of these data for chronic water column criterion derivation was based on best scientific judgement and were restricted to the first 200 days of the experiment. After 200 days, nymph survival in the control and the PFOS treatments decreased. This drop in survival likely coincided with metamorphosis. However, control survival at the end of the exposure duration was only roughly 40% of the starting nymphs and therefore, survival after 200 days of exposure was not considered a viable test endpoint for this particular study.

The other possible observed effects of PFOS on *E. cyathigerum* reported by the authors included decreased survival over the exposure duration and decreased metamorphosis success. Nymph survival after five days did not differ between the control, 0.01 and 0.100 mg/L treatments and was significantly lower in the 1.0 and the 10.0 mg/L treatments. After 10 days of exposure, 80% of the nymphs in the 1.0 mg/L treatment and all nymphs in the 10 mg/L treatment

NMED Exhibit 62

died. After 20 days of exposure, all nymphs in the 1.0 mg/L treatment died. However, there was no observed statistical difference between the control and any of the other treatment groups during this exposure time through 120 days. Between 120 and 250 days of exposure there was not an observed difference in survival between the control and the lowest treatment group (0.01 mg/L). In contrast, nymph survival in the 0.100 mg/L treatment group started to decrease compared to the control and the 0.01 mg/L treatment group, with 60% survival in the control compared to 48.5% survival in the 0.100 mg/L treatment after 150 days of exposure. This decrease was statistically significantly different from controls. All nymphs in the 0.100 mg/L treatment group died within 250 days of exposure. While nymph survival in the control was roughly 40% at the end of the 320-day exposure duration, there was no observed difference between the control and the lowest treatment group of 0.01 mg/L. Lastly, the paper also reported observed effects of PFOS on metamorphosis success stating that metamorphosis success was lower with 75.5% success in the 0.01 mg/L treatment (the only treatment group to have nymphs survive to this life stage) compared to the control with 92.5%. However, data for this observed endpoint was not provided in the paper beyond the percentages observed in the control and 0.01 mg/L PFOS treatment group. The specific sample sizes for this endpoint were difficult to ascertain from the paper as only the total number of test organisms across all test treatments was provided.

As indicated in the summary of the results above, toxicity values through the experiment decline with exposure duration. The EPA took all of the author-reported toxicity values between 10 (which was considered to be the start of the chronic exposure) and 200 days of exposure into account. Independently-calculated EC_{10} values could not be determined given the level of data that were presented in the paper. Author-reported toxicity values after 10 days of exposure were

NMED Exhibit 62

a NOEC of 0.1 mg/L and a LOEC of 1.0 mg/L. The LOEC was associated with a 79% decrease in nymph survival compared to the control at this time. This NOEC and LOEC resulted in a MATC of 0.3162 mg/L. Author-reported toxicity values after 150 days of exposure were a NOEC of 0.01 mg/L and a LOEC of 0.1 mg/L. The LOEC was associated with a 19% decrease in nymph survival compared to the control at this time. This NOEC and LOEC resulted in a MATC of 0.03162 mg/L. Lastly, the authors also reported a NOEC of 0.01 mg/L for survival and an LOEC of < 0.01 mg/L for metamorphosis success after 320 days of exposure. Both of these toxicity values fell outside the 200-day exposure duration and were not considered for use in the freshwater chronic criterion calculation since control survival at this point was low (40%) and considered unacceptable for quantitative use. Additionally, there was insufficient data provided in the paper to evaluate the reported results for the endpoints at 320 days of exposure. Therefore, these toxicity values were considered as supporting information and only the toxicity values from 10 to 200 days of exposure range were considered further for chronic water column criterion derivation.

The 150-day MATC of 0.03162 mg/L for nymph survival was similar to the author-reported 10-day and 20-day survival and growth MATCs of 0.0687 and 0.0454 mg/L for chironomid (MacDonald et al. 2004), and these later toxicity values were therefore more comparable than the 10-day MATC of 0.3162 mg/L for nymph survival, which was focused on the effects of PFOS on a much earlier instar of odonate (which has a much longer development time and life span) in relation to the 20-day MATC of 0.0454 mg/L for chironomid. These results indicated that PFOS effects to the two aquatic insects was likely similar; however additional data are needed to fully understand the effects of PFOS to odonates. The MATC for nymph survival at 150-day reported above was used quantitatively to derive the chronic water column criterion.

NMED Exhibit 62

Additionally, the EPA ran additional analyses with some of the other toxicity values for *E. cyathigerum* to understand the influence of this study on the overall chronic criterion (see Section 4.1).

C.2.4.1 Bots et al. (2010) Concentration Response Curve – Enallagma (damselfly)

Publication: Bots et al. (2010)
Species: Damselfly, *Enallagma cyathigerum*
Genus: *Enallagma*
EPA-Calculated EC_{10}: Not calculable, concentration-response data not available

C.2.5 Fifth Most Sensitive Freshwater Genus for Chronic Toxicity: *Danio* (zebrafsh)

Wang et al. (2011) evaluated the full life-cycle effects of PFOS (> 96% purity) on *Danio rerio* via a static-renewal study that reported nominal exposure concentrations. This test evaluated the effects of PFOS on a parental (F0) generation and included breeding trials to assess the effects of PFOS on an offspring (F1) generation exposed via maternal transfer. PFOS stock solutions were prepared in 100% dimethylsulfoxide (DMSO). Adult zebrafish (wild-type strain AB) were raised and kept at standard laboratory conditions of 28°C with a 14:10-hour light:dark cycle in a recirculation system according to standard zebrafish culture protocols. Water supplied to the system was filtered by reverse osmosis (pH 7.0-7.5), and Instant Ocean salt was added to the water to raise the conductivity to a range of 450 to 1,000 µS/cm (system water). Zebrafish embryos were obtained from spawning adults in tanks overnight with a sex ratio of 1:1. Embryos were collected within one hour after spawning and rinsed in embryo medium. High-quality 8-hpf embryos were divided into four treatment groups: DMSO vehicle control (0.01% v/v), and PFOS concentrations of 0.005, 0.050, and 0.250 mg/L. Embryos were first exposed to PFOS in a petri dish (100 embryos/treatment) for five days without media change, and all embryos hatched and survived in this stage. After five days, the fish were transferred into 2 L tanks for the period of 5-dpf to 30 dpf, and after that were raised in 9 L tanks (30 fish/tank) until the end of the

NMED Exhibit 62

experiment, 150 dpf. Fish were kept in a static system, and 50% water was renewed with freshly prepared solutions every five days. Each tank was checked for morbid fish on a daily basis, and water quality was monitored on a weekly basis. Feeding was initiated at day five. Between five and 14 dpf, fish were fed three times daily with zebrafish larval diet (Aquatic Habitats), and after 14 dpf they were fed twice daily with freshly hatched live *Artemia*. The experiment was repeated three times with embryos derived from different parental stocks. At the end of exposure period (150 dpf or five months), all fish were checked for their sex. However, the method used for determining sex, as either external morphology or genetic testing, was not stated in the paper. The EPA assumed external morphology was used and concluded that the effects on sex ratio may not be reliable since determining sex through external morphology in zebrafish is difficult. A subsample of 10 male and 10 female fish from each batch were also measured for standard body length and wet weight. Condition factor (K) was tabulated to determine their overall fitness, and sperm motility in male F0 fish was also determined after chronic PFOS exposure. The most sensitive endpoint was F0 parental male sperm density with a chronic value of <0.005 mg/L PFOS. However, as sperm density was not typically considered an apical endpoint and the reported effects of PFOS on sperm density did not translate to other reproductive effects (i.e., fertilization), this endpoint was not considered further. Instead, the most sensitive apical endpoint for the F0 generation was considered to be male growth (length and weight) with an author-reported MATC of 0.01581 mg/L PFOS. However, the EPA was unable to fit a C-R curve with significant model parameters for the male growth endpoints; and therefore, was unable to independently verify the reported toxicity value for the F0 generation.

Breeding trials were also carried out to produce F1 offspring. Six different crosses were employed between F0 females and males to incorporate both the exposure of the same treatment

NMED Exhibit 62

groups throughout and crosses between the control and highest treatment group. Specifically, for the groups exposed to the same treatment throughout the experiment, females were paired with males in the same treatment group (DMSO control or PFOS-exposed concentrations of 0.005, 0.050, and 0.250 mg/L). For the crosses between the control and the highest treatment group, some females from the 0.250 mg/L PFOS treatment group were paired with males from the DMSO controls, and some females from the controls were paired with males from the 0.250 mg/L PFOS treatment group. For each of these crosses, eight randomly selected female fish were paired with four male fish in two separate spawning tanks with four females and two males per tank. Spawning was induced every other day for five days, and embryos were used for monitoring their developmental progress. All eggs from each spawn were evaluated for fertilization success. Percent fertilization was expressed as the number of fertilized eggs divided by total number of eggs. Fifty fertilized embryos from each spawn were further monitored for continuous development. Percent hatch was calculated at 72 hpf. Larvae were also assessed for their morphological appearance. Percent survival was monitored until 8 dpf. Surviving larvae at 5 dpf with normal morphology were further subjected to behavior assessment (larval swimming speeds were recorded when they responded to a 70-minute dark to light, 10-minute for each period, transition stimulation). Following the receipt of treatment level data from the study authors, the EPA independently calculated an EC_{10} value of 0.0165 (0.01267 – 0.02033) mg/L for F1 survival. While this EC_{10} has some uncertainty given the wide spacing (10x) of the treatment concentrations, this toxicity value was supported by others in the PFOS toxicity literature (see Section 4.3.2.1.1 and Appendix G).The independently-calculated EC_{10} value of 0.01650 mg/L value for F1 survival from this study was used to derive the freshwater chronic water column criterion.

NMED Exhibit 62

Guo et al. (2019) evaluated the chronic effects of perfluorooctane sulfonate (PFOS solution of ~40% in water purchased from Sigma-Aldrich) to AB strain zebrafish (*Danio rerio*) males in a 21-day static-renewal, unmeasured study. Use of official test guidelines were not cited by the authors. Approximately 3.5-month-old male adult zebrafish were purchased from Taiyuan fish hatcheries in Shanxi Province, PR China. Prior to exposure, fish were acclimated for 15 days in a flow-through dechlorinated tap water system (<1% mortality during the holding period) with the following water quality characteristics and conditions: pH: 7.0-7.4, temperature: 28 ± 1°C and a 14:10-hour light:dark photoperiod. The fish were fed a commercially available adult zebrafish compound feed during both acclimation and exposure. Nominal concentrations of PFOS dissolved in dechlorinated tap water were reported to be 0 (control), 0.02, 0.04 and 0.08 mg/L. Three replicates were tested at each concentration. A total of 660 fish were divided equally among the four concentration groups. Water quality was maintained the same throughout the experiment as during acclimation, as well as to meet the following conditions: D.O. between 5 - 6 mg/L and total hardness 20.0 mg/L as $CaCO_3$. Exposure media was changed every three days and aquaria were cleaned during testing. On days 7, 14 and 21, 50 fish from each group were sacrificed, with 30 fish measured for length and body weight, while the other 20 dissected on ice to evaluate PFOS concentrations in the liver. The test fish had a mean body weight of 0.19 ± 0.03 g and a mean length of 2.5 ± 0.3 cm at test initiation. On day seven fish lengths ranged from >2 cm to <3 cm for all groups, and weights were >0.3 to <0.4 g for the control and 0.02 mg/L exposure. Mean fish weight measured for the 0.04 and 0.08 mg/L treatment groups were significantly different from the control group after 7 days. At days 14 and 21, the length of fish in the highest concentration (0.08 mg/L PFOS) was significantly different from the control group, and the same effect of PFOS on mean fish weight was observed at 14 and 21 days as

NMED Exhibit 62

reported at seven days. Therefore, weight was the most sensitive endpoint at 21 days, with a NOEC and LOEC of 0.02 and 0.04 mg/L PFOS, respectively. No mortality was observed in any treatment. An independently-calculated EC_{10} could not reliably be estimated for mean fish weight as the data were sparse, was inconsistent with the author-reported toxicity values, and the confidence bands were wide. Instead, the EPA's independently-calculated EC_{10} based on mean body length (in cm) at 21 days was 0.06274 (0.06229 – 0.06318) mg/L PFOS and used quantitatively to derive the freshwater chronic water column criterion.

C.2.6 Sixth Most Sensitive Freshwater Genus for Chronic Toxicity: *Daphnia* (cladoceran)

Logeshwaran et al. (2021) conducted acute and chronic toxicity tests with the cladoceran, *Daphnia carinata*, and PFOS-K (perfluorooctancesulfonate potassium salt, ≥ 98% purity, purchased from Sigma-Aldrich Australia). In-house cultures of daphnids were maintained in 2 L glass bottles with 30% natural spring water in deionized water, 21°C and a 16:8-hour light:dark photoperiod. The chronic test protocol followed OECD (2012). A PFOS stock solution (20 mg/mL) was prepared in dimethylformamide and diluted with deionized water to achieve a concentration of 200 mg/L PFOS. Cladoceran culture medium was used to prepare the PFOS stock and test solutions. One daphnid (6-12 hours old) was transferred to 100 mL polypropylene containers containing 50 mL of nominal test solutions (0, 0.001, 0.01, 0.1, 1.0 and 10 mg/L PFOS). Each test treatment was replicated ten times with test solutions renewed and daphnids fed daily. At test termination (21 days) test endpoints included survival, days to first brood, average offspring in each brood and total live offspring. At the higher test concentrations (1 and 10 mg/L) reproduction was completely inhibited. No mortality occurred in the controls and lowest test concentration. However, reproduction was inhibited at the lowest test concentration. The author-reported 21-day NOEC and LOEC, based on average offspring in each brood and total live offspring, was < 0.001 and 0.001 mg/L PFOS, respectively. Additionally, the author-

NMED Exhibit 62

reported 21-day NOEC and LOEC based on the days to first brood was 0.001 and 0.01 mg/L, respectively, resulting in an MATC of 0.003162 mg/L. The EPA could not independently calculate 21-day EC_{10} values for any of the endpoints given the level of data provided in the paper by the study authors. And while the endpoints of mean offspring per each brood and total living offspring appear to be more sensitive than the days to first brood, they result in less than LOECs of 0.001 mg/L and are not consistent with other chronic toxicity values for this species. Therefore, the author-reported MATC of 0.003162 mg/L for the days to first brood was used to derive the freshwater chronic water column criterion.

Exclusion of the *D. carinata* SMCV under the basis of being an overly sensitive outlier (relative to *D. magna* and the chronic data overall except for aquatic insects [*N. triangulifer* and *C. dilutus*]) had the possibility that the *Daphnia* GMCV could be underproductive. Conversely, excluding the *D. magna* SMCV under the basis of being a tolerant outlier (relative to *D. carinata*) would result in the *Daphnia* GMCV being highly influenced by a single test/species with a relatively sensitive chronic value. The *D. carinata* chronic value was also an MATC, calculated as the geometric mean of the NOEC (0.001 mg/L) and LOEC (0.01 mg/L) from a 10X dilution series, meaning the MATC was influenced by a relatively low NOEC. However, offspring-based endpoints reported by (Logeshwaran et al. 2021) suggest a LOEC of <0.001 mg/L. Using both the *D. magna* and *D. carinata* SMAVs resulted in protective a *Daphnia* GMCV based on the *Daphnia* data as a whole. Finally, the chronic PFOS freshwater criterion (i.e., 0.00025 mg/L) is four times lower than the offspring-based LOECs (i.e., 0.001 mg/L) reported by (Logeshwaran et al. 2021) and should be protective of *D. carinata* based on all endpoints measured by (Logeshwaran et al. 2021).

NMED Exhibit 62

Drottar and Krueger (2000e) reported the results of a life-cycle, 21-day renewal, measured test of PFOS (potassium salt, CAS # 2795-39-3, 90.49% purity) with *Daphnia magna*. The GLP test was conducted at Wildlife International, Ltd. in Easton, MD in February, 1999. The test followed (U.S. EPA 1996c). *D. magna* used for the test were less than 24 hours old at test initiation. Dilution water was 0.45 µm filtered and UV sterilized well water [total hardness: 124 (120-128) mg/L as $CaCO_3$; alkalinity: 169 (164-172) mg/L as $CaCO_3$; pH: 8.2 (8.0-8.3); TOC: <1.0 mg/L; and conductivity: 329 (315-340) µmhos/cm]. Photoperiod was 16:8-hours light:dark with a 30 minute transition period. Light was provided at an intensity of 329-383 lux. A primary stock solution was prepared in dilution water at 46 mg/L. It was mixed until all test substance was dissolved prior to use. After mixing, the primary stock was proportionally diluted with dilution water to prepare the five additional test concentrations. Exposure vessels were 250 mL plastic beakers containing 200 mL of test solution. The test employed 10 replicates of one daphnid each in six measured test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 1.4, 2.9, 5.7, 11, 23, and 46 mg/L. Mean measured concentrations were < 0.458 mg/L (the LOQ), 1.5, 2.9, 5.6, 12, 24, and 48 mg/L, respectively. Analyses of test solutions were performed at Wildlife International Ltd. using HPLC/MS. The mean percent recovery of matrix fortifications analyzed concurrently during sample analysis was 104%. Measured values of new samples ranged from 94 to 121% of nominal. Measured values from the old solutions ranged from 90 to 108% of nominal. PFOS was stable throughout the renewal periods. Dissolved oxygen in new and old test concentrations ranged from 8.3-8.9 mg/L in the negative controls and 8.3-9.0 mg/L at the NOEC of 12 mg/L. Similarly, pH ranged from 8.1-8.4 and 8.2-8.5, respectively, and test temperature from 19.4-20.1°C (negative control and at the NOEC). Cumulative young in the 1.5, 2.9, 5.6, 12, and 24 mg/L treatment groups was 100, 100,

NMED Exhibit 62

100, 90, and 0%, respectively. After 48 hours, cumulative young of the second generation in the negative control was 95%. The 21-day NOEC (survival, growth, and reproduction) was 12 mg/L. The 21-day LOEC was 24 mg/L and the calculated MATC is 16.97 mg/L. No second-generation *D. magna* survived the 24 mg/L treatment. The independently-calculated EC_{10} based on cumulative young was 11.19 (10.50 – 11.89) mg/L and used quantitatively to derive the freshwater chronic water column criterion.

Boudreau (2002) also conducted a chronic life-cycle 21-day renewal, unmeasured test of PFOS (potassium salt, CAS # 2795-39-3, 95% purity) with *Daphnia magna* as part of a Master's thesis at the University of Guelph, Ontario, Canada. The results were subsequently published in the open literature **Boudreau et al. (2003a)**. The test followed ASTM (1999a). *D. magna* used for testing were less than 24 hours old at test initiation. *D. magna* were obtained from a brood stock (Dm99-23) at ESG International (Guelph, ON, Canada). Dilution water was clean well water. Hardness was softened by addition of distilled deionized water to achieve a range of 200-225 mg/L of $CaCO_3$. Photoperiod was 16:8-hours light:dark under cool-white fluorescent light between 380 and 480 lux. Laboratory-grade distilled water was used for all solutions with maximum concentrations derived from stock solutions no greater than 450 mg/L. Test vessels consisted of 225 mL polypropylene disposable containers containing 120 mL of test solution. All toxicity testing involved four replicates of three daphnids each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 6, 13, 25, 50, and 100 mg/L. The test was conducted in environmental chambers at 21 ±1°C. Authors noted that temperature and pH were measured at the beginning and end of study, but the information was not reported. Survival of daphnids in the negative control was 100%. The 21-day NOEC (survival and reproduction) was 25 mg/L. The 21-day LOEC was 50 mg/L and the

NMED Exhibit 62

calculated MATC is 35.36 mg/L. The independently-calculated EC_{10} based on survival was 16.35 (7.377 – 25.33) mg/L and was used quantitatively to derive the freshwater chronic water column criterion.

Ji et al. (2008) conducted chronic life-cycle tests of the effects of PFOS (acid form, CAS # 1763-23-1, purity unreported) on *Daphnia magna*. Tests were done under renewal conditions over a 21-day period. The test followed OECD (1998). *D. magna* used for testing were obtained from brood stock cultured at the Environmental Toxicology Laboratory at Seoul National University (in South Korea). Organisms were less than 24 hours old at test initiation. Dilution water was moderately-hard reconstituted water (total hardness typically 80-100 mg/L as $CaCO_3$). Experiments were conducted in glass jars of unspecified size and fill volume. Photoperiod was assumed to be 16:8-hours light:dark as was used for daphnid culture. Preparation of test solutions was not described. The test involved 10 replicates of one daphnid each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 0.3125, 0.625, 1.25, 2.5, and 5 mg/L. Test temperature was 21 ±1°C. Authors noted water quality parameters (pH, temperature, conductivity, and D.O.) were measured after changing the medium, but the information was not reported. Survival of daphnids in the negative control was 100%. The author reported *D. magna* 21-day NOEC for the reproductive endpoint of number of young per brood was 1.25 mg/L. The author reported 21-day LOEC for the same endpoint was 2.5 mg/L. The calculated MATC was 1.768 mg/L. In the independent verification of the toxicity values, the EPA recalculated the reproductive endpoint noted to be the number of young per brood. This recalculated reproductive endpoint took the full effects of PFOS into account as it was representative of the full life cycle. The calculated EC_{10} for *D. magna* was 1.051 (0.2680 –

NMED Exhibit 62

1.834) mg/L. The independently-calculated EC_{10} of 1.051 mg/L was used quantitatively to derive the freshwater chronic water column criterion.

Li (2010) conducted a chronic life-cycle 21-day test on the effects of PFOS (potassium salt, >98% purity) on *Daphnia magna*. The test followed OECD (1998). *D magna* used for the test were maintained in the laboratory for more than one year and were less than 24 hours old at test initiation. Dilution water was distilled water with ASTM medium (0.12 g/L $CaSO_4.2H_2O$, 0.12 g/L $MgSO_4$, 0.192 g/L $NaHCO_3$, and 0.008 g/L KCl – calculated total hardness 169 mg/L as $CaCO_3$). Photoperiod was 16:8-hours light:dark at an unreported light intensity. A primary stock solution was prepared in dilution water and did not exceed 400 mg/L. Exposure vessels were 50 mL polypropylene culture tubes with 50 mL fill volume. The test involved 10 replicates of one daphnid each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 0.5, 1, 5, 10, and 20 mg/L. Test temperature was maintained at 20 ±1°C. Water quality parameters measured in test solutions were not reported. Survival of daphnids in the negative control was 96.7%. The *D. magna* 21-day NOEC (reproduction – no. young per female) was 1 mg/L. The 21-day LOEC was 5 mg/L and the calculated MATC was 2.236 mg/L. The independently-calculated toxicity value (EC_{10}) based on total neonates per female was 3.030 (-1.280 – 7.340) mg/L and was used quantitatively to derive the freshwater chronic water column criterion.

Yang et al. (2014) evaluated the chronic 21-day renewal, measured test of PFOS (potassium salt, CAS # 2795-39-3, 99% purity) with *Daphnia magna*. The test followed (ASTM 1993). *D. magna* used for the test were donated by the Chinese Research Academy of Environmental Sciences, and less than 24 hours old at test initiation. Dilution water was dechlorinated tap water (pH, 7.0 ± 0.5; D.O., 7.0 ± 0.5 mg/L; total organic carbon, 0.02 mg/L;

NMED Exhibit 62

and total hardness, 190.0 ± 0.1 mg/L as $CaCO_3$). Photoperiod was 12:12-hours light:dark at an unreported light intensity. A primary stock solution was prepared by dissolving PFOS in deionized water and cosolvent DMSO. The primary stock was proportionally diluted with dilution water to prepare the test concentrations. Exposure vessels were 200 mL beakers of unreported material type containing 100 mL of test solution. The test employed 10 replicates of one daphnid each in six test concentrations (measured in low and high treatments) plus a negative and solvent control. Nominal concentrations were 0 (negative and solvent controls), 2.00, 2.60, 3.38, 4.39, 5.71 and 7.43 mg/L. Mean measured concentrations before and after renewal were 1.74 and 1.98 mg/L (lowest concentration) and 6.78 and 7.54 mg/L (highest concentration). Analyses of test solutions were performed using HPLC/MS and negative electrospray ionization. The concentration of PFOS was calculated from standard curves (linear in the concentration range of 1-800 ng/mL), and the average extraction efficiency was in the range of 70-83%. The concentrations and chromatographic peak areas exhibited a significant positive correlation ($r=0.9987$, $p<0.01$), and the water sample-spiked recovery was 105%. Test temperature was maintained at 22 ±2°C. The D.O. and pH were reported as having been measured, but results are not reported. Negative and solvent control survival was 100%. The *D. magna* 21-day EC_{10} for reproduction was reported to be 2.26 mg/L from the study authors and 4.17 mg/L for survival. The independently-calculated EC_{10} based on survival was 2.610 (1.291 – 3.929) mg/L and was used quantitatively to derive the freshwater chronic water column criterion.

Lu et al. (2015) conducted a chronic life-cycle 21-day renewal, unmeasured test of PFOS (purity 98%) with *Daphnia magna*. The test followed OECD (2012). *D. magna* used for the test were originally obtained from the Chinese Center for Disease Control and Prevention (Beijing, China) and cultured in the laboratory according to the International Organization for

NMED Exhibit 62

Standardization (ISO 1996). Daphnids were less than 24 hours old at test initiation. Dilution water was the same used for daphnid culture and was reconstituted according to OECD (2004) with a total hardness of 250 mg/L as $CaCO_3$, as calculated based on the recipe provided, and pH ranging from 7.7 to 8.4. Photoperiod was 16:8-hours light:dark at an unreported light intensity. The test solution was prepared immediately prior to use by diluting the stock solution with culture medium. Exposure vessels were 100 mL glass beakers containing 45 mL of test solution. The test employed 20 replicates of one daphnid each in six nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 0.008, 0.04, 0.2, 1, and 5 mg/L. Exposure water quality was checked daily and maintained at 20 ±1°C, pH of 7.2 ±0.3, and D.O. of 5.3 mg/L. Negative control survival was 100%. The author reported *D. magna* 21-day NOEC (no. offspring per brood per female) was 0.008 mg/L and the 21-day LOEC was 0.04 mg/L. The calculated MATC was 0.0179 mg/L and the independently-calculated EC_{10} was 0.001818 (-0.0000395 – 0.003675) mg/L for the same endpoint. Other endpoints, including growth and other reproductive endpoints, could not be independently-calculated by the EPA. The independently-calculated EC_{10} from this study was acceptable for quantitative use to derive the freshwater chronic water column criterion.

Liang et al. (2017) conducted a chronic life-cycle 21-day renewal, unmeasured test of PFOS (potassium salt, CAS # 2795-39-3, ≥98% purity) with *Daphnia magna*. The test organisms were originally obtained from State Key Laboratory of Environmental Aquatic Chemistry (Eco-Environmental Sciences of Chinese Academy of Sciences, Beijing) and cultured in the laboratory according to Revel et al. (2015). Daphnids were less than 24 hours old at test initiation. Dilution water was artificial medium "M4 (Elendt)" at 20°C and pH 7. Photoperiod was 16:8-hours light:dark at an unreported light intensity. The test solution was prepared

NMED Exhibit 62

immediately prior to use by diluting the stock solution with M4 medium. Exposure vessels were 80 mL glass beakers containing an unspecified volume of test solution. The test employed 10 replicates of one daphnid each in six nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 1, 2, 4, 8, and 16 mg/L. No mention was made of water quality being checked during the exposure. Negative control survival was 100%. The *D. magna* 21-day NOEC (days to 1st brood, intrinsic rate of natural increase, r) was 4 mg/L. The 21-day LOEC was 8 mg/L and the calculated MATC was 5.657 mg/L. The independently-calculated EC_{10} based on survival was 3.596 (2.1207 – 5.0704) mg/L and used quantitatively to derive the freshwater chronic water column criterion.

Yang et al. (2019) evaluated the chronic effects of perfluorooctane sulfonate, potassium salt (PFOS-K, CAS# 2795-39-3, 98% purity, purchased from Sigma-Aldrich in St. Louis, MO) on *Daphnia magna* via a 21-day unmeasured, static-renewal test that evaluated growth and reproductive effects. *D. magna* cultures were obtained from the Institute of Hydrobiology of Chinese Academy of Science in Wuhan, China. Organisms were cultured in Daphnia Culture Medium according to the parameters laid out in OECD Guideline 202 and all testing followed OECD Guideline 211. Cultures were fed green algae daily and were acclimated for two to three weeks before testing. The 21-day chronic study had nominal concentrations of 0 (control), 0.00000124, 0.00000188, 0.0000281 and 0.00000420 mol/L (or 0 (control), 0.6674, 1.012, 1.512, and 2.261 mg/L given the molecular weight of the form of PFOS used in the study, CAS # 2795-39-3, of 538.22 g/mol). Each neonate (12–24 hours old) was placed in a 100 mL glass beaker, in which there were 10 replicates, each filled with 80 mL of test solution maintained at 20 ±1°C and a 16:8-hour light:dark photoperiod with a light intensity maintained at 1000 - 1500 lux. *D. magna* were fed green algae and test solutions were renewed every 72 hours. Test

NMED Exhibit 62

organisms were counted daily, with any young also removed. The author-reported NOEC and LOEC for reproduction (measured as mean offspring proportion relative to control at 21 days) was <0.6674 and 0.6674 mg/L PFOS, respectively. The author-reported NOEC and LOEC for growth (measured as length) was 0.6674 and 1.012 mg/L PFOS (MATC = 0.8218 mg/L). The independently-calculated EC_{10} values for reproduction and growth are 0.3773 and 0.9093 mg/L, respectively. However, the reproduction EC_{10} of 0.3773 mg/L was determined to be less statistically robust as the independently-calculated toxicity values were control normalized and could not be weighted given the level of data provided by the study authors in the paper. Therefore, the independently-calculated EC_{10} for growth of 0.9093 (0.7423 – 1.076) mg/L was used quantitatively to derive the freshwater chronic water column criterion freshwater.

Seyoum et al. (2020) evaluated the chronic effects of perfluorooctane sulfonic acid (PFOS, CAS# 1763-23-1, > 99%, purchased from Sigma) on *Daphnia magna* neonates via a 21-day unmeasured, static-renewal study. The study authors did not report following any specific protocol. *D. magna* ephippia were purchased from MicroBioTests Inc. (Belgium) and were activated by rinsing in tap water. Ephippia were hatched by incubating at 20-22 ºC for 72 to 90 hours in standard freshwater under a continuous light intensity (6,000 lux). Newly hatched neonates (<24-hour old) were fed a suspension of Spirulina micro-algae two hours before testing. Nominal concentrations of 0 (control), 1, 10 and 25 µM (or 0 (control), 0.5001, 5.001, and 12.50 mg/L given the molecular weight of the form of PFOS used in the study, CAS # 176-23-1, of 500.13 g/mol) were prepared by mixing the respective amounts of PFOS in dimethyl sulfoxide (DMSO). Ten <24-hour old neonates, exposed in triplicate, were placed into 250 mL crystallization dishes with 100 mL of test solution. A mean temperature of 23°C, D.O. of 8 to 9 mg/L, total hardness of 250 mg/L as $CaCO_3$, pH of 7.5 ±0.25 and salinity of 0.02% were

NMED Exhibit 62

reported in the exposure water. *D. magna* were fed a mixture of *Spirulina* microalgae and yeast (*Saccharomyces cerevisiae*) daily during the test, and 50% of the test solution was changed every other day. Neonates were counted daily and removed. At day 21, neonate counts were reported to be highest in the control with >40 to < 60 neonates, and >20 to <40 neonates were reported at the 0.5001 and 5.001 mg/L (or 1 and 10 µM) concentrations, respectively. Neonate counts for the 12.50 mg/L (or 25 µM) concentration were not reported. A reproductive NOEC of 0.5001 mg/L and a LOEC of 5.001 mg/L were reported by the study authors, resulting in an MATC of 1.581 mg/L. This LOEC of 5.001 mg/L was associated with a 42.95% decrease in reproduction (measured as the mean number of daphnids at 21 days) compared to control. An independently-calculated EC_{10} value could not be determined as the EPA was unable to fit a model with significant parameters. Instead, the author-reported MATC of 1.581 mg/L PFOS was used quantitatively to derive the chronic water column criterion for freshwater.

C.2.7 Seventh Most Sensitive Freshwater Genus for Chronic Toxicity: *Salmo* (salmon)

Atlantic salmon, *Salmo salar*, embryos were evaluated by **Spachmo and Arukwe (2012)** via a 56-day unmeasured exposure to PFOS (98% purity). Eggs were obtained from Lundamo Hatcheries, Norway (Aquagen) and transported to the Norwegian University of Science and Technology Centre of Fisheries and Aquaculture in Trondheim, Norway. The eggs were kept in plastic tanks (25 L) at 5-7°C with filtered, re-circulating and aerated water. Approximately one-third of the water volume was changed once per week. The eggs and larvae were exposed to PFOS (100 µg/L) for 49 days representing the developmental period from 404 to 679-degree days. PFOS was dissolved in methanol (carrier solvent: 0.01%) and control group was exposed to the carrier solvent only. Hatching occurred at 20 calendar days after start of exposure, at an effective developmental age of 504-degree days, after which riverbed environment was simulated by tank bed gravel and continuous water flow. Fish sampling was performed at 21, 35,

NMED Exhibit 62

49 and 56 calendar days after exposure, or at respective developmental ages of 549, 597, 679 and 721 degree days. The exposure was terminated at 679-degree days, and 712-degree days represents the end of a one-week exposure-free recovery period. Thus, day 49 sampling was performed 24 hours after terminating the exposure and no exposure related differences in hatching rate were observed. The 49-day growth NOEC and LOEC were 0.10 and >0.10 mg/L PFOS, respectively. These data are deemed quantitative and used to derive the freshwater chronic water column criterion.

C.2.8 Eighth Most Sensitive Freshwater Genus for Chronic Toxicity: *Pimephales* (minnow)

Drottar and Krueger (2000d), associated with Wildlife International, conducted a good laboratory practice (GLP) 47-day flow-through measured early life-stage toxicity test with <24-hour old *P. promelas* embryos. A primary stock solution was prepared by dissolving PFOS (90.49% purity) in dilution water at a concentration of 88.4 mg a.i./L, then proportionally diluted with dilution water to prepare five secondary stock solutions at concentrations of 44.2, 22.1, 11.0, 5.52 and 2.76 mg a.i./L. Stock solutions were prepared every three to four days during the test. The five stocks were injected into the diluter mixing chambers (at a rate of 6.0 mL/minute) where they were mixed with dilution water (at a rate of 116 mL/minute) to achieve the desired test concentrations. The water used for culturing and testing was freshwater obtained from a well approximately 40 meters deep located on the Wildlife International Ltd. site. The well water was characterized as moderately-hard water. The well water was passed through a sand filter to remove particles greater than approximately 25 μm and then pumped into a 37,800-L storage tank where the water was aerated with spray nozzles. Prior to delivery to the diluter system, the water again was filtered (0.45 μm), then passed through a UV sterilizer to remove microorganisms and particles. Fathead minnow embryos used in this test originated from cultures maintained by Wildlife International Ltd., Easton, MD. The embryos were removed

NMED Exhibit 62

from spawning substrates and examined under the dissecting microscope to select healthy specimens at approximately the same stage of development. Embryos collected for use in the test were from six individual spawns. Embryos were exposed to a geometric series of six test concentrations and a negative (dilution water) control under flow-through conditions at 24.5°C, pH of 8.2, total hardness of 140 mg/L as $CaCO_3$ and a photoperiod of 16:8-hours light:dark. Four replicate test chambers (9 L glass aquaria) were maintained in each treatment and the control group. Each test chamber contained one incubation cup with 20 embryos, resulting in a total of 80 embryos per treatment. The exposure period included a five-day embryo hatching period, and a 42-day post-hatch juvenile growth period. Nominal test concentrations were 0.14, 0.29, 0.57, 1.1, 2.3 and 4.6 mg/L a.i. Mean measured test concentrations (0, 0.15, 0.30, 0.60, 1.2, 2.4 and 4.6 mg/L) were determined from samples of test water collected from each treatment and the control group at the beginning of the test, on day four, at weekly intervals during the test, and at test termination. To start the test, embryos less than 24 hours old were collected from cultures and groups of one and two individuals were impartially distributed among incubation cups until each cup contained 20 embryos. One cup was then placed in each treatment and control test chamber. Twice during the next twenty-four hours and daily thereafter, all dead embryos were counted and removed from the cups to avoid contaminating viable embryos. All eggs that remained were considered viable. Dead embryos continued to be removed daily. After hatching, the larvae were counted and released into the test chambers, where exposure continued until test termination. Observations of mortality and other clinical signs were made daily during the test. Time to hatch, hatching success, growth, and survival were monitored in each treatment and control group. The most sensitive 47-day chronic value (MATC) of 0.4243 mg/L PFOS was based on post-hatch survival as reported by the study authors. The independently-calculated EC_{10} based on survival

NMED Exhibit 62

was 0.4732 (0.3308 – 0.6156) mg/L and used quantitatively to derive the freshwater chronic water column criterion.

Ankley et al. (2005) also exposed *Pimephales promelas* to PFOS (potassium salt, > 98% pure) under flow-through measured conditions for 21 days. Stock solutions were prepared by dissolving crystals in Lake Superior control water with stirring (mean measured test conditions: 25°C, pH of 7.3, total hardness of 46 mg/L as $CaCO_3$, alkalinity of 40 mg/L as $CaCO_3$ and D.O. of 6.2 mg/L). Two stock solutions of approximately 9.7 and 97 mg/L were used to span the desired range of target concentrations in test water. Final test concentrations were generated by appropriate dilution of the PFOS stocks with Lake Superior water and were supplied to the test tanks at a flow rate of approximately 45 mL/min. Sexually mature fathead minnows (six to seven months old) obtained from the on-site culture facility were used for the toxicity test. Eight pairs of fish (one male and one female) were exposed at each treatment level, 0 (control), 0.03, 0.1, 0.3, and 1.0 mg PFOS/L. Assays were conducted using glass aquaria containing 10 L of test solution, with two pairs of fish separated by perforated nylon screening in each tank. Reproductive viability of the fish used for the test was documented during a 27-day acclimation phase in the same tanks in which the tests were conducted. The number of eggs spawned by each pair was evaluated daily by inspecting the underside of a polyvinyl chloride spawning tile placed on the bottom of the test chambers. Egg fertility was assessed using an optical microscope. The animals were held at 25 ±1°C under 16:8-hour light:dark photoperiod and fed frozen brine shrimp to satiation twice daily. Conditions during the 21-day reproduction phase of the PFOS exposure were the same as during the acclimation phase. To evaluate possible early developmental toxicity of PFOS, 50 to 75 eggs from single viable spawns were collected during the final 7-day of the reproduction phase of the test. A subset of eggs was reserved for the

NMED Exhibit 62

determination of PFOS concentrations. Embryos were held in 300 mL Pyrex beakers in the same aquaria as the parental fish. Embryos hatched within four to five days and thereafter were fed live brine shrimp twice daily. After 12 days, fry were randomly sampled for PFOS analysis and to reduce the number of animals per chamber to ≤30. Remaining fry were maintained in a larger chamber (1 L plastic container) within the original tank. Developing fish were inspected daily to assess survival. After 24 days, they were anesthetized and weighed. A subset of the fry was collected for PFOS measurements, while others were preserved in Bouin's fixative for histological analyses. The authors reported a 21-day EC_{50} (fecundity) of 0.23 mg/L PFOS, and a chronic value of 0.4794 mg/L PFOS for percent hatch (21-day), probability of survival, and larval weight endpoints (21-day (F0) + 24-day (F1)). The independently-calculated EC_{10} was 0.05101 (0.0408 – 0.0613) mg/L based on fecundity and used quantitatively to derive the freshwater chronic water column criterion.

Suski et al. (2021) reported the chronic toxicity of PFOS-K (perfluorooctancesulfonate potassium salt, CAS # 2795-39-3, ≥ 98%, purchased from Sigma-Aldrich) on the fathead minnow, *Pimephales promelas*. Adult (5-month old) fathead minnows were purchased from a commercial supplier (Aquatic Biosystems) and were sexually mature when the test was initiated. Fish were fed twice a day and held in dechlorinated tap water at test conditions (mean conditions: 24.96°C, D.O. of 7.68 mg/L, pH 7.9 and conductivity of 347.3 µS/cm). Stock solutions of PFOS (150 mg/L) were made without a solvent and prepared weekly with stock solutions shaken at 80 rpm for 24 hours to ensure mixing. Test solutions were made by diluting the stock with dechlorinated tap water and shaking the solutions for 10 minutes prior to water exchanges. Half of the total volume (10 L) in each exposure 5-gallon polycarbonate tank was renewed three times per week. Measured PFOS concentrations were 0.14 (control), 44, 88, 140

NMED Exhibit 62

and 231 µg/L PFOS (or 0.00014 (control), 0.044, 0.088, 0.14, and 0.231 mg/L PFOS). Each test treatment was replicated six times for each treatment and consisted of two females and one male per tank with exposures lasting 42 days. Tanks were expected daily for eggs and all eggs collected were assumed to be per single female regardless of the number of females per tank. On the last week of testing, eggs were carried through hatching in their respective test treatments, and 20 larval fish per concentration were exposed for an additional 21 days to investigate developmental effects. One liter polypropylene beakers were used for the F1 generation exposure with solutions renewed daily. Survival of adult fathead minnows in the control and two lowest test concentrations was ≥80% at test termination. Survival of male fish in the highest test treatment was significantly less than male control fish, and while female survival was also less compared to control fish, the effects were not significant. The mean number of spawning events per female was also reduced in the two high test treatments, but the effect was only significant in the 140 µg/L (0.14 mg/L) treatment. Larval survival in the F1 generation was significantly reduced in the highest test treatment. The most sensitive endpoint from the study was a significant decrease in the mean mass of individuals in the larval F1 generation with reported values of 3.76, 3.53, 3.09, 2.64 and 2.00 mg for the test treatments of control, 0.044, 0.088, 0.14, and 0.231 mg/L PFOS, respectively. The author-reported NOEC and LOEC, based on growth in the F1 generation, were 0.044 (6% reduction in growth compared to controls) and 0.088 mg/L PFOS (associated with an 18% reduction in growth), respectively, with a MATC of 0.06223 mg/L. The independently-calculated EC_{10} value was 0.0549 (0.0396 – 0.0701) mg/L and used in the derivation of the freshwater chronic column criterion.

C.2.9 Ninth Most Sensitive Freshwater Genus for Chronic Toxicity: *Procambarus* (crayfish)

Funkhouser (2014) conducted a chronic 28-day renewal test of PFOS (potassium salt, ≥98% purity) with a crayfish species, *Procambarus fallax* (f. *virginalis*). The study was

NMED Exhibit 62

conducted as part of a Master's thesis at Texas Tech University, Lubbock, TX. Juvenile *P. fallax* (4-weeks old, 0.056 g) used for the test were originally purchased from a private collector. The crayfish reproduced for several generations before being used for experiments. Based on an average reproductive age of 141-255 days, an interclutch period of 50-85 days, and a brooding time of 22-42 days, the author estimated the experimental animals to be stage F4-F6 (Seitz et al. 2005). Dilution water was moderately hard reconstituted laboratory water (3.0 g $CaSO_4$, 3.0 g $MgSO_4$, 0.2 g KCl, and 4.9 g $NaHCO_3$ added to 50 L deionized water). Photoperiod was 14:10-hours light:dark at an unreported light intensity. PFOS was dissolved in dilution water to prepare the test concentrations. Exposure vessels were 1 L polypropylene containers containing 500 mL of test solution. The test employed eight replicates of one crayfish each in five test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 0.2, 0.5, 1.3, 3.2, 8 and 20 mg/L. Exposure concentrations were reportedly measured, but concentrations were not provided. Analyses of test solutions were performed using LC-MS/MS. Standards were used as part of the analytical method, but details were not reported. The reporting limit was 0.010 mg/L. Experiments were conducted in an incubator set at 25 ±1°C and covered with plastic opaque sheeting to limit evaporation. No other water quality parameters were reported as having been measured in test solutions. Negative control survival was 85% after 28 days. The 28-day LC_{20} was reported as 0.167 mg/L. An independently-calculated EC_{10} could not be calculated given the level of data that were presented in the paper. The study author-reported LC_{20} value was used quantitatively to derive the freshwater chronic water column criterion.

C.2.10 Tenth Most Sensitive Freshwater Genus for Chronic Toxicity: *Moina* (cladoceran)

Ji et al. (2008) conducted a chronic life-cycle test of the effects of PFOS (acid form, CAS # 1763-23-1, purity unreported) on *Moina macrocopa*. The test was performed under renewal conditions over a 7-day period. The *M. macrocopa* test followed a protocol developed

NMED Exhibit 62

and reported by Sutherland and Krueger (2001) that was similar to OECD (1998), but with slight modification. *M. macrocopa* used for testing were obtained from brood stock cultured at the Environmental Toxicology Laboratory at Seoul National University (in South Korea). Test organisms were less than 24 hours old at test initiation. Dilution water was moderately hard reconstituted water (total hardness typically 80-100 mg/L as $CaCO_3$). Experiments were conducted in glass jars of unspecified size and fill volume. Photoperiod was assumed 16:8-hours light:dark as was used for daphnid culture. Preparation of test solutions was not described. The test involved 10 replicates of one daphnid each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 0.3125, 0.625, 1.25, 2.5, and 5 mg/L. Test temperature was 25 ±1°C. Authors noted that water quality parameters (pH, temperature, conductivity, and D.O.) were measured after changing the medium, but the information was not reported. Survival of daphnids in the negative control was 100%. The author reported *M. macrocopa* 7-day LOEC for the reproductive endpoint of number of young per surviving adult was 0.3125 mg/L. In the independent verification of the toxicity value, the EPA recalculated the reproductive endpoint to be the number of young per starting adult (instead of surviving adult). This recalculated reproductive endpoint took the full effects of PFOS into account as it was representative of the full life cycle. The independently-calculated EC_{10} for *M. macrocopa* was 0.1789 (0.041 – 0.399) mg/L and used to derive the freshwater chronic water column criterion.

C.2.11 Eleventh Most Sensitive Freshwater Genus for Chronic Toxicity: *Brachionus* (rotifer)

Zhang et al. (2013) conducted a chronic life-cycle renewal test of PFOS (potassium salt, CAS # 2795-39-3, ≥98% purity) with *Brachionus calyciflorus*. The test duration was five days in a full-life cycle test (primary emphasis) and 28 days in a multi-generation population growth test (secondary emphasis – only two exposure concentrations plus a control). Test organisms were

NMED Exhibit 62

less than two hours old at test initiation. All animals were parthenogenetically-produced offspring of one individual from a single resting egg collected from a natural lake in Houhai Park (Beijing, China). The rotifers were cultured in an artificial inorganic medium at 20°C (16:8-hours light:dark; 3,000 lux) for more than six months before toxicity testing to acclimate to the experimental conditions. Culture medium was an artificial inorganic medium and all toxicity tests were carried out in the same culture medium and under the same conditions as during culture (i.e., pH, temperature, illumination). Solvent-free stock solutions of PFOS (1,000 mg/L) were prepared by dissolving the solid in deionized water via sonication. After mixing, the primary stock was proportionally mixed with dilution water to prepare the test concentrations. Exposures were carried out in 24-well cell culture plates (assumed plastic) containing 2 mL of test solution per cell. The test employed four measured test concentrations plus a negative control. Each treatment consisted of one replicate plate of 15 rotifers each in individual cells. Treatments were repeated six times. Nominal concentrations were 0 (negative control), 0.25, 0.5, 1.0, and 2.0 mg/L. PFOS concentrations were not measured in the rotifer exposures, but rather, in a side experiment using HPLC/MS. The side experiment showed that the concentration of PFOS measured every eight hours over a 24-hour period in rotifer medium with green algae incurs minimal change in the concentration range 0.25 to 2.0 mg/L. One hundred percent survival was observed at 24 hours in the negative control in the corresponding acute test but was not provided for the life-cycle test. The *B. calyciflorus* 5-day LOEC (net reproductive rate and intrinsic rate of natural increase) was 0.25 mg/L. The author-reported value (<0.25 mg/L) was used quantitatively to derive the freshwater chronic water column criterion.

NMED Exhibit 62

C.2.12 Twelfth Most Sensitive Freshwater Genus for Chronic Toxicity: *Xiphophorus* (swordtail fish)

The toxicity of PFOS (potassium salt, > 98% purity) to the swordtail fish, *Xiphophorus helleri*, was evaluated by **Han and Fang (2010)**. A PFOS stock solution (250 mg/L) was prepared by dissolving crystals in dechlorinated tap water (from the same water source as that used in fish keeping). Six- to seven-month old adult swordtails were purchased from a local fish farm with no water pollution. The fish were separated by sex into different aquaria. Both the males and females were acclimated for eight weeks under semi-static conditions in charcoal filtered, aerated tap water at 27 ±1°C with a 14:10-hour light:dark photoperiod. The water in each aquarium was completely renewed every 48 hours. The fish were fed once daily in the morning with flake food and once daily at dusk with frozen blood worms. Adult male fish were then randomly distributed into 30 L tanks containing 20 L dechlorinated tap water or a corresponding PFOS solution. Swordtail fish were exposed to 0 (control), 0.1, 0.5 or 2.5 mg/L PFOS for three weeks and then transferred into clean water for one-week recovery. Every day, half of the water in each tank was replaced with fresh water, and the fish were exposed to the appropriate concentrations daily. Exposure conditions were the same as those during the acclimation period. Each aquarium housed 10 swordtails. Three aquaria were used for each exposure concentration and for the controls, resulting in three full biological replicates for each exposure group. Body, liver and testis weights were determined at 7, 14, 21 and 28 days after ice-bath anaesthetization. The livers were weighed immediately, then frozen in liquid nitrogen and stored at -80°C for RNA extraction. The hepatosomatic index (HSI) and gonadal somatic index (GSI) values were also calculated. Nonpregnant adult female fish were housed under the same exposure conditions as the males for the six-week exposure period. At the same time, to ensure impregnation of the females, nine adult females were paired with three adult males and

NMED Exhibit 62

kept in each aquarium for one week, after which the males were taken out. There were also three biological replicates for each exposure group. One pregnant female per aquarium was isolated and housed until giving birth. Larvae were maintained in clean water for up to 14 days after birth to calculate their survival rate. At the end of the exposure period, the survival rate, HSI and GSI values of all groups were determined. The total number of puerperal females and females with eggs or embryos in each group was recorded to determine their corresponding ratios. More than 100 adult swordtails (with a male:female ratio of about 1:3) were housed together to obtain at least 240 juveniles (20-30 days old). All of the fry were then randomly separated into two exposure groups (0 and 0.1 mg/L) and kept under the same housing conditions as the males. Each tank contained 40 fry. There were also three biological replicates in each group. After a 90-day exposure period, the HSI, GSI, and condition factor (CF) values and the sex ratio of each group were calculated by sex category. Body length from the snout to the end of the caudal fin and sword length from the distal end of the middle rays of the caudal fin to the tip of the sword were measured for each young male. After an extended period of stable breeding, part of the juveniles became young females and some of them were with eggs, embryos or puerperal. So, just like adult females, the total number of puerperal females and females with eggs or embryos in each group were recorded as a single entity to determine their corresponding ratios. The 4-week (adult male), 6-week (adult female) and 90-day (juvenile female and male) survival chronic values were >2.5, 1.118 and >0.1 mg/L PFOS, respectively. The study-author reported survival chronic value for offspring of females exposed for six weeks was 0.2236 mg/L PFOS, and the 90-day growth and percent females with eggs chronic value was <0.1 mg/L PFOS. The independently-calculated EC_{10} for adult female survival was 0.5997 (0.2336 – 0.9658) mg/L, which was acceptable for quantitative use.

NMED Exhibit 62

C.2.13 Thirteenth Most Sensitive Freshwater Genus for Chronic Toxicity: *Xenopus* (frog)

Lou et al. (2013) evaluated the chronic toxicity of PFOS to the African clawed frog, *Xenopus laevis*. PFOS (98% purity) stock solutions (8 mg/mL) were prepared by dissolving in DMSO every four weeks and stored at 4°C. Stock solutions were diluted by charcoal-filtered tap water to prepare test water. DMSO concentrations were 0.001% (v/v) in all tanks including the solvent control group. The same charcoal-filtered tap water (pH 6.5-7.0, D.O. >5 mg/L, and total water hardness, as $CaCO_3$, of approximately 150 mg/L) was used to raise *X. laevis* frogs and tadpoles. Adult female and male *X. laevis* (3 years old, obtained from Nasco, USA.) were raised separately in glass tanks at 22 ±2°C with a 12:12-hour light:dark cycle and fed with chopped pork liver (commercial amphibian diet three times a week). A pair of *X. laevis* was injected by human chorionic gonadotropin to induce breeding. Fertilized eggs were incubated in the same dechlorinated tap water at 22 ±2°C for six days (and were fed live *Artemia* starting on the 5^{th} day). On the fifth day postfertilization, tadpoles at NF stage 46/47 were exposed to PFOS (nominal: 0.0001, 0.001, 0.100 and 1.0 mg/L; measured: 0, 0.00009, 0.001, 0.1117, 0.7160 mg/L) until two months post-metamorphosis. Each exposure group and control group consisted of three replicated tanks. Each tank with 18 L water was assigned randomly 25 tadpoles. The tadpoles were fed with live *Artemia* three times daily. After metamorphosis, the juvenile frogs were fed with live *Artemia* daily and chopped pork liver every other day. The test water (22 ±2°C) was completely replaced every other day. Fluorescent lighting provided a photoperiod of 12 hours and a light intensity ranging from 600 to 1,000 lux at the water surface. During the exposure, the animals were observed for mortality and growth daily and dead tadpoles were removed. At the end of exposure, the survival rate of the frogs in each tank was recorded. After anaesthetization, the frogs were weighted and dissected. The liver tissue of each frog was weighed and hepatosomatic index (HSI) was calculated. The sex or intersex of each frog was

NMED Exhibit 62

determined by examining the gross gonadal morphology with a stereo microscope. The survival, weight and sex ratio/intersex chronic value were all > 0.7160 mg/L PFOS (or 1 mg/L PFOS as the nominal concentration). The study-author reported value was used quantitatively to derive the freshwater chronic water column criterion.

Fort et al. (2019) evaluated the chronic effects of perfluorooctane sulfonic acid (PFOS, ≥98% purity, CAS # 1763-23-1, lot # BCBH2834V from Sigma-Aldrich in St. Louis, MO) on clawed frogs (*Xenopus tropicalis*, formerly *Silurana tropicalis*) in a 150-day post-metamorphosis flow-through, measured study. Stock solutions were prepared by dissolving PFOS into filtered, dechlorinated tap water in 18 L glass carboys, which were then pumped into the master mixing cell of the continuous flow diluter. Adult frogs were obtained from Xenopus 1 and fed salmon starter pellets daily for 30 days during acclimation prior to breeding. Temperature during acclimation was maintained at 26 ±0.5ºC. Researchers followed the breeding guidance of Fort et al. (2002), and added human chorionic gonadotropin the day before breeding began. Three pairs of frogs were isolated and allowed to breed, but only a single clutch with a >70% spawn rate was utilized for the experiment. Normal appearing dejellied embryos (Nieuwkoop and Faber Stage 10) were randomly selected, and 20 were placed in each of four aquaria, each 4-L in size, for a total of 80 embryos per concentration. The frogs were subjected to a 12:12-hour light:dark photoperiod with a light intensity of 600 ± 50 lux, and the pH was maintained naturally at 7.5 ±0.3. The diluter system achieved a complete volume change every 6.5 hours, and diluter performance, flow rates, temperature, D.O. and light intensity were measured daily. Test organisms were exposed to mean measured concentrations of <0.03 (control), 0.05, 0.13, 0.31, 0.59 and 1.05 mg/L PFOS until metamorphosis, and liquid chromatography mass-spectrometry was used to verify differences in PFOS concentrations. At metamorphosis (NF Stage 66), weight

NMED Exhibit 62

and snout-vent lengths were measured. Frogs were kept an additional 150 days past metamorphosis without PFOS to determine weights, lengths, and sex differences amongst the organisms. Mortality data showed a NOEC value >1.05 mg/L while the pre-metamorphosis portion of the study showed a NOEC of 0.59 mg/L and a LOEC of 1.05 mg/L for both snout-vent length and weight (MATC = 0.7871 mg/L). The LOEC of 1.05 mg/L was associated with 5% (snout-vent length) and 14% (weight) decrease compared to controls, respectively. A significant increase in the median metamorphosis time was observed in the 1.05 mg/L PFOS treatment relative to the control. The post-metamorphosis LOEC was reported as 1.05 mg/L. No LC_{50} value was reported in that only 5.2 percent mortality was observed in the highest exposure concentration (1.05 mg/L) at test termination. Independently-calculated EC_{10}s could not be calculated as the EPA was unable to fit a model with significant parameters. Instead, the author-reported MATC of 0.7871 mg/L PFOS based on growth (measured as mean body weight at metamorphosis) was used quantitatively to derive the freshwater chronic water column criterion.

C.2.14 Fourteenth Most Sensitive Freshwater Genus for Chronic Toxicity: *Lithobates* (frog)

The chronic flow-through measured toxicity of PFOS (potassium salt, 98% purity) to the northern leopard frog, *Lithobates pipiens* (formerly, *Rana pipiens*), was investigated by **Ankley et al. (2004)**. Two PFOS stock solutions (708 and 21.7 mg/L) were prepared by dissolving solid PFOS with one liter of Lake Superior water in a glass carboy for 24 hours and then brought to a volume of 18 L for the final stock solutions. Contents were stirred at room temperature (~20°C) for 24 hours prior to being used. Solutions were pumped from the carboys to the glass aquaria through Teflon® tubing using fluid metering pumps equipped with stainless-steel rotary dispensers. Target concentrations were achieved by diluting the high and low stock solutions with an appropriate volume of the Lake Superior (control) water. The PFOS stock solutions were renewed every seven days. Fertilized eggs were collected from Grand Lake (St. Louis County,

NMED Exhibit 62

MN), near a sandy shoreline with no development. Tests were initiated with stage 8/9 embryos; animals were gently separated with a plastic spatula from the egg mass, inspected under a microscope for viability (evidence of cell division), and randomly allocated to treatment groups. Exposures were conducted in glass aquaria in 10 L of water, which was continually renewed at a flow rate of about 50 mL/minute (72 L/day). Duplicate tanks at target (nominal) PFOS concentrations of 0.03, 0.1, 0.3, 1, 3, and 10 mg/L and four replicate control aquaria were used. Embryos (n=120) were placed in each aquarium; in addition, two of the control tanks and the duplicate tanks at 0.1 and 1 mg PFOS/L received an extra 80 organisms (total of 200) at test initiation to provide animals for determination of PFOS concentrations during the early part of the assay. Although biomass varied between the tanks with 120 versus 200 tadpoles, in both situations total loading to the system was more than two orders of magnitude lower than guidance recommended for a test at this flow rate. Water temperature was maintained at 20 ± 0.5°C, and the photoperiod (provided by fluorescent lights) was a constant 16:8-hour light:dark cycle. On hatching (at approximately six days), animals were fed a mixture of live brine shrimp, ground trout chow, and Tetrafin *ad libitum* two times daily. Dead organisms were removed daily and inspected for gross abnormalities. On test day 6, 10 newly-hatched (<24 hours) animals were randomly removed from each tank, preserved in 10% neutral buffered formalin, and subsequently examined for developmental anomalies. Groups of animals were randomly selected from each treatment (excluding the 10 mg/L group, which had been terminated because of high mortality) on test days 35 (10 tadpoles/tank) and 54 (three tadpoles/tank). The animals were weighed, and developmental stage was recorded, before being processed for PFOS tissue analysis. The first tadpoles to undergo complete metamorphosis (defined as emergence of the forelimbs) were observed on test day 60. Metamorphs were removed from the test tanks,

NMED Exhibit 62

sacrificed with an overdose of MS-222, weighed, measured (total and snout-vent length), and assessed for gross abnormalities. Metamorphosis of the tadpoles continued over the next 51 days, until the test was terminated, when remaining tadpoles were counted, staged, and weighed. A subset of tadpoles from the control and 3 mg PFOS/L treatments were processed for histological analysis of the thyroid gland when they were sampled at forelimb emergence. The most sensitive apical chronic value was the 112-day growth MATC of 1.732 mg/L PFOS, followed by the 5-week LC_{50} of 6.21 mg/L PFOS. These data are considered quantitative even though the control mortality was >20% at test termination (Note: Excessive mortality of amphibian larvae should be expected within the full duration of this experiment given the life history strategy employed by amphibians. Therefore, the observed control survival for this study was considered within the acceptable range for this species and the toxicity data should be limited to the first 10 weeks of the experiment). The author-reported value (112-d growth MATC of 1.732 mg/L) was used quantitatively to derive the chronic water column criterion.

Hoover et al. (2017) also evaluated the chronic toxicity of PFOS (>98% purity) to *Lithobates pipiens*. Test solutions were renewed every four days and exposure concentrations were measured prior to and after each water change. Stock solutions consisted of 1 g of chemical dissolved in 2 L of Milli-Q water, then vacuum-filtered before storage in polycarbonate bottles. Eight northern leopard frog egg masses were collected during early spring from a temporary pond at the Purdue Wildlife Area in West Lafayette, IN, and randomly assigned to outdoor ~100 L wading pools. After hatching, larvae were checked daily for mortality and fed Purina Rabbit Chow *ad libitum*. Treatments consisting of a control and PFOS at three concentrations (nominally 0.010, 0.100, and 1.0 mg/L) were placed in two replicates on adjacent shelves within an environmental chamber. Experimental units consisted of 15 L plastic aquaria filled with 7.5 L

NMED Exhibit 62

of filtered, UV-irradiated well water. Tadpoles (n=35 per aquarium) were randomly assigned to the experimental units. Prior to addition to aquaria, a subset of animals was examined to confirm development at Gosner stage 26, when hind limb buds start to develop. Tadpoles with visible irregularities in morphology, coloration, or behavior were excluded. Animals were maintained at 20 ±2°C with a 12:12-hour light:dark photoperiod for 10 days to acclimate to indoor conditions and were fed a TetraMin® slurry *ad libitum*. Water changes (100%) were conducted every four days. Tadpoles were exposed for 40 days and were monitored daily for mortality and abnormalities. A water sample (~5 mL) was taken immediately prior to and after each water change to monitor concentration of test chemicals. Every 10 days, six animals were randomly collected from each aquarium. The animals were euthanized, measured (total length at 10 days, snout-vent length otherwise), and staged (Gosner) prior to storage at -20°C for chemical analyses. After 40 days, the depuration phase was initiated by removing animals, cleaning each aquarium with a methanol-soaked sponge, and rinsing to remove adsorbed compound. Aquaria were refilled with clean water; animals were returned to the same aquarium and monitored as described above. Water changes were carried out every four days with fresh water, and a water sample was taken prior to each water change. Two tadpoles were sampled every 10 days for an additional 30 days. The 40-day chronic value was 0.0316 mg/L PFOS based on Gosner stage reached at test termination. This study was deemed quantitative, even though PFOS was detected in the control organisms. While the concentrations were much lower than any of the PFOS treatment groups (3 orders of magnitude lower), it indicated that some potential contamination may have occurred in the controls. The author-reported value (a developmental-based MATC of 0.0316 mg/L) was used quantitatively to derive the freshwater chronic water column criterion.

NMED Exhibit 62

C.2.15 Fifteenth Most Sensitive Freshwater Genus for Chronic Toxicity: *Hyalella* (amphipod)

Krupa et al. (2022) conducted a 42-day chronic toxicity test with the amphipod, *Hyalella azteca*, and PFOS-K (perfluorooctanesulfonate potassium salt, > 98% purity, CAS No. 2795-39-3, purchased from Sigma-Aldrich). *H. azteca* were obtained from an in-house culture maintained according to U.S. EPA (2000b). Following published methods for conducting water-only testing with *H. azteca* (Bartlett et al. 2021; Ivey et al. 2016), the methods for this chronic 42-d static-renewal test were modified from standard guidance for sediment testing (U.S. EPA 2000b) to a water-only exposure to avoid sorption of PFOS to sediment. Juvenile amphipods approximately 7- to 8-d old were obtained from mixed-age animals passing through a 425 µm sieve and retained on a 355 µm sieve. Animals were then acclimated to test conditions for 2-days before the start of the exposures. Tests were conducted in 300 mL polycarbonate beakers containing 200 mL of test water, a thin layer of clean silica sand (250 – 500 mm diameter, 5 mL per beaker) and ten amphipods under a 16:8-hour light:dark cycle in an environmental chamber maintained at 23 ± 1°C for 42-days. Aeration was provided at a trickle flow rate via glass pipettes. Mean measured exposure concentrations were 0.0093 (control), 4.8, 9.3, 21, and 45 mg/L PFOS, with eight replicates per concentration. Three liters of a 300 mg/L PFOS stock solution was made by dissolving the PFOS salt into dechlorinated tap and mixing the solution on a stir plate for > 20-hours. A total of 10 L of each test concentration was then prepared by mixing the stock solution into carbon filtered dechlorinated tap water containing added sodium bromide (0.052 mg/L). Amphipods were fed 1 mL of YCT food mixture (1.8 g/L mixture) per beaker daily and a ramped (food increased over time) ration of finely ground TetraMin® (0.25 mg/day during week 1, 0.5 mg/day at week 2, 1 mg/day at week 3, and 1.5 mg/day thereafter). For beakers with ≤ 50 % survival, the feeding ration was halved. The YCT and TetraMin® were mixed together as a slurry. The test solution was renewed every 7 days. On Day 7, a partial water

NMED Exhibit 62

change removing about 150 mL of solution was performed to avoid disturbing the younger *H. azteca*. Complete renewal of the test solution started on Day 14 and continued weekly for the remainder of the test. For these water changes, the entire content of a beaker was transferred to a 12-inch diameter glass culture bowl. New sand and exposure solution were then placed in the beaker. Surviving adult amphipods were enumerated and transferred back to the beaker. On Day 21, all beakers were replaced with new ones. On days 28, 35 and 42, after the adults were transferred back to the beakers, the former contents of the beaker (all the discarded sand and water) were preserved in 70% ethanol with rose bengal stain for later enumeration of offspring. At test termination, sex and combined replicate dry biomass were determined for each replicate. To determine biomass, animals were loaded onto a pre-weighed pan made of aluminum foil and placed in a 60°C oven for a minimum of 24-hours. The pans were then placed in a desiccator for at least 1-hour before being weighed. Eight pans with ten animals each were loaded with organisms on Day 0 to establish a baseline for growth. Water quality parameters observed during testing ranged from 7.31 - 8.57 mg/L D.O., 7.77 - 8.10 SU pH, 22.1 - 22.8°C and 62 - 72 mg/L as $CaCO_3$ total hardness. Aqueous samples for PFOS concentration verification were collected before test initiation (day 0) and termination (day 42). Analytical samples were also collected during test solution renewals: out-water on days 7, 14, 21, 28 and 35; and in-water on day 21. The author- reported 42-day reproductive EC_{10} was 0.7 mg/L PFOS. The EPA's independently-calculated models for EC_{10} estimation were similar; however, the survival model was the most robust. The EPA's independently-calculated EC_{10}s for the other 2 endpoints (the growth as dry weight and reproduction as neonates per female) were different from the author-reported values of 0.9 and 0.7 mg/L, respectively. The study authors were not able to calculate an EC_{10} for survival and so was reported to be <4.8 mg/L. However, the EC_{50}s for all endpoints were similar

between the author-reported and the EPA's independently-calculated values. Thus, the differences in the EC_{10} values were considered to be a result of the difference in models. Therefore, the EPA's calculated value for the 42-day survival endpoint (EC_{10} = 2.899 mg/L PFOS-K; 1.132 - 4.667, 95% CI) was used to derive the chronic freshwater chronic water column criterion.

C.2.16 Sixteenth Most Sensitive Freshwater Genus for Chronic Toxicity: *Physella* (snail)

Funkhouser (2014) conducted a 44-day renewal test of PFOS (potassium salt, ≥98% purity) with *Physella heterostropha pomilia* as part of a Master's thesis at Texas Tech University, Lubbock, TX. Egg masses from 100 *P. pomilia* adults were collected from Canyon Lake 6, Lubbock Lakes System, Lubbock, TX, in May 2013 and used for testing. Dilution water was moderately hard reconstituted laboratory water (3.0 g $CaSO_4$, 3.0 g $MgSO_4$, 0.2 g KCl, and 4.9 g $NaHCO_3$ added to 50 L deionized water). Photoperiod was 12:12-hours light:dark at an unreported light intensity. PFOS was dissolved in dilution water to prepare the test concentrations. Exposure vessels were 250 mL polypropylene containers containing 200 mL of test solution. The test employed two replicates composed of four egg masses each with an average of 37.25 eggs/egg mass at start, then truncated to just four snails per replicate once snails hatched. The test consisted of seven test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 10, 20, 40, 50, 70, 80, and 90 mg/L. Exposure concentrations were reportedly measured, but concentrations were not provided. Analyses of test solutions were performed using LC-MS/MS. Standards were used as part of the analytical method, but details were not reported. The reporting limit was 0.010 mg/L. Experiments were conducted in incubators set to 25°C, which did not vary more than 1°C during the course of the studies. No other water quality parameters were reported as having been measured in test solutions. Negative control survival was not reported specifically for the test but was reported to

NMED Exhibit 62

be 85-100% across all experiments. The 44-day life-cycle MATC was 14.14 mg/L (from the author-reported NOEC and LOEC, 10 and 20 mg/L, respectively) for mean number of eggs per egg mass. The independently-calculated EC_{10} for the same endpoint was 8.527 (6.170 – 10.88) mg/L. The independent statistical analysis was conducted using data that was estimated (using Web plot digitizer) from the figures presented in the paper. This chronic value was acceptable for quantitative use and was used to derive the freshwater chronic water column criterion.

C.2.17 Seventeenth Most Sensitive Freshwater Genus for Chronic Toxicity: *Ceriodaphnia* (cladoceran)

Krupa et al. (2022) conducted a 6-day chronic toxicity test with the cladoceran, *Ceriodaphnia dubia*, and PFOS-K (perfluorooctanesulfonate potassium salt, > 98% purity, purchased from Sigma-Aldrich). In-house cultures of daphnids were reared according to U.S. EPA (2002) and maintained in 100 mL glass beakers filled with 80 mL of moderately hard reconstituted water (MHRW) prior to testing so that organisms used in the test were less than 24 hours old and were all released within an 8-hour period. The chronic toxicity test was conducted as a three-brood (6-d) static-renewal test according to standard protocol (U.S. EPA 2002). The measured exposure concentrations were < LOD-0.0003, 1.7, 3.5, 7.1, 13, 27, and 48 mg/L PFOS. There were 10 replicates per concentration with one organism per each replicate. The highest test concentration was prepared by dissolving the appropriate mass of PFOS into MHRW water. Once the compound was fully dissolved, the highest concentration was then serially diluted to the other, lower target concentrations. The tests were conducted in 20 mL glass scintillation vials containing 15 mL of test water under a 16:8-hour light:dark cycle in an environmental chamber maintained at 25 ± 1°C without aeration. *C. dubia* were fed daily with 0.45 mL of 1:1 *P. subcapitata* and YCT (yeast-cerophyll-trout chow). Survival and reproduction were recorded each day and neonates and any dead animals were removed. Complete renewal of the test

NMED Exhibit 62

solution and count of survivors and neonates was performed daily. Water quality parameters were measured at every water renewal for both the in-water and out-water and ranged from 6.1 - 12.4 mg/L D.O., 6.91 - 8.02 SU pH and 24.0 - 25.9°C. Water samples collected at test initiation (day 0), before (out-water) and after (in-water) test solution renewals, and at test termination (day 6) were analyzed to verify PFOS concentrations. The author-reported 6-day reproductive EC_{10} was 6.9 mg/L PFOS-K. The independently-calculated 6-day EC_{10} value based on reproduction was 10.69 (5.839 – 15.54) mg/L and was considered acceptable for quantitative use to the chronic freshwater chronic water column criterion.

Kadlec et al. (2024) tested the chronic toxicity of potassium perfluorooctanesulfonate (PFOS-K) on *Ceriodaphnia dubia* for 7 days in a measured, renewal experiment. Similar chronic tests were also performed with *Chironomus dilutus* and *Hyallela azteca*, but this summary is limited to the results of the *C. dubia* tests. Test chemicals were obtained from Sigma, Alfa Aesar, Synquest, and Toronto Research Chemical (purity 96-99%). Test organisms were obtained from in-house cultures maintained following ASTM and EPA protocols. Test water was UV-treated and sand-filtered Lake Superior water was supplemented with Na_2SO_4, NaCl, KCl, $CaCl_2$ x $2H_2O$, and $MgCl_2$ x $6H_2O$. Testing protocols followed species-specific ASTM methodologies (ASTM 2002). Three separate tests were conducted, each with a 0.5x dilution series of measured PFOS concentrations, with ten replicates of each concentration, and one organism per replicate. Test 1 mean concentrations were 0.23 (control), 2.3, 4.4, 8.8, 18, and 38 mg/L. Test 2 mean concentrations were 0.0049 (control), 0.049, 0.090, 0.25, 0.42, 0.92, 1.9, 3.9, 8.0, 17, and 35 mg/L. Test 3 mean concentrations were 0.27 (control), 2.7, 5.9, 11, 23, and 46 mg/L. *C. dubia* neonates (<8-hour) were placed in 1 oz polystyrene cups filled with 15 mL of solution. Dissolved oxygen and pH were measured twice in each exposure per treatment and twice in stock solutions.

Tests chambers were placed in a water bath to maintain a steady temperature under a 16:8 light:dark cycle. Study authors reported average water quality measurements of 24.7°C, 8.6 mg/L DO, 7.8 pH, 52 mg/L as $CaCO_3$ hardness, 41 mg/L as $CaCO_3$ alkalinity, and 145 µmhos/cm conductivity. Testing solutions were renewed daily, and organisms were fed daily with 100 µg/L YCT and algae. Control survival was 96.8% with a mean reproduction of 26.8. EC_{20}s and EC_{50}s for survival and young per surviving female were calculated following methods described in Mount et al. (2016), using custom software written with Intel Visual Fortran Compiler Xe and Winteracter 13.0. The author reported EC_{20}s for young per surviving female for tests 1, 2, and 3 were 10.0, 14.5 and 9.8, respectively. Concentration-response data were reported for these tests, allowing the EPA to independently model concentration-response curves using the dose-response curve package in R. The EPA-calculated EC_{10}s for tests 1, 2, and 3 were 8.371, 9.205, and 6.766 mg/L, respectively, which were determined to be acceptable for quantitative use.

NMED Exhibit 62

Appendix D Acceptable Estuarine/Marine Chronic PFOS Toxicity Studies

D.1 Summary Table of Acceptable Quantitative Estuarine/Marine Chronic PFOS Toxicity Studies

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Chronic Value Endpoint	Author Reported Chronic Value (mg/L)	EPA Calculated Chronic Value (mg/L)	Final Chronic Value (mg/L)[b]	Species Mean Chronic Value (mg/L)	Reference

NMED Exhibit 62

D.2 Detailed PFOS Acute Toxicity Study Summaries and Corresponding Concentration-Response Curves (when calculated for the most sensitive genera)

The purpose of this section was to present detailed study summaries for tests that were considered quantitatively acceptable for estuarine/marine chronic criterion derivation, with summaries grouped and ordered by genus sensitivity. Data for chronic PFOS toxicity were available for three saltwater invertebrate species, representing three genera and three families. Chronic PFOS toxicity data was available for one fish species. The data available fulfilled only four of the eight MDRs, therefore the EPA could not develop a chronic estuarine/marine criterion following the 1985 Guideline methods.

D.2.1 Most Sensitive Estuarine/Marine Genus: *Perna* (mussel)

Liu et al. (2013) evaluated the chronic effects of perfluorooctanesulfonate, potassium salt (PFOS-K, CAS# 2795-39-3, 98% purity, purchased from Sigma-Aldrich) on green mussels, *Perna viridis*) via a 7-day measured, static-renewal study. The mussels were obtained from a local farm in Singapore, and subsequently acclimated to laboratory conditions for seven days before testing. Mussels were kept at a salinity of 25 ppt (artificial seawater) and a temperature of 25ºC. Forty mussels (60-65 mm length) per 50-L polypropylene tank in duplicate were exposed to measured PFOS concentrations of 0 (control), 0.00012, 0.0011, 0.0096, 0.106 and 0.968 mg/L. Mussels were fed a commercial marine micro-alga purchased from Reed Mariculture on renewal days, which occurred every two days, two hours before the solution renewal. PFOS concentrations were verified through water and muscle tissue samples via LC/MS. Weights and lengths were determined on days 0 and 7. A NOEC of 0.0096 mg/L and a LOEC of 0.106 mg/L was determined for the growth condition index resulting in an MATC of 0.03190 mg/L. No LC_{50} value was reported. The EPA's independently-calculated EC_{10} is 0.0033 (0.00330 – 0.00332) mg/L and was acceptable for quantitative use.

NMED Exhibit 62

D.2.2 Second Most Sensitive Estuarine/Marine Genus: *Austrochiltonia* (amphipod)

Sinclair et al. (2022) tested perfluorooctane sulfonic acid (PFOS) on amphipods (*Austrochiltonia subtenuis*) in a 7-day unmeasured, static experiment. PFOS (purity not reported) was purchased from Sigma-Aldrich (Melbourne, VIV, Australia). Test organisms were originally field collected from Deep Creek, Victoria, Australia, but had been maintained in a laboratory culture for over five years at RMIT University in Melbourne, Australia. Organisms were cultured in standard artificial media (SAM) modified from Borgmann (1996) at 21±1°C under a 16:8 light:dark cycle, and they were fed powdered Tetramin fish food and YTC every two days. Two days prior to testing, 14-day old amphipods were selected and held in 2 L glass beakers until test initiation. The 7-day experiment consisted of five controls, one solvent control (methanol 0.25 mL/L), and five nominal PFOS concentrations (0.04, 0.2, 1.0, 5.0, 25 µg/L). Test vessels were 600 mL beakers with 400 mL of test material and a 2x2 cm gauze substrate. Each test vessel included 20 amphipods, and all test media was dissolved in SAM. Seven-day survival was assessed using a series of two-sample Student's t-tests (assuming equal variance) comparing survival in each treatment to its corresponding control. After seven days, PFOS in tissues was measured to calculate bioconcentration factors, and a suite of metabolites were also measured. Based on the results of the t-tests, there was a statistically significant ($p<0.05$) decrease in survival (21% mortality) at the highest concentration compared to its control. Setting the highest concentration 0.025 mg/L as the LOEC and the highest concentration with no adverse effect 0.005 mg/L as the NOEC, the resulting MATC was 0.01118 mg/L, which was determined to be acceptable for quantitative use.

D.2.3 Third Most Sensitive Estuarine/Marine Genus: *Americamysis* (mysid)

Drottar and Krueger (2000h) reported the results of a life-cycle, 35-day flow-through, measured test of PFOS-K (potassium salt, 90.49% purity) with *Americamysis bahia* (formerly

NMED Exhibit 62

Mysdiopsis bahia). This good laboratory practice (GLP) test was conducted at the Wildlife International, Ltd. toxicology facility in Easton, MD in June, 1999. The test followed U.S. EPA OPPTS 850.1350, and ASTM Standard E 1191-90 test guidelines. Mysids used for the test were neonates less than 24 hours old at test initiation. The dilution water was filtered natural seawater collected at Indian River Inlet, DE diluted to a salinity of approximately 20 ppt with well water [pH: 8.3 (8.2-8.4); TOC: ≥5.8 mg/L; temperature: 25±2°C]. Photoperiod was 16:8-hours, light:dark with a 30-minute transition period. Light was provided at an intensity of 623-815 lux. A primary stock solution was prepared in dilution water at 89.5 mg/L. It was mixed until all of the test substance was dissolved prior to use. After mixing, the primary stock was proportionally diluted with dilution water to prepare the five additional test concentrations. Exposure vessels were glass beakers with nylon mesh screens on each side placed in 9 L glass aquaria with 5 L of test solution. After mysids reached sexual maturity, they were placed in pairs in glass petri dishes to observe reproduction. The test employed four replicates of fifteen mysids each in six measured test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 0.086, 0.17, 0.34, 0.69, 1.4, and 2.7 mg/L. Mean measured concentrations were < 0.0458 (LOQ), 0.057, 0.12, 0.25, 0.55, 1.3, and 2.6 mg/L, respectively. Analyses of test solutions were performed at Wildlife International Ltd. using HPLC/MS. Measured values ranged from 66 to 96% of nominal. Mortality from test initiation to pairing (day 20) in the 0.057, 0.12, 0.25, 0.55, 1.3, and 2.6 mg/L treatment groups was 8, 25, 18, 17, 32 and 100%, respectively, and mean control mortality was 22%. From pairing until test termination (day 20 to day 35) survival was greater than 90% in the control and all but the 1.3 mg/L treatment, which had 57% survival during that period. The 35-day NOEC (reproduction and growth) was 0.25 mg/L and corresponding LOEC was 0.55 mg/L. The EPA-calculated MATC was 0.3708 mg/L. The EC_{10}

NMED Exhibit 62

could not be calculated at this time given the level of data that was presented in the paper. The chronic value was considered acceptable for quantitative use despite the control survival of 78% because it was only slightly below the 80% survival threshold, and because there were no other deficiencies in the study design.

D.2.4 Fourth Most Sensitive Estuarine/Marine Genus: *Tigriopus* (copepod)

A 20-day renewal, unmeasured full life-cycle test with PFOS (analytical grade) was conducted on the copepod, *Tigriopus japonicus* (non-North American species) by **Han et al. (2015)**. Copepods were cultured and maintained in 0.2 µm filtered artificial seawater adjusted to 32 psu salinity and 25°C under a 12-hour photoperiod. *T. japonicus* were fed with green algae, *Tetraselmis suecica*. PFOS (100 mg/L in MeOH) was concentrated by evaporation and re-dissolved in DMSO to obtain a maximum stock concentration (1,000 mg/L). The PFOS stock was diluted with artificial seawater to obtain four nominal test concentrations (0, 0.25, 0.5 and 1 mg/L PFOS). The final concentration of DMSO in seawater was 0.001% (v/v) or less for each treatment. Ten newly-hatched nauplii (<12 hour post hatch) were allocated to each well of a 12-well tissue culture plate with 4 mL of test solution. There were three replicates per each treatment. Organisms were fed algae during testing and 50% of test media was replaced daily. Over the next 20 days, the development of the copepod's growth from nauplii to copepodite and from nauplii to adults was determined daily based on morphological characteristics. Results were presented as the number of days needed to reach the normal development stages. The highest test concentration (1 mg/L PFOS) significantly increased the amount of time it took the copepods to reach the development stage. Additionally, the authors assessed the reproduction of the copepods by counting the nauplii produced by eight ovigerous females for 10 days in each well exposed to PFOS. However, it was unclear if this was a subsampling of the organisms used in the 20-day developmental test or if an independent assay with adult females. Results are presented

NMED Exhibit 62

graphically as daily nauplii production/individual. There was a statistically significant decrease in production (daily nauplii production/individual) in the 0.25, 0.5 and 1.0 mg/L PFOS concentrations compared to the control. It was decreased by approximately 50% in the highest concentration (1 mg/L). While this endpoint was more sensitive than the growth endpoint, the publication is unclear about the method used for the reproduction test endpoint and whether it was an independently-conducted 10-day test or a subsample of reproducing adults were observed from the 20-day test. The EPA sought but did not receive responses to clarifying questions posed to the authors. Additionally, the authors were asked if control survival for the test was above 80% and if the authors could provide the data. Based on the information presented in the paper without additional information and data provided by the authors to clarify adherence to the EPA data quality objectives and allow independent calculation and verification of point estimates, the developmental stage is considered for quantitative use and the reproductive endpoint for qualitative use. The 20-day MATC (based on time to reach development stage) was 0.7071 mg/L and was acceptable for quantitative use.

D.2.5 Fifth Most Sensitive Estuarine/Marine Genus: *Oryzias* (fish)

Oh et al. (2013) evaluated the 30-day chronic toxicity of PFOS to the Japanese medaka, *Oryzias latipes*, via an unmeasured static exposure. PFOS (98% pure, CAS No. 2795-39-3) was dissolved in filtered seawater with the minimal concentration (< 0.001%) of dimethyl sulfoxide (DMSO) used as a vehicle to prevent cellular damage to the fish. Chemical measurements were not made, and nominal concentrations were used throughout the study. Prior to test initiation, the fish were adapted to a seawater environment by first acclimation in a 50/50 freshwater/saltwater mix, then sequentially increasing the saltwater component by replacing half of the water with the same volume of seawater every day for 15 days. The fish were fed newly-hatched brine shrimp (< 24 hours after hatching) and commercial flake food twice per day. No mortality was observed

NMED Exhibit 62

during acclimation to the seawater over one month. The fish were maintained at 25°C under a constant photoperiod of 16:8-hour light:dark, and water quality was monitored by measuring the pH, D.O., and temperature. Fish from the third generation of *O. latipes* (n = 7/group) that had adapted to seawater for over one month were used in the series of exposure experiments. Fish were exposed for 30 days to one PFOS concentration (1 mg/L) plus a 0.22 µm filtered seawater control and a DMSO carrier solvent control to examine biological effects (specifically, the condition factor, K, a growth endpoint). Test conditions were maintained at an average temperature of 24.77 ℃, pH of 7.87 SU, D.O. of 5.90 mg/L, and salinity of 34.68 PSU with fish fed daily.

The 30-day NOEC condition factor of 1.0 mg/L PFOS was selected as the primary endpoint from this study. Authors also stated, "*In our preliminary study, fish mortality was altered 30 days after PFC (perfluorinated compounds) exposure, suggesting that repeated exposure to PFCs for 30 days at 1 µg/mL causes adverse effect on O. latipes*." The statement about results from the preliminary test is in direct conflict with the results of condition factor in the final test. Few details are provided about the preliminary test. Results of the final test were retained as quantitatively acceptable because they provide chronic estuarine/marine data that are limited.

NMED Exhibit 62

Appendix E Acceptable Freshwater Plant PFOS Toxicity Studies

E.1 Summary Table of Acceptable Quantitative Freshwater Plant PFOS Toxicity Studies

Species	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Effect	Reported Effect Concentration (mg/L)	Reference
Cyanobacteria, *Microcystis aeruginosa*	S, U	72 hr	PFOS-K 98%	7.4	23	MATC (cell density)	0.3162	Muhammad (2023)
Cyanobacteria, *Microcystis aeruginosa*	S, U	96 hr	PFOS-K 98%	-	25	EC30 (population growth rate)	77.39	Zhang et al. (2023b)
Diatom, *Navicula pelliculosa*	S, M	96 hr	PFOS-K 86.9%	7.5-8.9	24	EC50 (area under growth curve)	252	Sutherland and Krueger (2001)
Green alga, *Chlorella vulgaris*	S, U	96 hr	PFOS-K 95%	-	23	IC50 (cell density)	81.6	Boudreau (2002); Boudreau et al. (2003a)
Green alga, *Chlorella vulgaris*	S, U	96 hr	PFOS-K 98%	-	25	EC20 (population growth rate)	13.42	Zhang et al. (2023b)

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, NR=not reported

[b] The independently-calculated EC_{50} value was 176.0 mg/L as the test substance, or 49.28 mg/L based on the percentage of PFOS-K (active ingredient 28%) in the test substance.

NMED Exhibit 62

E.2 Summary of Plant PFOS Toxicity Studies Considered in the Aquatic Life Criterion Derivation

E.2.1 Cyanobacteria, *Microcystis aeruginosa*

Muhammad (2023) tested perfluorooctane sulfonic acid potassium salt (PFOS-K) on *Microcystis aeruginosa* for seven days in a static, unmeasured experiment. PFOS potassium salt (98% purity) was obtained from Sigma-Aldrich. Algae were obtained from Golder Laboratory, at the State University of New York, USA. Algae were cultured in 500 mL Erlenmeyer flasks containing 200mL of BG11 medium at the Phycology Laboratory of Ahmadu Bello University's Department of Botany in Zaria. Cultures were maintained at 23°C, pH 7.4, under a 16:8 hour light:dark photoperiod at a light intensity of 40 µmol/m^2/s. The BG11 growth medium was sterilized by autoclaving at 121°C 24 hours before use. Cultures were changed and maintained in a manner to insure they were experiencing exponential growth. *M. aeruginosa* in the exponential growth phase were added to test vessels containing test solution at a density of approximately $1.0x10^6$ cells/mL. The experimental design consisted of nominal concentrations of 0 (control), 0.001, 0.01, 0.1, 1 and 10 mg/L PFOS, diluted from a PFOS stock solution prepared in BG-11 medium, with three replicates per treatment level. Cell density was measured on days 1, 3, and 7. Cellular pigment content was measured on days 1 and 7, biochemical composition, antioxidant enzyme composition, and microcystin analysis was measured on day 7. One-way ANOVA and means comparisons tests were used to assess significant differences ($p<0.05$) between treatments, and repeated measures ANOVA was used to assess significant differences between sampling dates. All analyses were conducted using the R statistical analysis program v3.63. By day three, cell density in the 1 mg/L treatment were significantly lower than in controls, and by day seven, cell density in the 0.1 mg/L treatment were significantly lower than in controls. Chlorophyll *a* also decreased with increasing PFOS concentrations, and biochemical and

NMED Exhibit 62

enzymatic endpoints also differed among PFOS treatment concentrations. The author-reported 72 hour NOEC and LOEC for cell density were 0.1 and 1 mg/L, and the resulting MATC of 0.3162 mg/L was determined to be acceptable for quantitative use.

Zhang et al. (2023b) tested perfluorooctane sulfonic acid potassium salt (PFOS-K) on *Microcystis aeruginosa* for 12 days in a static, unmeasured experiment. PFOS potassium salt (98% purity) was purchased from Sigma-Aldrich (St. Louis, USA). Algae were obtained from the Freshwater Algae Culture Collection at the Institute of Hydrobiology in Wuhan, China. Algae were cultured in Erlenmeyer flasks within BG-11 media in an illumination incubator at 25±1°C on a 12:12 hour light-dark cycle at a light intensity of 4,000±50 lux. *M. aeruginosa* in the exponential growth phase were added to 100 mL Erlenmeyer flasks containing test solution at a density of approximately $1.0x10^5$ cells/mL. The experimental design consisted of nominal concentrations of 0 (solvent control), 0.01, 1, 20, 50, 100, 250 and 500 mg/L PFOS, diluted from a PFOS stock solution prepared in BG-11 medium and containing 0.05% formaldehyde as a solvent, with three replicates per treatment. Testing methods followed OECD guidelines with modifications (OECD 2006). Algal cell density was measured after 4 and 12 days using a UV-vis spectrophotometer. Algal cell densities were used to calculate growth inhibition at all concentrations relative to controls, and effect concentrations (ECs) were calculated using nonlinear regression modeling. Chlorophyll *a* and optical quantum yield were also measured after 4 and 12 days. ANOVA followed by Tukey's multiple comparison test was used to identify significant ($p<0.05$) differences between treatments and controls, using GraphPad Prism v8.0. EC_{20}s were calculated using a four-parameter nonlinear regression model in GraphPad Prism v8.0. A 96-hour EC_{20} was not reported, so the 96-hour EC_{30} for growth inhibition of 77.39 mg/L was determined to be acceptable for quantitative use.

NMED Exhibit 62

E.2.2 Diatom, *Navicula pelliculosa*

Sutherland and Krueger (2001) conducted a 96-hour static acute algal growth inhibition test on PFOS (potassium salt, 86.9% purity) with the freshwater diatom, *Navicula pelliculosa*. The good laboratory practice (GLP) test was conducted at the Wildlife International, Ltd. in Easton, Maryland in February-March, 2000. The test followed U.S. EPA (1996a) and ASTM (1990). The freshwater diatom was provided from in-house cultures that had been actively growing in the culture medium for at least two weeks. The test media was prepared by adding the stock nutrient solution to purified well water according to ASTM 1218 and adjusting pH to 7.5. Seven measured concentrations (0, 62.3, 83.2, 111, 150, 206, 266, 335 mg/L PFOS) were tested from one negative control and six nominal concentrations: 61.5, 81.3, 110, 147, 198, 264 and 347 mg/L based on PSOF-K purity. Solutions were stirred for approximately 24 hours before testing. Exposures were conducted in 250 mL plastic Erlenmeyer flasks containing 100 mL solution and plugged with foam stoppers. Each flask contained $1x10^4$ cells/mL and each test concentration had three replicates. Flasks were incubated in environmental chambers at 24±2°C under constant illumination (4,300 lux) and shaken continuously at ~100 rpm. pH in the test solutions ranged from 7.5-8.9 over the exposure period. Samples were collected daily to determine cell density and to calculate area under the curve and growth rates. The cell density of the control replicates increased by greater than two orders of magnitude during the test. The 96-hour EC_{50}, based on area under the growth curve, was 252 mg/L PFOS (NOEC<62.3 mg/L). The plant value was acceptable for quantitative use.

E.2.3 Green alga, *Chlorella vulgaris*

Boudreau (2002) performed a 96-hour static acute algal growth inhibition test on PFOS (potassium salt, 95% purity) with *Chlorella vulgaris* as part of a Master's thesis at the University of Guelph, Ontario, Canada. The same information was subsequently published in the open

NMED Exhibit 62

literature as **Boudreau et al. (2003a)**. The acute algal growth inhibition tests followed protocols found in ASTM (1999b) and Geis et al. (2000). All treatment concentrations were based on the PFOS anion (without K) and solutions were prepared in laboratory-grade distilled water. *C. vulgaris* (UTCC 266 strain) were obtained as slants from the University of Toronto Culture Collection (UTCC; Toronto, Canada). Toxicity testing consisted of initial range-finder tests (0, 28, 56, 113, 225, and 450 mg/L) followed by at least two definitive tests (0, 12.5, 25, 50, 100, 200, and 400 mg/L). Tests were conducted in 20 mL solution in 60 x 15 mm polyethylene disposable petri dishes. Each dish contained $1.5x10^4$ cells/mL and each test concentration had four replicates. Tests were continuously illuminated with cool-white fluorescent light between 3,800 and 4,200 lux and incubated at 23±1°C. Each dish was manually shaken twice a day during testing. Toxicity test endpoints included cell density and chlorophyll *a* content. The most sensitive endpoint, cell density, had a reported NOEC of 8.2 mg/L and an IC_{50} of 81.6 mg/L. The IC_{50} value was considered quantitatively acceptable for use.

Zhang et al. (2023b) tested perfluorooctane sulfonic acid potassium salt (PFOS-K) on *Chlorella vulgaris* for 12 days in a static, unmeasured experiment. PFOS potassium salt (98% purity) was purchased from Sigma-Aldrich (St. Louis, USA). Algae were obtained from the Freshwater Algae Culture Collection at the Institute of Hydrobiology in Wuhan, China. Algae were cultured in Erlenmeyer flasks within BG-11 media in an illumination incubator at 25±1°C on a 12:12 hour light-dark cycle at a light intensity of 4,000±50 lux. *C. vulgaris* in the exponential growth phase were added to 100 mL Erlenmeyer flasks containing test solution at a density of approximately $1.0x10^5$ cells/mL. The experimental design consisted of nominal concentrations of 0 (solvent control), 0.01, 1, 20, 50, 100, 250 and 500 mg/L PFOS, diluted from a PFOS stock solution prepared in BG-11 medium and containing 0.05% formaldehyde as a

NMED Exhibit 62

solvent, with three replicates per treatment. Testing methods followed OECD guidelines with modifications (OECD 2006). Algal cell density was measured after 4 and 12 days using a UV-vis spectrophotometer. Algal cell densities were used to calculate growth inhibition at all concentrations relative to controls, and EC_{50}s were calculated using nonlinear regression modeling. Chlorophyll *a* and optical quantum yield were also measured after 4 and 12 days. ANOVA followed by Tukey's multiple comparison test was used to identify significant ($p<0.05$) differences between treatments and controls, using GraphPad Prism v8.0. Effect concentrations (ECs) were calculated using a four-parameter nonlinear regression model in GraphPad Prism v8.0. The 96-hour EC_{20} for growth inhibition was 13.42 mg/L, and was determined to be acceptable for quantitative use.

E.2.4 Green alga, *Raphidocelis subcapitata*

3M Company (2000) provided the results of a 96-hour toxicity test completed in 1991 with the green alga, *Raphidocelis subcapitata* (formerly *Selenastrum capricornutum*), and PFOS-K (perfluorooctancesulfonate potassium salt, CAS # 2795-39-3) in a formulated mixture with diethylene glycol butyl ether and water (mixed product FM-3820, with 24-28% PFOS-K). Based on this purity the author made calculations to adjust test concentrations using 28% active ingredient, but the presence of diethylene glycol could also contribute to toxicity. The toxicity test followed OECD test guidelines with five test concentrations and control in a static unmeasured exposure. A stock culture of the alga was obtained from the Culture Collection of Algae at the University of Texas at Austin. Alga were transferred to 250 mL flasks with an initial density of $1x10^4$ cells/mL and 100 mL of test solution. There were three replicates for each of the five nominal test concentrations (62.5, 125, 250, 500 and 1,000 mg/L) and control. Synthetic nutrient medium was used as the dilution media for all test treatments. Alga were grown at 23°C and continuously shaken. The author-reported EC_{50}, based on average specific growth rate, was

NMED Exhibit 62

255 mg/L as the test substance, or 71 mg/L based on the percentage of PFOS-K (active ingredient 28%) in the test substance. The independently-calculated EC_{50} value was 176.0 mg/L as the test substance, or 49.28 mg/L based on the percentage of PFOS-K (active ingredient 28%) in the test substance. The plant value was acceptable for quantitative use.

3M Company (2000) provides the results of four separate toxicity tests completed in 1981 with the green alga, *Raphidocelis subcapitata* (formerly *Selenastrum capricornutum*), and PFOS-K (perfluorooctancesulfonate potassium salt, CAS # 2795-39-3, unknown purity). The toxicity tests followed a protocol modified from OECD (1979). There were four separate exposure regimes: 1) four day exposure + 10 day recovery period; 2) seven day exposure + seven day recovery period; 3) 10 day exposure + four day recovery period; and 4) 14 day continuous exposure. A bacteria-free culture of the alga was obtained from the U.S. EPA (Corvallis, OR) and stored in the dark until testing. Seven-day old stock cultures with an initial density of $1x10^4$ cells/mL were placed in 250 mL flasks with 50 mL of test solution. There were three replicates for each of the six nominal test concentrations (26, 40, 61, 93, 145 and 225 mg/L) and control. Nutrient medium was used as the dilution media for all test treatments and test solutions were not renewed during the exposure. Alga were grown at 23°C and continuously shaken at 100 rpm. The author-reported EC_{50}, based on cell counts, was 82, 99, 98, and 95 mg/L, for the 4-, 7-, 10- and 14-day exposures, respectively. However, it should be noted that the authors do not specify if the EC_{50}s were determined after the exposure period or the post-observation period. The independently-calculated EC_{50} values were 77.19, 76.68, 83.92, 76.78 mg/L and are acceptable for quantitative use.

Drottar and Krueger (2000b) conducted a 96-hour static acute algal growth inhibition test on PFOS (potassium salt, 90.49% purity) with the freshwater alga, *Raphidocelis subcapitata*

NMED Exhibit 62

(formerly *Selenastrum capricornutum*). The good laboratory practice (GLP) test was conducted at the Wildlife International, Ltd. in Easton, Maryland in April, 1999. The test followed ASTM (1990); OECD (1984); U.S. EPA (1996a) methodologies. The green alga was originally obtained from the culture collection at University of Texas at Austin (or another supplier) and maintained at Wildlife International Ltd. for a minimum of two weeks in culture medium. Algae used in tests were in exponential growth phase. The test media was prepared by adding the stock nutrient solution to purified well water according to ASTM 1218 and adjusting pH to 7.5. Seven measured concentrations (< 0.115, 5.5, 11, 21, 44, 86, 179 mg/L PFOS) were tested from a negative control and six nominal concentrations: 5.7, 11, 23, 46, 91, 183 mg/L based on PFOS-K purity. Test concentrations were measured at test initiation, at 72 hours, and at test termination by HPLC-MS with a mean recovery of 99.1%. Solutions were stirred for approximately 24 hours before testing. Exposures were conducted in 250 mL polycarbonate flasks containing 100 mL solution and plugged with foam stoppers. Each flask contained $1x10^4$ cells/mL and each test concentration had three replicates. Flasks were incubated in environmental chambers at 24±2°C under constant illumination (4,300 lux) and shaken continuously at ~100 rpm. The pH in test solutions ranged from 7.4-8.4 over the exposure period. Samples were collected daily to determine cell density and to calculate area under the curve and growth rates. The 96-hour EC_{50}, based on cell density and area under the growth curve, was 71 mg/L PFOS (NOEC=44 mg/L). The plant value was acceptable for quantitative use.

Boudreau (2002) performed a 96-hour static acute algal growth inhibition test on PFOS (potassium salt, 95% purity) with *Raphidocelis subcapitata* (formerly *Pseudokirchneriella subcapitata*). The study was part of a Master's thesis at the University of Guelph, Ontario, Canada and subsequently published in the open literature as **Boudreau et al. (2003a)**. The acute

NMED Exhibit 62

algal growth inhibition tests followed protocols found in ASTM (1999b); Geis et al. (2000) and Geis et al. (2000). All treatment concentrations were based on the PFOS anion (without K) and solutions were prepared in laboratory-grade distilled water. *R. subcapitata* (UTCC 37 strain) were obtained as slants from the University of Toronto Culture Collection (UTCC; Toronto, Canada). Toxicity testing consisted of initial range-finder tests (0, 28, 56, 113, 225, and 450 mg/L) followed by at least two definitive tests (0, 12.5, 25, 50, 100, 200, and 400 mg/L). Tests were conducted in 20 mL solutions in 60 x 15 mm polyethylene disposable petri dishes. Each dish contained $1.5x10^4$ cells/mL and each test concentration had four replicates. Tests were continuously illuminated with cool-white fluorescent light between 3,800 and 4,200 lux and incubated at 23±1°C. Each dish was manually shaken twice a day during testing. Toxicity test endpoints included cell density and chlorophyll *a* content. The reported NOEC and IC_{50} based on most sensitive endpoint, cell density, were 5.3 mg/L and 48.2 mg/L. The IC_{50} from the study was acceptable for quantitative use.

E.2.5 Green alga, *Scenedesmus quadricauda*

Yang et al. (2014) conducted a 96-hour static, measured test on the growth effects of PFOS (potassium salt, CAS # 2795-39-3, 99% purity) with the green alga, *Scenedesmus quadricauda*. Algae were obtained from in-house cultures from the Chinese Research Academy of Environmental Sciences. The algae used for testing were inoculated at a cell density equal to $2.0x10^4$ cells/mL in 50 mL beakers. PFOS was dissolved in deionized water and DMSO (amount not provided) and then diluted with M4 medium. Alga were exposed to 0 (solvent control), 50.00, 65.00, 84.50, 109.85, 142.81 and 185.65 mg/L PFOS. Each treatment was replicated three times. While the text implied the exposures were static, the supplemental information provided the measured test concentrations in the highest and lowest test treatments both before and after renewal. Measured concentrations ranged from 42.56 mg/L (before renewal) to 49.78 mg/L

NMED Exhibit 62

(after renewal) in the lowest treatment, and from 165.61 (before renewal) to 183.90 mg/L (after renewal) in the highest treatment. The experiments were conducted at 22±2°C with a 12:12-hour light:dark cycle. The initial pH of the test solution was 7.0±0.5, total hardness was 190±0.1 mg/L as $CaCO_3$, and total organic carbon was 0.02 mg/L. Algae concentrations in the beakers were measured daily with a microscope. The 96-hour EC_{50} (based on growth inhibition) was 89.34 mg/L and was acceptable for quantitative use.

E.2.6 Duckweed, *Lemna* sp.

Desjardins et al. (2001b) performed a static, measured 7-day growth inhibition study on the duckweed *Lemna gibba* with PFOS-K (perfluorooctanesulfonate potassium salt, 86.9% purity from 3M Corporation). The test protocol from U.S. EPA, OPPTS Number 850.4400 was followed. Duckweed was cultured and tested at Wildlife International Ltd. in 20X AAP medium and were actively growing for at least two weeks prior to testing. The pH of the medium was adjusted to pH 7.5 with HCl and filtered to sterilize before use. Test chambers were covered 250 mL plastic beakers with 100 mL of culture medium or test concentration and held at 25°C under continuous warm-white lighting with a target intensity of 5,000 lux. Fronds of duckweed were exposed to six test concentrations and a control with three replicates for each treatment. PFOS concentrations in the test medium were measured on day 0, 3, 5 and 7 with mean reported concentrations of <4.39 (LOQ), 7.74, 15.1, 31.9, 62.5, 147 and 230 mg/L PFOS active ingredient. Growth was defined as an increase in the total number of fronds in each replicate and measured by direct count on day 3, 5 and 7. Frond numbers on day seven in the 147 and 230 mg/L test treatments were inhibited by 65 and 81% as compared to the control. The reported 5-day IC_{10} based on frond number was 30.7 mg/L PFOS. The independently-calculated 5-day IC_{10} value was 18.06 mg/L and was acceptable for quantitative use.

NMED Exhibit 62

Wu et al. (2023) tested perfluorooctane sulfonate (PFOS) on duckweed, *Lemna minor*, for 96 hours in a static, measured experiment. PFOS (≥95.0% purity) was obtained from Dr. Ehrenstorfer GmbH (Augsburg, Germany). DMSO solvent (≥ 99.9% purity) was obtained from Merck (Germany). Duckweed was obtained from in house cultures that had been grown in a modified Swedish Standards Institute (SIS) medium. Duckweed cultures were housed in 150 mm petri dishes with 100 mL SIS medium that was changed every two weeks. SIS medium pH was adjusted to 6.5 by using NaOH or HCl. Plants were cultured at 25±1°C and 60% humidity under a 12:12 light dark cycle at 2,000 lux. Duckweed was precultured for 1 week in clean SIS media for seven days prior to testing. Duckweed experiments were conducted in 6-well polypropylene plates to avoid PFOS sorption to container walls. Each replicate well contained 10mL of test material and two colonies approximately the same size of a 3-frond *L. minor*. Nominal test concentrations were 0 (control), 0.001, 0.1, and 10 mg/L PFOS. All test chambers included DMSO solvent, and each treatment had three duplicates. PFOS concentrations measured on day 0 were 1.00±0.02, 90.0±0.73, and 9,859±2.83 µg/L. PFOS in solvent controls were not reported for day 0 but was below detection levels when measured after 96 hours. The number of fronds in each treatment well were counted after 48 and 96 hours. In addition, Fourier-transform infrared spectroscopy (FTIR) was performed on a subset of fronds from each treatment at the end of the 96-hour exposure to examine responses to PFOS at the biochemical level. Statistically significant ($p<0.05$) differences between treatment groups were assessed with one-way ANOVA followed by Dunnett's tests using SPSS Statistics 26. No statistically significant differences in frond number were observed. However, FTIR analysis revealed structural and functional alterations in response to PFOA at the biochemical level. The reported NOEC of 9.859 mg/L for population growth rate was determined to be acceptable for quantitative use.

NMED Exhibit 62

E.2.7 Watermilfoil, *Myriophyllum* sp.

Hanson et al. (2005) conducted a 42-day toxicity study of PFOS (potassium salt, purity not provided) with two species of submergent watermilfoils, *Myriophyllum spicatum* and *M. sibiricum*. The study was conducted in 12,000 L outdoor microcosms at the University of Guelph Microcosm Facility located in Ontario, Canada. Each microcosm was below ground and was flush with the surface. Plastic trays filled with sediment (1:1:1 mixture of sand, loam and organic matter, mostly manure) were placed in the bottom of each microcosm. The total carbon content of the sediment was 16.3%. Ten apical shoots, 5 cm in length, from in-house cultures using the same sediment were transferred to each microcosm, with three separate microcosms used for each treatment (0, 0.3, 10 and 30 mg/L). Endpoints of toxicity that were monitored on days 1, 14, 28 and 42 of the study included growth in plant length, root number, root length, longest root, node number, wet mass, dry mass, and chlorophyll *a* and *b* content. PFOS treatments were dissolved in the same water (well water) used to supply the microcosms. Measured concentrations in the microcosms were reported in a companion publication (Boudreau et al. 2003b). Results from the companion paper showed that measured concentrations remained similar to nominal concentrations throughout the entire exposure period and did not change appreciably over the course of the study. Water quality (i.e., pH, temperature, D.O., hardness, and alkalinity) and light levels were measured regularly, but were not reported. *M. sibiricum* was more sensitive to PFOS than *M. spicatum*. The 42-day EC_{10} (based on wet weight) was 0.6 mg/L for *M. sibiricum* and 3.5 mg/L for *M. spicatum*. The plant values were acceptable for quantitative use.

Appendix F Acceptable Estuarine/Marine Plant PFOS Toxicity Studies

F.1 Summary Table of Acceptable Quantitative Estuarine/Marine Plant PFOS Toxicity Studies

Species	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Effect	Reported Effect Concentration (mg/L)	Reference
Green alga, *Chlorella sp.*	S, U	96 hr	PFOS >98%	-	23	30[c]	EC50 (population abundance)	77.62	Mao (2023)

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, NR=not reported

[b] Salinity of Erdschreiber's medium

NMED Exhibit 62

F.2 Summary of Plant PFOS Toxicity Studies Considered in the Aquatic Life Criterion Derivation

F.2.1 Green alga, *Chlorella* sp.

Mao (2023) tested perfluorooctane sulfonate (PFOS) on an estuarine/marine *Chlorella sp.* for seven days in a static, unmeasured experiment. PFOS (>98% purity) was obtained from Tokyo Chemical Industry Co. Ltd. Algae were obtained from the Freshwater Algae Culture Collection at the Institute of Hydrobiology in Wuhan, China. Algae were obtained from the Algae Culture Collection at the Institute of Hydrobiology in Wuhan, China. Algae were cultured in Erdschreiber medium within a conical flask inside an illumination incubator at 23±1°C under a 12:12 light:dark cycle at 5,000 lux. Algae were shaken three times per day to prevent sticking to the sides of the flask, and inoculated once every two weeks to maintain optimal growth. *Chlorella sp.* in the exponential growth phase were added to test vessels containing test solution at a density of approximately $5.0x10^4$ cells/mL. The experimental design consisted of nominal concentrations of 0 (control), 5, 10, 20, 40, 80, and 160 mg/L PFOS. Testing protocols followed OECD guidelines, and all experiments were performed in triplicate. Statistical analysis included one-way ANOVA, using SPSS version 26 software. Algal cell density and size were measured daily, and algal growth inhibition was calculated using the equation provided in the OECD guidelines. Chlorophyll *a*, maximum quantal yield, cell membrane integrity, esterase activity relative to control, relative electron transfer rate, and reactive oxygen species were reported after 1, 3, 5, and 7 days, respectively. Algae exhibited maximum growth at 10 mg/L, but growth significantly declined at 40 mg/L and higher concentrations. Increasing PFOS concentrations also inhibited chlorophyll *a*, and increased oxidative stress. The 96-hour EC_{50} for algal growth inhibition was 77.62 mg/L, and was determined to be acceptable for quantitative use.

Black spotted frog, *Pelophylax nigromaculatus*	R, M	21 d	PFOS-K >98%	6.5	20	LOEC (gene expression)	-	0.00121	Non-apical endpoints	Liu et al. (2023b)
Black spotted frog (adult), *Pelophylax nigromaculatus*	R, M	21 d	PFOS ≥98%	6.5	20	LOEC (gene expression)	-	0.01114	Non-apical endpoint	Shi et al. (2023)
Tiger salamander (larva, 46 hr), *Ambystoma tigrinum*	R, M	30 d	PFOS ≥98%	-	20	NOEC (growth, survival)		0.6213	Lack of dose response	Flynn et al. (2022)

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

[b] Chemical concentrations made in a side-test representative of exposure and verified stability of concentrations of PFOS in the range of concentrations tested under similar conditions. Daily renewal of test solutions.

[c] Water concentrations were not measured, but PFOS concentrations were measured in the liver.

NMED Exhibit 62

[d] 36 days corresponds to the first of ten generations, the one with the most consistent negative response. The value at 36 days is 1/10 of the duration of this year-long 10-generation study.

[e] Reported in moles converted to gram based on a molecular weight of 500.13 g/mol (PFOS); 538.22 g/mol (PFOS-K); 629.4 g/mol (PFOS-TEA); 522.111 g/mol (PFOS-Na).

NMED Exhibit 62

Appendix H Other Estuarine/Marine PFOS Toxicity Studies

H.1 Summary Table of Acceptable Qualitative Estuarine/Marine PFOS Toxicity Studies

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Effect	Chronic Limits (NOEC-LOEC) (mg/L)	Reported Effect Conc. (mg/L)	Deficiencies	Reference
Bacterium, *Vibrio fischeri*	S, M	15 min	PFOS-K 98%	-	18	-	EC50 (bioluminescence inhibition)	-	>500	Duration too short for a plant test, missing some exposure details, non-apical endpoint	Rosal et al. (2010)
Cyanobacterium, *Anabaena sp.*	S, M	24 hr	PFOS-K 98%	-	28	-	EC50 (bioluminescence inhibition)	-	143.27	Duration too short for a plant test, missing some exposure details, non-apical endpoint	Rosal et al. (2010)
Dinoflagellate, *Pyrocystis lunula*	S, M	24 hr	PFOS-K 98%	-	19	-	EC50 (bioluminescence inhibition)	-	4.9	Duration too short for a plant test	Hayman et al. (2021)
Dinoflagellate, *Symbiodiniaceae*	R, M	7 d	L-PFOS Unreported	-	25	-	NOEC (population abundance)	0.0001->0.0001	0.0001	Only one exposure concentration	Bednarz et al. (2022)
Dinoflagellate, *Symbiodiniaceae*	R, M	14 d	L-PFOS Unreported	-	25	-	LOEC (population abundance)	<0.0001-0.0001	0.0001	Only one exposure concentration	Bednarz et al. (2022)
Dinoflagellate, *Symbiodiniaceae*	R, M	7 d	L-PFOS Unreported	-	32	-	NOEC (population abundance)	0.0001->0.0001	0.0001	Only one exposure concentration	Bednarz et al. (2022)
Dinoflagellate, *Symbiodiniaceae*	R, M	14 d	L-PFOS Unreported	-	32	-	LOEC (population abundance)	<0.0001-0.0001	0.0001	Only one exposure concentration	Bednarz et al. (2022)
Dinoflagellate, *Symbiodiniaceae*	R, M	28 d	L-PFOS Unreported	-	32	-	NOEC (population abundance)	0.0001->0.0001	0.0001	Only one exposure concentration	Bednarz et al. (2022)
Golden brown alga, *Isochrysis galbana*	S, U	72 hr	PFOS 98%	-	20	-	EC50 (growth inhibition)	-	37.5	Duration too short for a plant test	Mhadhbi et al. (2012)
Alga, *Ceratoneis closterium*	S, U	72 hr	PFOS-K Unknown	-	-	33	NOEC (growth)	4.16->4.16	4.16	Sediment and other PFAS present in exposure	Simpson et al. (2021)

NMED Exhibit 62

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Effect	Chronic Limits (NOEC-LOEC) (mg/L)	Reported Effect Conc. (mg/L)	Deficiencies	Reference
Diatom, *Skeletonema costatum*	S, M	96 hr	PFOS-K 86.9%	8.0-8.4	20	~30	EC50 (cell density)	-	>3.20	Only one exposure concentration	Desjardins et al. (2001a)
Sandworm (adult), *Perinereis wilsoni*	R, M	7 d	PFOS-K Unreported	8.1	17.1	36	NOEC (survival)	0.000028->0.000028	0.000028	Only one exposure concentration	Sakurai et al. (2017)
Sea urchin (adult), *Glyptocidaris crenularis*	R, U	21 d + 7 d observation	PFOS-K 98%	8.1	13	30	NOEC (mortality)	1.0->1.0	1.0	Not a true ELS test (started with adults); missing exposure details	Ding et al. (2015)
Sea urchin (adult), *Glyptocidaris crenularis*	R, U	21 d + 7 d observation	PFOS-K 98%	8.1	13	30	LOEC (SOD activity)	<0.01-0.01	0.01	Not a true ELS test (started with adults); missing exposure details; atypical endpoint	Ding et al. (2015)
Purple sea urchin (fertilized eggs), *Paracentrotus lividus*	S, U	48 hr	PFOS 98%	-	20	-	EC50 (growth inhibition)	-	20	Duration too short for an acute test	Mhadhbi et al. (2012)
Purple sea urchin (sperm), *Paracentrotus lividus*	S, U	65 min	PFOS Unreported	7.69	22	-	NOEC (reproduction - egg fertilization)	-	0.0005	Duration too short, greater than low value	Munari et al. (2022)
Sea urchin (embryo), *Psammechinus miliaris*	R, U[b] (tissue)	72 hr	PFOS-K ≥98%	8	19	31	EC50 (morphological abnormality)	-	>0.3999[c]	Interpolated endpoint; missing some exposure details	Anselmo et al. (2011)
Sea urchin (embryo), *Psammechinus miliaris*	R, U[b] (tissue)	16 d	PFOS-K ≥98%	8	19	31	NOEC (morphological abnormalities, hatch success, development)	0.3999->0.3999	0.3999[c]	Duration too short for chronic test and too long for acute test	Anselmo et al. (2011)
Sea urchin (larva), *Psammechinus miliaris*	S, U	85 min.	PFOS-K ≥98%	-	19	-	IC50 (cellular efflux pump inhibition)	-	1.399[c]	Duration too short for a chronic test and too long for an acute test, atypical endpoint	Anselmo et al. (2012)
Eastern oyster (33.8mm), *Crassostrea virginica*	S, M	96 hr	PFOS-K 90.49%	7.5-8.1	22	20-21	EC50 (shell deposition)	-	>3.0	Lack of replication; atypical endpoint	Drottar and Krueger (2000i)

NMED Exhibit 62

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Effect	Chronic Limits (NOEC-LOEC) (mg/L)	Reported Effect Conc. (mg/L)	Deficiencies	Reference
Eastern oyster (adult, 70-100 mm), *Crassostrea virginica*	S, U	48 hr	PFOS ≥97%	7.5	24.9	20	LOEC (cellular lysosomal damage)	<3-3	3	Atypical endpoint	Aquilina-Beck et al. (2020)
Mediterranean mussel (6.4 cm), *Mytilus galloprovincials*	R, U	30 d	PFOS Analytical grade	8.1	17.5	34.5	LOEC (increase micronuclei nuclear aberrations in gills cells)	<2-2	2	Atypical endpoint; missing some exposure details	Nalbantlar and Arslan (2017)
Green mussel (adult), *Perna viridis*	R, M	7 d + 7 d observation	PFOS-K 98%	-	25	30	EC50 (integrative genotoxicity)	0.00095-0.0097	0.033	Duration too short for a chronic test and too long for an acute test, atypical endpoint	Liu et al. (2014a)
Green mussel (adult), *Perna viridis*	R, M	7 d	PFOS-K 98%	-	25	25	MATC (CAT and SOD activity)	0.106-0.968	0.3203	Duration too short for a chronic test and too long for an acute test, atypical endpoint	Liu et al. (2014b)
Green mussel (60-65 mm), *Perna viridis*	R, M	7 d	PFOS-K 98%	-	25	25	MATC (relative condition factor)	0.0096-0.106	0.0319	Duration too short for a chronic test and too long for an acute test, atypical endpoint	(Liu et al. 2014c)
Green mussel, *Perna viridis*	R, M	7 d + 7 d observation	PFOS-K 98%	8	25	30	MATC (hemocyte cell viability)	0.0096-0.106	0.0319	Duration too short for a chronic test and too long for an acute test, atypical endpoint	Liu and Gin (2018)
Green mussel, *Perna viridis*	R, U	7 d	PFOS >98%	-	25	3.2	MATC (biochemistry changes)	0.01-0.1	0.0316	Non-apical endpoint	Xu et al. (2022)
White sunset shell (15.0-20.3 mm), *Soletellina alba*	S, M	28 d	PFOS-K Unreported	8	19	30	NOEC (survival)	0.85->0.85	0.85	Other PFAS measured in the sediment and water	Simpson et al. (2021)
Bivalve (8.1-18.9 mm), *Tellina deltoidalis*	S, M	28 d	PFOS-K Unreported	8	19	30	MATC (growth - weight)	0.22-0.28	0.2482	Other PFAS measured in the sediment and water	Simpson et al. (2021)
Smooth cauliflower coral, *Stylophora pistillata*	R, U	7 d	L-PFOS Unreported	-	32	-	NOEC (lipid peroxidation)	0.0001->0.0001	0.0001	Atypical endpoint	Bednarz et al. (2022)

Appendix J Unused PFOS Toxicity Studies

J.1 Summary Table of Unused PFOS Toxicity Studies

Author	Citation	Reason Unused
Arukwe, A. and A.S. Mortensen	2011. Lipid peroxidation and oxidative stress responses of salmon fed a diet containing perfluorooctane sulfonic- or perfluorooctane carboxylic acids. Comp. Biochem. Physiol. Part C 154: 288-295.	Force-fed (oral gavage); only one exposure concentration
Arukwe, A., M.V. Cangialosi, R.J. Letcher, E. Rocha and A.S. Mortensen	2013. Changes in morphometry and association between whole-body fatty acids and steroid hormone profiles in relation to bioaccumulation patterns in salmon larvae exposed to perfluorooctane sulfonic or perfluorooctane carboxylic acids. Aquat. Toxicol. 130-131: 219-230.	Only one exposure concentration
Balbi, T., C. Ciacci, E. Grasselli, A. Smerilli, A. Voci and L. Canesi	2017. Utilization of *Mytilus* digestive gland cells for the in vitro screening of potential metabolic disruptors in aquatic invertebrates. Comp. Biochem. Physiol. Part C. 191: 26-35.	In vitro (excised cells)
Bilbao, E., D. Raingeard, O. Diaz de Cerio, M. Ortiz-Zarragoitia, P. Ruiz, U. Izagirre, A. Orbea, I. Marigómez, M.P. Cajaraville and I. Cancio	2010. Effects of exposure to Prestige-like heavy fuel oil and to perfluorooctane sulfonate on conventional biomarkers and target gene transcription in the thicklip grey mullet *Chelon labrosus*. Aquat. Toxicol. 98: 282-296.	Only one exposure concentration; the number of fish was not reported
Blanc, M., A. Karrman, P. Kukucka, N. Scherbak and S. Keiter	2017. Mixture-specific gene expression in zebrafish (*Danio rerio*) embryos exposed to perfluorooctane sulfonic acid (PFOS), perfluorohexanoic acid (PFHxA) and 3,3',4,4',5-pentachlorobiphenyl (PCB126). Sci. Total Environ. 590: 249-257.	Mixture (PFOS, PFHxA and PCB126)
Blanc, M., J. Ruegg, N. Scherbak and S.H. Keiter	2019. Environmental chemicals differentially affect epigenetic-related mechanisms in the zebrafish liver (zf-l) cell line and in zebrafish embryos. Aquat. Toxicol. 215:105272-9999.	Control absent from test
Chen, J., L. Zheng, L. Tian, N. Wang, L. Lei, Y. Wang, Q. Dong, C. Huang and D. Yang	2018. Chronic PFOS exposure disrupts thyroid structure and function in zebrafish. Bull. Environ. Contam. Toxicol. 101: 75-79.	Only one treatment concentration; severe lack of procedural details
Chen, K., N. Iwasaki, X. Qiu, H. Xu, Y. Takai, K. Tashiro, Y. Shimasaki and Y. Oshima	2020. Adipogenesis of perfluorooctanesulfonate (PFOS) on Japanese medaka (*Oryzias latipes*) embryo using ovo-nanoinjection-mRNA seq analysis. J. Fac. Agric. Kyushu Univ. 65(2): 295-303.	Injected toxicant in ova
Cheng, J., S. Lv, S. Nie, J. Liu, S. Tong, N. Kang, Y. Xiao, Q. Dong, C. Huang and D. Yang	2016. Chronic perfluorooctane sulfonate (PFOS) exposure induces hepatic steatosis in zebrafish. Aquat. Toxicol. 176: 45-52.	Only one exposure concentration; unmeasured chronic exposure
Consoer, D.M.	2017. A mechanistic investigation of perfluoroalkyl acid kinetics in rainbow trout (*Oncorhynchus mykiss*). A dissertation submitted to the faculty of the University of Minnesota.	Injected toxicant; only one exposure concentration
Cui, Y., W. Liu, W. Xie, W. Yu, C. Wang and H. Chen	2015. Investigation of the effects of perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS) on apoptosis and cell cycle in a zebrafish (*Danio rerio*) liver cell line. Int. J. Environ. Res. Public Health 12(12): 15673-15682.	Excised cells (liver cell line)
Dale, K., F. Yadetie, T. Horvli, X. Zhang, H.G. Froysa, O.A. Karlsen and A. Goksoyr	2022. Single PFAS and PFAS mixtures affect nuclear receptor- and oxidative stress-related pathways in precision-cut liver slices of Atlantic cod (*Gadus morhua*). Sci. Total Environ. 814: 1-12.	In vitro; no apical endpoints

NMED Exhibit 62

Author	Citation	Reason Unused
Diaz de Cerio, O., E. Bilbao, M.P. Cajaraville and I. Cancio	2012. Regulation of xenobiotic transporter genes in liver and brain of juvenile thicklip grey mullets (*Chelon labrosus*) after exposure to Prestige-like fuel oil and to perfluorooctane sulfonate. Gene. 498: 50-58.	Only one exposure concentration
Dorts, J., P. Kestemont, P.A. Marchand, W. D'Hollander, M.L. Thezenas, M. Raes and F. Silvestre	2011. Ecotoxicoproteomics in gills of the sentinel fish species, *Cottus gobio*, exposed to perfluorooctane sulfonate (PFOS). Aquat. Toxicol. 103: 1-8.	Only two exposure concentrations, not North American species
Dragojevic, J., P. Maric, J. Loncar, M. Popovic, I. Mihaljevic, and T. Smital	2020. Environmental Contaminants Modulate Transport Activity of Zebrafish Organic Anion Transporters Oat1 and Oat3. Comp. Biochem. Physiol. C Toxicol. Pharmacol.231:8 p.	In vitro; no apical endpoints
Du, J., S. Wang, H. You and Z. Liu	2016b. Effects of ZnO nanoparticles on perfluorooctane sulfonate induced thyroid-disrupting on zebrafish larvae. J. Environ. Sci. 47: 153-164.	Only 72-75% control survival in 14-day test
Du, J., J. Tang, S. Xu, J. Ge, Y. Dong, H. Li and M. Jin	2018. Parental transfer of perfluorooctane sulfonate and ZnO nanoparticles chronic co-exposure and inhibition of growth in F1 offspring. Regul. Toxicol. Pharmacol. 98: 41-49.	Excessive control mortality in the F0 generation
Fang, C., Q. Huang, T. Ye, Y. Chen, L. Liu, M. Kang, Y. Lin, H. Shen and S. Dong	2013. Embryonic exposure to PFOS induces immunosuppression in the fish larvae of marine medaka. Ecotox. Environ. Saf. 92: 104-111.	Excessive control mortality (~60% control survival)
Fernández-Sanjuan, M., M. Faria, S. Lacorte and C. Barata	2013. Bioaccumulation and effects of perfluorinated compounds (PFCs) in zebra mussels (*Dreissena polymorpha*). Environ. Sci. Pollut. Res. 20:2661–2669.	Mixture
Garoche, C., A. Boulahtouf, M. Grimaldi, B. Chiavarina, L. Toporova, M.J. Den Broeder, J. Legler, W. Bourguet and P. Ba	2021. Interspecies differences in activation of peroxisome proliferator-activated receptor gamma by pharmaceutical and environmental chemicals. Environ. Sci. Technol. 55(24): 16489-16501.	In vitro
Gorrochategui, E., S. Lacorte, R. Tucker and F.L. Martin	2016. Perfluoroalkylated substance effects in *Xenopus laevis* A6 kidney epithelial cells determined by ATR-FTIR spectroscopy and chemometric analysis. Chem. Res. Toxicol. 29: 924-932.	The tests were performed on cell cultures obtained from an outside source. Whole organisms were not investigated.
Hagenaars A., I.J. Meyer, D. Herzke, B.G. Pardo, P. Martinez, M. Pabon, W. De Coen and D. Knapen	2011. The search for alternative aqueous film forming foams (AFFF) with a low environmental impact: Physiological and transcriptomic effects of two Forafac® fluorosurfactants in turbot. Aquat. Toxicol. 104: 168-176.	Only one exposure concentration; missing detail (focus is on other chemicals)
Hoff, P.T., W. Van Dongen, E.L. Esmans, R. Blust and W.M. De Coen	2003. Evaluation of the toxicological effects of perfluorooctane sulfonic acid in the common carp (*Cyprinus carpio*). Aquat. Toxicol. 62 (4): 349-359.	Exposure was from a single intra-peritoneal injection
Hoff, P.T., K. Van Campenhout, K. Van de Vijver, A. Covaci, L. Bervoets, L. Moens, G. Huyskens, G. Goemans, C. Belpaire, R. Blust and W. De Coen	2005. Perfluorooctane sulfonic acid and organohalogen pollutants in liver of three freshwater fish species in Flanders (Belgium): relationships with biochemical and organismal effects. Environ. Pollut. 137: 324-333.	Field exposure, but concentrations were not measured so no BAFs could be calculated
Honda, M., A. Muta, T. Akasaka, Y. Inoue, Y. Shimasaki, K. Kanna, N. Okino and Y. Oshima	2014. Identification of perfluorooctane sulfonate binding protein in the plasma of tiger pufferfish *Takifugu rubripes*. Ecotox. Environ. Safety. 104: 409-413.	Injected toxicant; only one exposure concentration
Honda, M., A. Muta, A. Shimazaki, T. Akasaka, M. Yoshikuni, Y. Shimasaki and Y. Oshima	2018. High concentrations of perfluorooctane sulfonate in mucus of tiger puffer fish *Takifugu rubripes*: a laboratory exposure study. Environ. Sci. Pollut. Res. 25: 1551-1558.	Injected toxicant
Huang, T.S., P.A. Olsvik, A. Krovel, H.S. Tung and B.E. Torstensen	2009. Stress-induced expression of protein disulfide isomerase associated 3 (PDIA3) in Atlantic salmon (*Salmo salar* L.). Comp. Biochem. Physiol. Part B Biochem. Mol. Biol. 154(4): 435-442.	In vitro (cultured hepatocytes)

Appendix K EPA Methodology for Fitting Concentration-Response Data and Calculating Effect Concentrations

Toxicity values, including LC_{50} and EC_{10} values, were independently-calculated from the data presented in the toxicity studies meeting the inclusion criteria described above (see Section 2.10) and when adequate concentrations-response data were published in the study or could be obtained from authors. When concentration-response data were not presented in toxicity studies, concentration-response data were requested from study authors to independently calculate toxicity values. In cases where study authors did not respond to the EPA's request for data or were unable to locate concentration-response data, the toxicity values were not independently-calculated by the EPA, and the reported toxicity values were retained for criteria deviation. The EPA also retained author-reported effect concentrations when data availability did not support effect concentration calculation by the EPA. This retention was done to be consistent with use of author-reported toxicity values in previous criteria documents and retain informative toxicity values (that would have otherwise not been used only on the basis of lacking the underlying C-R data). Where concentration-response data were available, they were analyzed using the statistical software program R (version 3.6.2) and the associated dose-response curve (drc) package.

In some cases, the author reported toxicity values were different than the corresponding effect concentrations calculated by the EPA. Overall, the magnitude of such discrepancies were limited and largely occurred for several potential reasons such as: (1) instances where authors were presumed to calculate effect concentrations using replicate level data, but the EPA only had access to treatment mean data; (2) the model selected to fit a particular set of C-R data, and; (3) the software used to fit a model to C-R data and calculate an effect concentration.

NMED Exhibit 62

K.1 Fitting Concentration Response Data in R

Concentration-response data were obtained from quantitatively-acceptable toxicity studies when reported data were available. In many scenarios, toxicity studies report treatment-level mean concentrations and mean organismal responses; however, individual-replicate data may also be reported. When fitting C-R curves, replicate-level data were preferred over treatment-level data, if both types of data were available. Within R, the drc package can fit a variety of mathematical models to each set of C-R data.

K.1.1 Fitting Acute Mortality Data

K.1.1.1 Dichotomous Data

Dichotomous data are binary in nature (e.g., live/dead or 0/1) and are typical of survival experiments. They are usually represented as a proportion survived.

K.1.2 Fitting Chronic Growth, Reproduction, and Survival Data

K.1.2.1 Continuous Data

Continuous data take on any value along the real number line (e.g., biomass).

K.1.2.2 Count Data

Count data take on only integer values (e.g., number of eggs hatched).

K.1.2.3 Dichotomous Data

Dichotomous data are binary in nature (e.g., live/dead or 0/1) and are typical of survival experiments. They are usually represented as a proportion survived.

K.2 Determining Most Robust Model Fit for Each C-R curve

The R drc package was used to fit a variety of models to each individual C-R dataset. A single model was then selected from these candidate models to serve as the representative C-R model. The selected model represented the most statistically-robust model available. To determine the most-statistically-robust model for a C-R dataset, all individual model fits were assessed on a suite of statistical metrics.

NMED Exhibit 62

K.2.1 Selecting Candidate Models

Initially, models were ranked according to the Akaike information criteria (AIC). The AIC provides a measure of the amount of information lost for a given model by balancing goodness of fit with model parsimony. The models with the lowest AIC, relative to other models based on the same data, tend to be optimal. In some instances, however, the model with the lowest AIC possessed a questionable characteristic that suggested said model was not the most appropriate. Rather than selecting a model based solely on the lowest AIC, the initial ranking step was only used to identify a subset of candidate models that were more closely examined before selecting a model fit for each C-R dataset.

K.2.2 Assessment of Candidate Models to Determine the Most Appropriate Model

Candidate models (i.e., models with low AIC scores relative to other models produced for a particular C-R dataset) were further evaluated based on additional statistical metrics to determine a single, statistically robust curve for each quantitatively-acceptable toxicity test. These additional statistical metrics were evaluated relative to the other candidate curve fits produced for each C-R dataset. Of these statistical metrics, residual standard errors, confidence intervals relative to effects concentration estimates, and confidence bands carried the most weight in determining the most appropriate model to be representative of an individual C-R dataset. These additional statistical metrics included:

K.2.2.1 Comparison of residual standard errors

As with AIC, smaller values were desirable. Residual standard errors were judged relative to other models.

K.2.2.2 Width of confidence intervals for EC estimates

Confidence intervals were assessed on standard error relative to estimate and confirming that the intervals were non-negative. Judged in absolute and relative to other models.

NMED Exhibit 62

K.2.2.3 Width of confidence bands around the fitted model

A general visual inspection of the confidence bands for the fitted model. Wide bands in the area of interest were undesirable. Judged in absolute and relative to other models.

K.2.2.4 P-values of parameters estimates and goodness of fit tests

Hypothesis tests of parameter values to determine whether an estimate is significantly different from zero. Goodness of fit tests were used to judge the overall performance of the model fit. Typically, the level of significance was set at 0.05. There may have been occasional instances where the 0.05 criterion may not be met, but there was little recourse for choosing another model. Judged in absolute terms.

K.2.2.5 Residual plots

Residuals were examined for homoscedasticity and biasedness. Judged in absolute and relative to other models.

K.2.2.6 Overly influential observations

Observations were judged based on Cook's distance and leverage. When an observation was deemed overly influential, it was not reasonable to refit the model and exclude any overly influential observations given the limited data available with typical C-R curves. Judged in absolute terms.

K.3 Determining Curve Acceptability for use in Criteria Derivation

The final curve fits selected for each of the quantitatively-acceptable toxicity tests were further evaluated and classified to determine whether the curves were: 1) quantitatively acceptable for use, 2) qualitatively acceptable for use, or 3) unacceptable. To determine curve acceptability for use in deriving an effect concentration, each individual curve was considered based on the statistical metrics described above and assessed visually to compare how the calculated effect concentration aligned with the underlying raw C-R data. Instead of evaluating

NMED Exhibit 62

curves fits relative to other curve fits for the same data (as was previously described to select the most-robust curve for each test), curve fit metrics were used to assign each curve a score:

- **Quantitatively Acceptable Model**. Model performed well on most/all statistical metrics and resultant effect concentrations were typically used in a quantitative manner.
- **Qualitatively Acceptable Model**. Model generally performed well on statistical metrics; however, the model presented some characteristic(s) that called estimates into question. Such models were considered with caution. These problems may have consisted of any number of issues such as a parameter with a high p-value, poor goodness of fit p-value, wide confidence bands for fit or estimate interval, or residuals that indicate model assumptions are not met. Broadly, effect concentrations from models that were deemed qualitatively acceptable were not used numerically in criteria derivation if quantitatively acceptable models for different endpoints or tests from the same publication were available. If quantitatively acceptable models for different endpoints or tests from the same publication were not available, effect concentrations from the qualitatively acceptable model were used numerically in criteria derivation on a case-by-case basis.
- **Unacceptable Model**. Model poorly fit the data. These models were not used for criteria derivation.

No single statistical metric can determine a given model's validity or appropriateness. Metrics should be considered as a whole. As such, there is a slightly subjective component to these evaluations. That said, this assessment scheme was developed to aid in evaluating models as to their quantitative or qualitative attributes in a transparent and relatively repeatable manner.

NMED Exhibit 62

Appendix L Derivation of Acute Protective PFOS Benchmarks for Estuarine/Marine Waters through a New Approach Method (NAM): WebICE

The 1985 *Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses* (U.S. EPA 1985) recommend that data for a minimum of eight families be available to fulfill taxonomic minimum data requirements (MDRs) to calculate criteria values, including to calculate estuarine/marine aquatic life criteria. Acute estuarine/marine test data are currently available for only five of the eight family MDRs (the dataset was missing another family in the Phylum Chordata, a family in a phylum other than Chordata, and any other family); thus, the EPA was not able to derive an acute estuarine/marine criterion element for PFOS based on the 1985 Guidelines MDR specifications (Section 3.2.1.2). However, the EPA was able to develop an acute PFOS protective benchmark for aquatic life using a New Approach Methods (NAMs) process, via the application of Interspecies Correlation Estimation (ICE) models (Raimondo et al. 2010). Although not a criterion based on 1985 Guidelines MDR specifications, because of gaps in available data for several of the taxonomic MDRs listed in the 1985 Guidelines for the derivation of aquatic life criteria, this benchmark represents an aquatic life value derived to be protective of aquatic communities. The ICE model predictions supplement the available test dataset to fulfill the missing MDRs and allow the derivation of an acute estuarine/marine benchmark for aquatic life using procedures consistent with those in the 1985 Guidelines. This is important as it provides an approach by which values that are protective of aquatic life communities can be developed, even when MDRs are not fulfilled by PFOS test data. This approach is consistent with both the 1985 Guidelines "good science" clause, the EPA's interest in providing useful information to states and Tribes regarding protective values for aquatic life, and the EPA's intention to reduce the use of animal testing via

NMED Exhibit 62

application of NAMs (https://www.epa.gov/chemical-research/epa-new-approach-methods-work-plan-reducing-use-animals-chemical-testing).

L.1 Introduction to Web-ICE

ICE models, developed by the EPA's Office of Research and Development, are log-linear regressions of the acute toxicity (EC_{50}/LC_{50}) of two species across a range of chemicals, thus representing the relationship of inherent sensitivity between those species (Raimondo et al. 2010). Each model is derived from an extensive, standardized database of acute toxicity values by pairing each species with every other species for which acceptable toxicity data are available. Once developed, ICE models can be used to predict the sensitivity of an untested taxon (predicted taxa are represented by the y-axis) from the known, measured sensitivity of a surrogate species (represented by the x-axis) (Figure L-1).

ICE models have been developed for a broad range of different chemicals (e.g., metals and other inorganics, pesticides, solvents, and reactive chemicals) and across a wide range of toxicity values. There are approximately 3,400 significant ICE models for aquatic animal and plant species in the most recent version of web-ICE (v3.3, www3.epa.gov/webice, last updated June 2016; (Raimondo et al. 2015).

Models were validated using leave-one-out cross validation, which formed the basis for the analyses of uncertainty and prediction robustness. For this process, each datapoint within the model (representing the relative sensitivity of two species for a particular chemical) is systematically removed, one at a time. The model is then redeveloped with the remaining data (following each removal) and the removed value of the surrogate species is entered into the model. The estimated value for the predicted species is then compared to the measured value for that species (Raimondo et al. 2010; Willming et al. 2016).

NMED Exhibit 62

ICE models have high prediction accuracy when values are derived from models with robust parameters (e.g., mean square error, R^2), that fall within a defined range of acceptability, and with close prediction confidence intervals that facilitate evaluating the fit of the underlying data (Brill et al. 2016; Raimondo et al. 2010; Willming et al. 2016). Results of these analyses provide the basis of the user guidance for selecting ICE predicted toxicity with high confidence (Box 1).

ICE models have undergone extensive peer review and their use has been supported for multiple applications, including direct toxicity estimation for endangered species (NRC 2013) (Willming et al. 2016) and development of Species Sensitivity Distributions (SSDs) (Awkerman et al. 2014; Bejarano et al. 2017; Dyer et al. 2006; Dyer et al. 2008; Raimondo et al. 2010; Raimondo and Barron 2020). The application of ICE-predicted values to develop protective aquatic life values by multiple independent, international groups confirms that values developed from ICE-generated SSDs provide a level of protection that is consistent with using measured laboratory data (Dyer et al. 2008; Feng et al. 2013; Fojut et al. 2012; Palumbo et al. 2012; Wang et al. 2020; Wu et al. 2015; Wu et al. 2016; Zhang et al. 2017). A recent external review of ICE models additionally supports their use in regulatory applications based on the reliability of underlying data, model transparency, statistical robustness, predictive reliability, proof of principle, applicability to probabilistic approaches, and reproducibility of model accuracy by numerous independent research teams (Bejarano and Wheeler 2020).

NMED Exhibit 62

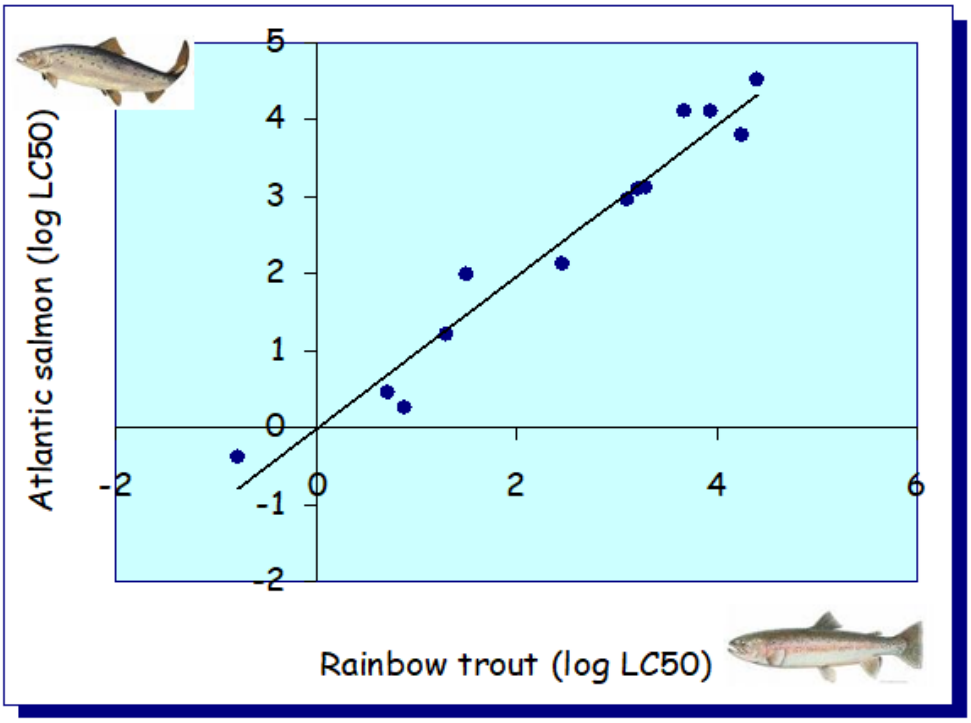

Figure L-1. Example ICE Model for Rainbow Trout (surrogate) and Atlantic Salmon (predicted).
Each model datapoint is a common chemical that was tested in both species to develop a log-linear regression.

Box 1. ICE Model User Guidance Recommended for Listed Species (Willming et al. 2016):

- Close taxonomic distance (within class)
- Low MSE (<~ 0.95)
- High R^2 (>~ 0.6)
- High slope (>~ 0.6)
- Prediction confidence intervals should be used to evaluate the prediction using professional judgement for the application (Raimondo et al. 2024).
- For models between vertebrates and invertebrates, using those with lower MSE or MOA-specific models (not available for PFAS) has been recommended for listed species predictions (Willming et al. 2016).

NMED Exhibit 62

L.2 Application of Web-ICE with PFOS

ICE models are developed using a diversity of compounds (e.g., metals and other inorganics, pesticides, solvents, and reactive chemicals) across a wide range of toxicity values; however, PFAS are not included in web-ICE v3.3 due to the lack of available PFAS toxicity data when web-ICE v3.3 was created. PFAS acute values (typically reported as mg/L) can be greater than those used to develop an ICE model (ICE database toxicity range $1E^{-4}$ to $1E^{8}$ µg/L) such that the input PFAS value of the surrogate would be outside the model domain. In these cases, a user can either enter the value as µg/L and allow the model to extrapolate beyond its range or enter the toxicity as a "scaled" value (i.e., enter and estimate the value as mg/L). The principal assumptions of ICE models are: 1) they represent the relationship of inherent sensitivity between two species, which is conserved across chemicals, mechanisms of action, and ranges of toxicity; and 2) the nature of a contaminant that was tested on the surrogate reflects the nature of the contaminant in the predicted species (e.g., effect concentration (EC_{50}) or lethal concentration (LC_{50}), percentage of active ingredient, technical grade; Raimondo et al. (2010)). While neither of these assumptions are violated by either extrapolating beyond the range of the model or using scaled toxicity data, the uncertainty of using ICE models in either manner had not been thoroughly evaluated. Additionally, since PFAS were not included in the database used to develop web-ICE v3.3, the validation of ICE models to accurately and specifically predict to these compounds has not been previously explored. We address both these topics in the sections below.

L.2.1 Prediction Accuracy of Web-ICE for Scaled Toxicity and Values Beyond the Model Domain

The accuracy of using scaled toxicity data as input into ICE models was evaluated using an analysis with the existing ICE models (v3.3) and as described in detail in Raimondo et al.

NMED Exhibit 62

(2024). Briefly, ICE models containing a minimum of 10 datapoints and spanning at least five orders of magnitude were separated into two subsets: 1) a lower subset that contained all paired chemical data corresponding to values below the 75th percentile of surrogate species values; and 2) an upper subset containing paired chemical data above the 75th percentile of surrogate values. The Raimondo et al. (2024) lower subset was used to develop "truncated" ICE models. The surrogate values in the upper subset were converted to mg/L and entered into the truncated ICE model. The predicted mg/L value was compared to the respective value of the measured predicted species. Prediction accuracy was determined as the fold difference (maximum of the predicted/measured and measured/predicted) between the predicted and the measured value, consistent with previously published evaluations of ICE models (Raimondo et al. 2010; Willming et al. 2016). Accuracy of using scaled toxicity as input into ICE models was compared to overall ICE prediction accuracy as previously reported and prediction accuracy of the respective upper subset data points that were entered into the models as µg/L (i.e., values beyond the model domain). A total of 3,104 datapoints from 398 models were evaluated. A match-paired comparison showed that the average fold differences of toxicity values predicted using scaled toxicity was not significantly different than the respective average fold differences of all cross-validated data points reported in Willming et al. (2016) (Wilcoxon paired rank sum test, V = 42741, p-value 0.11). Additionally, Raimondo et al. (2010) and Willming et al. (2016) showed a consistent and reproducible relationship between the taxonomic distance of the predicted and surrogate species, which was also reproduced using scaled values; the percentage of datapoints predicted using scaled toxicity was within 5-fold of the measured value for over 94% of all validated datapoints for species pairs within the same order, with a reduction in accuracy coinciding with decreasing taxonomic relatedness Raimondo et al. (2024). Comparison of scaled

NMED Exhibit 62

values with those predicted from µg/L values beyond the model domain showed that predicted values varied by a factor of 10 for models with slopes ranging from 0.66 – 1.33. Toxicity values predicted from models with slopes within this range had a median fold difference of 2.4 using mg/L values and 2.8 using µg/L values (Wilcoxon paired rank sum test, V = 1334749, p-value 0.77). These results and a detailed review of ICE model assumptions are provided in Raimondo et al. (2024)[4].

L.2.2 Direct Comparison of Web-ICE and Measured Toxicity Values

Since limited PFOS toxicity test data are available for estuarine/marine species, the ability of ICE models to predict PFOS toxicity was evaluated using direct comparisons of freshwater species sensitivity as reported in the criteria document and predicted by web-ICE. In this comparison, the measured species mean acute values (SMAVs) for PFOS reported in Appendix A.1 and Appendix B.1 were used as values for surrogate species to predict all possible species that also had a measured PFOS SMAV reported. The available SMAVs for PFOS that could be used as ICE surrogate values along with the number of ICE models (i.e., potential predicted species) corresponding to each surrogate are shown in Table L-1.

[4] Use of scaled toxicity values and the use of surrogate toxicity values beyond the bounds of the ICE model that are input as µg/L are two approaches that both make extrapolations beyond the bounds of the underlying data. Actual predictions resulting from the two approaches from the same ICE model begin to deviate from one another the further the slope of the ICE model deviates from 1.0 (which is a primary reason why scaled toxicity data were only employed on ICE models with slopes ranging from 0.66 – 1.33). Overall, use of the scaled approach compared to direct extrapolation results a negligible change in the final estuarine/marine benchmark, primarily because the three of the four most sensitive estuarine/marine GMAVs were based on direct toxicity test results, and secondarily, because only a subset of ICE models required use of scaled toxicity data to account for predicting beyond the bounds of the underlying ICE model. For example, the final acute PFOS estuarine/marine benchmark was 0.55 mg/L (see section L.2.4). Had the values in Table L-4 been predicted using unscaled data that were input as µg/L only (and the model slope requirement of 0.66 -1.33 been retained), the final acute estuarine/marine benchmark would remain unchanged at 0.55 mg/L. Had the values in Table L-4 been predicted using unscaled data input as µg/L only (and the model slope requirement of 0.66 -1.33 was removed), the final acute estuarine/marine benchmark would increase slightly to 0.57 mg/L. While both approaches contain uncertainty, use of the scaled approach resulted in a more protective acute PFOS estuarine/marine benchmark (i.e., CMC = 0.55 mg/L) than an exploratory benchmark that used acute toxicity data estimated through direct extrapolation, with the model slope requirement of 0.66 -1.33 removed (i.e., exploratory CMC = 0.57 mg/L).

NMED Exhibit 62

Table L-1. Surrogate Species Measured Values for PFOS and Corresponding Number of ICE Models for Each Surrogate.

For example, there are 53 species for which *Daphnia magna* can predict toxicity.

Broad Taxon	Species		PFOS SMAV (mg/L)	Number of ICE Models
	Common Name	Scientific		
Amphibian	Bullfrog	*Lithobates catesbeiana* [a]	133.3	9
Amphibian	African clawed frog	*Xenopus laevis*	15.99	2
Crustacean	Mysid	*Americamysis bahia*	4.914	28
Crustacean	Cladoceran	*Daphnia magna*	51.86	53
Fish	Zebrafish	*Danio rerio*	27.86	2 (juvenile models) 6 (embryo models)
Fish	Rainbow trout	*Oncorhynchus mykiss*	7.515	77
Fish	Fathead minnow	*Pimephales promelas*	6.95	74
Mollusc	Fatmucket	*Lampsilis siliquoidea*	16.5	29
Mollusc	Black sandshell	*Ligumia recta*	13.5	1

[a] *Lithobates catesbeianus* was used in web-ICE.

Table L-2 shows direct comparisons for PFOS measured and ICE-predicted values. The regressions for these comparisons are provided in the Appendix L.2.6. Comparisons are limited by the number of measured toxicity values and models available. To be included in this comparison, a measured value was needed for both species in an ICE model pair. For direct comparison of predicted and measured PFOS values, the measured SMAV of the surrogate species is entered into a model for which the measured SMAV for the intended predicted species is also known. The PFOS toxicity predicted by this model is then compared to the measured SMAV for the predicted species as listed in Appendix A.1, Appendix B.1 and Table L-1. This allows both species of an ICE model to serve as either the predicted or surrogate species. The exception to this was in cases involving zebrafish embryos, as web-ICE v3.3 only included models for which zebrafish embryos were used as surrogates. Accuracy of ICE predictions are presented as the "fold-difference" between the measured and the predicted species, such that fold

NMED Exhibit 62

difference is the maximum of the ratio of the predicted LC_{50}/measured LC_{50} or measured LC_{50}/predicted LC_{50}. Analyses of ICE prediction accuracy have shown that ICE models over- and under-estimate toxicity values randomly, i.e., there is no systematic bias associated with the models (Table L-2) (Raimondo et al. 2010; Raimondo et al. 2024). For accuracy assessments, the fold difference provides a simplified metric to easily see how close predictions are to measured values at a glance. A 5-fold difference has been demonstrated to be the average interlaboratory variability of acute aquatic toxicity tests and represents a conservative amount of variance under standardized test conditions for a given life stage (Fairbrother 2008; Raimondo et al. 2010). This inter-test variation can increase significantly where experimental variables differ between tests; however, all ICE models are based on standardized life stages to minimize extraneous variability (Raimondo et al. 2010).

These comparisons are consistent with web-ICE user guidance (Raimondo et al. 2015), previously published reports on ICE model accuracy (Raimondo et al. 2010; Willming et al. 2016), and the above presented uncertainty analysis of using scaled toxicity as model input. ICE models predict with acceptable accuracy for PFOS when invertebrates were used to predict to invertebrate species and vertebrates were used to predict to vertebrate species in these comparisons. Models validated across a wide range of species, chemicals, and toxicity values show an acceptable level of prediction accuracy (>90% values predicted within 5-fold of measured value) when adhering to the model guidance listed in Box 1 (Raimondo et al. 2010; Willming et al. 2016).

The results summarized in Sections L.2.1 and L.2.2 demonstrate that the relationship of inherent sensitivity represented by ICE models is preserved across taxa, chemicals, and range of toxicity values when using robust ICE models. While the current analysis uses freshwater species

NMED Exhibit 62

to predict to estuarine/marine species, previous model validation and uncertainty analyses did not indicate the habitat of the species to be an influential source of ICE model uncertainty (Raimondo et al. 2010; Willming et al. 2016).

NMED Exhibit 62

Table L-2. Comparison of ICE-predicted and measured values of PFOS for species using both scaled values (entered as mg/L) and values potentially beyond the model domain (entered as µg/L).

Measured SMAVs are for the predicted species as listed in Appendix A.1, Appendix B.1 and Table L-1. Footnotes indicate where predictions or models do not meet one or more of the user guidance criteria.

Predicted Species	Surrogate Species	Toxicity Values Potentially Beyond Model Domain				Scaled Toxicity Values			
		Measured SMAV (µg/L)	web-ICE Predicted (µg/L)	95% Confidence Intervals (ug/L)	Fold Difference	Measured SMAV (mg/L)	web-ICE Predicted (mg/L)	Confidence Interval (mg/L)	Fold Difference

[c] Guidance for model mean square error, R^2, and/or slope not met.
[d] Does not meet slope criteria for using scaled toxicity (0.66-1.33).

L.2.3 Prediction of Estuarine/Marine Species Sensitivity to PFOS

A value of PFOS sensitivity was predicted with web-ICE v3.3 for all possible species using all available surrogate species (Table L-1). Predicted values were obtained by entering all available surrogate species into the web-ICE SSD generator, which predicts to all possible species from all available surrogates simultaneously and exports results into an excel spreadsheet. Web-ICE results were generated using both mg/L and µg/L values to evaluate the full set of possible predictions using both units of measure against the model domain, confidence intervals, and model parameters. First, all available models were evaluated based on the parameter (MSE, R^2, slope) guidance in Box 1, which are the same for an ICE species pair regardless of input value (Table L-3). Models that did not meet the parameter criteria in Box 1 were rejected in this first pass. In the next step, values that were predicted using µg/L were evaluated against the model domain and selected for the next tier of evaluation when the surrogate value was within the range of data used to develop the model. If the surrogate value reported as µg/L was beyond the model domain, the mg/L value was evaluated if it was within the model domain and if the model slope was between 0.66-1.33 (Raimondo et al. 2024). Cases in which both units were outside the model domain were not included quantitatively, but the value with the narrowest confidence intervals was included for qualitative considerations. Values (using either µg/L or mg/L input value) were excluded quantitatively from the SMAVs but retained for qualitative consideration if an evaluation of confidence intervals, model parameters, and the model domain indicated the relationship between surrogate and predicted species was not informed by robust underlying data. At this stage, specific predictions should be based on holistic evaluation of all available information provided by the model, confidence interval, and data used to develop the model. Decisions to exclude a prediction from the SMAV are clarified

NMED Exhibit 62

in footnotes. Because the sensitivity of a single species can be predicted by multiple surrogates, we calculated the SMAV where multiple robust models were available for a predicted species. Each predicted species was then assigned to the appropriate saltwater MDRs as defined in the 1985 *Guidelines.*

Saltwater MDRs:

a. Family in the phylum Chordata
b. Family in the phylum Chordata
c. Either the Mysidae or Penaeidae family
d. Family in a phylum other than Arthropoda or Chordata
e. Family in a phylum other than Chordata
f. Family in a phylum other than Chordata
g. Family in a phylum other than Chordata
h. Any other family

The acute sensitivity of estuarine/marine species to PFOS is presented in Table L-4. A total of 36 models representing 19 estuarine/marine species were available in web-ICE to predict the toxicity of PFOS to saltwater species (Table L-3). Of these, 12 models were initially rejected based on model parameters not meeting the guidance in Box 1, reducing the number of predicted species to 17 represented by 24 models. Further evaluation of ICE predictions resulted in 12 SMAVs. The range of sensitivity for the predicted taxa is consistent with the range of sensitivity of freshwater species for this compound.

NMED Exhibit 62

Table L-3. All ICE Models Available in web-ICE v3.3 for Saltwater Predicted Species Based on Surrogates with Measured PFOS.

Model parameters are used to evaluate prediction robustness. Cross-validation success is the percentage of all model data that were predicted within 5-fold of the measured value through leave-one-out cross-validation (Willming et al. 2016). Taxonomic distance describes the relationship between surrogate and predicted species (e.g., 1 = shared genus, 2 = shared family, 3 = shared order, 4 = shared class, 5 = shared phylum, 6 = shared kingdom).

L.2.4 Derivation of Acute Water Quality Benchmark for Estuarine/Marine Water

The web-ICE predicted acute dataset for PFOS contains 15 genera, representing the eight MDR groups that would be necessary for developing an estuarine/marine criterion. The EPA fulfilled these eight MDRs by integrating the acceptable quantitative study data (discussed in Section 3.1.1.2) with data derived using web-ICE to support calculating a protective benchmark. In scenarios where both empirical LC_{50} values and estimated LC_{50} values were available for the same species, only the empirical data were used to derive the species mean acute value. The ranked GMAVs for these combined data along with the MDR met by each GMAV is summarized in Table L-5. From this dataset, an acute benchmark was calculated using procedures consistent with the 1985 Guidelines and with those used for the derivation of freshwater criteria values for PFOS. GMAVs for the four most sensitive genera were within a factor of 1.7 of each other (Table L-6). The estuarine/marine FAV (the 5^{th} percentile of the genus sensitivity distribution) for PFOS is 1.096 mg/L (Table L-6). The FAV is lower than all of the GMAVs for both the tested species and for values derived using web-ICE. The FAV was then divided by two to obtain a concentration yielding a minimal effects acute benchmark. The FAV/2, which is the estuarine/marine acute water column benchmark magnitude, is 0.55 mg/L PFOS (rounded to two significant figures) and is expected to be protective of 95% of estuarine/marine genera potentially exposed to PFOS under short-term conditions of one-hour of duration, if the one-hour average magnitude is not exceeded more than once in three years (Figure L-2). This acute benchmark for estuarine/marine aquatic life is greater than the recommended acute freshwater criterion (0.071 mg/L), suggesting that estuarine/marine species may be less acutely sensitive to PFOS and emphasizing the importance of having a separate benchmark value for the protection of estuarine/marine aquatic life.

NMED Exhibit 62

Table L-5. Ranked Estuarine/Marine Genus Mean Acute Values.

Values in bold were derived from empirical toxicity tests with the species.

MDR Group	Name	Species (lifestage)	SMAV	GMAV	Rank	Percentile

L.2.5 Estuarine Marine/Benchmark Uncertainty

Epistemic uncertainty of individual ICE estimates used for SMAV calculation was quantified through the calculation of corresponding 95% confidence intervals for each ICE estimate. Of the individual models and resultant ICE-estimated LC_{50} values estimates from the available and quantitatively acceptable models (see bolded and underlined values in Table L-4; n =16), the range of individual 95% CIs (i.e., 95% CI range = upper 95% CI – lower 95% CI) as a percent of the corresponding LC_{50} estimate (i.e., = [95% CI range/LC50 estimate]*100) ranged from 92.23% to 530.04%. The ICE model with the lowest 95% CI range relative to the LC_{50} estimate (i.e., 92.23%) employed *Oncorhynchus mykiss* as the predictor species and *Cyprinodon variegatus* as the predicted species. The ICE model with the largest 95% CI range relative to the LC_{50} estimate (i.e., 530.04%) employed *Daphnia magna* as the predictor species and *Fenneropenaeus merguiensis* as the predicted species. Fifteen of the 16 ICE-predicted values in Table L-4 that were used for SMAV calculation had 95% CI ranges that were greater than the corresponding LC_{50} estimate (i.e., 95% CI range was >100% of the LC_{50} estimate). The relatively wide ranging 95% CIs demonstrate the underlying uncertainty in the PFOS estuarine/marine benchmark.

Six of the 15 GMAVs used to derive the acute PFOS estuarine/marine benchmark were based on empirical toxicity tests. The six GMAVs based on empirical data were not evenly distributed across the GSD, with all empirical data falling below the 60^{th} percentile of sensitivity (Table L-2). Also, three of the four most sensitive GMAVs in the GSD (Figure L-2) were based on empirical data and five of the six most sensitive GMAVs were based empirical acute values, meaning final estuarine/benchmark magnitude was primarily based on relatively certain empirical toxicity tests and the inherent uncertainty in the ICE models had little influence on the final acute estuarine/marine benchmark magnitude.

NMED Exhibit 62

The estuarine/marine benchmark appears adequately protective based on the available high quality empirical data (Appendix B.1). The acute PFOS estuarine/marine benchmark (i.e., 0.55 mg/L) is two times lower than the lowest GMAV (i.e., 1.1 mg/L), which was based on empirical data for *Mytilus*. The EPA further evaluated the appropriateness of the estuarine/marine benchmark by comparing it to empirical, but qualitatively acceptable, data for estuarine/marine species. The EPA specifically focused on qualitatively-acceptable estuarine/marine tests reported in Table H.1 that: (1) tested an animal species; (2) exposed test organisms to PFOS for a continuous exposure duration that was reasonably similar to standard acute exposures (e.g., 48 hours to seven days); (3) reported acute apical effects; and (4) reported effect concentrations that were lower than the acute estuarine/marine benchmark final acute value (i.e., 1.096 mg/L). The EPA identified three individual tests in Table H.1 as meeting the previous criteria:

1. Park et al. (2015) conducted a seven-day test with the mud crab, *Macrophthalmus japonicus*. Exposures lasted seven days, but survival was also recorded at 96 hours. The authors did not calculate an LC_{50}, but at 96 hours there was 36% mortality in the highest test concentration (i.e., 0.03 mg/L). Therefore, the 96-hour LC_{50} was >0.03 mg/L. The test was not used quantitatively because an LC_{50} could not be calculated based on the three exposure concentrations used. Overall, 36% mortality after 96 hours in the 0.03 mg/L treatment suggests this species may be sensitive to acute PFOS exposures relative to the acute estuarine/marine benchmark. However, the source of the organisms (fish market) could be problematic as there is no mention of potential previous exposure or measures of PFOS in test organisms at any point during the experiment.

NMED Exhibit 62

2. Mhadhbi et al. (2012) conducted a 6-day test with the turbot, *Schophthalmus maximus*. Endpoints included dead embryos, malformation, hatch success at 48 hours and larval survival (missing heartbeat and a non-detached tail) at six days. The 6-day LC_{50} of 0.11 mg/L PFOS was not acceptable for acute benchmark derivation because of the relatively long exposure duration. Nevertheless, the 6-day LC_{50} is nearly an order of magnitude lower than the acute estuarine/marine benchmark final acute value (i.e., 1.096 mg/L) and five times lower than the acute estuarine/marine benchmark, suggesting *S. maximus* is sensitive to acute PFOS exposures at concentrations below the acute estuarine/marine benchmark.
3. Jeon et al. (2010) performed a 6-day test on blackrock fish, *Sebastes schlegeli*. There were no significant differences in total length, weight and survival (no mortality observed in any of the exposures) over the 6 - day exposure. The NOEC (survival and growth) was 1 mg/L at each test salinity (10, 17.5, 25 and 34 ppt), which is less than the acute estuarine/marine benchmark final acute value (i.e., 1.096 mg/L). The lack of effects observed at 1.0 mg/L preclude this test from providing meaningful information about the protectiveness of the acute estuarine/marine benchmark.

Results from Mhadhbi et al. (2012), which was determined to only be acceptable for qualitative use, suggests *S. maximus* is sensitive to acute PFOS exposures at concentrations below the acute estuarine/marine benchmark, but at an exposure duration that was 50% longer than the standard 96- hour exposure duration from quantitatively acceptable tests. Additionally, results of quantitatively acceptable empirical toxicity studies with estuarine/marine organisms do not provide any evidence that the aquatic estuarine/marine community will experience unacceptable acute effects at the acute estuarine/marine PFOS benchmark.

Appendix M Environmental Fate of PFOS in the Aquatic Environment

Natural degradation of PFOS has not been observed. As described above in Section 2.2 above, under environmental conditions, PFOS does not photolyze, hydrolyze, or biodegrade and is thermally stable. For these reasons, PFOS is considered to be highly persistent in the environment (Beach et al. 2006; OECD 2002).

M.1 Photolysis

PFOS does not appear to photolyze (OECD 2002). No experimental evidence of direct or indirect photolysis was available (Hatfield 2001). The indirect photolytic half-life of PFOS using an iron oxide photo-initiator matrix model was estimated to be ≥ 3.7 years at 25°C. This half-life was based on the analytical method of detection (Giesy et al. 2010).

M.2 Hydrolysis

No hydrolytic loss of PFOS was observed in a 49 day study under experimental conditions of 50°C and pH conditions of 1.5, 5, 7, 9 or 11 (Hatfield 2001). Instead, the half-life of PFOS was estimated to be ≥41 years at 25°C. However, this estimate was influenced by the analytical limit of quantification and that no loss of PFOS was actually detected (Giesy et al. 2010).

M.3 Biodegradation

Several studies have demonstrated that PFOS does not biodegrade under aerobic or anaerobic conditions (Gledhill and Markley 2000c; Gledhill and Markley 2000b; Gledhill and Markley 2000a; Key et al. 1998; Laboratory 2002; Lange 2001; Remde and Debus 1996; Saez et al. 2008). Results from a study conducted by Kurume Laboratory in 2002 showed no biodegradation of PFOS after 28 days as measured by net oxygen demand, loss of total organic carbon, and loss of parent material. Key et al. (1998) demonstrated that even under sulfur-

NMED Exhibit 62

limiting conditions, PFOS did not degrade. Similarly, Saez et al. (2008) observed no PFOS degradation under aerobic or anaerobic conditions in municipal sewage sludge. In contrast, Schröder (2003) reported that PFOS was anaerobically degraded; however, the reported results are uncertain as the results could likely be attributed to sorption and there was a lack of increased fluoride concentrations reported (Frömel and Knepper 2010).

The persistence of PFOS has been attributed to the strong C-F bond. Additionally, there have been limited indications that naturally occurring, defluorinating enzymes exist that can break a C-F bond, which is likely due to the rarity of fluorinated molecules in nature (Frömel and Knepper 2010). To date, no laboratory data exist that demonstrates the PFOS undergoes significant biodegradation in environmental conditions (Beach et al. 2006; Giesy et al. 2010; OECD 2002).

M.4 Thermal Stability

Based on carbon-sulfur (C-S) bond energy, which is weaker than the carbon-carbon (C-C) or the C-F bond energies, PFOS is considered to have relatively low thermal stability. Thus, PFOS would more easily breakdown under incineration conditions and would be nearly completely destroyed when incinerated (Beach et al. 2006; Giesy et al. 2010).

M.5 Adsorption/Desorption

In general, PFOS may adsorb to sediments (with a K_d greater than 1 mL/g; (Giesy et al. 2010)). However, this sorption to sediment is limited since PFOS has a K_{oc} of 2.57, indicating that PFOS is relatively mobile in water and the physicochemical characteristics of the sediment ultimately influence the sorption of PFOS (Ahrens et al. 2011b; Beach et al. 2006; Giesy et al. 2010; Higgins and Luthy 2006). Sediment characteristics have a strong influence on the partitioning of PFOS (You et al. 2010). Specifically, organic content was found to have a

NMED Exhibit 62

significant influence on the partitioning of PFOS. Density of the sediment was also found to be an important factor influencing partitioning (Ahrens et al. 2011b). PFOS has a high affinity to bind to organic carbon with log K_{oc} values ranging between 2.57 and 3.8 cm^3/g ((Higgins and Luthy 2006) and (Ahrens et al. 2010); respectively). A sorption mechanism could be a salting-out and calcium-bridging effect, as PFOS sorption to sediment increased with increased salinity, pH, and calcium (You et al. 2010). Thus, the sorption of PFOS is a complicated process that is partially dependent on other factors such as metal anion concentrations, pH, temperature, and salinity; however, the strong relationship between PFOS concentrations and organic carbon in soil, sediment, and sludge indicates that these other factors have a minor influence on PFOS sorption (Ahrens et al. 2011b; Chen et al. 2012; Higgins and Luthy 2006; You et al. 2010).

[1] Name of Waterbody Sampled for PFOS. Name or description of waterbody above is consistent with that provided in cited reference.
[2]Calculation of arithmetic mean and median includes lower of ½ LOD or ½ LOQ, depending on information provided. See full occurrence table in Appendix N for waterbody-specific details.
[3] Study authors conducted additional sampling of this waterbody but were unable to detect the initial high PFOS concentrations in any of the additional samples.
[4] Reported as ng/g by the study authors.

N.2 PFOS occurrence and concentrations in the Great Lakes region

The Great Lakes are among the most widely studied waterbodies in the U.S. for PFOS occurrence. However, occurrence data are still relatively limited for this system. Comparisons across the Great Lake system indicate PFOS concentrations are higher in Lakes Erie and Ontario, ranging between 2.8 and 38.5 ng/L and 2.6 and 85.5 ng/L, respectively (Figure 2-3) (Boulanger et al. 2004; De Silva et al. 2011; Furdui et al. 2008; Sinclair et al. 2006), compared to the more northern Great Lakes. These northern Great Lakes (i.e., Lakes Huron, Michigan, and Superior) have a maximum observed concentration of 5.46 ng/L, which was observed in Lake Huron (Remucal 2019). However, current measured PFOS concentrations were not from sampling sites around urbanized areas (such as Chicago and Detroit) and may not be representative of the potential sources of PFOS related to these areas. The measured concentrations of PFOS in the surface waters of Lakes Huron and Michigan range between 0.24 and 5.46 ng/L (De Silva et al. 2011; Furdui et al. 2008) and 0.93 and 3.13 ng/L (De Silva et al. 2011; Simcik and Dorweiler 2005), respectively. In contrast, measured PFOS concentrations observed in Lake Superior were considerably lower and range between 0.074 and 0.996 ng/L (De Silva et al. 2011; Furdui et al. 2008; Scott et al. 2010). The higher PFOS concentrations in Lakes Erie and Ontario are likely due to higher levels of industrial activities and urbanization around these lakes (Boulanger et al. 2004; Remucal 2019) and could also be associated with the sampling locations. A mass balance constructed for Lake Ontario by Boulanger et al. (2004) indicated wastewater effluent was the

NMED Exhibit 62

major source of PFOS to the lake. In contrast, inputs from Canadian tributaries and atmospheric deposition of PFOS, and other PFAS that may be transformed into PFOS, were the major contributing sources of PFOS to Lake Superior. Inputs from Canadian tributaries and atmospheric deposition were estimated to contribute 57 and 32% of PFOS inputs into Lake Superior, respectively (Scott et al. 2010).

N.3 PFOS occurrence and concentrations in the southeastern U.S.

Measured PFOS concentrations in southeastern U.S. surface waters were similar to those measured in Lakes Erie and Ontario, with some of the highest observed concentrations occurring in waterbodies near areas with PFOS manufacturing. In 2001, the 3M Company conducted a multi-city study measuring PFOS concentrations across waterbodies with known manufacturing and/or industrial uses of PFOS (3M Company 2001). In the 3M Company's 2001 report, PFOS concentrations from sites with known PFOS discharges were compared to PFOS concentrations measured in waterbodies with no known sources of any PFAS (3M Company 2001). In this comparison study, cities with known PFOS exposure were Mobile and Decatur, Alabama, Columbus, Georgia, and Pensacola, Florida. Measured PFOS concentrations ranged from not detected (reported detection limit of 2.5 ng/L; 3M Company 2001) to 80 ng/L in the cities with known PFOS discharges. These PFOS concentrations were compared to those measured in control cities. These control cities were Cleveland, Tennessee and Port St. Lucie, Florida and PFOS concentrations ranged from not detected to 137.5 ng/L (3M Company 2001). The PFOS concentrations measured in Cleveland, Tennessee were below the limit of quantification (25 ng/L) and were lower than the PFOS concentrations observed in the cities with known PFOS exposure, as was expected in the report for the control cities. However, PFOS concentrations around Port St. Lucie, Florida, the other control city, were unexplainably similar to, and at times

NMED Exhibit 62

higher than, the waterbodies with known PFOS discharges. The sources of PFOS near Port St. Lucie, Florida remain unknown; however, observed PFOS concentration suggest the presence of a potential manufacturing/industrial source or the use of AFFF in this area (3M Company 2001).

Water samples were collected from ponds near all of the sampling sites except those in Cleveland, Tennessee. PFOS concentrations in these additional pond sites were similar to those measured in Mobile, Alabama (ranging between 32 and 33 ng/L), lower than those observed in Columbus, Georgia (as PFOS was not detected with a detection limit of 2.5 ng/L), and higher than those measured in Decatur, Alabama (ranging between 108 and 111 ng/L) and in Port St. Lucie, Florida (ranging between 1,830 and 48,200 ng/L). Samples collected from the pond site near Port St. Lucie, Florida had some of the highest measured PFOS concentrations in publicly available literature with the maximum concentration of 48,200 ng/L. In the report, the 3M Company conducted additional sampling at the pond site in Port St. Lucie, Florida and determined that the measured PFOS concentrations at this site were more variable than the initial measurements indicated and were lower than the previous measurements, ranging between below detection (i.e., <2.5 ng/L) and 2,340 ng/L. Aside from the samples collected in Port St. Lucie, Florida, this report demonstrated that measured PFOS concentrations in surface waters tend to be higher in areas with PFOS manufacturing and/or industrial use (3M Company 2001).

In separate studies, PFOS and PFOA concentrations were measured in surface waters by Hansen et al. (2002) near Decatur, Alabama, and Konwick et al. (2008) in Georgia. Hansen et al. (2001) studied a stretch of the Tennessee River near Decatur, Alabama, and Konwick et al. (2008) focused on the Conasauga River in Georgia, both areas with known PFOS discharge and use. In Hansen et al. (2002), discharge from a fluorochemical manufacturing facility entered the Tennessee River towards the middle of the study area. In contrast, Konwick et al. (2008)

NMED Exhibit 62

compared the PFOS concentrations measured in the Conasauga River with those from sites with no known exposure along the Altamaha River. In both studies, mean PFOS concentrations were higher in the study areas with PFOS sources. Specifically, Hansen et al. (2002) observed mean PFOS concentrations upstream of the fluorochemical manufacturing facility were 30.85 ng/L (ranging between 16.0 and 52.6 ng/L) and were 103.9 ng/L (ranging between 30.3 and 144 ng/L) downstream of the fluorochemical manufacturing facility. Similarly, Konwick et al. (2008) observed higher measured PFOS concentrations in the Conasauga River, which ranged from below the limit of detection (i.e., 1.5 ng/L) to 321 ng/L, compared to those in the Altamaha River, ranging between 2.6 and 2.7 ng/L. Consistent with the report from the 3M Company summarized above, effluents from manufacturing facilities, WWTP, and carpet mill effluents were determined to be the source of increased PFOS concentrations in both the Tennessee and Conasauga Rivers (Hansen et al. 2002; Konwick et al. 2008; respectively). These PFOS concentrations are relatively consistent with those measured in Alabama and Georgia as reported by the 3M Company (3M Company 2001).

Nakayama et al. (2007) and Cochran (2015) measured PFAS, including PFOS, in the Cape Fear Drainage Basin in North Carolina and waterbodies on Barksdale Air Force Base in Bossier City, Louisiana, respectively. PFOA and PFOS were found to be the dominant PFAS detected in both studies. Nakayama et al. (2007) detected PFOS in 97.5% of all samples above the limit of quantification of 1 ng/L. PFOS concentrations in the Cape Fear Drainage Basin ranged between <1 (the lower limit of quantification) and 132 ng/L with a mean concentration of 31.2 ng/L. As in other studies summarized above, lower PFAS concentrations, including PFOS, were found in the upland tributaries and concentrations were highest in the middle reaches of the Cape Fear Drainage Basin, nearer expected sources. Wastewater treatment plant effluents were

NMED Exhibit 62

identified as the source of PFAS to the study area. AFFF usage at the Department of Defense base in Fayetteville, North Carolina and the land application of contaminated biosolids likely contributed as well (Nakayama et al. 2007). Cochran (2015) detected PFOS in 79% of all water samples collected and concentrations ranged between below the limit of quantification (i.e., 10 ng/L) and 7,070 ng/L, with an average concentration of 776.7 ng/L. PFOS concentrations collected in Barksdale Air Force Base varied based on proximity to fire training areas. Cochran (2015) attributed the evaluated PFOS concentrations to runoff and ground infiltration of AFFF formerly used on the base during firefighting and/or training.

N.4 PFOS occurrence and concentrations in the midwestern U.S.

Similar PFOS concentrations were reported in the publicly available literature for waterbodies in urban areas across the midwestern U.S., with lower PFOS concentrations reported in remote areas in the same states (Newsted et al. 2017; Simcik and Dorweiler 2005). In Minnesota, Simcik and Dorweiler (2005) observed PFOS concentrations ranged between 2.4 and 50.4 ng/L in urban areas near Minneapolis and between less than the limit of quantification (i.e., 0.27 ng/L) and 1.2 ng/L in remote areas in northern Minnesota. Additionally, Newsted et al. (2007) reported an average PFOS concentration of 528.9 ng/L (ranging between below limit of quantification and 18,200 ng/L; limit of quantification not provided) in surface waters collected from the Upper Mississippi River near the Minneapolis/St. Paul, Minnesota metropolitan area. The source of PFOS at these urban sites was attributed to manufacturing (3M plant), runoff, and wastewater discharge (Newsted et al. 2017; Simcik and Dorweiler 2005).

N.5 PFOS occurrence and concentrations in the northeastern U.S.

Several studies measured PFOS concentrations in surface waters in the northeastern U.S. that are comparable to those reported in Minnesota (NJDEP 2019; Sinclair et al. 2006). Sinclair

NMED Exhibit 62

et al. (2006) measured PFOS in various waterbodies across New York state and observed a median concentration of 756 ng/L in surface waters collected from the Superfund site at Lake Onondaga (ranging between 198 and 1,090 ng/L; Table N.1) and attributed these elevated concentrations to several industries located along Lake Onondaga. All other observed concentrations of PFOS in New York, including sites along the Niagara River, the Finger Lakes, Lakes Oneida and Champlain, the Erie Canal, and the Hudson River, had lower median PFOS concentrations ranging between 0.8 and 13 (Table N.1)(Sinclair et al. 2006).

The New Jersey Department of Environmental Protection (NJDEP) measured PFOS in surface water samples collected from 14 different sites across New Jersey. PFOS concentrations ranged from below the detection limit of 2.0 ng/L and 102 ng/L (NJDEP 2019). Individual samples collected along Pine, Little Pine, and Mirror Lakes had measured PFOS concentrations of 102, 100, and 72.9 ng/L, respectively. All other observed concentrations of PFOS in New Jersey freshwaters were below 15 ng/L. NJDEP attributed the elevated concentrations of PFOS observed at Pine, Little Pine, and Mirror Lakes to the use of AFFF in training and/or fire-fighting on the Department of Defense (DoD) Joint Base McGuire-Lix-Lakehurst (NJDEP 2019).

N.6 PFOS occurrence and concentrations in the western U.S.

PFOS concentrations in surface waters of western U.S. states are consistent with the lower-end concentrations (less than 100 ng/L) measured in eastern states; however, the monitoring data for PFOS was limited in the western U.S. Plumlee et al. (2008) measured PFOS concentrations in Coyote Creek and a tributary of Upper Silver Creek in San Jose, California and found concentrations to be similar to those measured in eastern states. Concentrations of PFOS in Coyote Creek ranged from 4.8 to 25 ng/L and concentrations in Upper Silver Creek ranged from 27 to 56 ng/L. The source of PFOS to these aquatic systems was unknown, however,

NMED Exhibit 62

Plumlee et al. (2008) stated that a combination of atmospheric deposition of volatile precursors and surface runoff were likely sources of PFOS to both Coyote and Upper Silver Creeks.

Lastly, Dinglasan-Panlilio et al. (2014) measured PFOS concentrations in surface waters along the Puget Sound in Washington, as well as Clayoquot and Barkley Sounds in British Columbia, Canada. PFOS concentrations measured by Dinglasan-Panlilio et al. (2014) were lower than those observed from sites in eastern states (such as those summarized above for Alabama, Florida, and North Carolina with known manufacturing and/or industrial use of PFOS). Concentrations ranged from 0.2 to 5.9 ng/L in Puget Sound and 0.25 to 0.7 ng/L in Clayoquot and Barkley Sound, British Columbia. These concentrations are consistent with those reported in the publicly available literature for remote areas, such as in Minnesota (Simcik and Dorweiler 2005) and in New York (Sinclair et al. 2006), as summarized above. The study authors indicated specific regional sources and atmospheric deposition were likely PFOS sources to these remote areas (Dinglasan-Panlilio et al. 2014).

N.7 Comparison of PFOS occurrence in the U.S. to global surface waters

Similar to surface waters in the U.S., generally PFOS and PFOA were the most commonly detected PFAS in surface waters around the world (Ahrens 2011). On a global scale, PFOS concentrations in surface waters generally range between picogram/liter and nanogram/liter with some concentrations in the milligram/liter range. However, PFOS occurrence data were limited for surface waters in Africa and South America. Based on the currently available data, PFOS concentrations in the U.S. were relatively similar to those reported in studies with sampling sites in other countries. Global surface water PFOS concentrations reported in the public literature ranged between not detected and 2,100,000 ng/L

NMED Exhibit 62

(Jarvis et al. 2021). These global surface water concentrations are summarized in Jarvis et al. (2021) to provide a comparison with those observed in the U.S.

Overall, the currently available data on PFOS occurrence in ambient surface waters show the widespread distribution and variability of PFOS concentrations in surface waters around the world and that surrounding land use has a large influence on PFOS concentrations in surface waters. In general, urbanized areas with high population densities tended to have elevated PFOS concentrations in surface waters (Jarvis et al. 2021). Like in the U.S., PFOS concentrations in surface waters around the world vary widely and current information on the environmental distribution of PFOS in surface waters around the world is relatively limited.

N.8 PFOS Occurrence and Detection in Aquatic Sediments

PFOS has been detected in sediments of aquatic environments across various countries (Lau et al. 2007). Typically, in the U.S., soil and sediment measurements of PFOS occur in the µg/kg dry weight (dw) range with measured concentrations in the public literature ranging from not detected (with a detection limit of 0.08 µg/kg dw) to 31.38 µg/kg dw (3M Company 2001; Cochran 2015). Anderson et al. (2016), measured concentrations of PFAS in sediment across ten U.S. Air Force bases where there is a known history of use of AFFF use and found that PFOS concentrations were detected in 94% of samples. The median concentration of PFOS across all sample sites was 31.0 µg/kg, with a maximum concentration of 190,000 µg/kg (Anderson et al. 2016). Arias et al. (2015) measured PFOS in sediment from an evaporation pond used to collect the wastewater arising from fire-fighting exercises at an Australian military air base. Despite the discontinued use of PFOS/PFOA-based foams six years earlier, the PFOS sediment concentration was 38,000,000 µg/kg, a million times higher than the average global values for sediments (0.28 - 3.8 µg/kg PFOS) reported by the authors (Arias et al. 2015).

NMED Exhibit 62

These observed concentrations were similar to other sediment concentrations in areas with known perfluorinated chemical discharges and manufacturing. Lasier et al. (2011) measured PFOS in sediment from the Coosa River, Georgia watershed, upstream, and downstream of a land-application site of municipal/industrial wastewater with sediment concentrations ranging from less than the method detection limit (MDL) to 1.73 µg/kg dw upstream of the land-application and 1.66 - 20.18 µg/kg dw PFOS downstream. Giesy and Kannan (2001), as presented in OECD (2002), measured PFOS in sediments collected from locations upstream and downstream of the 3M facility in Decatur, Alabama. The two closest sites downstream of the 3M facility had significantly greater concentrations (1,299 and 5,930 µg/kg ww) than the two upstream sites (~0.18 and 0.98 µg/kg ww; OECD 2002).

Other sediment concentrations across the U.S. were much lower: <4 µg/kg across sites in Puget Sound, Washington, San Francisco and Monterey Bay California, the Niagara River in New York, and Lake Michigan. These concentrations appeared to be similar to other sediment concentrations across the globe (Table N-1).

Table N-1. Global Sediment Concentration of PFOS.

Location	PFOS concentration	Reference
Tokyo Bay, Japan	0.29-0.36 µg/kg dw	Ahrens et al. (2010)
Ariake Sea, Japan	0.11 µg/kg ww	Nakata et al. (2006)
Toronto, Canada	<0.1-2.2 µg/kg ww	Vedagiri et al. (2018)
Lake Ontario, Canada	10 µg/kg dw	ECCC (2018)
Lake Ontario, Niagara Basin	27-47 µg/kg	Meyers et al. (2012)
Lake Ontario, Mississauga Basin	4.4-19 µg/kg	Meyers et al. (2012)
Lake Ontario, Rochester Basin	8.1-49 µg/kg	Meyers et al. (2012)
Resolute Lake, Canada	24-85 µg/kg ww	Butt et al. (2010)

Faroe Islands	< 50 - 0.11 µg/kg	Butt et al. (2010); Kallenborn (2004)
Urban reservoir, Singapore	2.8-3.6 µg/kg dw	Nguyen et al. (2016)

NMED Exhibit 62

N.9 PFOS Occurrence and Detection in Air and Rain

Air concentrations of PFOS in the atmosphere varied widely across the globe. In an urban area in Albany, NY, perfluorinated acids were measured in air samples in both the gas and particulate phase in May and July of 2006 (Kim and Kannan 2007). PFOS in the gas phase had a mean concentration of 1.70 pg/m^3 (range: 0.94-3.0) and the particulate phase had a mean concentration of 0.64 pg/m^3 (range: 0.35-1.16) (Kim and Kannan 2007). Kim and Kannan (2007) also reported mean PFOS concentrations of 0.36 ng/L and 0.62 ng/L in rain and snow, respectively.

Above Lake Ontario, concentrations of PFOS in the particulate phase measured in air samples over the lake were higher than those observed by Kim and Kannan (2007) near Albany, NY. The mean concentration of PFOS at Lake Ontario was 6.4 ± 3.3 pg/m^3 (Boulanger et al. 2005a), with a range of concentrations from not detected to 8.1 pg/m^3 (Martin et al. 2010). In an urban area in Minneapolis, Minnesota, PFOS was measured in both the particulate and gas phase. PFOS in the particulate phase ranged from 2.1 - 7.9 pg/m^3 and the gas phase ranged from 1.8 - 5.0 pg/m^3 in across the five samples (MPCA/STS 2007).

In Canada, PFOS air concentrations measured in 2009 showed widespread distribution with remote sites having similar concentrations as urban sites (ECCC 2018). Using passive samplers, PFOS concentrations were detected in Toronto, Ontario (8 pg/m^3), an agricultural site in Saskatchewan (5 pg/m^3), Whistler, British Columbia (4 pg/m^3), and Alert, N Nunavut (2 pg/m^3) (ECCC 2013).

Other reported concentrations of PFOS in air samples included Sydney, Florida (3.4 pg/m^3), Tudor Hill, Bermuda (6.1 pg/m^3), Malin Head, Ireland (3.3 pg/m^3), and Hilo, Hawaii (6.6 pg/m^3) are similar to the concentrations reported in Canada (ECCC 2018) and Japan (Sasaki et al. 2003). The annual geometric mean concentration of PFOS in air samples collected monthly

NMED Exhibit 62

from 2001-2002 in the town of Oyamazaki and Fukuchiyama City were 5.3 and 0.6 pg/m^3, respectively (Sasaki et al. 2003).

Across Europe, PFOS air concentrations were reported to be variable. In the particulate phase PFOS concentrations ranged from < 1.8 - 46 pg/m^3. Most locations had low (~1-2 pg/m^3) to less than the reported Minimum Detection Limit (MDL) and included Hazelrigg, United Kingdom, Kjeller Norway, and Mace Head, Ireland (Barber et al. 2007). The highest concentrations were reported in Manchester, United Kingdom. Similarly, high concentrations were reported for another urban area, 150 pg/m^3 for Paris, France (ECCC 2018).

Even in the Arctic, PFOS, its precursors, and degradation products, have been detected in air samples in Resolute Bay, Nunavut, Canada, during the summer of 2004 (Stock et al. 2007). PFOS in the filter samples were 1-2 orders of magnitude greater than other compounds, with a mean concentration of 5.9 pg/m^3 (Butt et al. 2010). These concentrations are greater than PFOS concentrations measured in the particle phase of air samples measured in Zeppelinstasjonen, Svalbard, Norway (Butt et al. 2010). PFOS was measured in September and December, 2006 and August and December, 2007, with mean concentrations of 0.11 pg/m^3 (range: 0.03 - 0.50 pg/m^3) and 0.18 pg/m^3 (range: 0.02 - 0.97 pg/m^3), respectively (NILU 2007).

N.10 PFOS Occurrence and Detection in Groundwater

Similar to surface water, PFOS and PFOA are the dominant PFAS detected in groundwater. Generally, PFOS concentrations tend to occur in the ng/L range, with some elevated detections in the µg/L range (Ahrens 2011; Xiao 2017). Concentrations of PFOS were detected in groundwater samples across Minnesota in 2006 and 2007, approximately five years after the 3M Corporation phased out PFOS production in Minnesota in 2002 (MPCA/STS 2007). Data collected from shallow aquifers across Minnesota in both urban and agricultural areas were

NMED Exhibit 62

likely affected by a variety of different contamination sources (i.e., industrial and municipal stormwater, pesticides, land application of contaminated biosolids and atmospheric deposition) and indicated that perfluorinated chemicals are present in areas beyond the disposal sites and aquifers associated with these disposal sites (MPCA/STS 2007). Groundwater samples of PFOS ranged from < 0.00222 - 0.037 µg/L across urban areas, with most of the perfluorinated compound detections in the Twin Cities metro area (MPCA/STS 2007). Concentrations in rural areas of Minnesota were all less than the analytical method reporting limit (0.025 µg/L).

Detections of PFOS in groundwater have been associated with the use of AFFF and fire-training locations (Ahrens 2011; Xiao 2017). The use of AFFF to suppress fires resulted in the release of various PFAS into the environment as AFFF contains high levels of PFAS (Ahrens 2011; Moody and Field 2000). The use of AFFF in particular has been identified as an important source of groundwater contamination with PFAS (Moody and Field 2000). This contamination is often persistent, lasting for many years after the release (Moody and Field 2000; Xiao 2017). The transformation of PFOS precursor compounds (see Section 2.3) by soil micro-organisms may be a contributing source of PFOS in groundwater (Xiao 2017).

Groundwater samples from wells in the area of a known plume were measured in 1998 and 1999. Samples were taken at the Wurtsmith Air Force Base in northeastern Michigan, a base where fire-training exercises were conducted from the 1950's until the base was decommissioned in 1993. PFOS concentrations ranged from 4.0 to 110 µg/L depending on the proximity to the training pad, demonstrating that PFOS is still present in measurable quantities for at least five or more years after the use of AFFF (Moody et al. 2003). These values are consistent with ten other U.S. Air Force bases where there is a known historic use of AFFF to extinguish hydrocarbon-based fires but were not active fire-training areas. Anderson et al. (2016) measured groundwater

NMED Exhibit 62

samples between March and September 2014 at the ten locations with PFOS concentrations detected in 96% of samples. The median groundwater concentration of PFOS across all sites was 2.17 µg/L, with a maximum concentration of 8,970 µg/L (Anderson et al. 2016). Other reported groundwater concentrations at other U.S. military installations summarized by Cousins et al. (2016) include: Tyndall Air Force Base (147 - 2,300 µg/L; Schultz et al. 2004), Fallon Naval Air station (< LOD - 380 µg/L; Schultz et al. 2004) and Ellsworth Air Base (5 - 75 µg/L; McGuire et al. 2014). Similar concentrations are reported at other airports and bases globally, including at a fire training area in Cologne, Germany (0.02 - 8.35 µg/L; Weiß et al. 2012); air force base F18 in Sweden (< 0.001 - 42.2 µg/L; Filipovic et al. 2015) and the Jersey airport in the United Kingdom (10 - 98 µg/L; Rumsby et al. 2009).

N.11 PFOS Occurrence and Detection in Ice

Very little information was provided about PFOS concentrations in ice. Saez et al. (2008) found PFOS in a Russian Artic ice core sampled in 2007. The PFOS concentration reported was 0.0053 ng/L.

NMED Exhibit 62

Appendix O Bioaccumulation Factors (BAFs) Used to Calculate PFOS Tissue Values

O.1 Summary Table of PFOS BAFs used to calculate tissue criteria and supplemental fish tissue values

Common Name	Scientific Name	Tissue[a]	BAF (L/kg-ww)	Site Species BAF (L/kg-ww)[b]	Ranking	Location	Reference
common carp	*Carassius auratus*	Blood	11167	**11167**	high	17 Sites in six major rivers, Korea	Lam et al. (2014)

a – WB (Fish whole body); Invert (Invertebrate whole body)
b – Lowest species level BAF (highlighted in bold) at each site represents the site-level BAF
c – One site level BAF represented by two species tied for lowest species level BAF

NMED Exhibit 62

O.2 Summary of PFOS BAFs used to calculate tissue criteria and supplemental fish tissue values

Field measured BAFs used to calculate fish and invertebrate PFOS tissue criteria (fish muscle, fish whole body, and invertebrate whole body) and supplemental fish tissue values (blood, reproductive tissue, liver) are shown in Appendix O.1. Summary statistics for the BAFs from this table used to derive tissue criteria and additional tissue values (i.e., lowest species-level BAF from each site) are reported in Table 3-11 and Table P-2, respectively. Rankings for individual BAFs were determined by Burkhard (2021), who devised a ranking system based on five characteristics: 1) number of water samples; 2) number of tissue samples; 3) spatial coordination of water and tissue samples; 4) temporal coordination of water and tissue samples; and 5) general experimental design. For the first four characteristics, a score of one to three was assigned, based on number of samples or how closely the water and tissue measurements were paired. For the experimental design characteristic, a default value of zero was assigned; unless the measured tissues were composites of mixed species, in which case it was assigned a three (Burkhard 2021). These sub-scores were then summed and assigned a rank based on the final score. Studies with high quality rankings had scores of four or five, studies with medium quality rankings had scores of five or six, and studies with low quality rankings had scores of seven or higher (Burkhard 2021). Parameters for the scores assigned to the five characteristics are listed in Table 2-2, and additional details can be found in Burkhard (2021). Only BAFs from studies with high or medium quality rankings were included for the final BAF geometric mean calculations used to derive tissue criteria (Table 3-12) and supplemental tissue values (Table P-3).

NMED Exhibit 62

Appendix P Translation of Chronic Water Column Criterion into Other Fish Tissue Types (liver, blood, reproductive tissues)

The PFOS aquatic life criteria (summarized in Section 3.3) include chronic tissue criteria for fish whole body, fish muscle, and invertebrate whole-body. Additional values for fish liver, fish blood, and fish reproductive tissues were also calculated by transforming the chronic water column criterion (i.e., 0.00025 mg/L) into representative tissue concentrations using tissue-specific bioaccumulation factors (BAFs). Fish BAFs for liver, blood, and reproductive tissues were identified following the same approaches used to identify fish whole body, muscle, and inverterbrate whole body BAFs, which are described in detail in Section 2.11.3.1. Briefly, BAFs were determined from field measurements and calculated using the equation:

$$BAF = \frac{C_{biota}}{C_{water}} \qquad (Eq.\ P\text{-}1)$$

Where:
C_{biota} = PFOS concentration in organismal tissue(s)
C_{water} = PFOS concentration in water

For further details on BAFs compilation and ranking, see Section 2.11.3.1 and Burkhard (2021). BAFs based on reproductive tissues identified by Burkhard (2021) were further screened to evaluate characteristics that influence reproductive tissue BAFs. These characteristics included timing of sample collection and organism sex, age, length and weight. However, since the data were limited, the influence of these characteristics could not be fully evaluated to determine their potential influence on PFOS BAFs for reproductive tissues. Therefore, characteristics of timing of sample collection and organism age, length or weight were currently not considered to be influential given available data. Reproductive tissue BAFs were additionally screened to ensure only BAFs based on adult females were considered, because female

NMED Exhibit 62

reproductive tissues are most relevant to potential maternal transfer to offspring. This subset of reproductive-based BAFs and corresponding species and sampling locations are described in Table P-1.

Table P-1. Characteristics of adult fish sampled for the calculation of PFOS reproductive tissue BAFs.

All sampled fish were adults, and all reproductive tissues identified as gonad. Weights, lengths, and BAFs are averages.

[5]Range

The distributions of fish liver, fish blood, and fish reproductive BAFs identified in the literature used to calculate tissue-specific BAFs were determined in the same manner as invertebrate, fish muscle, and fish whole body BAFs (Section 3.2.3.1). Briefly, distributions of BAFs used to derive additional tissue values were based on the lowest species-level BAF

NMED Exhibit 62

reported at a site. When more than one BAF was available for the same species at the same site, the species-level BAF was calculated as the geometric mean of all BAFs for that species at that site. Summary statistics for the PFOA BAFs used in the derivation of the additional tissue-based values are presented below (Table P-2) and individual BAFs are provided in Appendix O.

Table P-2. Summary Statistics for PFOS BAFs in Additional Fish Tissues[1].

Category	n	Geometric Mean BAF (L/kg-wet weight)	Median BAF (L/kg-wet weight)	20th Centile BAF (L/kg-wet weight)	Minimum (L/kg-wet weight)	Maximum (L/kg-wet weight)
Liver	19	5,688	4,572	2,462	111	83,753
Blood	11	14,355	11,167	6,273	3,500	80,168
Reproductive Tissue	8	8,903	9,006	5,155	2,222	25,645

1- Based on the lowest species-level BAF measured at a site (i.e., when two or more BAFs were available for the same species at the same site, the species-level geometric mean BAF was calculated, and the lowest species-level BAF was used).

The chronic freshwater column criterion (see Section 3.2.1.3) was then translated into tissue values using the 20th centile BAFs from the distributions of BAFs summarized in Table P-2 using the following equation:

$$Tissue\ Value = Chronic\ Water\ Column\ Criterion \times 20th\ \ Centile\ BAF \qquad (Eq.\ Q\text{-}2)$$

The resulting tissue values that correspond to the 20th centile tissue-specific BAF used in equation Q-2 are reported in Table P-3. The values reported in Table P-3 represent tissue-based concentrations that offer a level of protection that is equal to the magnitude components of the chronic water column criterion as well as the fish whole body, fish muscle, and invertebrate whole-body tissue-based criteria; however, the tissue-based values reported in Table P-3 are only presented for comparative purposes and are not recommended criteria.

NMED Exhibit 62

Table P-3. PFOS Concentrations for Additional Fish Tissue.[1, 2]

Category	PFOS Concentration (mg/kg ww)
Liver	0.616
Blood	1.57
Reproductive Tissue	1.29

[1] These PFOS concentrations are provided as supplemental information and are not intended to replace the PFOS fish tissue criteria provided in Table .

[2] Tissue criteria derived from the chronic water column concentration (CCC) with the use of bioaccumulation factors and are expressed as wet weight (ww) concentrations.

Appendix Q Example Data Evaluation Records (DERs)

The PFOS toxicity literature evaluated and used to derive the PFOS aquatic life criteria was identified using the ECOTOXicology database (ECOTOX; https://cfpub.epa.gov/ecotox/) as meeting data quality standards. ECOTOX is a source of high-quality toxicity data for aquatic life, terrestrial plants, and wildlife. The database was created and is maintained by the EPA, Office of Research and Development, Center for Computational Toxicology and Exposure. The ECOTOX search generally begins with a comprehensive chemical-specific literature search of the open literature conducted according to ECOTOX Standard Operating Procedures (SOPs). The search terms are often comprised of chemical terms, synonyms, degradates and verified Chemical Abstracts Service (CAS) numbers. After developing the literature search strategy, ECOTOX curators conduct a series of searches, identify potentially applicable studies based on title and abstract, acquire potentially applicable studies, and then apply the applicability criteria for inclusion in ECOTOX. Applicability criteria for inclusion into ECOTOX generally include:

1. The toxic effects are related to single chemical exposure (unless the study is being considered as part of a mixture effects assessment);
2. There is a biological effect on live, whole organisms or *in vitro* preparation including gene chips or omics data on adverse outcome pathways potentially of interest;
3. Chemical test concentrations are reported;
4. There is an explicit duration of exposure;
5. Toxicology information that is relevant to OW is reported for the chemical of concern;
6. The paper is published in the English language;
7. The paper is available as a full article (not an abstract);
8. The paper is publicly available;
9. The paper is the primary source of the data;
10. A calculated endpoint is reported or can be calculated using reported or available information;
11. Treatment(s) are compared to an acceptable control;
12. The location of the study (*e.g.*, laboratory vs. field) is reported; and
13. The tested species is reported (with recognized nomenclature).

NMED Exhibit 62

Following inclusion in the ECOTOX database, toxicity studies are subsequently evaluated by the Office of Water. All studies were evaluated for data quality generally as described by U.S. EPA (1985) in the 1985 Guidelines and in the EPA's Office of Chemical Safety and Pollution Prevention (OCSPP)'s Ecological Effects Test Guidelines (U.S. EPA 2016b), and the EPA OW's internal data quality SOP, which is consistent with OCSPP's data quality review approach (U.S. EPA 2018). These toxicity data were further screened to ensure that the observed effects could be primarily attributed to PFOS exposure. Office of Water completed a DER for each species by chemical combination from the PFOS studies identified by ECOTOX. Example DERs are presented here to convey the meticulous level of evaluation, review, and documentation each PFOS study identified by ECOTOX was subject to. Appendix Q.1 shows an example fish DER and Appendix Q.2 shows an example aquatic invertebrate DER.

NMED Exhibit 62

Q.1 Example Fish DER

Part A: Overview

I. Test Information

Chemical name:

CAS name: CAS Number:
Purity: Storage conditions:
Solubility in Water (units):

____ **Controlled Experiment** (*manipulated*) ____ **Field Study/Observation** (*not manipulated*) (*Place X by One*)

Primary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)

Secondary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)
(*At least one reviewer should be from EPA for sensitive taxa*)

Citation: *Indicate: author(s), year, study title, journal, volume, and pages*.
(e.g., Slonim, A.R. 1973. Acute toxicity of beryllium sulfate to the common guppy. J. Wat. Pollut. Contr. Fed. 45(10): 2110-2122)

Companion Papers: *Identify any companion papers associated with this paper using the citation format above.*

Were other DERs completed for Companion Papers? ____ **Yes** ____ **No** (*If yes, list file names of DERs below*)

Study Classification for Aquatic Life Criteria Development: *Place X by One Based on Highest Use*

_____ Acceptable for Quantitative Use
_____ Acceptable for Qualitative Use
_____ Not Acceptable for Use/Unused

General Notes: *Provide any necessary details regarding the study's use classification for all pertinent endpoints, including non-apical endpoints within the study (e.g., note all study classifications for each endpoint if the use varies)*

Major Deficiencies (note any stated exclusions): *Check all that apply. Checking any of these items make the study "**Not Acceptable for Use**"*

_____ Mixture (for controlled experiments only)
_____ No Controls (for controlled experiments only)
_____ Excessive Control Mortality (> 10% for acute and > 20% for chronic)
_____ Dilution water not adequately characterized
_____ Bioaccumulation: steady state not reached
_____ Dermal or Injection Exposure Pathway
_____ Review paper or previously published without modification

_____ Other: *(if any, list here*)

POTENTIAL CHEMICAL MIXTURES: *Describe any potential chemicals mixtures as characterized by study authors (including any confirmation of chemical mixtures).*

DESCRIPTION OF DILUTION WATER: *Describe concerns with characterization of and/or major deficiencies with dilution water.*

General Notes:

Minor Deficiencies: *List and describe any minor deficiencies or other concerns with test. These items may make the study "**Acceptable for Qualitative Use**"* **(exceptions may apply as noted)**

***For Field Studies/Observations**: A field study/observation may be considered "**Acceptable for Quantitative Use**" if it consisted of a range of exposure concentrations and the observed effects are justifiably contributed to a single chemical exposure*

_____ Mixture (observed effects not justifiably contributed to single chemical exposure)
_____ Uncharacterized Reference Sites/Conditions

POTENTIAL CHEMICAL MIXTURES PRESENT AT SITE: *Describe any potential chemicals mixtures present at the site as characterized by study authors (including any confirmation of chemicals present at study site).*

EXPOSURE VARIABILITY ACROSS STUDY SITE(S): *Describe any exposure variability across study site(s) as characterized by study authors (i.e., description of study design with reference and contaminated sites).*

General Notes:

Reviewer's Comments: *Provide additional comments that do not appear under other sections of the DER*.

NMED Exhibit 62

ABSTRACT: *Copy and paste abstract from publication.*

SUMMARY*: Fill out and modify as needed.*

Acute:

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Hardness (mg/L as $CaCO_3$) or Salinity (ppt)	DOC (mg/L)	Effect	Reported Effect Concentration (mg/L)	Verified Effect Concentration (mg/L)	Classification
											Quantitative / Qualitative / Unused

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

Chronic:

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Hardness (mg/L as $CaCO_3$) or Salinity (ppt)	DOC (mg/L)	Chronic Limits	Reported Chronic Value (mg/L or µg/g)	Verified Chronic Value (mg/L or µg/g)	Chronic Value Endpoint	Classification
												Quantitative / Qualitative / Unused

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

II. Results *Provide results as reported in the publication (including supplemental materials). Include screen shots of tables and/or figures reporting results from the article following tabulated data table in each associated results section for all studies. Complete tabulated data tables for all studies for studies marked "**Acceptable for Quantitative Use"** and **"Acceptable for Qualitative Use**".*

Water Quality Parameters: *If only general summary data of water quality parameters is provided by study authors (i.e., no specific details of water quality parameters on a treatment level is provided), summarize any information regarding water quality parameters under General Notes below and indicate data not provided in* Table A.II.1.

General Notes: *For aquatic life criteria development, measured water quality parameters in the treatments nearest the toxicity test endpoint(s), e.g., LC_{50}, EC_{20}, etc., are most relevant.*

Table A.II.1. Measured Water Quality Parameters in Test Solutions.

Dissolved oxygen, temperature, pH and [other parameters (hardness, salinity, DOC)] in test solutions during the *[X]*-day exposure of *[test organism]* to *[concentration of treatment(s)]* of *[test substance]* under *[static renewal/flow-through]* conditions.

Parameter	Treatment	Mean	Range

Part B: Detailed Review
I. Materials and Methods

Protocol/Guidance Followed: *Indicate if provided by authors.*

Deviations from Protocol: *If authors report any deviations from the protocol noted above indicate here.*

Study Design and Methods: *Copy and paste methods section from publication.*

TEST ORGANISM: *Provide information under Details and any relevant or related information or clarifications in Remarks.*

Parameter	Details	Remarks
Species:	Common Name: Scientific Name:	North American species? ____ Surrogate for North American Taxon? ____ *(Place X if applicable)*

Strain/Source:
• Wild caught from unpolluted areas [1]
  o Quarantine for at least 14 days or until they are disease free, before acclimation [1]
• Must originate from same source and population [1]
• Should not be used:
  o If appeared stressed, such as discoloration or unusual behavior [1]
  o If more than 5% die during the 48 hours before test initiation [1]
  o If they were used in previous test treatments or controls [2]
• No treatments of diseases may be administered:
  o Within 16 hour of field collection [1]
  o Within 10 days or testing or during testing [1]		

Age at Study Initiation:
Acute:
• Juvenile stages preferred [1]
Chronic:
• Life-cycle test:
  o Embryos or newly hatched young < 48 hours old [2]
• Partial life-cycle test:
  o Immature juveniles at least 2 months prior to active gonad development [2]
• Early life-stage test:
  o Shortly after fertilization [2]		

Was body weight or length recorded at test initiation?	____ Yes ____ No	
Was body weight or length recorded at regular intervals?	____ Yes ____ No *If yes, describe regular intervals:*	

STUDY PARAMETERS: *Provide information under Details and any relevant information of deficiencies in Remarks. Complete for <u>both Controlled Experiments and Field Studies/Observations.</u>*

	Parameter	Details	Remarks
For Both Controlled Experiments and Field Observations	**Number of Replicates per Treatment Group:** • At least 2 replicates/treatment recommended for acute tests [1] • At least 2 replicates/treatment recommended for chronic tests [3]	Control(s): Treatment(s):	
	Number of Organisms per Replicate/ Treatment Group: • At least 10 organisms/treatment recommended [3] • At least 7 organisms/treatment acceptable [4]	Control(s): Treatment(s):	
	Exposure Pathway: *(i.e., water, sediment, gavage, or diet).* *Note: all other pathways (e.g., dermal, single dose via gavage, and injection) are unacceptable.*		
	Exposure Duration: **Acute** • Should be 96 hours [2] **Chronic** • Life-cycle tests: o Ensure that all life stages and life processes are exposed [2] o Begin with embryos (or newly hatched young), continue through maturation and reproduction, and should end not less than 24 days (90 days for salmonids) after the hatching of the next generation [2] • Partial life-cycle tests: o Allowed with species that require >1 year to reach sexual maturity, so that all major life stages can be exposed to the test material in <15 months [2] o Begin with immature juveniles at least 2 months prior to active gonad development, continue through maturation and reproduction, and end not less than 24 days (90 days for salmonids) after the hatching of the next generation [2] • Early life-cycle tests: o 28 to 32 day (60 day post hatch for salmonids) exposures from shortly after fertilization through embryonic, larval, and early juvenile development [2]	____ Acute ____ Partial Life Cycle ____ Early Life Stage ____ Full Life Cycle ____ Other *(please remark):*	
	Test Concentrations (remember units): *Recommended test concentrations include at least three concentrations other than the control; four or more will provide a better statistical analysis* [3]	Nominal: Measured: Media measured in:	
	Observation Intervals: • Should be an appropriate number of observations over the study to ensure water quality is being properly maintained [4]		

CONTROLLED EXPERIMENT STUDY PARAMETERS: *Provide information under Details and any relevant information of deficiencies in Remarks. Complete for Controlled Experiments only.*

For Controlled Experiments Only

Parameter	Details	Remarks

Acclimation/Holding:
• Should be placed in a tank along with the water in which they were transported
  o Water should be changed gradually to 100% dilution water (usually 2 or more days) [1]
  o For wild-caught animals, test water temperature should be within 5°C of collection water temperature [1]
  o Temperature change rate should not exceed 3°C within 72 hours [1]
• To avoid unnecessary stress and promote good health:
  o Organisms should not be crowded [1]
  o Water temperature variation should be limited [1]
  o Dissolved oxygen:
  ▪ Maintain between 60 - 100% saturation [1]
  ▪ Continuous gentle aeration if needed [1]
  o Unionized ammonia concentration in holding and acclimation waters should be < 35 µg/L [1]
	Duration:
	Feeding:
	Water type:
	Temperature (°C):
	Dissolved Oxygen (mg/L):
	Health (*any mortality observed?*):
		Identify number of individuals excluded from testing and/or analysis (if any):

Acclimation followed published guidance? *Describe, if any*	____ Yes ____ No *If yes, indicate which guidance:*	

Test Vessel:
• Test chambers should be loosely covered [1]
• Test chamber material:
  o Should minimize sorption of test chemical from water [1]
  o Should not contain substances that can be leached or dissolved in solution and are free of substances that could react with exposure chemical [1]
  o Glass, No. 316 stainless steel, nylon screen and perfluorocarbon (e.g. Teflon) are acceptable [1]
  o Rubber, copper, brass, galvanized metal, epoxy glues, lead and flexible tubing should not come into contact with test solution, dil. water, or stock [1]
• Size/volume should maintain acceptable biomass loading rates (see Biomass Loading Rate below) [1]
	Material:
	Size:
	Fill Volume:
		Briefly describe the test vessel:

Test Solution Delivery System/Method:
• Flow-through preferred for some highly volatile, hydrolysable or degradable materials [2]
  o Concentrations should be measured often enough using acceptable analytical methods [2]
• Chronic exposures:
  o Flow-through, measured tests required [2]
	Test Concentrations Measured
	____ Yes ____ No
	
	Test Solution Delivery System:
	____ Static
	____ Renewal
	Indicate Interval:
	
	____ Flow-through
	Indicate Type of Diluter:	

Source of Dilution Water:
• Freshwater hardness range should be < 5 mg/L or < 10% of the average (whichever is greater) [1]
• Saltwater salinity range should be < 2 g/kg or < 20% of the average (whichever is greater) [1]
• Dilution water must be characterized (natural surface water, well water, etc.) [3]
  o Distilled/deionized water without the addition of appropriate salts should not be used [2]
• Dilution water in which total organic carbon or particulate matter >5 mg/L should not be used [2]
  o Unless data show that organic carbon or particulate matter do not affect toxicity [2]		

Dilution Series (*e.g., 0.5x, 0.6x, etc.*):		

	Parameter	Details	Remarks
For Controlled Experiments Only	**Dilution Water Parameters:** *Measured at the beginning of the experiment or averaged over the duration of the experiment (details of water quality parameters measured in test solutions should be included under the results section)*	Dissolved Oxygen (mg/L): pH: Temperature (°C): Hardness (mg/L as $CaCO_3$): Salinity (ppt): Total Organic Carbon (mg/L): Dissolved Organic Carbon (mg/L):	
	Aeration: • Acceptable to maintain dissolved oxygen at 60 - 100% saturation at all times [1] • Avoid aeration when testing highly oxidizable, reducible and volatile materials [1] • Turbulence should be minimized to prevent stress on test organisms and/or re-suspend fecal matter [1] • Aeration should be the same in all test chambers at all times [1]	____ Yes ____ No	
	Describe Preparation of Test Concentrations (e.g., water exposure, diet):		
	Test Chemical Solubility in Water: *List units and conditions (e.g., 0.01% at 20ºC)*		
	Were concentrations in water or diet verified by chemical analysis? *Measured test concentrations should be reported in* Table A.II.2 *above.*	__Yes __No *Indicate media:*	
	Were test concentrations verified by chemical analysis in tissue? *Measured test concentrations can be verified in test organism tissue (e.g., blood, liver, muscle) alone if a dose-response relationship is observed.* *Measured test concentrations should be reported in* Table A.II.2 *above.*	__Yes __No *Indicate tissue type:*	*If test concentrations were verified in test organism tissue, was a dose-response relationship observed?*
	Were stability and homogeneity of test material in water/diet determined?	__Yes __No	
	Was test material regurgitated/avoided?	__Yes __No	
	Solvent/Vehicle Type (Water or Dietary): • When used, a carrier solvent should be kept to a minimum concentration [1] • Should not affect either survival or growth of test organisms [1] • Should be reagent grade or better [1] • Should not exceed 0.5 ml/L (static) or 0.1 ml/L (flow through) unless it was shown that higher concentrations do not affect toxicity [3]		
	Negative Control:	____ Yes ____ No	
	Reference Toxicant Testing:	____ Yes ____ No	*If Yes, identify substance:*
	Other Control: *If any (e.g. solvent control)*		

	Biomass Loading Rate:
	• Loading should be limited so as not to affect test results. Loading will vary depending on temperature, type of test (static vs. flow-through), species, food/feeding regime, chamber size, test solution volume, etc. [1]
	• This maximum number would have to be determined for the species, test duration, temperature, flow rate, test solution volume, chamber size, food, feeding regime, etc.
	• Loading should be sufficiently low to ensure:
	  ○ Dissolved oxygen is at least 60% of saturation (40% for warm-water species) [1,5]
	  ○ Unionized ammonia does not exceed 35 µg/L [1]
	  ○ Uptake by test organisms does not lower test material concentration by > 20% [1]
	  ○ Growth of organisms is not reduced by crowding
	• Generally, at the end of the test, the loading (grams of organisms; wet weight; blotted dry) in each test chamber should not exceed the following:
	  ○ Static tests: > 0.8 g/L (lower temperatures); > 0.5 g/L (higher temperatures) [1]
	  ○ Flow through tests: > 1 g/L/day or > 10 g/L at any time (lower temperatures); > 0.5 g/L/day or > 5 g/L at any time (higher temperatures) [1]
	• Lower temperatures are defined as the lower of 17˚C or the optimal test temperature for that species [1]		

	Parameter	Details	Remarks

For Controlled Experiments Only	**Feeding:**
	• Unacceptable for acute tests [2]
	  o Exceptions:
	  ▪ Data indicate that the food did not affect the toxicity of the test material [2]
	  ▪ Test organisms will be severely stressed if they are unfed for 96 hours [2]
	  ▪ Test material is very soluble and does not sorb or complex readily (e.g., ammonia) [2]
		____ Yes ____ No	

	Lighting:
	• Depends on the type of test (acute or chronic) and endpoint (e.g., reproduction) of interest.
	  o Embryos should be incubated under dim incandescent lighting (≤ 20 fc) or total darkness during early life-stage toxicity testing
	  o Embryos must not be subjected to prolonged exposure to direct sunlight, fluorescent lighting, or high intensity incandescent lighting
	• Generally, ambient laboratory levels (50-100 fc) or natural lighting should be acceptable, as well as a diurnal cycle consisting of 50% daylight or other natural seasonal diurnal cycle.
	• Artificial light cycles should have a 15 – 30-minute transition period to avoid stress due to rapid increases in light intensity [1]		

Study Design/Methods Classification: *(Place X by One Based on Overall Study Design/Methods Classification)*
Provide details of Major or Minor Deficiencies/Concerns with Study Design in Associated Sections of Part A: Overview
This classification should be taken into consideration for the overall study classification for aquatic life criteria development in Part A.

_____ Study Design Acceptable for Quantitative Use
_____ Study Design Acceptable for Qualitative Use
_____ Study Design Not Acceptable for Use

Additional Notes: *Provide additional considerations for the classification of study use based on the study design.*

OBSERVATIONS: *Provide information under Details and any relevant information in Remarks. This information should be consistent with the Results Section in Part A.*

Parameter	Details	Remarks

Parameters measured including sublethal effects/toxicity symptoms:
Common Apical Parameters Include:
Acute
• EC_{50} based on percentage of organisms exhibiting loss of equilibrium plus the percentage of organisms immobilized plus percentage of organisms killed [2]
  ○ If not available, the 96-hr LC_{50} should be used [2]
Chronic
• Life-cycle/Partial Life-cycle test:
  ○ Survival and growth of adults and young, maturation of males and females, eggs spawned per female, embryo viability (salmonids only), and hatchability [2]
• Early life-cycle test:
  ○ Survival and growth [2]
	List parameters:	

Was control survival acceptable? **Acute** • > 90% control survival at test termination [2] **Chronic** • > 80% control survival at test termination [2]	____ Yes ____ No Control survival (%):	
Were individuals excluded from the analysis?	____ Yes ____ No *If yes, describe justification provided:*	
Was water quality in test chambers acceptable? • If appropriate, describe any water quality issues (e.g., dissolved oxygen level below 60% of saturation)	____ Yes ____ No	
Availability of concentration-response data: • Were treatment level concentration-response data included in study publication (can be from tables, graphs, or supplemental materials)? *specify endpoints in remarks* • Were replicate level concentration-response data included in study publication (can be from tables, graphs, or supplemental materials)? *specify endpoints in remarks* • If treatment and/or replicate level concentration-response data were included, how was data presented? *(check all that apply)* • Were concentration-response data estimated from graphs study publication or supplemental materials? • Should additional concentration-response data be requested from study authors? *If concentration-response data are available, complete **Verification of Statistical Results (Part C)** for sensitive species.*	____ Yes ____ No ____ Yes ____ No ____ Tables ____ Graphs ____ Supplemental Files ____ Yes ____ No *If yes, indicate software used:* ____ Yes ____ No Requested by: Request date: Date additional data received:	

Part C: Statistical Verification of Results

I. Statistical Verification Information: *Report the statistical methods (e.g., EPA TRAP, BMDS, R, other) used to verify the reported study or test results for the five (5) most sensitive genera and sensitive apical endpoints (including for tests where such estimates were not provided). If values for the LC_{50}, LT_{50} and NOEC are greater than the highest test concentration, use the ">" symbol.*

Primary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)

Secondary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)
(*At least one reviewer should be from EPA for sensitive taxa*)

Endpoint(s) Verified:

Additional Calculated Endpoint(s):

Statistical Method (e.g., TRAP, BMDS, R, other):

II. Toxicity Values: *Include confidence intervals if applicable*

NOEC:
LOEC:
MATC:

EC_5:
EC_{10}:
EC_{20}:
EC_{50} or LC_{50}

Dose-Response Curve Classification: *(Place X by One)*
This classification should be taken into consideration for the overall study classification for aquatic life criteria development in Part A

_____ Dose-Response Curve Acceptable for Quantitative Use
_____ Dose-Response Curve Acceptable for Qualitative Use
_____ Dose-Response Curve Not Acceptable for Use

Summary of Statistical Verification: *Provide summary of methods used in statistical verification.*

Additional Notes:

Attachments:

1. *Provide attachments to ensure all data used in Part C are captured, whether from study results reported in the publication and/or from additional data requested from study authors*
    - *Data from study results of the publication should be reported in Results section of Part A*
    - *Additional data provided upon request from study authors should be reported in Table C.II.1 below and original correspondence with study authors should be included as attachments*
2. *Model assessment output (including all model figures, tables, and fit metrics)*
3. *Statistical code used for curve fitting*

III. Attachments: *Include all attachments listed above after the table below.*

Additional Data Used in Response-Curve: *Provide all data used to fit dose-response curve not captured in Results section of DER above in Part A. Add rows as needed. First row in italicized text is an example.*

Table C.II.1 Additional Data Used in Dose-Response Curve.

Curve ID	Species	Endpoint	Treatment	Replicate	[Standard Deviation or Standard Error]	# of Survivors	N[a]	k[a]	n[a]	Response	Response Unit	Conc	Conc units
Alchronic1	*Ceriodaphnia dubia*	*# of young/female*	*0*	*6*			*10*	*10*	*1*	*18*	*count*	*0.03*	*mg/L*

[a] N = number of individuals per treatment; k = number of replicates per treatment level; n = number of individuals per replicate

Q.2 Example Aquatic Invertebrate DER

Part A: Overview

I. Test Information

Chemical name:

CAS name: CAS Number:
Purity: Storage conditions:
Solubility in Water (units):

____ **Controlled Experiment** (*manipulated*) ____ **Field Study/Observation** (*not manipulated*) (*Place X by One*)

Primary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)

Secondary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)
(*At least one reviewer should be from EPA for sensitive taxa*)

Citation: *Indicate: author(s), year, study title, journal, volume, and pages.*
(e.g., Keller, A.E and S.G. Zam. 1991. The acute toxicity of selected metals to the freshwater mussel, *Anodonta imbecilis*. Environ. Toxicol. Chem. 10(4): 539-546.)

Companion Papers: *Identify any companion papers associated with this paper using the citation format above.*

Were other DERs completed for Companion Papers? ____ **Yes** ____ **No** (*If yes, list file names of DERs below*)

Study Classification for Aquatic Life Criteria Development:

_____ Acceptable for Quantitative Use
_____ Acceptable for Qualitative Use
_____ Not Acceptable for Use/Unused

General Notes: *Provide any necessary details regarding the study's use classification for all pertinent endpoints, including non-apical endpoints within the study (e.g., note all study classifications for each endpoint if the use varies)*

Major Deficiencies (note any stated exclusions): *Check all that apply. Checking any of these items make the study "**Not Acceptable for Use**"*

_____ Mixture (for controlled experiments only)
_____ No Controls (for controlled experiments only)
_____ Excessive Control Mortality (> 10% for acute and > 20% for chronic)
_____ Dilution water not adequately characterized
_____ Bioaccumulation: steady state not reached
_____ Dermal or Injection Exposure Pathway
_____ Review paper or previously published without modification

NMED Exhibit 62

_____ Other: *(if any, list here)*

POTENTIAL CHEMICAL MIXTURES: *Describe any potential chemicals mixtures as characterized by study authors (including any confirmation of chemical mixtures).*

DESCRIPTION OF DILUTION WATER: *Describe concerns with characterization of and/or major deficiencies with dilution water.*

General Notes:

Minor Deficiencies: *List and describe any minor deficiencies or other concerns with test. These items may make the study "**Acceptable for Qualitative Use**"* **(exceptions may apply as noted)**

***For Field Studies/Observations**: A field study/observation may be considered "**Acceptable for Quantitative Use**" if it consisted of a range of exposure concentrations and the observed effects are justifiably contributed to a single chemical exposure*

_____ Mixture (observed effects not justifiably contributed to single chemical exposure)
_____ Uncharacterized Reference Sites/Conditions

POTENTIAL CHEMICAL MIXTURES PRESENT AT SITE: *Describe any potential chemicals mixtures present at the site as characterized by study authors (including any confirmation of chemicals present at study site).*

EXPOSURE VARIABILITY ACROSS STUDY SITE(S): *Describe any exposure variability across study site(s) as characterized by study authors (i.e., description of study design with reference and contaminated sites).*

General Notes:

Reviewer's Comments: *Provide additional comments that do not appear under other sections of the template*.

ABSTRACT: *Copy and paste abstract from publication.*

SUMMARY*: Fill out and modify as needed.*

Acute:

Species (lifestage)	Method[a]	Test duration	Chemical / Purity	pH	Temp. (°C)	Hardness (mg/L as $CaCO_3$) or Salinity (ppt)	DOC (mg/L)	Effect	Reported Effect Concentration (mg/L)	Verified Effect Concentration (mg/L)	Classification
											Quantitative / Qualitative / Unused

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

Chronic:

Species (lifestage)	Method[a]	Test duration	Chemical / Purity	pH	Temp. (°C)	Hardness (mg/L as $CaCO_3$) or Salinity (ppt)	DOC (mg/L)	Chronic Limits	Reported Chronic Value (mg/L or µg/g)	Verified Chronic Value (mg/L or µg/g)	Chronic Value Endpoint	Classification
												Quantitative / Qualitative / Unused

[a] S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

II. Results *Provide results as reported in the publication (including supplemental materials). Include screen shots of tables and/or figures reporting results from the article following tabulated data table in each associated results section for all studies. Complete tabulated data tables for all studies for studies marked "**Acceptable for Quantitative Use"** and **"Acceptable for Qualitative Use**".*

Water Quality Parameters: *If only general summary data of water quality parameters is provided by study authors (i.e., no specific details of water quality parameters on a treatment level is provided), summarize any information regarding water quality parameters under General Notes below and include data not provided in* Table A.II.1.

General Notes: *For aquatic life criteria development, measured water quality parameters in the treatments nearest the toxicity test endpoint(s), e.g., LC_{50}, EC_{20}, etc., are most relevant.*

Table A.II.1. Measured Water Quality Parameters in Test Solutions.

Dissolved oxygen, temperature, pH and [other parameters (hardness, salinity, DOC)] in test solutions during the *[X]*-day exposure of *[test organism]* to *[concentration of treatment(s)]* of *[test substance]* under *[static renewal/flow-through]* conditions.

Parameter	Treatment	Mean	Range
Dissolved oxygen (% saturation or mg/L)	*[1]*

Part B: Detailed Review

I. Materials and Methods

PROTOCOL/GUIDANCE FOLLOWED: *Indicate if provided by authors.*

DEVIATIONS FROM PROTOCOL: *If authors report any deviations from the protocol noted above indicate here.*

Study Design and Methods: *Copy and paste methods section from publication.*

TEST ORGANISM: *Provide information under Details and any relevant or related information or clarifications in Remarks.*

Parameter	Details	Remarks
Species:	Common Name: Scientific Name:	North American species? ____ Surrogate for North American Taxon? ____ *(Place X if applicable)*

Strain/Source:
• Wild caught from unpolluted areas [1]
  o Quarantine for at least 7 days or until they are disease free, before acclimation [1]
• Must originate from same source and population [1]
• Should not be used:
  o If appeared stressed, such as discoloration or unusual behavior [1]
  o If more than 5% die during the 48 hours before test initiation [1]
  o If they were used in previous test treatments or controls [2]
• No treatments of diseases may be administered:
  o Within 16 hours of field collection [1]
  o Within 10 days of testing or during testing [1]		

Age at Study Initiation:
Acute:
• Larval stages preferred [1]
• Mayflies and Stoneflies
  o Early instar [1]
• Daphnids/cladocerans:
  o < 24-hr old [1]
• Midges:
  o 2nd or 3rd instar larva [1]
• *Hyalella azteca* (chronic exposure)
  o Generally, 7 - 8 days old [3]
• Freshwater mussels (chronic exposure)
  o Generally, 2 month old juveniles [4]
• Mysids (chronic exposure)
  o < 24-hr old [1]		

Was body weight or length recorded at test initiation and/or at regular intervals?	____ Yes ____ No	
Was body weight or length recorded at regular intervals?	____ Yes ____ No *If yes, describe regular intervals:*	

STUDY PARAMETERS: *Provide information under Details and any relevant information of deficiencies in Remarks. Complete for both Controlled Experiments and Field Studies/Observations.*

For Both Controlled Experiments and Field Observations

Parameter	Details	Remarks
Number of Replicates per Treatment Group: • At least 2 replicates/treatment recommended for acute tests [1] • At least 2 replicates/treatment recommended for chronic tests [5]	Control(s):	
	Treatment(s):	
Number of Organisms per Replicate/ Treatment Group: • At least 10 organisms/treatment recommended.	Control(s):	
	Treatment(s):	
Exposure Pathway: *(i.e., water, sediment, or diet). Note: all other pathways (e.g., dermal, injection) are unacceptable.*		
Exposure Duration: **Acute** • Cladocerans and midges should be 48 hours [2] o Longer durations acceptable if test species not fed and had acceptable controls [2] • Freshwater mussel glochidia should be a maximum of 24 hours [4] o Shorter durations (6, 12, 18 hours) acceptable so long as 90% survival of control animals achieved (see below) [4] • Embryo/larva (bivalve mollusks, sea urchins, lobsters, crabs, shrimp and abalones) should be 96 hours, but at least 48 hours [2] • Other invertebrate species should be 96 hours **Chronic** • Daphnids/cladocerans should be 21 days (3-brood test) [2] o Exception 7 days acceptable for *Ceriodaphnia dubia* [2] • Freshwater juvenile mussels should be at least 28 days [4] • *Hyalella azteca* should be at least 42 days o Beginning with 7 - 8 day old animals [3] • Mysids should continue until 7 days past the median time of first brood release in the controls [4]	____ Acute ____ Chronic ____ Other *(please remark):*	
Test Concentrations (remember units): *Recommended test concentrations include at least three concentrations other than the control; four or more will provide a better statistical analysis.*	Nominal:	
	Measured:	
	Media measured in:	
Observation Intervals: • Should be an appropriate number of observations over the study to ensure water quality is being properly maintained [1]		

CONTROLLED EXPERIMENT STUDY PARAMETERS: *Provide information under Details and any relevant information of deficiencies in Remarks. Complete for Controlled Experiments only.*

For Controlled Experiments Only

Parameter	Details	Remarks

Acclimation/Holding:
• Should be placed in a tank along with the water in which they were transported [1]
  o Water should be changed gradually to 100% dilution water (usually 2 or more days) [1]
  o For wild-caught animals, test water temperature should be within 5°C of collection water temperature [1]
  o Temperature change rate should not exceed 3°C within 72 hours [1]
• To avoid unnecessary stress and promote good health:
  o Organisms should not be crowded [1]
  o Water temperature variation should be limited
  o Dissolved oxygen:
  ▪ Maintain between 60 - 100% saturation [1]
  ▪ Continuous gentle aeration if needed [1]
  o Unionized ammonia concentration in holding and acclimation waters should be < 35 µg/L [1]
	Duration:
	Feeding:
	Water:
	Temperature (°C):
	Dissolved Oxygen (mg/L):
	Health (*any mortality observed?*):
		Identify number of individuals excluded from testing and/or analysis (if any):

Acclimation followed published guidance? *Describe, if any*	____ Yes ____ No *If yes, indicate which guidance:*	

Test Vessel:
• Test chambers should be loosely covered [1]
• Test chamber material:
  o Should minimize sorption of test chemical from water [1]
  o Should not contain substances that can be leached or dissolved in solution and free of substances that could react with exposure chemical [1]
  o Glass, No. 316 stainless steel, nylon screen and perfluorocarbon (e.g. Teflon) are acceptable [1]
  o Rubber, copper, brass, galvanized metal, epoxy glues, lead and flexible tubing should not come into contact with test solution, dilution water or stock [1]
• Size/volume should maintain acceptable biomass loading rates (see below) [1]
• Substrate:
  o Required for some species (e.g., *Hyalella azteca*) [3]
  o Common types: stainless steel screen, nylon screen, quartz sand, cotton gauze and maple leaves [3]
  o More inert substances preferred over plant material, since plants may break down during testing and promote bacterial growth [3]
  o Consideration should be given between substrate and toxicant [3]
  ▪ Hydrophobic organic compounds in particular can bind strongly to Nitex® screen, reducing exposure concentrations, especially for studies using static or intermittent renewal exposure methods [3]
	Material:
	Size:
	Fill Volume:
	Substrate Used *(if applicable)*:
		Briefly describe the test vessel here

	Parameter	Details	Remarks

For Controlled Experiments Only	**Test Solution Delivery System/Method:**
	• Flow-through preferred for some highly volatile, hydrolyzable or degradable materials [2]
	  o Concentrations should be measured often enough using acceptable analytical methods [2]
	• Chronic exposures:
	  o Flow-through, measured tests required [2]
	  o Exception: renewal is acceptable for daphnids [2]
		Test Concentrations Measured
		____ Yes ____ No
		
		Test Solution Delivery System:
		____ Static
		____ Renewal
		Indicate Interval:
		
		____ Flow-through
		Indicate Type of Diluter:	

	Source of Dilution Water:
	• Freshwater hardness range should be < 5 mg/L or < 10% of the average (whichever is greater) [1]
	• Saltwater salinity range should be < 2 g/kg or < 20% of the average (whichever is greater) [1]
	• Dilution water must be characterized (natural surface water, well water, etc.) [2]
	  o Distilled/deionized water without the addition of appropriate salts should not be used [2]
	• Dilution water in which total organic carbon or particulate matter exceed 5 mg/L should not be used
	  o Unless data show that organic carbon or particulate matter do not affect toxicity [2]
	• Dilution water for tests with *Hyalella azteca*
	  o Reconstituted waters should have at least 0.02 mg bromide/L; natural ground or surface water presumed to have sufficient bromide [3]
	  o Recommended that control/dilution waters have chloride concentrations at or above 15 mg/L [3]		

	Dilution Series (*e.g., 0.5x, 0.6x, etc.*):		
	Dilution Water Parameters: *Measured at the beginning of the experiment or averaged over the duration of the experiment (details of water quality parameters measured in test solutions should be included under the results section)*	Dissolved Oxygen (mg/L): pH: Temperature (°C): Hardness (mg/L as $CaCO_3$): Salinity (ppt): Total Organic Carbon (mg/L): Dissolved Organic Carbon (mg/L):	
	Aeration: • Acceptable to maintain dissolved oxygen at 60 - 100% saturation at all times [1] • Avoid aeration when testing highly oxidizable, reducible and volatile materials • Turbulence should be minimized to prevent stress on test organisms and/or re-suspend fecal matter [1] • Aeration should be the same in all test chambers at all times [1]	____ Yes ____ No	
	Describe Preparation of Test Concentrations (e.g., water exposure, diet):		

	Parameter	Details	Remarks
For Controlled Experiments Only	**Test Chemical Solubility in Water:** • List units and conditions (e.g., 0.01% at 20ºC)		
	Were concentrations in water or diet verified by chemical analysis? *Measured test concentrations should be reported in* Table A.II.2 *above.*	____ Yes ____ No *Indicate media:*	
	Were test concentrations verified by chemical analysis in tissue? *Measured test concentrations can be verified in test organism tissue (e.g., blood, liver, muscle) alone if a dose-response relationship is observed.* *Measured test concentrations should be reported in* Table A.II.2 *above.*	____ Yes ____ No *Indicate tissue type:*	*If test concentrations were verified in test organism tissue, was a dose-response relationship observed?*
	Were stability and homogeneity of test material in water/diet determined?	____ Yes ____ No	
	Was test material regurgitated/avoided?	____ Yes ____ No	
	Solvent/Vehicle Type: • When used, a carrier solvent should be kept to a minimum concentration [1] • Should not affect either survival or growth of test organisms [1] • Should be reagent grade or better [1] • Should not exceed 0.5 ml/L (static), or 0.1 ml/L (flow through) unless it was shown that higher concentrations do not affect toxicity [5]		
	Negative Control:	____ Yes ____ No	
	Reference Toxicant Testing:	____ Yes ____ No *If yes, identify substance:*	
	Other Control: *If any (e.g. solvent control)*		
	Biomass Loading Rate: • Loading should be limited so as not to affect test results. Loading will vary depending on temperature, type of test (static vs. flow-through), species, food/feeding regime, chamber size, test solution volume, etc. [1] • This maximum number would have to be determined for the species, test duration, temperature, flow rate, test solution volume, chamber size, food, feeding regime, etc. • Loading should be sufficiently low to ensure: o Dissolved oxygen is at least 60% of saturation (40% for warm-water species) [1,6] o Unionized ammonia does not exceed 35 µg/L [1] o Uptake by test organisms does not lower test material concentration by > 20% [1] o Growth of organisms is not reduced by crowding • Generally, at the end of the test, the loading (grams of organisms; wet weight; blotted dry) in each test chamber should not exceed the following: o Static tests: > 0.8 g/L (lower temperatures); > 0.5 g/L (higher temperatures) [1] o Flow through tests: > 1 g/L/day or > 10 g/L at any time (lower temperatures); > 0.5 g/L/day or > 5 g/L at any time (higher temperatures) [1] o Lower temperatures are defined as the lower of 17˚C or the optimal test temperature for that species. [1]		

For Controlled Experiments Only	**Feeding:**
	• Unacceptable for acute tests [2]
	  o Exceptions:
	  ▪ Data indicate that the food did not affect the toxicity of the test material [2]
	  ▪ Test organisms will be severely stressed if they are unfed for 96 hours [2]
	  ▪ Test material is very soluble and does not sorb or complex readily (e.g., ammonia) [2]
		____ Yes ____ No	

	Lighting: • No specific requirements for lighting • Generally, ambient laboratory levels (50 - 100 fc) or natural lighting should be acceptable, as well as a diurnal cycle consisting of 50% daylight or other natural seasonal diurnal cycle • Artificial light cycles should have a 15 - 30 minute transition period to avoid stress due to rapid increases in light intensity [1] • Depends on the type of test (acute or chronic) and endpoint (e.g., reproduction) of interest.		

Study Design/Methods Classification: *(Place X by One Based on Overall Study Design/Methods Classification)*
Provide details of Major or Minor Deficiencies/Concerns with Study Design in Associated Sections of Part A: Overview
This classification should be taken into consideration for the overall study classification for aquatic life criteria development in Part A.

_____ Study Design Acceptable for Quantitative Use
_____ Study Design Acceptable for Qualitative Use
_____ Study Design Not Acceptable for Use

Additional Notes: *Provide additional considerations for the classification of study use based on the study design.*

OBSERVATIONS: *Provide information under Details and any relevant information in Remarks. This information should be consistent with the Results Section in Part A.*

Parameter	Details	Remarks

Parameters measured including sublethal effects/toxicity symptoms:
Common Apical Parameters Include:
Acute
• Daphnids/cladocerans:
  ○ EC_{50} based on percentage of organisms immobilized plus percentage of organisms killed [2]
• Embryo/larva (bivalve molluscs, sea urchins, lobsters, crabs, shrimp, and abalones):
  ○ EC_{50} based on the percentage of organisms with incompletely developed shells plus the percentage of organisms killed [2]
  ▪ If not available, the lower of the 96 hour EC_{50} based on the percentage of organisms with incompletely developed shells and the 96-hr LC_{50} should be used [2]
• Freshwater mussel (glochidia and juveniles):
  ○ Glochidia: EC_{50} based on 100 x number closed glochidia after adding NaCl solution - number closed glochidia before adding NaCl solution) / Total number open and closed glochidia after adding NaCl solution [4]
  ○ Juvenile: EC_{50} based on percentage exhibiting foot movement within a 5-min observation period [4]
• All other species and older life stages:
  ○ EC_{50} based on the percentage of organisms exhibiting loss of equilibrium plus the percentage of organisms immobilized plus the percentage of organisms killed [2]
  ▪ If not available, the 96 hour LC_{50} should be used [2]
Chronic
• Daphnid:
  ○ Survival and young per female [2]
• Mysids:
  ○ Survival, growth and young per female [2]
	List parameters:	

Was control survival acceptable?
Acute
• > 90% control survival at test termination [2]
  ○ Glochidia 90% after 24 hours, or, the next longest duration less than 24 hours that had at least 90% survival [4]
Chronic
• > 80% control survival at test termination [2]
  ○ 80% in 42 day test with *Hyalella azteca*, slightly lower in tests substantially longer than 42 days [3]
	____ Yes ____ No
	Control survival (%):	

Parameter	Details	Remarks
Were individuals excluded from the analysis?	____ Yes ____ No *If yes, describe justification provided:*	
Was water quality in test chambers acceptable? • If appropriate, describe any water quality issues (e.g., dissolved oxygen level below 60% of saturation)	____ Yes ____ No	
Availability of concentration-response data: • Were treatment level concentration-response data included in study publication (can be from tables, graphs, or supplemental materials)? *specify endpoints in remarks* • Were replicate level concentration-response data included in study publication (can be from tables, graphs, or supplemental materials)? *specify endpoints in remarks* • • If treatment and/or replicate level concentration-response data were included, how was data presented? *(check all that apply)* • Were concentration-response data estimated from graphs study publication or supplemental materials? Should additional concentration-response data be requested from study authors? *If concentration-response data are available, complete **Verification of Statistical Results (Part C)** for sensitive species*.	____ Yes ____ No ____ Yes ____ No ____ Tables ____ Graphs ____ Supplemental Files ____ Yes ____ No *If yes, indicate software used:* ____ Yes ____ No Requested by: Request date: Date additional data received:	

Part C: Statistical Verification of Results

I. Statistical Verification Information: *Report the statistical methods (e.g., EPA TRAP, BMDS, R, other) used to verify the reported study or test results for the five (5) most sensitive genera and sensitive apical endpoints (including for tests where such estimates were not provided). If values for the LC_{50}, LT_{50} and NOEC are greater than the highest test concentration, use the ">" symbol.*

Primary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)

Secondary Reviewer: _____ **Date:** _____ ____ **EPA** ____ **Contractor** (*Place X by One*)
(*At least one reviewer should be from EPA for sensitive taxa*)

Endpoint(s) Verified:

Additional Calculated Endpoint(s):

Statistical Method (e.g., TRAP, BMDS, R, other):

II. Toxicity Values: *Include confidence intervals if applicable*

NOEC:
LOEC:
MATC:

EC_5:
EC_{10}:
EC_{20}:
EC_{50} or LC_{50}

Dose-Response Curve Classification: *(Place X by One)*
This classification should be taken into consideration for the overall study classification for aquatic life criteria development in Part A

_____ Dose-Response Curve Acceptable for Quantitative Use
_____ Dose-Response Curve Acceptable for Qualitative Use
_____ Dose-Response Curve Not Acceptable for Use

Summary of Statistical Verification: *Provide summary of methods used in statistical verification.*

Additional Notes:

Attachments:

1. *Provide attachments to ensure all data used in Part C is captured, whether from study results reported in the publication and/or from additional data requested from study authors*
    - *Data from study results of the publication should be reported in Results section of Part A*
    - *Additional data provided upon request from study authors should be reported in Table C.II.1 below and original correspondence with study authors should be included as attachments*
2. *Model assessment output (including all model figures, tables, and fit metrics)*
3. *Statistical code used for curve fitting*

NMED Exhibit 62

III. Attachments: *Include all attachments listed above after the table below.*

Additional Data Used in Response-Curve: *Provide all data used to fit dose-response curve not captured in Results section of DER above in Part A, rows as needed. First row in italicized text is an example.*

Table C.II.1 Additional Data Used in Dose-Response Curve.

Curve ID	Species	Endpoint	Treatment	Replicate	[Standard Deviation or Standard Error]	# of Survivors	N[a]	k[a]	n[a]	Response	Response Unit	Conc	Conc units
Alchronic1	*Ceriodaphnia dubia*	*# of young/female*	*0*	*6*			*10*	*10*	*1*	*18*	*count*	*0.03*	*mg/L*

[a] N = number of individuals per treatment; k = number of replicates per treatment level; n = number of individuals per replicate

NOTICES

This document provides information that states and authorized Tribes may consider when establishing water quality standards under the Clean Water Act (CWA) to protect aquatic life from effects of Perfluorooctanoic acid (PFOA). Under the CWA, states and authorized Tribes establish water quality criteria to protect designated uses. State and Tribal decision makers retain the discretion to adopt approaches that are scientifically defensible that differ from these recommended criteria or benchmarks, including to reflect site-specific conditions. While this document contains the Environmental Protection Agency's (EPA) scientific recommendations regarding ambient concentrations of PFOA that protect aquatic life, the PFOA Criteria Document does not substitute for the Clean Water Act or the EPA's regulations; nor is this document or the values it contains a regulation itself. This document does not establish or affect legal rights or obligations, or impose legally binding requirements on the EPA, states, Tribes, or the regulated community. It cannot be finally determinative of the issues addressed. This document has been approved for publication by the Office of Science and Technology, Office of Water, U.S. Environmental Protection Agency.

Mention of trade names or commercial products does not constitute endorsement or recommendation for use. This document can be downloaded from: https://www.epa.gov/wqc/aquatic-life-criteria-perfluorooctanoic-acid-pfoa.

NMED Exhibit 63

FOREWORD

The Clean Water Act (CWA) Section 304(a)(l) (P.L. 95-217) directs the Administrator of the EPA to develop and publish water quality criteria recommendations that accurately reflect the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare that might be expected from the presence of pollutants in any body of water, including groundwater. This document includes EPA's recommended ambient water quality criteria (AWQC) for the protection of aquatic life based upon consideration of all available information relating to effects of perfluorooctanoic acid on aquatic organisms in freshwaters, as well as an informational acute saltwater benchmark developed under CWA Section 304(a)(2).

Aquatic life benchmarks, developed by the EPA under 304(a)(2) of the CWA, are informational values that EPA generates when there are limited high quality toxicity data available and data gaps exist for several aquatic organism families. EPA develops aquatic life benchmarks to provide information that states and Tribes may consider in their water quality protection programs, including when developing water quality standards. In developing aquatic life benchmarks, data gaps may be filled using new approach methods (NAMs), such as computer-based toxicity estimation tools (e.g., EPA's Web-ICE) or other new approach methods intended to reduce reliance on additional animal testing (https://www.epa.gov/chemical-research/epa-new-approach-methods-work-plan-reducing-use-vertebrate-animals-chemical), including the use of read-across estimates based on other chemicals with similar structures. Like criteria recommendations developed under Section 304(a)(l), the EPA's aquatic life benchmark values are not regulatory, nor do they automatically become part of a state's water quality standards.

NMED Exhibit 63

Under CWA Section 303, states or authorized Tribes adopt water quality standards and submit them to EPA for review and approval. If approved by EPA as water quality standards, they become the CWA water quality standards applicable in ambient waters within that state or authorized Tribe. A state or authorized Tribe may, where appropriate, adopt water quality criteria that have the same numerical values as recommended criteria or benchmarks developed by EPA under CWA Section 304. States and authorized Tribes have discretion to adopt criteria that modify EPA's recommended criteria to reflect site-specific conditions, such as the local water chemistry or ecological conditions, or to develop criteria based on other scientifically defensible methods that are protective of designated uses (40 C.F.R. 131.11[b]). Guidelines to assist the states and authorized Tribes in modifying the criteria presented in this document are contained in the Water Quality Standards Handbook (see Chapter 3 titled "Water Quality Criteria"; U.S. EPA 2023).

Office of Science and Technology

NMED Exhibit 63

EXECUTIVE SUMMARY

The U.S. Environmental Protection Agency (EPA) developed the recommended perfluorooctanoic acid (PFOA) freshwater aquatic life ambient water quality criteria and an acute saltwater benchmark in accordance with the provisions of Section 304(a) of the Clean Water Act. This document provides the EPA's basis for and derivation of the national PFOA ambient water quality criteria recommendations to protect aquatic life. The EPA has derived the recommended PFOA aquatic life criteria and benchmark to be consistent with methods described in the EPA's "*Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses*" (U.S. EPA 1985).

PFOA is an organic, human-made perfluorinated compound, consisting of a seven-carbon backbone and a carboxylate functional group. PFOA (and other related chemicals in the perfluorocarboxylic acids, PFCAs) is used primarily in specialized applications associated with surface coatings in a variety of industrial and commercial products. This document provides a critical review of toxicity data for aquatic life identified in the EPA's literature search for PFOA, including the anionic form (CAS No. 45285-51-6), the acid form (CAS No. 335-67-1), and the ammonium salt (CAS No. 3825-26-1). It also quantifies the toxicity of PFOA to aquatic life and provides final criteria recommendations to protect aquatic life in freshwater from the acute and chronic toxic effects of PFOA.

The Aquatic Life Ambient Water Quality Criteria for PFOA document includes water column-based acute and water column-based chronic criteria, as well as chronic tissue-based criteria for freshwaters. Quantitatively-acceptable estuarine/marine toxicity data only fulfilled three of the eight minimum data requirements (MDRs) for deriving an acute estuarine/marine criterion, and one of the eight MDRs for deriving a chronic estuarine/marine criterion per the 1985 Guidelines. The EPA did, however, include an acute aquatic life benchmark for

NMED Exhibit 63

estuarine/marine environments in Appendix L, using available estuarine/marine species toxicity data and the New Approach Methods (NAMs) application of the EPA Office of Research and Development's (ORD) peer-reviewed web-based Interspecies Correlation Estimate tool (Web-ICE; Version 3.3; https://www.epa.gov/webice/). The estuarine/marine benchmarks are CWA Section 304(a)(2) information provided for states and authorized Tribes to consider in their state/tribal water quality protection programs. However, the acute estuarine/marine benchmark magnitude is less certain than the freshwater criteria as the benchmark was based on both direct laboratory-based and estimated PFOA acute toxicity data (Appendix L).

The final freshwater acute water column-based criterion magnitude is 3.1 mg/L, and the final chronic water column-based chronic criterion magnitude is 0.10 mg/L. The final chronic freshwater criterion also contains tissue-based criteria with magnitudes of 6.49 mg/kg wet weight (ww) for fish whole-body, 0.133 mg/kg ww for fish muscle tissue, and 1.18 mg/kg ww for invertebrate whole-body tissue. All criteria are intended to be equally protective against adverse PFOA effects and are intended to be independently applicable. The three tissue criteria magnitudes (for fish and invertebrate tissues) are translations of the chronic water column criterion for freshwater using bioaccumulation factors (BAFs) derived from a robust national dataset of BAFs (Burkhard 2021). The assessment of the available data for fish, invertebrates, amphibians, and plants indicates these criteria recommendations are expected to protect the freshwater aquatic community.

NMED Exhibit 63

Table Ex-1. Recommended Perfluorooctanoic acid (PFOA) Ambient Water Quality Criteria for the Protection of Aquatic Life in Freshwater.

Type/Media	Acute Water Column (CMC)[1,4]	Chronic Water Column (CCC)[1,5]	Chronic Invertebrate Whole-Body[1,2]	Chronic Fish Whole-Body[1,2]	Chronic Fish Muscle[1,2]
Magnitude	3.1 mg/L	0.10 mg/L	1.18 mg/kg ww	6.49 mg/kg ww	0.133 mg/kg ww
Duration	One-hour average	Four-day average	Instantaneous[3]		
Frequency	Not to be exceeded more than once in three years on average	Not to be exceeded more than once in three years on average	Not to be exceeded[6]		

[1] All five of these water column and tissue criteria are intended to be independently applicable and no one criterion takes primacy. All of the above recommended criteria (acute and chronic water column and tissue criteria) are intended to be protective of aquatic life. These criteria are applicable throughout the year.
[2] Tissue criteria derived from the chronic water column concentration (CCC) with the use of bioaccumulation factors and are expressed as wet weight (ww) concentrations.
[3] Tissue data provide instantaneous point measurements that reflect integrative accumulation of PFOA over time and space in aquatic life population(s) at a given site.
[4] Criterion Maximum Concentration; applicable throughout the water column.
[5] Criterion Continuous Concentration; applicable throughout the water column.
[6] PFOA chronic freshwater tissue-based criteria should not be exceeded, based on measured tissue concentrations representing the central tendency of samples collected at a given site and time.

Table Ex-2. Acute Perfluorooctanoic Acid (PFOA) Benchmark for the Protection of Aquatic Life in Estuarine/Marine Waters.

Type/Media	Acute Water Column Benchmark
Magnitude	7.0 mg/L
Duration	One hour average
Frequency	Not to be exceeded more than once in three years on average

NMED Exhibit 63

1 INTRODUCTION AND BACKGROUND

National Recommended Ambient Water Quality Criteria (AWQC) are established by the EPA under the CWA. Section 304(a)(1) states that aquatic life criteria serve as recommendations to states and authorized Tribes by defining ambient water concentrations that are expected to protect against unacceptable adverse ecological effects to aquatic life resulting from exposure to pollutants found in water. States and authorized Tribes may adopt these criteria into their water quality standards (WQS) to protect the designated uses of water bodies. States and authorized Tribes may also modify these criteria to reflect site-specific conditions or use other scientifically defensible methods to develop criteria before adopting these into standards. After adoption, states/authorized Tribes submit new and revised WQS to the EPA for review and approval or disapproval. When approved by the EPA, the state's/Tribe's WQS become the applicable WQS for CWA purposes. Such purposes include identification of impaired waters and establishment of Total Maximum Daily Loads (TMDLs) under CWA Section 303(d) and derivation of water quality-based effluent limitations in permits issued under the CWA Section 402 National Pollutant Discharge Elimination System (NPDES) program. The EPA recommends the adoption of both the acute and chronic water column criteria as well as the chronic tissue-based criteria to ensure the protection of aquatic life through all exposure pathways, including direct aqueous exposure and bioaccumulation. Aquatic life benchmarks, developed by EPA under 304(a)(2) of the CWA, are informational values that EPA generates when there are limited high quality toxicity data available and data gaps exist for several aquatic organism families. EPA provided an acute estuarine/marine benchmark in Appendix L as additional information on protective values that states and tribes may consider in their water quality programs.

This document provides a critical review of toxicity data identified in the EPA's literature search for PFOA, including the anionic form (CAS No. 45285-51-6), the acid form (CAS No.

NMED Exhibit 63

335-67-1), and the ammonium salt (CAS No. 3825-26-1). It also quantifies the toxicity of PFOA to aquatic life and provides criteria to protect aquatic life in freshwater from the acute and chronic toxic effects of PFOA.

The EPA derived the recommended criteria using the best available data to reflect the latest scientific knowledge on the toxicological effects of PFOA on aquatic life. The EPA developed the criteria following the general approach outlined in the EPA's "*Guidelines for Deriving Numerical Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses"* (U.S. EPA 1985). The PFOA criteria, if adopted and implemented, are expected to be protective of most aquatic organisms, including species listed as threated or endangered, in the community (i.e., approximately 95 percent of tested aquatic organisms representing the aquatic community) and are derived to be protective of aquatic life designated uses established by states and authorized Tribes for freshwaters. The estuarine/marine benchmarks are also intended to be protective of aquatic life designated uses, but they are based on fewer empirical PFOA toxicity data and, therefore, have greater inherent uncertainty. The criteria recommendations presented herein are the EPA's best estimate of the concentrations of PFOA, with associated frequency and duration specifications, that would protect sensitive aquatic life from unacceptable acute and chronic effects of PFOA.

1.1 Previously Derived PFOA Toxicity Values and Thresholds

Other jurisdictions (e.g., states, countries, etc.) have previously published PFOA acute and chronic criteria, benchmarks, or thresholds, including values for both freshwater and marine systems. These values focus exclusively on water column-based values only; no other jurisdiction has previously derived tissue-based values. Within the United States, no states or Tribes have CWA Section 303(c) approved PFOA water quality standards for the protection of

NMED Exhibit 63

aquatic life. However, several states have published draft/interim acute and chronic ecological screening level values/benchmarks for the protection of aquatic life (e.g., Michigan, Minnesota, Texas, Florida, California).

These publicly available freshwater acute values range from 4.47 mg/L in Texas (TCEQ 2021) to 20 mg/L in Florida (Stuchal and Roberts 2019) (Table 1-1). The EPA's freshwater acute PFOA criterion (3.1 mg/L) is slightly lower than the range of state-derived values. No acute estuarine/marine criteria, benchmarks, or protective values have been established for PFOA, other than the benchmark provided herein.

Publicly available freshwater chronic values for other jurisdictions range from 0.22 mg/L in Australia/New Zealand (95% species protection level; CRC CARE 2017; EPAV 2016; HEPA 2020; Table 1-1) to 2.27 mg/L in Texas (TCEQ 2021), which are all higher than the EPA's freshwater chronic criterion of 0.10 mg/L, which includes more recently published data not accounted for in other previously published values.

Previously published estuarine/marine chronic values are available for Australia/New Zealand with a chronic protective value of 0.22 mg/L (95% species protection level) and California with a chronic "interim final screening level value" of 0.54 mg/L (Table 1-1).

NMED Exhibit 63

Table 1-1. Previously Derived PFOA Toxicity Values and Thresholds.

State/Country of Applicability	Aquatic Life Protective Value (mg/L)	Criteria or Benchmark and Calculation Approach	Source
Freshwater Acute			
Texas	4.47	Based on NOAELs, LOAELs, or similar values from specific toxicological studies. Contact the TCEQ for more information. This is an acute surface water benchmark and does not represent a CWA Section 303(c) approved water quality standard for PFOA.	TCEQ 2021
Michigan	7.7	Calculated from a species sensitivity distribution (SSD) consisting of two species-specific values. The Final Acute Value (FAV) was based on the lowest EC_{50} divided by a safety factor of 13 (following the U.S. EPA Great Lakes Initiative [GLI; U.S. EPA 1995a]). This protective value is a translation of narrative water quality criteria and does not represent a CWA Section 303(c) approved water quality standard for PFOA.	EGLE 2010
Minnesota	15	Calculated from a species sensitivity distribution (SSD) consisting of three species-specific values. The Maximum Criterion (MC) was based on the lowest EC_{50} divided by a safety factor of 13 (following the U.S. EPA Great Lakes Initiative [GLI; U.S. EPA 1995a]). This draft value is does not represent a CWA Section 303(c) approved water quality standard for PFOA.	STS/MPCA 2007
Florida	20	Secondary Acute Value (SAV) calculated using the U.S. EPA Great Lakes Initiative (GLI; U.S. EPA 1995a) Tier II Methodology. FAV calculated as the lowest GMAV (unspecified) divided by a safety factor of 5.2. This value was released in a White Paper sponsored by Florida Department of Environmental Protection and is considered a draft eco-based surface water screening level, it is not a CWA Section 303(c) approved water quality standard.	Stuchal and Roberts 2019

State/Country of Applicability	Aquatic Life Protective Value (mg/L)	Criteria or Benchmark and Calculation Approach	Source
Freshwater Chronic			
Australia, New Zealand	0.019 (99% species protection – high conservation value systems)	Guidelines calculated from a species sensitivity distribution (SSD) consisting of 12 species-specific values for fish, insects, crustaceans, rotifers, algae, and plants following the guidance of Warne et al. (2018) and Batley et al. (2014)	CRC CARE 2017, EPAV 2016, HEPA 2020
	0.22 (95% species protection – slightly to moderately disturbed systems)		
	0.632 (90% species protection – highly disturbed systems)		
	1.824 (80% species protection – highly disturbed systems)		
California	0.54 (99% species protection)	HC1 calculated from an acute and chronic NOEC-based SSD as reported in DoD-SERDP Project ER18-1614 (DoD-SERDP 2019). Acute NOEC values were converted to chronic values using mean acute-to-chronic ratios derived from Giesy et al. (2010). This value represents an "Interim Final Environmental Screening Level" and does not represent a CWA Section 303(c) approved water quality Standard for PFOA.	San Francisco Bay RWQCB 2020; DoD-SERDP 2019
Michigan	0.88	Final Chronic Value (FCV) was calculated as the FAV ÷ Final Acute: Chronic ratio (ACR) (following the GLI; U.S. EPA 1995a). This protective value is a translation of narrative water quality criteria and does not represent a CWA Section 303(c) approved water quality standard for PFOA.	EGLE 2010

State/Country of Applicability	Aquatic Life Protective Value (mg/L)	Criteria or Benchmark and Calculation Approach	Source
Florida	1.3	Secondary Chronic Value (SCV) calculated using the U.S. EPA Great Lakes Initiative (GLI; U.S. EPA 1995a) Tier II Methodology with acute-to-chronic ratio (ACR) of 15.3. SCV = SAV (20,000 µg/L) ÷ ACR (15.3) = 1,300 µg/L or 1.3 mg/L. This value was released in a White Paper sponsored by Florida Department of Environmental Protection and is considered a draft eco-based surface water screening level, it is not a CWA Section 303(c) approved water quality standard.	Stuchal and Roberts 2019
Minnesota	1.7	Chronic Criterion (CC) calculated as the FAV ÷ a generic ACR following Minnesota Rules Chapter 7050. No species-specific ACRs were available at the time to calculate the FACR. This draft value idoes not represent a CWA Section 303(c) approved water quality standard for PFOA.	STS/MPCA 2007
Texas	2.77	Based on NOAELs, LOAELs, or similar values from specific toxicological studies. Contact the TCEQ for more information. This is a chronic surface water benchmark and does not represent a CWA Section 303(c) approved water quality standard for PFOA.	TCEQ 2021
Marine Chronic			
California	0.54 (99% species protection)	HC1 calculated from an acute and chronic NOEC-based SSD as reported in DoD-SERDP Project ER18-1614 (DoD-SERDP 2019). Acute NOEC values were converted to chronic values using mean acute-to-chronic ratios derived from Giesy et al. (2010). This value represents an "Interim Final Environmental Screening Level" and does not represent a CWA Section 303(c) approved water quality Standard for PFOA.	San Francisco Bay RWQCB 2020; DoD-SERDP 2019
Australia, New Zealand	0.019 (99% species protection – high conservation value systems) 0.22 (95% species protection – slightly to moderately disturbed systems)	Freshwater values are to be used on an interim basis until final marine guideline values can be set using the nationally agreed process under the Australian and New Zealand Guidelines for Fresh and Marine Water Quality.	HEPA 2020

State/Country of Applicability	Aquatic Life Protective Value (mg/L)	Criteria or Benchmark and Calculation Approach	Source
	0.632 (90% species protection – highly disturbed systems)		
	1.824 (80% species protection – highly disturbed systems)		

1.2 Overview of Per- and Polyfluorinated Substances (PFAS)

Perfluorooctanoic acid (PFOA), and its salts, belong to the per- and polyfluorinated substances (PFAS) group of chemicals. PFAS are a large group of structurally diverse anthropogenic chemicals that include PFOA, PFOS, and thousands of other fully or partially fluorinated chemicals. There are many families or subclasses of PFAS, and each contains many individual structural homologues and can exist as either branched-chain or straight-chain isomers (Buck et al. 2011; U.S. EPA 2021). These PFAS families can be divided into two primary categories: non-polymers and polymers. The non-polymer PFAS include perfluoroalkyl and polyfluoroalkyl substances. Polymer PFAS include fluoropolymers, perfluoropolyethers, and side-chain fluorinated polymers (Table 1-2). Several U.S. federal, state, and industry stakeholders as well as European entities have posited various definitions of what constitutes a PFAS. OECD, an international organization comprised of 38 countries, recently published a practical guidance regarding the terminology of PFAS (OECD 2021). The OECD-led "Reconciling Terminology of the Universe of Per- and Polyfluoroalkyl Substances: Recommendations and Practical Guidance" workgroup provided an updated definition of PFAS, originally posited in part by Buck et al. (2011), as follows: "PFASs are defined as fluorinated substances that contain at least one fully fluorinated methyl or methylene carbon atom (without any H/Cl/Br/I atom attached to it), i.e. with a few noted exceptions, any chemical with at least a perfluorinated methyl group (–CF3) or a perfluorinated methylene group (–CF2–) is a PFAS". It is not within the scope of this framework to compare and contrast the various definitions, or the nuances associated with defining or scoping PFAS; rather the reader of this document is referred to OECD (2021) for review. Generally, the structural definition of PFAS includes chemicals that contain at least one of the following three structures:

NMED Exhibit 63

- R-(CF_2)-CF(R′)R″, where both the CF_2 and CF moieties are saturated carbons, and none of the R groups can be hydrogen (TSCA draft definition);
- R-CF_2OCF_2-R′, where both the CF_2 and CF moieties are saturated carbons, and none of the R groups can be hydrogen; and
- $CF_3C(CF_3)$R′R ″, where both the CF_2 and CF moieties are saturated carbons, and none of the R groups can be hydrogen.

It should also be noted that what defines or constitutes a PFAS may change or evolve over time and under different purviews (e.g., federal, state, international).

NMED Exhibit 63

Table 1-2. Two Primary Categories of PFAS[1].

PFAS Non-polymers	Structural Elements	Example PFAS Families
Perfluoroalkyl acids	Compounds in which all carbon-hydrogen bonds, except those on the functional group, are replaced with carbon-fluorine bonds	Perfluoroalkyl carboxylic and sulfonic acids (e.g., PFOA, PFOS), perfluoroalkyl phosphonic and phosphinic acids, perfluoroalkylether carboxylic and sulfonic acids
Polyfluoroalkyl acids	Compounds in which all carbon-hydrogen bonds on at least one carbon (but not all) are replaced with carbon-fluorine bonds	polyfluoroalkyl carboxylic acids, polyfluoroalkylether carboxylic and sulfonic acids
PFAS Polymers	**Structural Elements**	**Example PFAS Families**
Fluoropolymers	Carbon-only polymer backbone with fluorines directly attached	polytetrafluoroethylene, polyvinylidene fluoride, fluorinated ethylene propylene, perfluoroalkoxyl polymer
Polymeric perfluoropolyethers	Carbon and oxygen polymer backbone with fluorines directly attached to carbon	F-(CmF2mO-)nCF3, where the CmF2mO represents -CF2O, -CF2CF2O, and/or -CF(CF3)CF2O distributed randomly along polymer backbone
Side-chain fluorinated polymers	Non-fluorinated polymer backbone with fluorinated side chains with variable composition	n:1 or n:2 fluorotelomer-based acrylates, urethanes, oxetanes, or silicones; perfluoroalkanoyl fluorides; perfluoroalkane sulfonyl fluorides

[1:] Amalgamation of information from Figure 9 of OECD (2021) and Buck et al. (2011).

PFOA belongs to the perfluoroalkyl acids (PFAAs) of the non-polymer perfluoroalkyl substances category of PFAS (Table 1-2). PFAAs are among the most researched PFAS (Wang et al. 2017). The family PFAAs includes perfluoroalkyl carboxylic, sulfonic, sulfinic, phosphonic, and phosphinic acids (Table 1-3). PFAAs are highly persistent and are frequently found in the environment (Ahrens 2011; Wang et al. 2017). PFAAs may dissociate to their anions in aqueous environmental media, soils, or sediments depending on their acid strength (pK_a value). Although the protonated and anionic forms may have different physiochemical

NMED Exhibit 63

properties, the anionic form is the dominant form in the aquatic environment, including in the toxicity tests used to derive the PFOA criteria.

Table 1-3. Classification and Chemical Structure of Perfluoroalkyl Acids (PFAAs).[1]

Classification	Functional Group	Example
Perfluoroalkyl carboxylic acids (PFCAs)	-COOH	Perfluorooctanoic acid (PFOA)[2]
Or Perfluoroalkyl carboxylates (PFCAs)	$-COO^-$	Perfluorooctanoate (PFO)
Perfluoroalkane sulfonic acids (PFSAs)	$-SO_3H$	Perfluorooctane sulfonic acid (PFOS)
Or Perfluorokane sulfonates (PFSAs)	$-SO_3^-$	Perfluorooctane sulfonate (PFOS)
Perfluoroalkyl sulfinic acids (PFSIAs)	$-SO_2H$	Perfluorooctane sulfinic acid (PFOSI)
Perfluoroalkyl phosphonic acids (PFPAs)	$-P(=O)(OH)_2$	Perfluorooctyl phosphonic acid (C8-PFPA)
Perfluoroalkyl phosphinic acids (PFPIAs)	$-P(=O)(OH)(C_mF_{2m+1})$	Bis(perfluorooctyl) phosphinic acid (C8/C8-PFPIA)
Perfluoroalkylether carboxylic acids (PFECAs)	$CF_3(OCF_2)_nCOO^-$	perfluoro (3,5,7-trioxaoctanoic) acid
Perfluoroalkylether sulfonic acids (PFESAs)	$CF_3(OCF_2)_nSO_3H$	6:2 Cl-PFESA
Perfluoroalkyl dicarboxylic acids (PFdiCAs)	$HOOC\text{-}C_nF_{2n}\text{-}COOH$	9:3 Fluorotelomer betaine
Perfluoroalkane disulfonic acids (PFdiSAs)	$HO_3S\text{-}C_nF_{2n}\text{-}SO_3H$	Perfluoro-1,4-disulfonic acid

[1]: Modified from Buck et al. (2011) and OECD (2021).
[2]: At most environmentally relevant pH conditions, PFOA occurs in the anionic form.

Perfluoroalkyl carboxylic acids (PFCAs), including PFOA, consist of a general chemical structure of $C_nF_{2n+1}COOH$. This chemical structure makes PFOA (see Figure 1-1) extremely strong and stable, and resistant to hydrolysis, photolysis, microbial degradation, and metabolism (Ahrens 2011; Beach et al. 2006; Buck et al. 2011).

NMED Exhibit 63

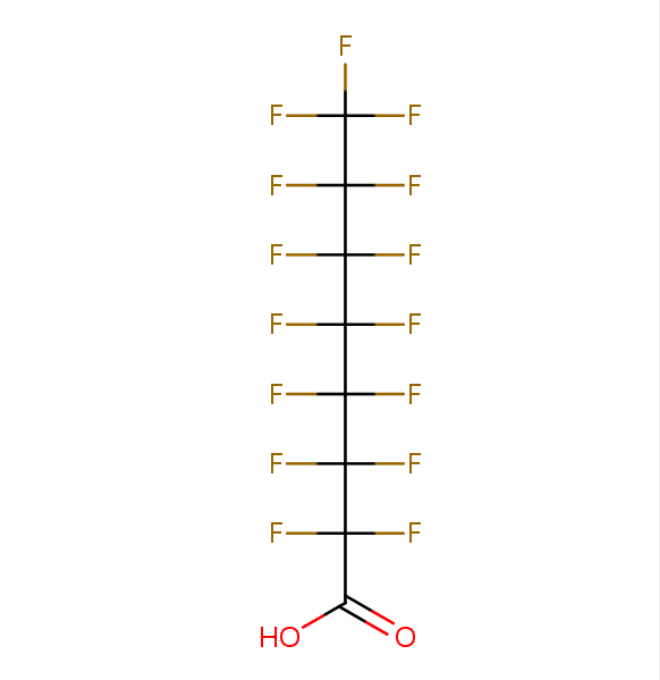

Figure 1-1. Chemical Structure of the Linear Isomer of Perfluorooctanoic acid (PFOA).
(Source: United States EPA Chemistry Dashboard; https://comptox.epa.gov/dashboard).

1.2.1 Physical and Chemical Properties of PFOA

Physical and chemical properties along with other reference information for PFOA are provided in Table 1-4. These physical and chemical properties helped to define the environmental fate and transport of PFOA in the aquatic environment. In the environment, PFOA rapidly ionizes in water to its anionic form (perfluorooctanoate, PFO). PFOA is highly stable and is resistant to hydrolysis, photolysis, volatilization, and biodegradation (UNEP 2015).

NMED Exhibit 63

Property	PFOA, acidic form[1]	Source
Half-Life in Water	Stable	UNEP (2015)
Half-Life in Air	Stable	UNEP (2015)

[1]: PFOA is most commonly produced as an ammonium salt (CASRN 3825-26-1). Properties specific to the salt are not included.

PFOA is water soluble, nonvolatile, and stable, with a low vapor pressure and is a solid at room temperature (UNEP 2015). The EPA's chemistry dashboard reported a mean experimental acid dissociation constant (pKa) for PFOA of 3.15 calculated from pKa values determined from Burns et al. (2008) and 3M Company (2003). Burns et al. (2008) measured an acid dissociation constant (pKa) for PFOA of 3.8 using a standard water-methanol mixed solvent approach, which indicates PFOA is a moderate acid, while 3M Company (2003) reported a measured PFOA pKa of 2.5.

Due to the surfactant properties of PFOA, it forms three layers when added to octanol and water in a standard test system used to measure a n-octanol-water partition co-efficient (K_{OW}), thus preventing direct measurement (EFSA 2008; Giesy et al. 2010). Although a K_{OW} cannot be directly measured, a K_{OW} for PFOA has been estimated from its individual water and octanol solubilities (estimated PFOA K_{OW} range = 2.69 – 6.3; UNEP 2015); however, the veracity of such estimates is uncertain (UNEP 2015). Lacking a reliable K_{OW} for PFOA precludes application of K_{OW}-based models commonly used to estimate various physiochemical properties for organic compounds, including bioconcentration factors and soil adsorption coefficients. Further, the unusual characteristics of PFOA would bring into question the use of K_{OW} as a predictor of environmental behavior; for example, bioaccumulation of PFOA is thought to be mediated via binding to proteins rather than partitioning into lipids (EFSA 2008; Giesy et al. 2010), the latter being the theoretical basis for K_{OW}-based prediction of bioaccumulation.

NMED Exhibit 63

2 PROBLEM FORMULATION

A problem formulation provides a strategic framework for water quality criteria development under the CWA by focusing on the most relevant chemical properties and endpoints. In the problem formulation, the purpose of the assessment is stated, the problem is defined, and a plan for analyzing and characterizing risk is developed. The structure of this problem formulation was consistent with the EPA's Guidelines for Ecological Risk Assessment (U.S. EPA 1998).

2.1 Overview of PFOA Sources

2.1.1 Manufacturing of PFOA

PFOA is primarily produced through Electrochemical Fluorination (ECF) in which an organic raw material, in the case of PFOA as octanoyl fluoride ($C_7H_{15}COF$), undergoes electrolysis in anhydrous hydrogen fluoride solution. This electrolysis leads to the replacement of all the hydrogen atoms by fluorine atoms and results in perfluorooctanoyl fluoride ($C_7F_{15}COF$), which is the major raw material used to manufacture PFOA and PFOA salts (Figure 2-1; Buck et al. 2011). Electrochemical Fluorination typically results in a mixture of branched and linear isomers.

NMED Exhibit 63

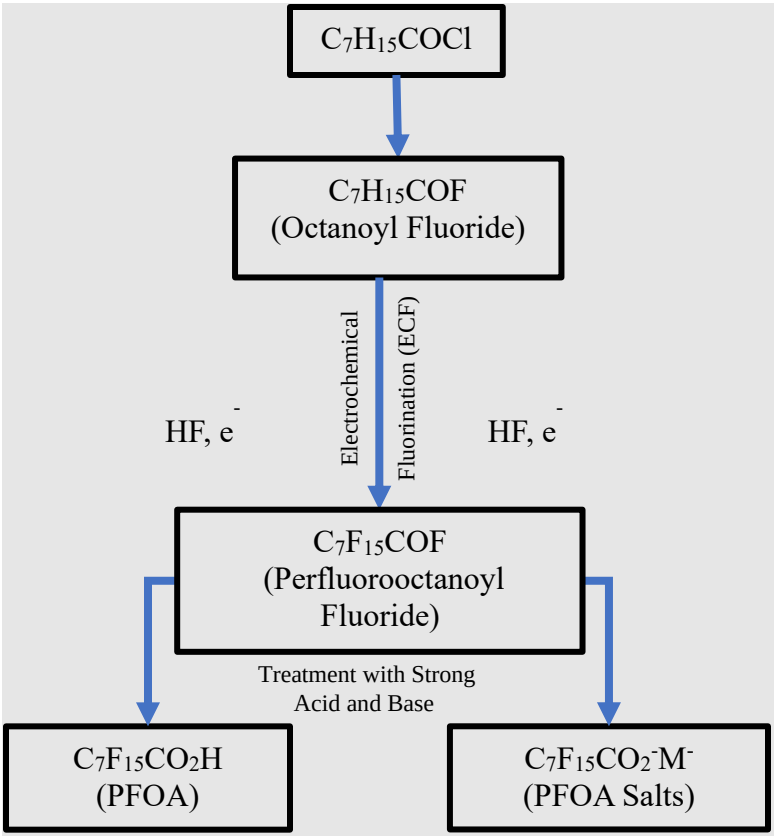

Figure 2-1. Synthesis of Perfluorooctanoic acid (PFOA) by Electrochemical Fluorination (ECF).
Modified from Buck et al. (2011).

Initial production of PFOA started in the 1940s and commercial production and use as protective coatings starting in the mid-1950s. From 1951 – 2004 the total global historic industry wide emission of PFCAs (including PFOA) from all sources (i.e., direct and indirect sources such as manufacture, use, consumer products, and PFCA precursors) ranged from 3,200 tons to 7,300 tons (Prevedouros et al. 2006). In 2006, the EPA initiated the 2010/2015 PFOA Stewardship Program, resulting in major PFOA producers committing to a 95% reduction in PFOA facility emissions and product contents across the globe by 2010. The 2010/2015 PFOA Stewardship Program further aimed to eliminate PFOA emissions and product content by 2015 (U.S. EPA 2006).

2.1.2 Sources of PFOA to Aquatic Environments

PFCAs, including PFOA are primarily released into water (95% of PFCAs are emitted to water; 3M Company 2000b) and can enter the aquatic environment from both industrial and consumer products during manufacturing, along the supply chains, during product use and/or disposal (Ahrens and Bundschuh 2014; Kannan 2011). Occurrence of PFOA in the aquatic environment arises from both direct and indirect sources (Ahrens et al. 2011a). However, the quantitative assessments of their production, direct and indirect emissions, and environmental measurements are lacking (Ahrens and Bundschuh 2014; Prevedouros et al. 2006).

The direct sources of PFOA to the aquatic environment include both municipal and industrial wastewater treatment plants (WWTPs), landfill leachate, and runoff from contaminated biosolids (Renner 2009). WWTPs in particular are an important source of PFOA to aquatic systems (Ahrens et al. 2009).

Indirect sources of PFOA to aquatic environments include dry and wet atmospheric deposition, runoff from contaminated soils, and consumer product use and disposal (Kannan 2011). Identification of indirect sources of PFOA and understanding their relative contribution to aquatic ecosystems is difficult. Overall, the presence of indirect sources of PFOA and their contributions are dependent on the system and the nearby land uses. Overall PFAS concentrations, including PFOA, in the environment are positively correlated with population density. Overall, PFOA occurrence in aquatic environments is driven by legacy PFOA sources because use of PFOA in the United States was largely phased out by 2010, and completely phased out by 2015 in accordance with the EPA's 2010/2015 PFOA Stewardship Program.

In addition to direct discharge, environmental breakdown of precursor compounds containing a seven-member perfluoro moiety can provide an additional source of PFOA. Metabolic transformation of PFAS precursors, such as PAPs, FTCAs, FTUCAs, FTSAs, and

NMED Exhibit 63

FASAAs, and the degradation of volatile PFAS, such as FTOHs, FASAs, and FASEs, can be potential sources of PFOA as these compounds can transform into more persistent PFAS, including PFCAs and PFOA (Ahrens and Bundschuh 2014). For example, fluoroacrylate polymers can breakdown in soil and release fluorotelomer alcohol (FTOH) which can further degrade into PFOA (Russell et al. 2008). Similarly, polyfluoroalkyl phosphoric acid diesters (diPAPs) are used in commercial applications, such as food packaging, and can be found in WWTP sludge and contaminated biosolids. In environmental media, diPAPs can release FTOH that further degrades into PFOA (Lee et al. 2010; Sinclair and Kannan 2006; Washington et al. 2009). Current understanding of these transformation processes remains limited, and additional work is needed to fully understand these processes and their role in generation of sources of PFOA to aquatic environments (Lau et al. 2007).

PFOA can also be re-emitted to the aquatic environment from ice melt and sediment transport. Release of PFOA will continue into the future from the transformation of other PFAS and the historical products still in use (e.g., consumer goods manufactured and/or obtained before the PFOA discontinuation).

2.2 Environmental Fate and Transport of PFOA in the Aquatic Environment

2.2.1 Environmental Fate of PFOA in the Aquatic Environment

In natural waters near neutral pH, PFOA rapidly dissociates into ionic components. In aquatic environments, PFOA has an affinity to remain in the water column rather than sediments, but can also adsorb to sediments in the presence of organic carbon, with the partitioning coefficients (K_d) increasing with salinity (Canada 2012; Hekster et al. 2003). Because of its water solubility and preferential binding to proteins, once PFOA enters a waterbody it tends to remain dissolved in the water column, where it is mobile, unless it adsorbs to organic particulate matter or is assimilated by organisms.

NMED Exhibit 63

PFOA has low volatility in the ionized form but can adsorb to particles in air where it can be transported globally, including remote locations (Del Vento et al. 2012; Shoeib et al. 2006). PFOA is water soluble and has been found in surface water, ground water, and drinking water. Because of the relatively low log K_{OC} of PFOA, it does not easily adsorb to sediments and tends to stay in the water column.

In the water column, and other environmental compartments, PFOA is stable and resistant to hydrolysis, photolysis, volatilization, and biodegradation (Higgins and Luthy 2006; UNEP 2015). The persistence of PFOA has been attributed to the strong carbon-fluorine (C-F) bond. Additionally, there are limited indications that naturally occurring defluorinating enzymes exist that can break a C-F bond. Consequently, no biodegradation or abiotic degradation processes for PFOA are known. In aquatic environments, the only dissipation mechanisms for PFOA are physical mechanisms, such as environmental dilution and sorption.

2.2.2 Environmental Transport of PFOA in the Aquatic Environment

The physiochemical properties discussed in Section 1.2.1 above enable PFOA to be highly persistent in the aquatic environment. PFOA tends to be distributed in waters and in the atmosphere (Ahrens 2011; Yamashita et al. 2008). PFOA concentrations in seawater are typically greater than PFOS, which has been attributed to the relatively lower bioaccumulation potential, lower sorption to sediments, and greater water solubility (Ahrens 2011; Ahrens et al. 2009).

Numerous uncertainties exist in the understanding of environmental transport of PFOA in aquatic systems. Both point and non-point sources contribute PFOA to the aquatic environment. PFOA can be transported from these sources into rivers, streams, lakes, and marine environments. There is a general decrease in PFOA concentrations along a transport pathway resulting from dilution in the water column. For example, measured PFOA concentrations in

NMED Exhibit 63

WWTP effluents were generally an order of magnitude greater than riverine concentrations, with the upper end of riverine concentrations being similar to WWTP effluents. Although minimum and maximum PFOA concentrations in coastal waters (ranging from hundreds of pg/L to several ng/L) were below corresponding measurements in riverine systems, coastal PFOA concentrations in general were largely similar to riverine concentrations. Open oceans contained the lowest PFOA concentrations resulting from immense dilution. Overall, open ocean concentrations of PFOA were roughly 2.5 orders of magnitude lower than those reported in WWTP effluents (Ahrens 2011).

PFOA has been found in a diversity of environments, including in the arctic and Antarctic, despite the limited number of manufacturing facilities and/or small population sizes typically found in these areas (Del Vento et al. 2012; Shoeib et al. 2006). Although PFOA has low volatility, particularly in the ionized form, it can absorb to air particles before being deposited via atmospheric deposition to these remote regions. For example, Kim and Kannan (2007) reported PFOA in snow in the United States ranging from below the limit of quantification to 20 ng/L. Similarly, Young et al. (2007) reported mean PFOA concentrations in snow in Canada ranging from 0.01 ng/L to 0.15 ng/L.

The continued presence of PFOA in open oceans and in remote polar areas may be due to multiple exposure pathways, including those caused by direct production, use, and discharge of PFOA itself, degradation and transformation of precursor compounds, and via long range aqueous and atmospheric transport (Armitage et al. 2009).

2.3 Transformation and Degradation of PFOA Precursors in the Aquatic Environment

Included among major sources of PFOA to the environment is from the abiotic and biotic transformation and degradation of polyfluoroalkyl precursor substances (see Section 2.2.2

NMED Exhibit 63

above). Polyfluoroalkyl substances are one type of precursor substance that have the potential to be transformed abiotically or biotically into PFCAs such as PFOA (Buck et al. 2011). On a global scale, production volumes of polyfluoroalkyl substances, many of which are likely polyfluoroalkyl precursor substances that ultimately degrade or transform to PFOA, greatly exceed direct emissions of PFOA through its manufacture, use and disposal (Butt et al. 2014; Liu and Mejia Avendaño 2013). According to the OECD (2006), there were approximately one thousand polyfluorylalkyl chemicals commercially produced at the time that could conceivably degrade to PFCAs such as PFOA. For example, Buck et al. (2011) identified 42 families of compounds and numerous individual PFAS detected in environmental and human matrices, many of which have not been evaluated for their biodegradability (Liu and Mejia Avendaño 2013). Any or all members of these PFAS have the ability to be transformed or degraded to PFAAs such as PFCAs or perfluoroalkane sulfonic acids (PFSAs).

Critical reviews by Butt et al. (2014) and Liu and Mejia Avendaño (2013) provided a comprehensive summary of the qualitative and quantitative relationships between biodegradation and transformation of polyfluoroalkyl precursors and generation of PFOA and other PFCAs. The most well-studied polyfluoroalkyl precursor substances are fluorotelomer-based compounds, which are produced through telomerization technology and are associated with PFOA as the final product (Buck et al. 2011).

2.3.1 Biodegradation of fluorotelomer-based precursors

The aerobic biodegradation pathway of fluorotelomer alcohols (8:2 and 6:2 FTOH) have been thoroughly studied. Dinglasan et al. (2004) was among the first to investigate the biotransformation of 8:2 FTOH in a mixed microbial culture. Additional studies of the aerobic microbial degradation of 8:2 FTOH by Liu et al. (2010) and Wang et al. (2005, 2009, and 2012) have since confirmed the formation of PFOA via this pathway. The observed half-lives of 8:2

NMED Exhibit 63

FTOH ranged from <2 days to 30 days in these laboratory studies. Molar yield of PFOA ranged anywhere from 0.5 to 40% depending on type of microbes or microcosm used in the study, with Wang et al. (2009) observing relatively higher PFOA yield in aerobic soils relative to PFOA yield in pure bacterial culture (Liu et al. 2010). Thus, aerobic microbial degradation of 8:2 FTOH can be a significant source of PFOA in some environmental compartments. Anaerobic microbial degradation of 8:2 FTOH, on the other hand, is inefficient and likely an insignificant source of PFOA to the environment (Zhang et al. 2013b). Additional studies are needed, however, to understand anaerobic biodegradability of FTOHs and related compounds in general (Liu and Mejia Avendaño 2013).

Aerobic biodegradation of several other types of fluorotelomer-based, polyfluoroalkyl precursor substances definitively linked to PFOA formation include: fluorotelomer stearate (8:2 FTS) with observed half-life in aerobic soils of 5-28 days and molar yield of about 01.7-4% (Dasu et al. 2012, 2013); fluorotelomer acrylate (8:2 FTAC) and fluorotelomer methacrylate (8:2 FTMAC) monomers with observed half-life in aerobic soils of 3-5 days and 15 days and molar yields of 7.8 and 10%, respectively (Royer 2011); fluorotelomer ethoxylates (FTEOs) with observed half-life in unfiltered WWTP effluent of approximately one day and molar yield of about 0.3% (Frömel and Knepper 2010); and fluorotelomer urethanes, specifically, aliphatic diurethane ester (8:2 HMU), with an half-life in aerobic soils of >180 days and molar yield of 0.9% (Dasu 2011).

2.3.2 Biodegradation of side-chain polymers

At present, a crucial need exists to understand the potential degradation of side-chain fluorinated polymers in natural environments because they currently represent a high percentage of all commercial and industrial PFAS sales products (Liu and Mejia Avendaño 2013). Side-chain polymers are those with polyfluoroalkyl or perfluoroalkyl chains attached to non-

NMED Exhibit 63

fluorinated backbones (Buck et al. 2011). Russell et al. (2008) investigated the biodegradation of a high molecular weight (~40,000 amu, 100–300 nm in diameter) polyacrylate polymer aqueous dispersion product in four aerobic soils over two years. Two approaches (molar mass balance and kinetic modeling) gave conflicting results. The molar mass balance approach indicated no evidence of biodegradation because the PFOA generated was mostly accounted for by impurity (residual non-polymerized PFAS) degradation. Conversely, using the kinetic modeling approach half-lives of PFOA were estimated to be around 1,200-1,700 years among the four soils tested. Upon further investigation using a low molecular weight (~3,500 amu) polyurethane polymer product and a similar approach, Russell et al. (2010) clearly demonstrated biodegradability of the low molecular weight polyurethane polymer product compared to the polyacrylate polymer, as the levels of PFOA produced were several orders of magnitude greater than what the impurities could account for. Applying a similar kinetic modeling approach, the half-lives of the polyurethane polymer were estimated to range from 28 to 241 years among the four test soils. Given the large disparity in half-life prediction between the two studies, however, additional research is needed to clarify the contributions of polyfluoroalkyl polymers to PFOA formation due to the high percentage of side-chain fluorinated polymers that exist in commercial and industrial sales products.

2.3.3 Biodegradation of other polyfluoroalkyl substances

Recently, Mejia-Avendaño et al. (2016) examined the formation of PFOA from aerobic biotransformation of quaternary ammonium polyfluoroalkyl surfactants (QACs). Capitalizing on several recent studies focused on identifying specific PFAS in major PFAS-based aqueous film-forming foam (AFFF) formulations, all the newly identified PFAS were polyfluoroalkyl compounds. These compounds have perfluoroalkyl carbon chain lengths varying from four to 12 and possess functionalities such as sulfonyl, thioether, tertiary amine, quaternary ammonium,

NMED Exhibit 63

carboxylate, sulfonate, amine oxide, and betaine, etc. (Mejia-Avendaño et al. 2016). Importantly, the identified cationic PFAS in these studies contain either tertiary amine or quaternary ammonium groups. In this first study of the fate of polyfluoroalkyl cationic surfactants used in aqueous AFFF formulations, the biotransformation of perfluorooctaneamido quaternary ammonium salt (PFOAAmS) was characterized by a DT50 value (time necessary to consume half of the initial mass) of 142 days and significant generation of perfluoroalkyl carboxylic acid (PFOA) at a yield of 30% (mol) by day 180. Three novel biotransformation intermediates were identified for PFOAAmS, and it was demonstrated that despite overall high stability of QACs and their biocide nature, the ones with perfluoroalkyl chains can be substantially biotransformed into perfluoroalkyl acids in aerobic soil.

The above microbial biotransformation and degradation pathways are all dependent on environmental conditions, degradation kinetics, and the chemical structures and properties of the individual polyfluoroalkyl precursors (Buck et al. 2011; Butt et al. 2014; Liu and Mejia Avendaño 2013). Of particular importance is the environmental stability of key chemical linkages (such as esters and ethers) as the stability of these chemical linkages determines the stability of the overall PFAS (Liu and Mejia Avendaño 2013). It is evident through these studies that the biotransformation and biodegradability of polyfluoroalkyl precursor substances is due to the breakdown of the non-fluorinated functionality of the precursor substances, which precedes the breakdown of the perfluorinated carbons. In contrast, perfluoroalkyl chemicals in general resist biotransformation and defluorination under natural conditions. Using ^{14}C-labeled PFOA to examine five different microbial communities, a range of electron donors for reductive defluorination processes, and the possibility of co-metabolism during reductive dechlorination of

NMED Exhibit 63

trichloroethene, Liou et al. (2010) was able to confirm that PFOA is highly resistant to microbial degradation in natural environments.

2.3.4 Non-microbial biodegradation of other polyfluoroalkyl substances

Butt et al. (2014) reviewed the current state of knowledge regarding the biotransformation of fluorotelomer-based, polyfluoroalkyl precursor substances that degrade to form PFCAs (PFOA) in microbial systems, rats, mice, and fish. Consistent with information presented above, the majority of biotransformation studies thus far used 8:2 FTOH (a fluorotelomer alcohol) as the substrate; only a few studies of non-FTOH biotransformation exist. The biotransformation studies of 8:2 FTOH metabolism universally show the formation of PFOA. As above, the overall yield of PFOA is low, presumably because of the multiple branches in the biotransformation pathways, including conjugation reactions in animal systems which are capable of phase II metabolism and results in the formation of conjugated metabolites such as glucuronide, sulfate, and glutathione metabolites. Butt et al. (2014) also showed that fluorotelomer carboxylates (FTCAs) appear to be more stable in animal models, whereas they are relatively labile in microbial systems. In contrast, the unsaturated form of FTCAs – FTUCAs appear to be readily degraded in animal models.

2.4 Environmental Monitoring of PFOA in Abiotic Media

PFOA has been detected in a variety of environmental abiotic matrices in aquatic environments around the globe. These abiotic media include surface water, soils, sediments, groundwater, air, and ice caps (Butt et al. 2010; Lau et al. 2007). Water is expected to be the primary environmental media that PFOA is found (Lau et al. 2007). Occurrence and detection of PFOA in other aquatic abiotic media found in the aquatic environment are summarized below.

NMED Exhibit 63

2.4.1 PFOA Occurrence and Detection in Ambient Surface Waters

PFOA is one of the dominant PFAS detected in ambient surface waters, along with PFOS (Ahrens 2011; Benskin et al. 2012; Dinglasan-Panlilio et al. 2014; Nakayama et al. 2007; Remucal 2019; Zareitalabad et al. 2013). Most of the current, published PFOA occurrence studies have focused on a handful of broad geographic regions, many times targeting sites with known manufacturing or industrial uses of PFAS, such as the Great Lakes, the Cape Fear River and waterbodies near Decatur, Alabama (Figure 2-2; Boulanger et al. 2004; Cochran 2015; Hansen et al. 2002; Konwick et al. 2008; Nakayama et al. 2007; 3M Company 2001).

NMED Exhibit 63

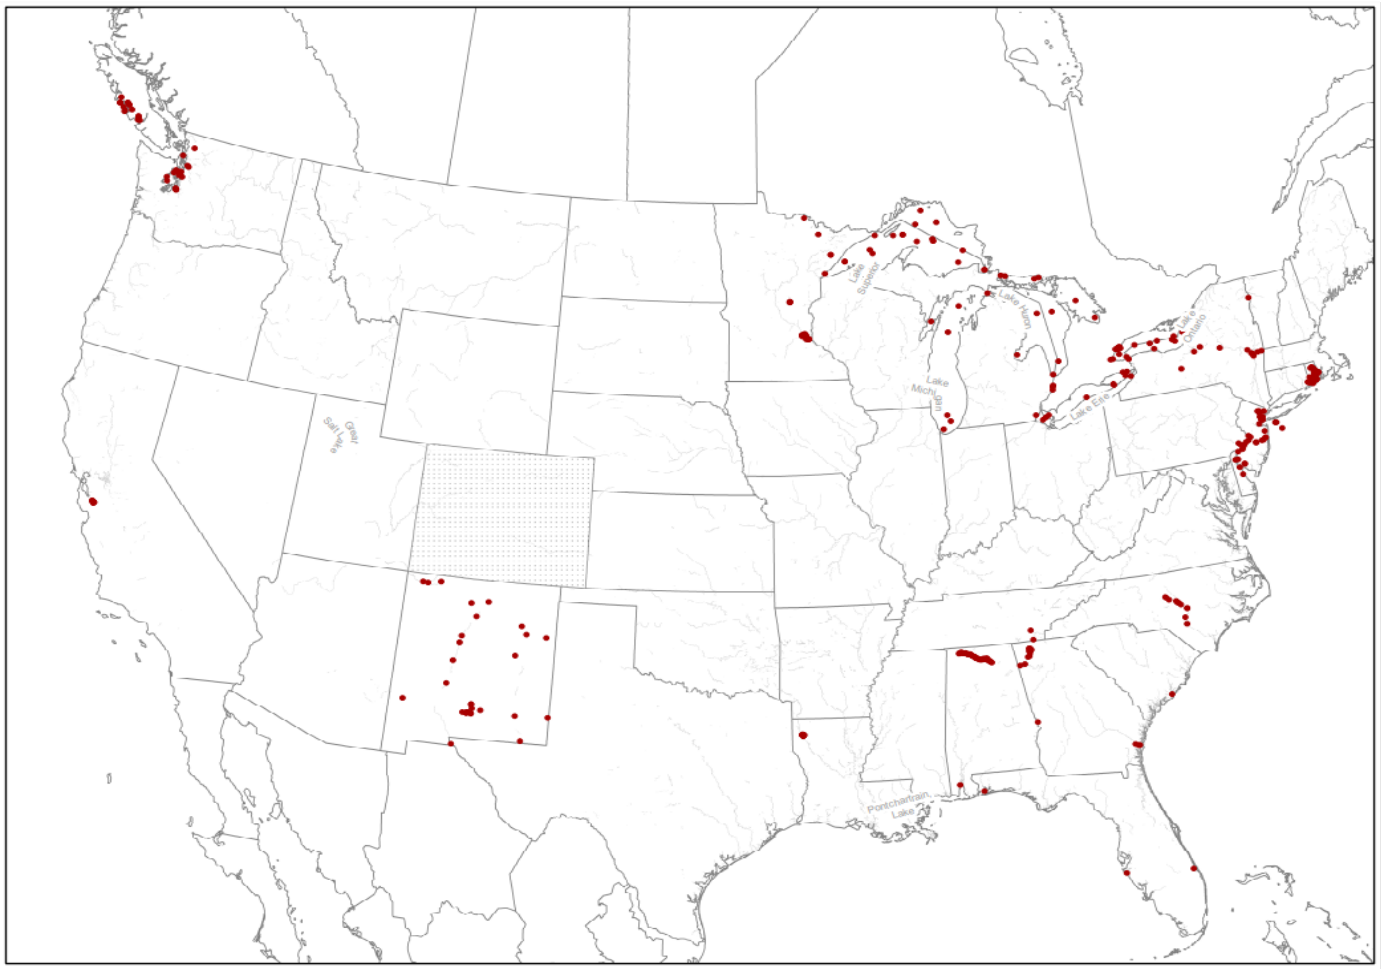

Figure 2-2. Map Indicating Sampling Locations for Perfluorooctanoic acid (PFOA) Measured in Surface Waters Across the United States (U.S.) Based on Data Reported in the Publicly Available Literature.
Colorado sampling coordinates were not available, these data are represented by the dash marks to indicate measured PFOA surface water concentrations are available in Colorado.

Concentrations of PFOA in surface waters vary widely (Figure 2-3), with observed concentrations ranging over seven orders of magnitude and detected generally between pg and ng per liter with some sites with reported concentrations in µg/L (Zareitalabad et al. 2013). For the purposes of this overview and comparison, all concentrations reported here are in ng per liter (ng/L). Unlike other contaminants commonly found in aquatic ecosystems, PFAS are synthetic compounds and therefore have no natural source. Thus, the occurrence of any PFAS in the environment is an indication of anthropogenic sources, including consumer and industrial use,

NMED Exhibit 63

long-range transport, atmospheric deposition, surface water runoff, and general persistence in the environment.

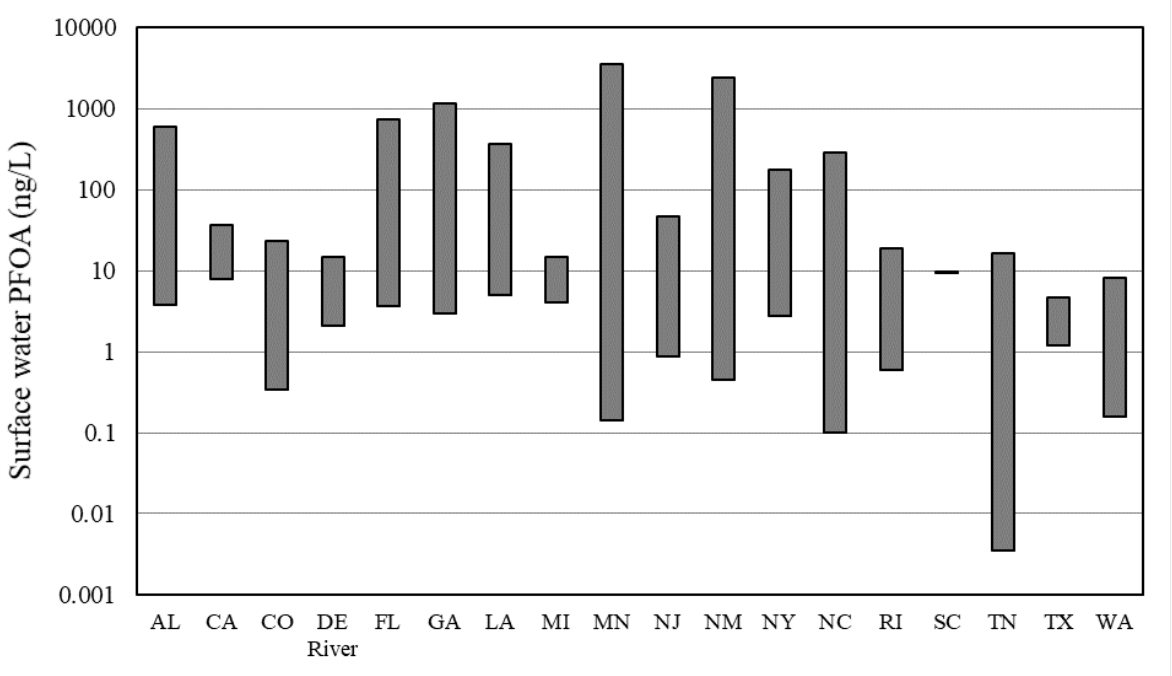

Figure 2-3. Distribution of the minimum and maximum concentrations (ng/L) of Perfluorooctanoic acid (PFOA) measured in surface waters for each state or waterbody (excluding the Great Lakes) with reported data in the publicly available literature.
The distribution is arranged alphabetically by state and waterbody.

PFOA concentrations in surface water tend to increase with levels of urbanization. Across the Great Lakes region, PFOA was higher in the downstream lakes of Erie and Ontario and lower in the upstream lakes of Superior, Michigan, and Huron (Remucal 2019). Similarly, Zhang et al. (2016) observed measured PFOA concentrations in urban areas (urban average PFOA concentration = 10.17 ng/L; n = 20) to be more than three time greater than concentrations in rural areas (rural average PFOA concentration = 2.95 ng/L; n = 17) within New Jersey, New York, and Rhode Island. Temporal variation of PFOA in surface waters remains largely unknown due to data limitations. See Appendix M for further discussion of PFOA occurrence in surface waters and other abiotic media such as aquatic sediments, groundwater, air, and ice.

NMED Exhibit 63

2.5 Bioaccumulation and Biomagnification of PFOA in Aquatic Ecosystems

PFOA is found in aquatic ecosystems around the globe (e.g., Ankley et al. 2020; Giesy and Kannan 2001; Houde et al. 2008). Although they were used predominantly in more populated areas, these compounds are resistant to hydrolysis, photolysis, and biodegradation, which facilitates their long-range transport to aquatic ecosystems in the remote arctic and mid-oceanic islands (Haukås et al. 2007; Houde et al. 2006a). Several physical-chemical properties of PFAS contribute to their bioaccumulation within aquatic and aquatic-dependent species once they have entered an aquatic ecosystem.

2.5.1 PFOA Bioaccumulation in Aquatic Life

In contrast to many persistent organic pollutants which tend to partition to fats, PFOA preferentially binds to proteins (Martin et al. 2003a, 2003b). Within the body, PFOA tends to bioaccumulate within protein-rich tissues, such as the blood serum proteins, liver, kidney, and gall bladder (De Silva et al. 2009; Jones et al. 2003; Martin et al. 2003a, 2003b). PFOA may also bind to ovalbumin, and the transfer of PFOA to such albumin in eggs can be an important mechanism for depuration in female oviparous species, as well as a mechanism for maternal transfer (Jones et al. 2003; Kannan et al. 2005).

The stability of PFOA contributes to its bioaccumulation potential, as PFOA has not been found to undergo biotransformation within the organism and is primarily depurated through excretion in urine or across gill surfaces (De Silva et al. 2009; Martin et al. 2003b). Within an organism, PFOA may undergo enterohepatic recirculation, in which PFOA is excreted from the liver in bile to the small intestine, then reabsorbed and transported back to the liver (Goecke-Flora and Reo 1996). Among PFAS, this process becomes increasingly more efficient the longer the perfluorinated chain length, resulting in longer half-lives for chemicals like PFOA with a relatively long chain length, as they are less readily excreted. PFAS with carboxylate head

NMED Exhibit 63

groups, such as PFOA, are less efficiently resorbed by the small intestine and transported back to the liver than sulfonate PFAS, resulting in lower bioaccumulation levels (Hassell et al. 2020; Martin et al. 2003a).

Sex differences in the elimination rate of PFOA chemicals have been observed in some species. Lee and Schultz (2010) observed that the elimination rate of PFOA from blood plasma was ten times faster in female fathead minnows compared to males. The faster elimination rate may be related to sex hormones (i.e., androgen and estrogen) levels, as the elimination rate in females decreased four-fold following exposure to the androgen trenbolone (Lee and Schultz 2010). This pattern has also been observed in rats, where the elimination of PFOA was 70 times faster in females than males and was attributed to sex-related differences in the expression of organic anion transporters in kidneys resulting in higher excretion rates (Kudo et al. 2002). The mechanism for the higher elimination rate in female fathead minnows has not been determined, and the degree to which gender-related differences in elimination rate apply to other fish species, or other taxonomic groups, is unknown. However, it does suggest that the sex of the organism should be considered when assessing ecosystem level bioaccumulation, and that there may be another mechanism in addition to egg production that can result in lower concentration of PFAS in females.

The structure of PFOA also contributes to its bioaccumulation potential, with linear forms being more bioaccumulative than branched forms (De Silva et al. 2009; Hassell et al. 2020). The preferential accumulation of linear PFOA occurs because the elimination rate, of branched isomers of PFOA is higher, particularly across gill surfaces (De Silva et al. 2009). This pattern has also been observed in the field, as the proportion of branched isomers was higher in

NMED Exhibit 63

water and sediment compared to fish tissue in Taihu Lake, China (Fang et al. 2014) and Lake Ontario (Houde et al. 2008).

2.5.2 Factors Influencing Potential for PFOA Bioaccumulation and Biomagnification in Aquatic Ecosystems

PFOA binding to the surface of sediment organic matter and biofilms is influenced by both hydrophobic and electrostatic effects, resulting from the hydrophobicity of the perfluorinated chain and the hydrophilicity of the carboxylate head groups (Higgins and Luthy 2006). In a series of laboratory studies, Higgins and Luthy (2006) demonstrated that PFOA sorption to sediments increased with increasing organic content, increasing calcium ions, and decreasing pH. The strongest effect was observed in response to increasing organic content, demonstrating the importance of hydrophobic effects, while the increased sorption in response to calcium ions and decreasing pH demonstrated the role of electrostatic effects (Higgins and Luthy 2006). Across all PFAS, sorption to sediments increased with increasing perfluorinated chain length, and for a given chain length, PFAS such as PFOS, had approximately 1.7 times the sorption capacity as perfluoroalkyl carboxylic acids (PFCA) such as PFOA (Higgins and Luthy 2006). The capacity of PFOA to bind to particulate matter increases with increasing salinity. Jeon et al. (2010) observed that water column PFOA partitioned more readily to particulate organic matter as salinity increased from 10 to 34 ppt, resulting in increased uptake of PFOA in Pacific oysters (*Crassostrea gigas*). In a recent review, Li et al. (2018a) found no single parameter strongly predicted PFOA sorption to sediments and Li et al. (2019) reported that the protein content of soil was a better predictor of sorption than organic carbon. Overall, these results suggest that sorption to sediments should be an important mechanism for PFOA entry into an aquatic ecosystem.

NMED Exhibit 63

Evidence of the PFOA sediment pathway in aquatic ecosystems, although mixed, overall demonstrates the importance of bioaccumulation from sediments and biofilms via diet into aquatic invertebrates. In laboratory studies, PFOA concentrations in sediment were positively correlated to PFOA tissue concentrations in *Lumbriculus variegatus* (Lasier et al. 2011), but not for *Chironomus plumosus* (Wen et al. 2016) or the amphipods *Gammarus fossarum* and *G. pulex* (Bertin et al. 2016). In field studies PFOA concentrations were positively correlated between sediments and biofilms and benthic feeding organisms (Lescord et al. 2015; Loi et al. 2011; Martin et al. 2004; Penland et al. 2020). In addition, the distribution of PFAS in sediments was more similar to their distribution in the tissues of benthic invertebrates (Lescord et al. 2015) and benthic-feeding fish (Thompson et al. 2011) than they were to their distribution in pelagic organisms.

PFOA can also enter aquatic organisms directly from the water column through respiration. Because of its binding affinity to proteins, PFOA can enter the body of gill-breathing organisms by binding to proteins in the blood at gill surfaces (De Silva et al. 2009; Jones et al. 2003; Martin et al. 2003a, 2003b).

The relative distribution of PFOA in tissues is related to the primary route of exposure (dietary or respiratory). In rainbow trout, the rank order of PFOA concentrations following aqueous exposure was blood>kidney>liver (Martin et al. 2003a). In contrast, their rank order following dietary exposure was liver>blood>kidney (Goeritz et al. 2013). Hong et al. (2015) observed the highest concentrations of PFAS in the intestines of green eel goby; soft tissues, shell, and legs of shore crabs; and gills and intestines of oysters, suggesting bioaccumulation through both dietary and aqueous uptake in invertebrates, and primarily dietary uptake in fish.

NMED Exhibit 63

Data from multiple field studies suggest trophic biomagnification potential of PFOA is low, and is often not observed, particularly with respect to aquatic organisms. In a review of PFOA and PFOS concentration data across major taxonomic groups, Ahrens and Bundschuh (2014) found that maximum PFOA and PFOS concentrations were similar for invertebrates, but that maximum PFOS concentrations in fish were nearly an order of magnitude greater than PFOA, and several orders of magnitude greater for aquatic-dependent birds and mammals.

When individual aquatic species pairs were considered, biomagnification factors (BMF) greater than one, indicating biomagnification, have been observed for PFOA (e.g., Fang et al. 2014; Penland et al. 2020; Tomy et al. 2009), suggesting trophic biomagnification. However, when ecosystem-level biomagnification is assessed using trophic biomagnification factors (TMF), which measures the change in the concentration of a chemical per trophic level within a food web, PFOA is nearly always shown not to biomagnify (Loi et al. 2011; Martin et al. 2004; Tomy et al. 2004; Xu et al. 2014; Zhou et al. 2012), unless aquatic-dependent species, such as aquatic-dependent birds, are included in the food web model (Houde et al. 2006a; Kelly et al. 2009; Tomy et al. 2009). The overall lack of biomagnification in PFOA relative to PFOS is attributed to its physical-chemical properties, including a shorter perfluorinated chain length and the carboxylate head group, both of which are associated with less efficient assimilation into tissues and faster excretion rates (e.g., Martin et al. 2003a, 2003b).

2.5.3 Environmental Monitoring of PFOA in Biotic Media

Generally, PFOA is one of the dominant PFAS detected in aquatic ecosystems, along with PFOS (Ahrens 2011; Benskin et al. 2012; Dinglasan-Panlilio et al. 2014; Nakayama et al. 2007; Remucal 2019; Zareitalabad et al. 2013). PFAS were first detected in human serum samples in the late 1960s, and subsequent studies across several continents demonstrated the global distribution of PFAS in humans (Giesy and Kannan 2001; Houde et al. 2006b). Since

NMED Exhibit 63

then, the global distribution of PFAS in tissues of aquatic and aquatic-dependent species has been demonstrated in studies conducted in freshwater and marine environments across every continent, including remote regions far from direct sources, such as the high arctic, Antarctica, and oceanic islands (Giesy and Kannan 2001; Houde et al. 2006b).

In lentic surface waters of the United States, one of the most comprehensive studies of PFOA concentrations included fish muscle tissue data from 157 near shore sites across the Great Lakes selected following a probabilistic design as part of the 2010 National Coastal Condition Assessment (Stahl et al. 2014). In this study, PFOA was measured in fish collected at 12% of the sites, with a 90th centile concentration of 0.16 ng/g wet weight (ww), and a maximum concentration of 0.97 ng/g ww (Stahl et al. 2014). Lake trout (31% of samples), smallmouth bass (14%), and walleye (13%) were the most commonly sampled species from the Great Lakes samples.

Martin et al. (2004) measured PFOA in whole body samples of invertebrates and fish in Lake Ontario, near the town of Niagara-on-the-Lake. PFOA concentrations were much higher in the benthic amphipod *Diporeia hoya* (90 ng/g ww) than in the more pelagic *Mysis relicta* (2.5 ng/g ww), suggesting sediments are an important source of PFOA in this area (Martin et al. 2004). Among the four fish species sampled, PFOA concentrations were highest in the slimy sculpin (44 ng/g ww), which feeds on *M. relicta* and *D. hoya*. Although lake trout occupy the highest trophic level at this site, their PFOA concentrations were the lowest of all sampled fish species (1.0 ng/g ww) (Martin et al. 2004). PFOA concentrations were lower in lake trout than in alewife (1.6 ng/g ww), which comprise 90% of the lake trout diet, suggesting a lack of PFOA biomagnification in this system (Martin et al. 2004).

NMED Exhibit 63

Guo et al. (2012) measured PFOA in lake trout muscle tissues in Canadian waters of Lakes Ontario, Erie, Huron, and Superior, as well as Lake Nipigon, Ontario. The average PFOA concentration across all sites was 0.045 ng/g ww and was not significantly different ($P<0.1$) across the different lakes (Guo et al. 2012). Finally, Delinsky et al. (2010) sampled bluegill, black crappie, and pumpkinseed muscle tissues in 59 lakes in Minnesota, including four lakes in the Minneapolis-St. Paul metropolitan area, and did not detect PFOA in any of the samples (limit of quantification = 0.77 ng/g ww; see Table 2 of Delinsky et al. 2009).

In flowing surface waters of the United States, one of the most comprehensive studies of PFOA concentrations included fish muscle tissue data from 164 urban river sites (5^{th} order or higher) across the coterminous U.S. selected following a probabilistic design as part of the 2008-2009 National Rivers and Streams Assessment and the National Coastal Condition Assessment (Stahl et al. 2014). Largemouth bass (34% of samples), smallmouth bass (25%), and channel catfish (11%) were the most commonly sampled species from the urban stream sites (Stahl et al. 2014). PFOA was not detected in any of the urban river sites (Stahl et al. 2014). The lack of detection may have been related to the method detection limit of 2.37 ng/g ww, which was higher than the highest PFOA concentration measured in the Great Lakes coastal survey described above, which also followed a probabilistic sampling design (Stahl et al. 2014).

In 2005, Ye et al. (2008) detected average PFOA concentrations of 0.17 ng/g ww and 0.2 ng/g ww from whole body composite samples of multiple fish species from the Ohio River and Mississippi River, respectively. PFOA was not detected (<1.0 ng/g ww) in whole body composite fish samples collected from the Missouri River (Ye et al. 2008). Delinsky et al. (2010) sampled PFOA in bluegill, black crappie, and pumpkinseed muscle tissues at eleven locations

NMED Exhibit 63

along the upper Mississippi River in 2007, and did not detect it at any location, including the heavily impacted Pool Two site in the Minneapolis-St. Paul metropolitan area.

In a more recent study, Penland et al. (2020) measured PFAS concentrations in invertebrates and vertebrates along the Yadkin – Pee Dee River, in North and South Carolina in 2015. PFOA was detected in whole body tissues of unionid mussels (7.41 ng/g ww) and aquatic insects (10.68 ng/g ww), but was not detected in Asian clam, snails, or crayfish. PFOA was measured in muscle tissue of two of the 11 sampled fish species, the channel catfish (21.19 ng/g ww) and notchlip redhorse (45.66 ng/g ww). PFOA was not detected in the eggs of a robust redhorse sample, which had the highest measured PFOS concentration (482.9 ng/g ww) of any sample from the Penland et al. (2020) study.

Houde et al. (2006a) measured whole body PFOA in six fish species in Charleston Harbor, South Carolina, and whole body PFOA of zooplankton and five fish species in Sarasota Bay, Florida. Charleston Harbor was the more developed of the two sites and had higher overall PFOA concentrations. PFOA was detected in four of the six fish species in Charleston Harbor and ranged from 0.5 ng/g ww in spot to 1.8 ng/g ww in spotted seatrout. In Sarasota Bay, PFOA concentrations averaged 0.3 ng/g ww in zooplankton and was not detected in any of the fish species (Houde et al. 2006a).

Overall, these results illustrate the distribution of PFOA in biotic media collected from invertebrate and fish samples. In contrast to PFOS, PFOA concentrations in biotic media are often low, or below detection levels, highlighting the lower overall bioaccumulation potential for this chemical, based on its physical-chemical properties, including a shorter perfluorinated chain length, and a carboxylate head group. In addition, trophic biomagnification is rarely observed with PFOA, as concentrations in invertebrates are often similar to concentrations in fish.

NMED Exhibit 63

2.6 Exposure Pathways of PFOA in Aquatic Environments

There are multiple potential exposure pathways of PFOA in the aquatic environment, including: (1) direct aqueous (dermal and respiratory) exposure, (2) direct exposure from contaminated sediment (for benthic organisms), (3) diet (e.g., bioaccumulation and biomagnification), and (4) maternal transfer (Ankley et al. 2020). Exposure of PFOA through water and sediment occurs through direct contact with the respective media, such as water passing across the gills, or consumption of suspended and deposited sediments (Prosser et al. 2016). Elevated PFOA concentrations in eggs of fish and piscivorous birds suggests that PFOA may maternally transfer to offspring. Given these exposure pathways, aquatic organisms, such as fish and aquatic invertebrates, are exposed to PFOA when it is present in the environment. This exposure occurs through multiple exposure routes including water, sediment, diet, and maternal transfer.

2.7 Effects of PFOA on Biota

Currently, PFOA aquatic ecotoxicity data are primarily available for freshwater fish, aquatic invertebrates, plants, and algae. Section 3 and Section 4 provide study summaries of individual publicly available ecotoxicity studies, Appendix A through Appendix F summarize the current quantitatively acceptable PFOA aquatic life ecotoxicity data, and Appendix G and Appendix H list current qualitatively acceptable PFOA aquatic life ecotoxicity data.

2.7.1 Mechanisms of PFOA Toxicity

The mechanisms underpinning the toxicity of PFOA to aquatic organisms, like other PFAS, is an active and on-going area of research. Much work is still needed from a mechanistic perspective to better understand how the different modes of action elicit specific biological responses. Molecular disturbance at the cellular- and organ-level resulting in effects on reproduction, growth and development at the individual-level are associated with the sex-related

NMED Exhibit 63

endocrine system, thyroid-related endocrine system, and neuronal-, lipid-, and carbohydrate-metabolic systems (see Ankley et al. 2020 and Lee et al. 2020 for the latest reviews on the subject). The underlying mechanisms of PFOA toxicity to aquatic animals, and fish in particular, appear to be related to oxidative stress, apoptosis, thyroid disruption, and development-related gene expression (Lee et al. 2020). The published research suggests that many of these molecular pathways interact with each other and could be linked. For example, for several PFAS including PFOA, oxidative stress appears correlated with effects on egg hatching and larval formation, linking reproductive toxicity, oxidative stress, and developmental toxicity (Lee et al. 2020). The actual mechanism(s) through which PFAS induce oxidative stress require additional study, but increased ß-oxidation of fatty acids and mitochondrial toxicity are proposed triggers (Ankley et al. 2020).

Of particular importance to this document is that PFOA exposure-related disruption of the sex-related endocrine system (e.g., androgen and estrogen) at the molecular, tissue and organ levels appears to have adverse reproductive outcomes in fish and invertebrates, and likely in both freshwater and saltwater and via multiple exposure routes, i.e., waterborne and dietary (Lee at al. 2020). The reproductive effects were observed in the F_0, F_1 and F_2 generations of zebrafish, *Danio rerio*, in the multi-generational PFOA exposure reported by Lee et al. (2017).

It is clear that PFOA, and many other PFAS, cause a wide range of adverse effects in aquatic organisms, including: reproductive failure, developmental toxicity; androgen, estrogen and thyroid hormone disruption; immune system disruption; and, neuronal and developmental damage. Study of the systematic interactions among the relevant biological pathways in fish is a research need, as well as a better understanding of several knowledge gaps in non-fish aquatic organisms where mechanistic-based investigations need to be prioritized.

NMED Exhibit 63

2.7.2 Potential Interactions with Other PFAS

PFAS may occur as mixtures in the environment. Occurrence studies document the presence of complex mixtures of PFAS in surface waters in the U.S. and across the globe (Ahrens 2011; Ahrens and Bundschuh 2014; Giesy and Kannan 2002; Houde et al. 2006a, 2006b; Keiter et al. 2012; Wang et al. 2017; see Section 2.4.1). Although the EPA's PFOA criteria are based solely on single chemical exposure aquatic toxicity tests, it is recognized that PFAS are often introduced into the environment as end-use formulations comprised of mixtures of PFAS and or PFAS-precursors, the ecological effects of which are poorly understood (Ankley et al. 2020). It is useful, therefore, to briefly summarize the types of interactions that might be expected based on the few PFAS mixtures studies involving PFOA and one or more PFAS to date. Note that for purposes of this document, the reader is referred to Ankley et al. (2020) and elsewhere for more comprehensive reviews of PFAS mixtures in general, and the challenges they are expected to present in ecological risk assessment. Beyond PFOA and PFOS, systematic reviews of chemical mixture studies across various compound classes indicate that departures from dose additivity are uncommon and rarely exceed minor deviations (~2-fold) from predictions based on additivity (Martin et al. 2021).

Findings of the PFAS-specific studies described below are as reported by the study authors without any additional interpretation or analysis of uncertainty. At both the organismal and cellular levels, studies on zebrafish (*Danio rerio*; Ding et al. 2013), a water flea (*Daphnia magna*; Yang et al. 2019), a bioluminescent cyanobacterium (*Anabaena sp.*; Rodea-Palomares et al. 2012), or with cultured hepatocytes of the cyprinid, *Gobiocypris rarus* (Wei et al. 2009), demonstrate that the effects observed from *in vivo* and *in vitro* tests on PFAS mixtures vary. PFAS mixture studies on zebrafish reported interactions for combinations of PFOA and PFOS, but departures from additive models were also minor (Ding et al. 2013). Menger et al. (2020)

NMED Exhibit 63

reported zebrafish behavioral effects from a PFAS mixture that were less than individual PFAS, however evaluation of chemical dose response and comparison to mixture models was not conducted. Yang et al. (2019) exposed the water flea, *Daphnia magna,* to single and binary mixtures of PFOA and PFOS. The authors reported synergism in acute and chronic toxic effects. Conversely, Rodea-Palomares et al. (2012) showed binary PFOA and PFOS mixture as having an antagonistic interaction at the whole range of effect levels tested using the bioluminescent cyanobacterium, *Anabaena.*

In tests with cultured hepatocytes of the cyprinid *G. rarus,* co-exposure of PFOA with a mixture of five other PFAS [PFNA, PFDA, PFDoA, PFOS, 8:2 FTOH] altered genes involved in multiple biological functions and processes, including fatty acid metabolism and transport, xenobiotic metabolism, immune response, and oxidative stress. Additionally, greater than 80% of the altered genes in both the PFOA- and PFOS-dominant mixture groups were of the same gene set (Wei et al. 2009). Finally, Conley et. al. (2022) observed PFOA and PFOS interacting in an additive manner to reduce pup body weight, pup liver weight, and maternal liver weight in the Sprague-Dawley rat.

2.8 Conceptual Model of PFOA in the Aquatic Environment and Effects

A conceptual model depicts the relationship between a chemical stressor and ecological compartments, linking exposure characteristics to ecological endpoints. The conceptual model provided in Figure 2-4 summarizes sources, potential pathways of PFOA exposure for aquatic life and aquatic-dependent wildlife and possible toxicological effects.

PFOA initially enters the aquatic environment through direct discharge from wastewater treatment facilities, atmospheric deposition, and runoff from contaminant surfaces such as PFAS disposal sites or contaminated biosolids. PFOA enters the aquatic environment primarily in the

NMED Exhibit 63

dissolved form and to a lesser extent, particle-bound forms. Exposure pathways for the biological receptors of concern (i.e., aquatic organisms) and potential effects (e.g., impaired survival, growth, and reproduction) in those receptors are represented in the conceptual model (Figure 2-4). Both direct (i.e., exposure from the water column which is represented by *) and indirect (i.e., bioconcentrated by producers and bioaccumulated by consumers in higher trophic levels represented by **) pathways are represented in the conceptual model.

NMED Exhibit 63

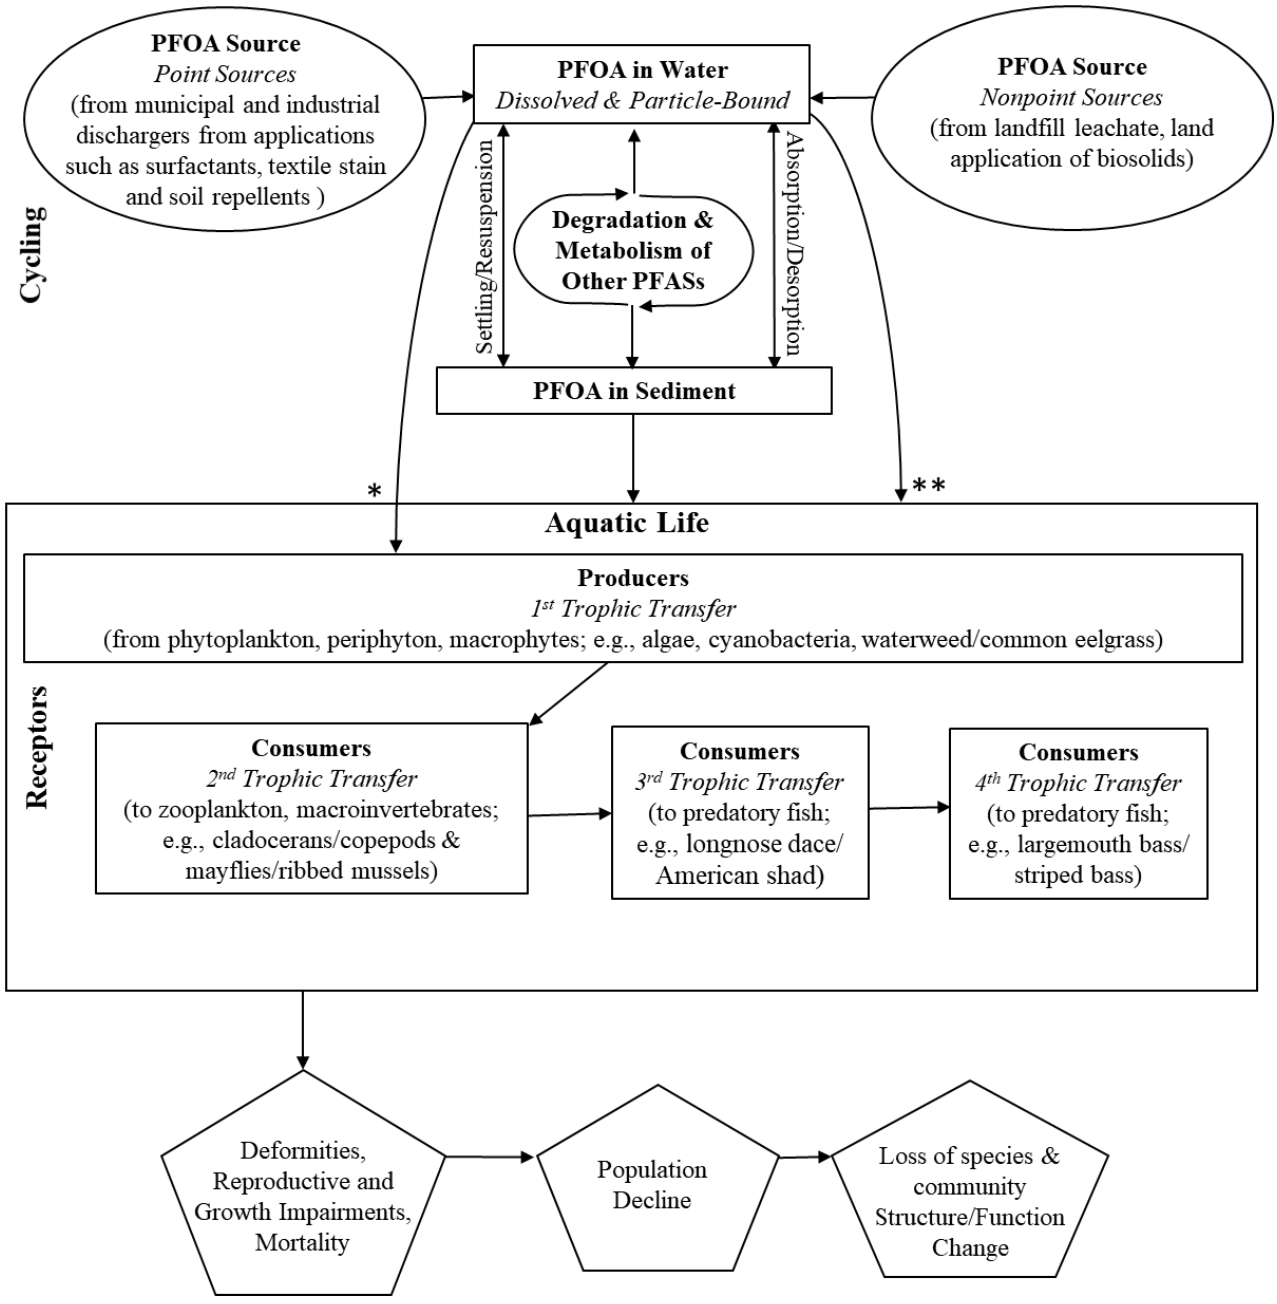

Figure 2-4. Conceptual Model Diagram of Sources, Compartmental Partitioning, and Trophic Transfer Pathways of Perfluorooctanoic acid (PFOA) in the Aquatic Environment and its Bioaccumulation and Effects in Aquatic Life and Aquatic-dependent Wildlife.

PFOA sources represented in ovals, compartments within the aquatic ecosystem represented by rectangles, and effects (on trophic levels of aquatic-dependent wildlife, represented by shaded box) in pentagons. Examples of organisms in each trophic transfer provided as freshwater/marine. Movement of PFOA from water to receptors indicated by two separate pathways: direct exposure to all trophic levels within box (*) and bioconcentration by producers (**). Relative proportion of PFOA transferred between each trophic level is dependent on life history characteristics of each organism.

NMED Exhibit 63

2.9 Assessment Endpoints

Assessment endpoints are defined as the explicit expressions of the environmental values to be protected and are comprised of both the ecological entity (e.g., a species, community, or other entity) and the attributes or characteristics of the entity to be protected (U.S. EPA 1998). Assessment endpoints may be identified at any level of organization (e.g., individual, population, community). In context of the CWA, aquatic life criteria for toxic substances are typically determined based on the results of toxicity tests with aquatic organisms, for which adverse effects on growth, reproduction, or survival are measured. This information is typically compiled into a sensitivity distribution based on genera and representing the impact on taxa across the aquatic community. Criteria are based on the 5^{th} percentile of genera and are, thus intended to be protective of approximately 95 percent of aquatic genera to ensure aquatic communities are protected. Assessment endpoints consistent with the criteria developed in this document are summarized in Table 2-1.

The use of laboratory toxicity tests to protect bodies of water and resident aquatic species was based on the theory that effects occurring to a species in appropriate laboratory tests will generally occur to the same species in comparable field situations. Since aquatic ecosystems are complex and diverse, the 1985 Guidelines recommend that acceptable data be available for at least eight genera with a specified taxonomic diversity (the standard eight minimum data requirements, or MDRs). The intent of the eight MDRs is to serve as a typical surrogate sample community representative of the larger and generally much more diverse natural aquatic community, not necessarily the most sensitive species in a given environment. The 1985 Guidelines note that since aquatic ecosystems can tolerate some stress and occasional adverse effects, protection of all species at all times and places are not deemed necessary (the intent is to

NMED Exhibit 63

protect 95 percent of a group of diverse taxa, and any commercially and recreationally important species).

2.10 Measurement Endpoints

2.10.1 Overview of Toxicity Data Requirements

To ensure the protection of various components of an aquatic ecosystem, the EPA collects acute toxicity test data from a minimum of eight diverse taxonomic groups.

- Acute freshwater criteria require data from the following eight taxonomic groups:
    a) the family Salmonidae in the class Osteichthyes
    b) a second family in the class Osteichthyes, preferably a commercially or recreationally important warmwater species (e.g., bluegill, channel catfish)
    c) a third family in the phylum Chordata (may be in the class Osteichthyes or may be an amphibian)
    d) a planktonic crustacean (e.g., cladoceran, copepod)
    e) a benthic crustacean (e.g., ostracod, isopod, amphipod, crayfish)
    f) an insect (e.g., mayfly, dragonfly, damselfly, stonefly, caddisfly, mosquito, midge)
    g) a family in a phylum other than Arthropoda or Chordata (e.g., Rotifera, Annelida, Mollusca)
    h) a family in any order of insect or any phylum not already represented

- Acute estuarine/marine criteria require data from the following taxonomic groups:
    a) two families in the phylum Chordata
    b) a family in a phylum other than Arthropoda or Chordata
    c) a family from either Mysidae or Penaeidae
    d) three other families not in the phylum Chordata (may include Mysidae or Penaeidae, whichever was not used above)
    e) any other family

Additionally, to ensure the protection of various components of the aquatic ecosystem from long term exposures, chronic toxicity test data are recommended for the same minimum of eight diverse taxonomic groups that are recommended for freshwater acute criterion derivation. If the eight diverse taxonomic groups are not available to support chronic criterion derivation using a genus distribution approach, the chronic criterion may be derived using an acute-to-

NMED Exhibit 63

chronic ratio (ACR) approach. To apply an ACR approach to derive a chronic freshwater criterion a minimum of three taxa are recommended, with at least one chronic test being from an acutely sensitive species. Acute-to-chronic ratios (ACRs) can be calculated with data for aquatic organisms.

- Chronic aquatic life criteria require data from the following taxonomic groups:
    a) At least one is a fish
    b) At least one is an invertebrate
    c) At least one is an acutely sensitive freshwater species, for freshwater chronic criterion (the other two may be saltwater species)
    d) At least one is acutely sensitive saltwater species for estuarine/marine chronic criterion (the other two may be freshwater species)

The 1985 Guidelines also specified at least one quantitative test with a freshwater alga or vascular plant. If plants are among the most sensitive aquatic organisms, toxicity test data from a plant in another phylum should also be available. Aquatic plant toxicity data are examined to determine whether aquatic plants are likely to be adversely affected by the concentration expected to be protective for other aquatic organisms.

2.10.2 Measure of PFOA Exposure Concentrations

These PFOA ambient water quality criteria are for the protection of aquatic life. This criteria document provides a critical review of all data identified in the EPA's literature search for PFOA, including:

- the anionic form (CAS No. 45285-51-6),
- the acid form (CAS No. 335-67-1), and;
- the ammonium salt (CAS No. 3825-26-1).

PFOA toxicity studies typically do not conduct an analysis or separation sufficient to determine if the test compound is purely linear or branched. Data for possible inclusion in the PFOA criteria were obtained from published literature reporting acute and chronic exposures of PFOA that were associated with mortality, growth, and reproduction. This set of published

NMED Exhibit 63

literature was identified using the ECOTOXicology database (ECOTOX; https://cfpub.epa.gov/ecotox/) as meeting data quality standards. ECOTOX is a source of high-quality toxicity data for aquatic life, terrestrial plants, and wildlife. The database was created and is maintained by the EPA, Office of Research and Development, Center for Computational Toxicology and Exposure. The ECOTOX search generally begins with a comprehensive chemical-specific literature search of the open literature conducted according to ECOTOX Standard Operating Procedures (SOPs; Elonen 2020). The search terms are often comprised of chemical terms, synonyms, degradates and verified Chemical Abstracts Service (CAS) numbers. After developing the literature search strategy, ECOTOX curators conduct a series of searches, identify potentially applicable studies based on title and abstract, acquire potentially applicable studies, and then apply the applicability criteria for inclusion in ECOTOX. Applicability criteria for inclusion into ECOTOX generally include:

1. The toxic effects are related to single chemical exposure (unless the study is being considered as part of a mixture effects assessment);
2. There is a biological effect on live, whole organisms or *in vitro* preparation including gene chips or omics data on adverse outcome pathways potentially of interest;
3. Chemical test concentrations are reported;
4. There is an explicit duration of exposure;
5. Toxicology information that is relevant to OW is reported for the chemical of concern;
6. The paper is published in the English language;
7. The paper is available as a full article (not an abstract);
8. The paper is publicly available;
9. The paper is the primary source of the data;
10. A calculated endpoint is reported or can be calculated using reported or available information;
11. Treatment(s) are compared to an acceptable control;
12. The location of the study (*e.g.*, laboratory vs. field) is reported; and
13. The tested species is reported (with recognized nomenclature).

Following inclusion in the ECOTOX database, toxicity studies were subsequently evaluated by the Office of Water. All studies were evaluated for data quality as described by U.S. EPA (1985), the EPA's Office of Chemical Safety and Pollution Prevention (OPP)'s

NMED Exhibit 63

Ecological Effects Test Guidelines (U.S. EPA 2016b), and the EPA OW's internal data quality standard operating procedure (SOP), which is consistent with OPP's data quality review approach (U.S. EPA 2016b). Office of Water completed a Data Evaluation Record (DER) for each species by chemical combination from the PFOA studies identified by ECOTOX. This in-depth review ensured the studies used to derive the criteria resulted in robust scientifically defensible criteria. Example DERs are shown in Appendix P with the intent to convey the meticulous level of evaluation, review, and documentation each PFOA study identified by ECOTOX was subject to.

Studies that did not fully meet the data quality objectives outlined by the EPA SOP were not considered for inclusion in the criteria derivation, including some studies with other PFAS exposures, but were considered qualitatively as supporting information and are characterized in the Effects Characterization. These studies are listed in Appendix G and Appendix H. Furthermore, only single chemical toxicity tests with PFOA were considered for possible inclusion in criteria derivation, studies that tested chemical mixtures, including mixtures with PFAS were excluded from criteria derivation. Both controlled laboratory experiments and field observations/studies were included.

The 1985 Guidelines recommend only toxicity tests focused on North American resident species be considered. Due to the EPA's interest in using all available quality data, particularly for a data-sparse chemical like PFOA (relative to chemicals such as cadmium or ammonia), toxicity studies were considered for possible inclusion regardless of the test species residential status in North America. Use of non-North American residential species is also consistent with other published aquatic life criteria (U.S. EPA 2018). Non-North American resident species also serve as taxonomically-related surrogate test organisms for the thousands of untested resident

NMED Exhibit 63

species. Supporting analyses to evaluate the influence of including non-resident species on the freshwater criteria magnitudes were conducted by limiting toxicity datasets to North American resident species with established populations in North America (see Section 4.1). These analyses provided an additional line-of-evidence that supports inclusion of non-resident species in PFOA criteria derivation.

Toxicity tests used in many previous aquatic life criteria documents are typically based on measured chemical concentrations only. For PFOA, the EPA has examined the issue of whether nominal (unmeasured) and measured concentrations are in close agreement with each other (Jarvis et al. 2023). While measured PFOA toxicity tests are generally preferred, results of Jarvis et al. (2023) demonstrated that experimental conditions had little influence on observed discrepancies between nominal and measured concentrations for PFOA, with the exception of freshwater studies that contained substrate. Nominal and measured concentrations in the analysis generally displayed a high degree of linear correlation (>0.98 freshwater, >0.84 saltwater) and relatively low median percent differences (Jarvis et al. 2023). In freshwater tests, when tests with substrate were removed, 89% of the 527 PFOA and PFOS measured concentrations were within 20% of their nominal counterparts (Note: the EPA's OCSPP's Ecological Effects Test Guidelines (2016b) consider tests acceptable when measured concentrations are within 20% of nominal, and Rewerts et al. (2021) suggested that PFAS-specific toxicity tests may even be acceptable if measured and nominal concentrations do not differ by up to 30%.). Of the observed disparities between measured and nominal concentrations in the PFOA freshwater data sets, those with substrate (McCarthy et al. 2021; Oakes et al. 2004) were concluded to be the primary contributor to observed differences with measured PFOA concentrations systematically lower than corresponding nominal concentrations, indicating that added PFOA may have sorbed to

NMED Exhibit 63

substrate, reducing PFOA in the water column (Jarvis et al. 2023). PFOA concentrations in test waters are expected to remain relatively constant over the course of acute and chronic exposures given its ability to resist breakdown and transformation (Ahrens 2011). Since toxicity tests with substrate and nominal concentrations only were not used quantitatively in PFOA criteria derivation, the EPA determined nominal test concentrations adequately represent actual PFOA exposures in standard acute and chronic laboratory-based toxicity tests. Consequently, PFOA toxicity tests were not excluded from quantitative use in criteria derivation on the basis of unmeasured test concentrations alone.

Typically, per the 1985 Guidelines acute toxicity data from all measured flow-through tests would be used to calculate species mean acute values (SMAVs), unless data from a measured flow-through test were unavailable, in which case the acute criterion would be calculated as the geometric mean of all the available acute values (i.e., results of unmeasured flow-through tests and results of measured and unmeasured static and renewal tests). Chronic unmeasured flow-through tests, as well as measured and unmeasured static and renewal tests are not typically considered to calculate chronic values. In the case of the PFOA, static, renewal, and flow-through experiments were considered for possible inclusion for both species mean acute and chronic values regardless of whether PFOA concentrations were measured because PFOA is a highly stable compound, resistant to hydrolysis, photolysis, volatilization, and biodegradation (Section 1.2.1) and, therefore, expected to vary only minimally in the course of a toxicity test.

Additionally, chronic values were based on endpoints and exposure durations that were appropriate to the species. Thus, both life- and partial life-cycle tests were utilized for the derivation of the chronic criterion. However, it should be noted that the 1985 Guidelines specify life-cycle chronic tests are typically used for invertebrates. The chronic studies used in the

NMED Exhibit 63

derivation of the chronic water column-based PFOA criterion followed taxon-specific exposure duration requirements from various test guidelines (i.e., the EPA's 1985 Guidelines and the EPA's OCSPP's Ecological Effects Test Guidelines) when available. For example, only chronic daphnid studies of 21 days were considered in the chronic criterion derivation because the EPA 1985 Guidelines states daphnid tests should begin with young < 24-hours old and last at least 21 days. When taxon-specific exposure duration requirements were not available for a particular test organism in the PFOA toxicity literature, both life- and partial life-cycle tests were considered in the derivation of the chronic criterion.

PFOA toxicity in aquatic life is manifested as effects on survival, growth, and reproduction. Measurements of fish tissue may be linked to the chronic adverse effects of PFOA, since PFOA is highly persistent and potentially bioaccumulative.

2.10.3 Measures of Effect

Each assessment endpoint requires one or more "measures of ecological effect," which are defined as changes in the attributes of an assessment endpoint itself or changes in a surrogate entity or attribute in response to chemical exposure. Ecological effects data were used as measures of direct and indirect effects to growth, reproduction, and survival of aquatic organisms.

2.10.3.1 Acute Measures of Effect

The acute measures of effect on aquatic organisms are the lethal concentration (LC_{50}), effect concentration (EC_{50}), or inhibitory concentration (IC_{50}) estimated to produce a specific effect in 50 percent of the test organisms. LC_{50} is the concentration of a chemical that is estimated to kill 50 percent of the test organisms. EC_{50} is the concentration of a chemical that is estimated to produce a specific effect in 50 percent of the test organisms. And the IC_{50} is the concentration of a chemical that is estimated to inhibit some biological process (e.g., enzyme

NMED Exhibit 63

inhibition associated with an apical endpoint such as mortality) in 50 percent of the test organisms.

2.10.3.2 Chronic Measures of Effect

The endpoint for chronic exposures is the effect concentration estimated to produce a chronic effect on survival, growth, or reproduction in 10 percent of the test organisms (EC_{10}). The EPA selected an EC_{10} to estimate a low level of effect that would be both different from controls and not expected to be severe enough to cause effects at the population level for a potentially bioaccumulative contaminant, such as PFOA. The use of the EC_{10}, instead of an EC_{20}, is also consistent with the use of this metric for the bioaccumulative pollutant selenium in the recent 2016 Selenium Freshwater Aquatic Life Criteria (U.S. EPA 2016a). Use of a 10% effect concentration for deriving chronic criteria magnitudes is also consistent with the harmonized guidelines from OECD and the generally preferred effect level for countries such as Canada, Australia, and New Zealand (CCME 2007; Warne et al. 2018).

Regression analysis was used preferentially to characterize a concentration-effect relationship and to estimate concentrations at which chronic effects are expected to occur (i.e., point estimate). Reported No Observed Effect Concentrations (NOECs) and Lowest Observed Effect Concentrations (LOECs) were only used for the derivation of a chronic criterion when a robust EC_{10} could not be calculated for the genus. A NOEC is the highest test concentration at which none of the observed effects are statistically different from the control. A LOEC is the lowest test concentration at which the observed effects are statistically different from the control. When LOECs and NOECs were used, a Maximum Acceptable Toxicant Concentration (MATC) was calculated, which is the geometric mean of the NOEC and LOEC. For the calculation of a chronic criterion, point estimates were selected for use as the measure of effect in favor of MATCs, as MATCs are highly dependent on the concentrations tested. Point estimates also

NMED Exhibit 63

provide additional information that is difficult to determine with an MATC, such as a measure of effect level across a range of tested concentrations. A decision rule was also applied to the PFOA toxicity data when an author-reported NOEC or LOEC was used in conformity with the 2013 Ammonia Freshwater Aquatic Life Criteria (U.S. EPA 2013) such that "greater than" values for concentrations of a relatively low magnitude compared to the other available toxicity data, and "less than" values for concentrations of relatively high magnitude were considered to add little significant information to the analyses and were not used quantitatively. Conversely, if data from studies with relatively low "less than" values indicated a significant effect or studies with relatively high "greater than" values only found an incomplete response for a chronic endpoint (indicating low toxicity of the test material), those data significantly enhanced the understanding of PFOA toxicity. Thus, the decision rule was applied as follows: "greater than" (>) high toxicity values and "less than" (<) low toxicity values were used quantitatively to derive the chronic water column-based PFOA criterion (U.S. EPA 2013). Data that met the quality objectives and test requirements were utilized quantitatively in deriving freshwater criteria for aquatic life and are presented in Table 3-3 and Table 3-7.

Table 2-1. Summary of Assessment Endpoints and Measures of Effect Used in the Criteria Derivation for PFOA.

Assessment Endpoints for the Aquatic Community	Measures of Effect
Aquatic Life: Survival, growth, and reproduction of freshwater and estuarine/marine aquatic life (i.e., fish, amphibians, aquatic invertebrates)	For effects from acute exposure: 1. LC_{50}, EC_{50}, or IC_{50} concentrations in water For effects from chronic exposure: 1. EC_{10} concentrations in water 2. NOEC and LOEC concentrations in water; Only used when an EC_{10} could not be calculated for a genus.

NOEC = No observed effect concentration
LOEC = Lowest observed effect concentration
EC_{10} = 10% Effect Concentration

NMED Exhibit 63

2.10.3.3 Summary of Independent Calculation of Toxicity Values

Toxicity values, including LC_{50} and EC_{10} values, were independently calculated from the data presented in the toxicity studies meeting the inclusion criteria described above when adequate concentrations-response data were published in the study or could be obtained from authors. When concentration-response data were not presented in toxicity studies, concentration-response data were requested from study authors to independently calculate toxicity values. In cases where study authors did not respond to the EPA's request for data or were unable to locate concentration-response data, the toxicity values were not independently calculated by the EPA, and the reported toxicity values were retained for criteria deviation. Where concentration-response data were available, they were analyzed using the statistical software program R (version 3.6.2) and the associated dose-response curve (drc) package. The R drc package has various models available for modeling a concentration-response relationship for each toxicity study. The specific model used to calculate toxicity values was selected following the details provided in Appendix K, and the models performed well on most or all statistical metrics. The independently calculated toxicity values used to derive the PFOA aquatic life criteria were included in each study summary below and were used to derive criteria for aquatic life, where available. Details relating to the independent verification of toxicity values for each toxicity study used to derive the criteria were included in Appendix A.2 and Appendix C.2.

2.11 Analysis Plan

2.11.1 Derivation of Water Column Criteria

During CWA Section 304(a) criteria development, the EPA reviews and considers all relevant toxicity test data. Information available for all relevant species and genera were reviewed to identify: 1) data from acceptable tests that meet data quality standards, and 2)

NMED Exhibit 63

whether the acceptable data meet the MDRs as outlined in the EPA's 1985 Guidelines (U.S. EPA 1985). The taxa represented by the different MDR groups represent taxa with different ecological, trophic, taxonomic and functional characteristics in aquatic ecosystems, and are intended to be a representative subset of the diversity within a typical aquatic community. MDRs for derivation of acute and chronic freshwater criteria were met for all the eight MDRs.

Acute and chronic MDRs for PFOA estuarine/marine criteria derivation were not met and, consequently, acute and chronic estuarine/marine criteria were not derived. The EPA is, however, including an acute aquatic life benchmark for estuarine/marine environments (see Appendix L), using available estuarine/marine species toxicity data and application of ORD's peer-reviewed web-ICE tool. A minimal number of tests from acceptable studies of aquatic algae and vascular plants were also available for possible derivation of a Final Plant Value. However, the relative sensitivity of freshwater plants to PFOA exposures indicated plants are less sensitive than aquatic vertebrates and invertebrates so plant criteria were not developed.

2.11.2 Derivation of Tissue-Based Criteria

Chronic toxicity studies (both laboratory and field studies) were further screened to ensure they contained the relevant chronic PFOA exposure conditions to aquatic organisms (i.e., dietary, or dietary and waterborne PFOA exposure), measurement of chronic effects, and measurement of PFOA in tissue(s). The EPA considered deriving tissue-based criteria using empirical toxicity tests with studies that exposed organisms to PFOA in water and/or diet and reported exposure concentrations based on measured tissue concentrations. This approach would also correspond with the 2016 Selenium Aquatic Life Freshwater Criterion, which is the only 304(a) aquatic life criterion with tissue-based criterion elements. However, the freshwater chronic PFOA toxicity data with measured tissue concentrations were limited, with no quantitatively acceptable tissue-based tests. Qualitatively acceptable tissue-based tests were

NMED Exhibit 63

reported for four species (three fish species and one amphibian) across five publications. Therefore, there were insufficient data to derive tissue-based criteria using a GSD approach from empirical tissue data from toxicity studies. The EPA thus developed protective tissue-based criteria through a bioaccumulation factor approach (Burkhard 2021).

2.11.3 Translation of Chronic Water Column Criterion to Tissue Criteria

Because there were insufficient chronic toxicity data with measured tissue concentrations to derive chronic PFOA tissue criteria using a GSD approach, the EPA derived PFOA chronic tissue-based criteria by translating the chronic freshwater water column criterion (see Section 3.2.1.3) into tissue-based criteria magnitudes using bioaccumulation factors and the following equation:

$$Tissue\ Criteria = Chronic\ Water\ Column\ Criterion \times BAF \quad \textit{(Equation 1)}$$

The resulting tissue-based criteria magnitudes correspond to the tissue type from the BAF used in the equation (see Section 2.11.3.1).

2.11.3.1 Aquatic Life Bioaccumulation Factors

A bioaccumulation factor (BAF) is determined from field measurements and is calculated using the equation:

$$BAF = \frac{C_{biota}}{C_{water}} \quad \textit{(Equation 2)}$$

Where:
C_{biota} = PFOA concentration in the organismal tissue(s)
C_{water} = PFOA concentration in water where the organism was collected

The EPA considered BAF data from field measurements to capture all PFOA exposure routes, *i.e.*, dietary, water, contact with sediments via dermal exposure and ingestion, and

NMED Exhibit 63

maternal transfer. Depending on the tissue residue measurement, BAFs can be based upon residues in the whole organism, muscle, liver, or any other tissue.

Searching for literature reporting on PFOA was implemented by developing a series of chemical-based search terms. These terms included chemical names and Chemical Abstracts Service registry numbers (CASRN or CAS), synonyms, tradenames, and other relevant chemical forms (i.e., related compounds). Databases searched were Current Contents, ProQuest CSA, Dissertation Abstracts, Science Direct, Agricola, TOXNET, and UNIFY (database internal to the U.S. EPA's ECOTOX database). The literature search yielded numerous citations and the citation list was further refined by excluding citations on analytical methods, human health, terrestrial organisms, bacteria, and where PFOA was not a chemical of study. The citations meeting the search criteria were reviewed for reported BAFs and/or reported concentrations in which BAFs could be calculated for freshwater and estuarine/marine species. BAFs from both freshwater and estuarine/marine species were considered because: (1) inclusion of estuarine/marine BAFs expanded the relatively limited PFOA BAF dataset, and (2) Burkhard (2021) did not specifically observe notable differences in PFAS BAFs between freshwater and estuarine/marine systems, instead stating additional research is needed to formulate conclusions.

Data from papers with appropriate BAF information were further screened for data quality. Four factors were evaluated in the screening of the BAF literature: (1) number of water samples, (2) number of organism samples, (3) water and organism temporal coordination in sample collection, and (4) water and organism spatial coordination in sample collection. Additionally, the general experimental design was evaluated. Table 2-2 below outlines the screening criteria for study evaluation and ranking. Only BAFs of high and medium quality were

NMED Exhibit 63

used to derive the tissue criteria (Appendix O). For further details on BAFs compilation and ranking, see Burkhard (2021).

Table 2-2. Evaluation Criteria for Screening Bioaccumulation Factors (BAFs) in the Public Literature.

Screening Factor	High Quality	Medium Quality	Low Quality
Number of Water Samples	>3	2 – 3	1
Number of Organism Samples	>3	2 – 3	1
Temporal Coordination	Concurrent collection	Within one year	Collection period >1 year
Spatial Coordination	Collocated collection	Within 1 - 2 km	Significantly different locations (>2 km)
General Experimental Design			Mixed species tissues samples

Modified from Burkhard (2021).

PFOA bioaccumulation potential in aquatic life is expected to be relatively low compared to PFOS bioaccumulation, or PFOA bioaccumulation in aquatic-dependent birds and mammals The high water solubility of PFOA may allow aquatic organisms to excrete PFOA through the gills. Conversely, aquatic dependent birds and mammals lack such an excretion mechanism, as the low vapor pressure of PFOA limits its ability to be transferred across the alveolar membrane from lungs to air (Canada 2012; Kelly et al. 2004). The tissue criteria for fish and invertebrates presented here protect aquatic life populations from PFOA exposure accumulating in tissues and provide U.S. states and Tribes greater context to their fish-tissue monitoring programs, which are actively measuring PFAS, including PFOA.

NMED Exhibit 63

3 EFFECTS ANALYSIS FOR AQUATIC LIFE

3.1 Toxicity to Aquatic Life

All available studies relating to the acute and chronic toxicological effects of PFOA on aquatic life were considered in the derivation of these national recommended PFOA criteria. Data for possible inclusion in these PFOA criteria were obtained from published literature reporting acute and chronic exposures of PFOA that were associated with mortality, survival, growth, and reproduction. The latest search was conducted through the March 2024 ECOTOX database update. Acute and chronic data meeting the quality objectives and test requirements were utilized quantitatively in deriving these criteria for aquatic life and are presented in Appendix A: Acceptable Freshwater Acute PFOA Toxicity Studies; Appendix B: Acceptable Estuarine/Marine Acute PFOA Toxicity Studies; Appendix C: Acceptable Freshwater Chronic PFOA Toxicity Studies, and; Appendix D: Acceptable Estuarine/Marine Chronic PFOA Toxicity Studies.

3.1.1 Summary of PFOA Toxicity Studies Used to Derive the Aquatic Life Criteria

Quantitatively acceptable acute PFOA toxicity data were available for 27 freshwater species, representing 19 genera and 17 families in five phyla, and four estuarine/marine species, representing four genera and three families in three phyla (Table 3-1). Quantitatively acceptable chronic PFOA toxicity data were available for 13 freshwater species, representing 12 genera and ten families in three phyla and two estuarine/marine species, representing two genera and two families in two phyla. The following study summaries present the key acute and chronic freshwater toxicity data with effect values that were used quantitatively to derive the acute and chronic freshwater and estuarine/marine criteria to protect aquatic life. Study summaries for the most sensitive taxa are presented below and are grouped by acute or chronic exposure and sorted by sensitivity to PFOA.

NMED Exhibit 63

Acute and chronic values were presented as reported by the study authors for each individual study, unless stated otherwise. The EPA independently calculated these toxicity values if sufficient raw data were available for the EPA to conduct statistical analyses. The EPA's independently-calculated toxicity values were used preferentially, where available. Author-reported toxicity values and the EPA's independently calculated values (where available) were included in each study summary and in appendices, as applicable. The results of all toxicity values, such as LC values, EC values, NOECs, LOECs, and species- and genus-mean values, are given to four significant figures to prevent round-off error in subsequent calculations, not to reflect the precision of the value. The specific toxicity value utilized in the derivation of the corresponding PFOA criteria is stated for each study at the end of the summaries below and in the respective appendices.

NMED Exhibit 63

Table 3-1. Summary Table of Minimum Data Requirements per the 1985 Guidelines Reflecting the Number of Acute and Chronic Genus and Species Level Mean Values in the Freshwater and Saltwater Toxicity Datasets for PFOA.

MDR[a, b]	Freshwater			
	GMAV	**SMAV**	**GMCV**	**SMCV**
Family Salmonidae in the class Osteichthyes	1	1	1	1
Second family in the class Osteichthyes, preferably a commercially or recreationally important warmwater species	3	3	2	2
Third family in the phylum Chordata (may be in the class Osteichthyes or may be an amphibian, etc.)	5	10	2	2
Planktonic Crustacean	3	6	3	4
Benthic Crustacean	1	1	1	1
Insect	1	1	1	1
Family in a phylum other than Arthropoda or Chordata (e.g., Rotifera, Annelida, or Mollusca)	4	4	1	1
Family in any order of insect or any phylum not already represented	1	1	1	1

Family in the phylum Chordata	0	0	0	0
Either the Mysidae or Penaeidae family	2	2	0	0
Family in a phylum other than Arthropoda or Chordata	1	1	0	0
Family in a phylum other than Chordata	1	1	1	1
Family in a phylum other than Chordata			0	0
Family in a phylum other than Chordata			0	0
Any other family			0	0
Total	**4**	**4**	**2**	**2**

[a] The 1985 Guidelines require that data from a minimum of eight families are needed to calculate an estuarine/marine criterion. Insufficient data exist to fulfill all eight of the taxonomic MDR groups. Consequently, the EPA cannot derive an estuarine/marine acute criterion, based on the 1985 Guidelines. However, the EPA has developed estuarine/marine benchmarks through use of surrogate data to fill in missing MDRs using the EPA's WebICE tool and other New Approach Methods. These benchmarks are provided in Appendix L.

NMED Exhibit 63

3.1.1.1 Summary of Acute PFOA Toxicity Studies Used to Derive the Freshwater Aquatic Life Criterion

The acute data set for PFOA contains 19 genera representing all eight taxonomic MDR groups (Table 3-3). Quantitatively-acceptable data for acute PFOA toxicity were available for four freshwater fish species, representing four genera and three families and fulfilled two of the eight MDRs. Quantitatively acceptable data for acute PFOA toxicity were also available for 13 freshwater invertebrate species, representing ten genera and nine families, and fulfilled five of the eight MDRs. Quantitatively acceptable acute data were available for 10 freshwater amphibian species, representing five genera and five families fulfilling one of the MDRs. Summaries of studies for the most sensitive acute genera are described below, with the four most sensitive genera provided in Table 3-2.

Table 3-2. The Four Most Sensitive Genera Used in Calculating the Acute Freshwater Criterion (Sensitivity Rank 1-4).
Ranked Below from Most to Least Sensitive

Rank	Genus	GMAV (mg/L)	Species
1	*Moina*	8.885	Cladoceran (*Moina macrocropa*)
			Cladoceran (*Moina micrura*)
2	*Neocloeon*	13.05	Mayfly (*Neocloeon triangulifer*)
3	*Chydorus*	93.17	Cladoceran (*Chydorus sphaericus*)
4	*Daphnia*	142.8	Cladoceran (*Daphnia carinata*)[a]
			Cladoceran (*Daphnia magna*)
			Cladoceran (*Daphnia pulicaria*)

[a] Not a North American resident but in same genus as resident species.

3.1.1.1.1 Most acutely sensitive genus: Moina (cladoceran)

Ji et al. (2008) performed a 48-hour static, unmeasured acute test of PFOA (CAS # 335-67-1, purity unreported) with *Moina macrocopa*. Testing method followed U.S. EPA/600/4-

NMED Exhibit 63

90/027F (2002). The test involved four replicates of five daphnids (<24 hours old) each in five unmeasured test concentrations (62.5, 125, 250, 500 and 1,000 mg/L) plus a negative control. Dilution water was moderately hard reconstituted water. Survival of daphnids in the negative control was not reported, although EPA/600/4-90/027F requires at least 90% survival for test acceptability. The author-reported 48-hour EC_{50} for the study was 199.51 mg/L. The EPA performed C-R analysis for the test. The EPA-calculated EC_{50} (166.3 mg/L PFOA) was acceptable for quantitative use in deriving the acute freshwater PFOA criterion and served directly as the *Moina macrocopa* Species Mean Acute Value (SMAV).

Razak et al. (2023) tested the acute toxicity of perfluorooctanoic acid (PFOA, ≥98% purity) to *Moina micrura* in a 48-hour static measured experiment. Testing methods followed OECD 202 (OECD 2004) with nominal testing concentrations of 10, 25, 50, 75, 100, 250, 500, 750, 1,000, 2,500, 5,000, 7,500, and 10,000 µg/L, plus a control, with four replicates per treatment. Filtered surface lake water was used as test water. Measured concentrations were not reported, but the authors noted they were 94.3±6.1% of nominal on average. Each replicate consisted of 10 neonates (<48 hours old) in 50 mL of solution in a 100 mL beaker, and organisms were not fed during the study. Lethal effect concentrations (LC) were calculated using Probit analysis, and the 48-hour LC_{50} value of 474.7 µg/L, or 0.4747 mg/L was determined to be acceptable for quantitative use. The 48-hr LC_{50} was acceptable for quantitative use in deriving the acute freshwater PFOA criterion and served directly as the *Moina micrura* SMAV.

Moina macrocopa (SMAV of 166.3 mg/L) is much more tolerant to acute freshwater PFOA exposures than *M. micrura* (SMAV of 0.4747 mg/L) but both species were used to determine the *Moina* Genus Mean Acute Value (GMAV) of 8.885 mg/L. If the EPA were to exclude the *M. micrura* SMAV on the basis of it being an overly sensitive outlier (relative to *M.*

macrocopa and the overall quantitatively acceptable acute data), that would result in the final PFOA acute criterion potentially being underprotective of untested sensitive invertebrate species or other taxa, considering that the available data serve as surrogate information for the thousands of untested freshwater species. Conversely, excluding the *M. macrocopa* SMAV on the basis of it being a tolerant outlier (relative to *M. micrura*) would result in the final PFOA acute criterion being highly influenced by a single test/species with an LC_{50} that was uniquely sensitive (i.e., *M. micrura* SMAV = 0.4747 mg/L) compared to the overall acute data. Averaging the *M. micrura* and *M. moina* SMAVs resulted in a GMAV (8.885 mg/L) that was the most sensitive GMAV, yet still in the general range of the data overall.

3.1.1.1.2 Second most acutely sensitive genus: Neocloeon (mayfly)

Soucek et al. (2023) exposed the parthenogenetic mayfly, *Neocloeon triangulifer*, to PFOA (CAS # 335-67-1, 95% purity) in water in a 96-hour acute toxicity test. The test was performed under static, non-renewal conditions beginning with <24-hour old larvae. Mayflies were fed live diatom biofilm scraping beginning on day 0. Feeding only occurred on day 0, and the authors indicated test organisms required food to survive the entire 96-hour exposure, with previous studies demonstrating greater than 80% mortality at 48 hours with no food (Soucek and Dickinson 2015). Percent survival in the control treatment after 96 hours was 100%. The EPA-calculated acute LC_{50} (i.e., 13.045 mg/L) was similar to the author-reported LC_{50} of 13.451 mg/L. The EPA-calculated LC_{50} value (i.e., 13.045 mg/L) was acceptable for quantitative use in deriving the acute freshwater PFOA criterion and served directly as the *Neocloeon* GMAV.

3.1.1.1.3 Third most acutely sensitive genus: Chydorus (cladoceran)

Le and Peijnenburg (2013) performed a 48-hour static unmeasured acute PFOA toxicity test with the cladoceran, *Chydorus sphaericus*. The authors reported the 48-hour EC_{50} was 0.22 mM PFOA (91.10 mg/L). The EPA performed concentration-response (C-R) analysis for the test

NMED Exhibit 63

and calculated a LC_{50} of 93.17 mg/L PFOA that is acceptable for quantitative use. No other quantitatively acceptable acute toxicity data were available for *Chydorus sphaericus* or other members of the genus *Chydorus*. Therefore, the LC_{50} (i.e., 93.17 mg/L) from this test served directly as the *Chydorus sphaericus* SMAV and the *Chydorus* GMAV.

3.1.1.1.4 Fourth most acutely sensitive genus: Daphnia (cladoceran)

Logeshwaran et al. (2021) conducted an acute PFOA test with the cladoceran, *Daphnia carinata*, and PFOA (95% purity, purchased from Sigma-Aldrich Australia) following OECD guidelines (2000) with slight modifications. Authors used nominal test concentrations (0, 0.5, 1, 2.5, 5, 10, 20, 30, 40, 50, 100, 150, 200 and 250 mg/L PFOA) with three replicates per treatment. No mortality occurred in the controls. The author-reported 48-hour EC_{50} was 78.2 mg/L PFOA. The EPA-calculated 48-hour EC_{50} value was 66.80 mg/L, which was acceptable for quantitative use. No other quantitatively acceptable acute tests were available for this species and the EC_{50} of 66.80 mg/L from Logeshwaran et al. (2021) served directly as the *Daphnia carinata* SMAV.

Boudreau (2002) performed a 48-hour static PFOA (CAS # 335-67-1, ≥97% purity) acute test with *Daphnia pulicaria*, following ASTM E729-96 (1999). Five unmeasured test concentrations plus a negative control were used with 3-4 replicates per treatment and 10 daphnids per replicate. Nominal concentrations were 0 (negative control), 26.3, 52.6, 105, 210 and 420 mg/L. Mortality of daphnids in the negative control was not reported, but the protocol followed by the authors (i.e., ASTM E729-96) required ≥ 90% survival in negative controls. The 48-hour *D. pulicaria* EC_{50} reported in the publication was 203.7 mg/L, which was acceptable for quantitative use. No other quantitatively acceptable acute tests were available for this species and the EC_{50} of 203.7 mg/L from Boudreau (2002) served directly as the *D. pulicaria* SMAV.

Boudreau (2002) also performed a 48-hour static PFOA (CAS # 335-67-1, ≥97% purity) acute test with *Daphnia magna* following the same methods used in the *D. pulicaria* acute test.

NMED Exhibit 63

The 48-hour *D. magna* EC_{50} reported in the publication was 223.6 mg/L, which was acceptable for quantitative use.

Colombo et al. (2008) conducted a 48-hour static PFOA (ammonium salt, CAS # 3825-26-1, 99.7% purity) acute test on *Daphnia magna*. Authors stated the test followed OECD test guideline 202 (1992). The nominal test concentrations included control, 100, 178, 316, 562 and 1,000 mg/L, with four replicates/treatment and five animals/replicate. No mortality was observed in the controls, and the 48-hour EC_{50} reported in the study was 480 mg/L, which was acceptable for quantitative use.

Ji et al. (2008) performed a 48-hour static acute test of PFOA (CAS # 335-67-1, purity unreported; obtained from Sigma Aldrich, St. Louis, MO) on *D. magna*. Authors stated the test followed U.S. EPA/600/4-90/027F (2002). The test involved four replicates of five daphnids each in five unmeasured test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 62.5, 125, 250, 500 and 1,000 mg/L. Mortality of daphnids in the negative control was not reported, although EPA/600/4-90/027F requires at least 90% survival for test acceptability. The author-reported 48-hour EC_{50} for the study was 476.52 mg/L (95% C.I. = 375.3 – 577.7 mg/L). The EPA performed C-R analysis for the test. The EPA-calculated EC_{50} was 542.5 mg/L PFOA and was acceptable for quantitative use.

Li (2009) conducted a 48-hour static PFOA (ammonium salt, >98% purity) acute test with *Daphnia magna*. Authors stated the test generally followed OECD 202 (1984). The test employed five replicates of six daphnids each in five test concentrations (nominal range = 31 – 250 mg/L) plus a negative control. No control daphnids were immobile at the end of the test. The author-reported 48-hour EC_{50} for the study was 181 mg/L (95% C.I.: 166-198 mg/L) which was averaged across three tests. The EPA performed C-R analysis for each individual test. All three

NMED Exhibit 63

tests had acceptable curves with the EPA-calculated EC_{50} values of 220.8 mg/L, 157.9 mg/L, and 207.3 mg/L, which were acceptable for quantitative use.

Yang et al. (2014) conducted a 48-hour acute test of PFOA (CAS # 335-67-1, 99% purity) with *Daphnia magna*, following ASTM E729 (1993). The test employed three replicates of 10 daphnids each in six test concentrations plus a negative and solvent control. Nominal concentrations were 0 (negative and solvent controls), 50, 80, 128, 204.8, 327.68 and 524.29 mg/L. Test concentrations were measured in low and high treatments only. Negative control and solvent control mortality were 0% each. The author-reported 48-hour LC_{50} was 201.85 mg/L (95% C.I. = 134.68 – 302.5 mg/L). The EPA performed C-R analysis for the test and fit an acceptable curve with an EPA-calculated LC_{50} of 222.0 mg/L PFOA, which was acceptable for quantitative use.

Barmentlo et al. (2015) performed a 48-hour static, measured acute test of PFOA (CAS # 335-67-1, >96% purity) with *Daphnia magna* following OECD 202 (2004) test guidelines. The test involved four to six replicates of five daphnids each in five test concentrations plus a negative control. Nominal concentrations were not provided, but PFOA was measured in the control, lowest, and highest test concentrations. Based on these measurements, the authors interpolated all test concentrations to be: 0.053 (negative control), 81, 128, 202, 318 and 503 mg/L. The author-reported 48-hour EC_{50} was 239 mg/L (95% C.I. = 190-287 mg/L). The EPA performed C-R analysis for the test and fit an acceptable curve with an EPA-calculated EC_{50} of 215.6 mg/L PFOA, which was acceptable for quantitative use.

Ding et al. (2012a) conducted a 48-hour static, partially measured acute test on PFOA (CAS # 335-67-1; 96% purity from Sigma Aldrich) with *D. magna*. The test generally followed OECD test guideline 202 (2004). Authors employed four replicates of five daphnids each in six

NMED Exhibit 63

test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 144.9, 165.6, 186.3, 207.0, 227.7, and 248.4 mg/L. Concentrations of PFOA were confirmed in the highest and lowest concentrations, though only nominal concentrations were reported. It was stated that the verified concentrations were "well in line with nominal concentrations". The 48-hour EC_{50} was reported as 211.6 mg/L (95% C.I. = 184.7 – 255.5 mg/L). The EPA performed C-R analysis for the test. The EPA-calculated EC_{50} was 216.1 mg/L PFOA, which was acceptable for quantitative use.

Lu et al. (2016) evaluated the acute toxicity of PFOA (CAS# 335-67-1, 98% purity, purchased from Tokyo Chemical Industry Co., Ltd., Tokyo, Japan) on *Daphnia magna* immobilization. The test was conducted following modified OECD standard test procedure 202, whereby five concentration treatments (3, 10, 30, 100 and 300 mg/L) plus a blank control were employed with three replicates per treatment. Authors reported immobility/survival to be a more sensitive endpoint than survival alone. The author-reported 48-hour EC_{50} for immobility/survival was 110.7 mg/L and the EPA-calculated 48-hour EC_{50} was 114.6 mg/L, which was acceptable for quantitative use.

Yang et al. (2019) evaluated the acute effects of PFOA (CAS# 335-67-1, purchased from Sigma-Aldrich in St. Louis, MO) on *Daphnia magna* in a 48-hour unmeasured static exposure. Authors stated the protocol for all testing followed OECD Guideline 202. Nominal acute test concentrations included 0 (control), 66.67, 79.92, 96.06, 115.1, 138.3, and 166.0 mg/L PFOA, with four replicates per treatment. Authors reported an LC_{50} of 120.9 mg/L PFOA. The EPA-calculated 48-hour LC_{50} was 117.2 mg/L, which was acceptable for quantitative use.

Chen et al. (2022) tested the acute toxicity of ammonium perfluorooctanoic acid (APFO, $\geq$98% purity) to *Daphnia magna* in a 48-hour unmeasured, static experiment. The acute APFO

NMED Exhibit 63

exposure generally followed test method OECD 202 (OECD 2004). For each replicate, 10 neonates were exposed to 50 mL of test solutions with nominal concentrations of 0, 10, 50, 100, 200, and 500 mg/L APFO, made by diluting the stock solution with culture medium. There were three replicates per treatment and test organisms were not fed during the experiment. Control mortality was less than 10% in the AFPO and reference toxicity tests. The 48-hour EC_{50} for immobility was 156.9 mg/L, which was acceptable for quantitative use.

Quantitatively acceptable *D. magna* acute values from Boudreau (2002; EC_{50} = 223.6 mg/L), Colombo et al. (2008; EC_{50} = 480 mg/L), Ji et al. (2008; EC_{50} = 542.5 mg/L), Li (2009; EC_{50} = 220.8, 157.9, and 207.3 mg/L), Yang et al. (2014; LC_{50} = 222.0 mg/L), Barmentlo et al. (2015; EC_{50} = 215.6 mg/L), Ding et al. (2012a; EC_{50} = 216.1 mg/L), Lu et al. (2016; EC_{50} = 114.6 mg/L), Yang et al. (2019; LC_{50} = 117.2 mg/L), and Chen et al. (2022; EC_{50} = 156.9 mg/L) were taken together as a geometric mean value to calculate the *D. magna* SMAV of 213.9 mg/L. The *D. carinata* SMAV (i.e., 66.80 mg/L), *D. pulicaria* SMAV (i.e., 203.7 mg/L), and *D. magna* SMAV (i.e., 213.9 mg/L) were used to determine the *Daphnia* GMAV of 142.8 mg/L.

NMED Exhibit 63

Table 3-3. Ranked Freshwater Genus Mean Acute Values.

Rank[a]	GMAV (mg/L PFOA)	MDR Group[c]	Genus	Species	SMAV[b] (mg/L PFOA)
1	8.885	D	*Moina*	Cladoceran, *Moina macrocopa*	166.3
				Cladoceran, *Moina micrura*	0.4747

a Ranked from the most sensitive to the most resistant based on Genus Mean Acute Value.
b From Appendix A: Acceptable Freshwater Acute PFOA Toxicity Studies.
c MDR Groups – Freshwater:

A. the family Salmonidae in the class Osteichthyes
B. a second family in the class Osteichthyes, preferably a commercially or recreationally important warmwater species (e.g., bluegill, channel catfish, etc.)
C. a third family in the phylum Chordata (may be in the class Osteichthyes or may be an amphibian, etc.)
D. a planktonic crustacean (e.g., cladoceran, copepod, etc.)
E. a benthic crustacean (e.g., ostracod, isopod, amphipod, crayfish, etc.)
F. an insect (e.g., mayfly, dragonfly, damselfly, stonefly, caddisfly, mosquito, midge, etc.)
G. a family in a phylum other than Arthropoda or Chordata (e.g., Rotifera, Annelida, Mollusca, etc.)
H. a family in any order of insect or any phylum not already represented.

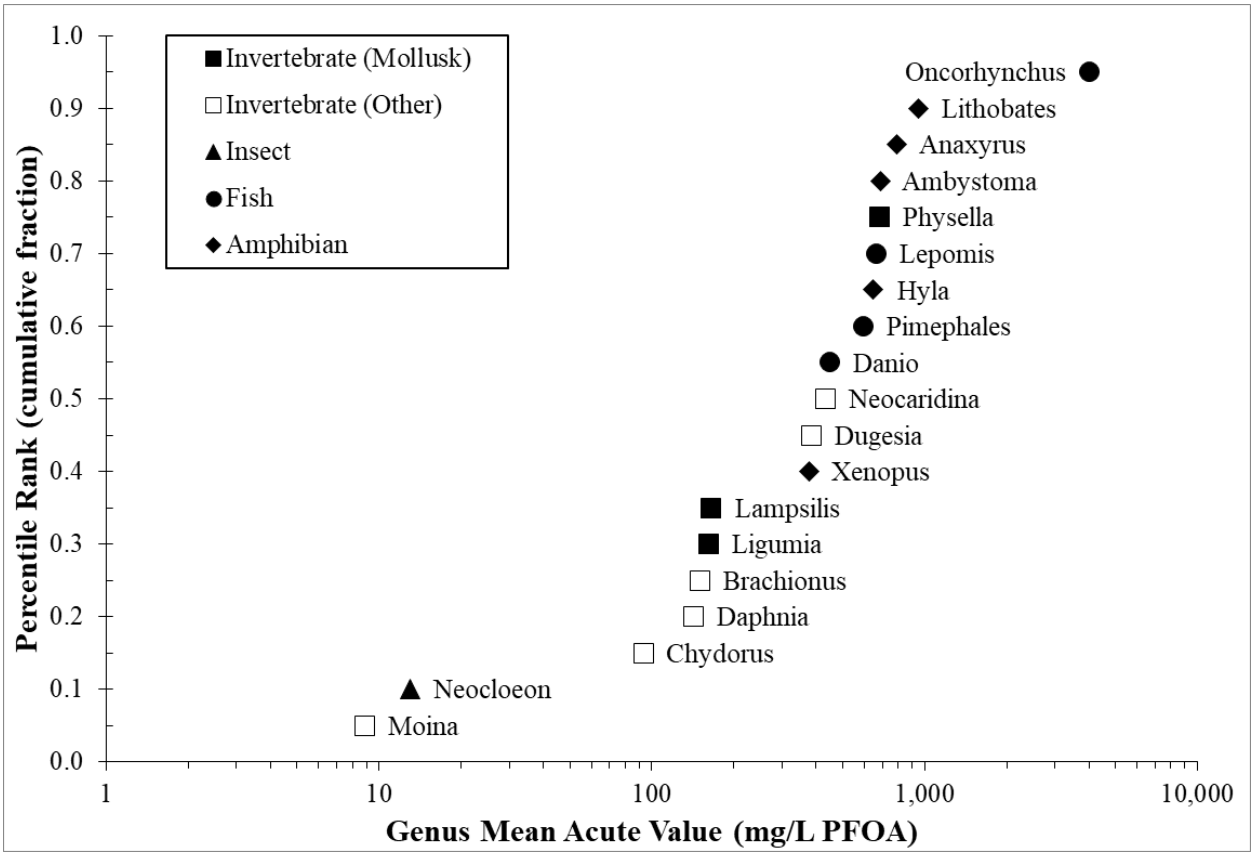

Figure 3-1. Ranked Freshwater Acute PFOA GMAVs Fulfilling the Acute Family MDR.

3.1.1.2 Summary of Quantitatively Acceptable Acute PFOA Toxicity Studies for Estuarine/Marine Species

Quantitatively-acceptable empirical data for acute PFOA toxicity were available for four estuarine/marine species, representing four genera and three families in three phyla. The data available for estuarine/marine invertebrates fulfilled three of the eight MDRs. In the interest of providing information to states/authorized Tribes on protective values, the EPA developed an estuarine/marine acute benchmark using the available empirical data supplemented with toxicity values generated through the use of new approach methods, specifically through the use of the EPA Office of Research and Development's peer-reviewed publicly-available Web-based Interspecies Correlation Estimation (web-ICE) tool (Raimondo et al. 2010). These benchmarks are provided in Appendix L.

NMED Exhibit 63

The following section provides information and summaries of studies for the sensitive estuarine/marine taxa, based on the limited available data (Table 3-4). Study summaries for the 4 most sensitive genera are provided below.

Table 3-4. Estuarine/Marine Acute PFOA Genera.
Ranked Below from Most to Least Sensitive

Rank	Genus	GMAV (mg/L)	Species
1	*Siriella*	15.5	Mysid (*Siriella armata*)[a]
2	*Mytilus*	17.58	Mediterranean mussel (*Mytilus galloprovincialis*)
3	*Strongylocentrotus*	20.63	Purple sea urchin (*Strongylocentrotus purpuratus*)
4	*Americamysis*	24	Mysid (*Americamysis bahia*)

[a] Not a North American resident species, but a member of the *Siriella* genus and serves as a surrogate for untested *Siriella* species residing in North America (Heard et al. 2006).

3.1.1.2.1 Most sensitive estuarine/marine genus: Siriella (mysid)

Mhadhbi et al. (2012) performed a 96-hour static, unmeasured acute test with PFOA (96% purity) on the mysid, *Siriella armata*. Mysids were exposed to one of ten nominal PFOA treatments (0.1, 0.5, 1, 2, 5, 10, 20, 30, 40 and 80 mg/L). Neonates were fed 10-15 *Artemia salina* nauplii daily and mortality was recorded after 96 hours. The 96-hour LC_{50} reported in the study was 15.5 mg/L PFOA and was acceptable for quantitative use. No other quantitatively acceptable acute toxicity data were available for *Siriella armata* or other members of the genus *Siriella*. Therefore, the LC_{50} (i.e., 15.5 mg/L) from this test served directly as the *Siriella* GMAV. Although *S. armata* is not a North American resident species, it is a member of the Mysidae Family and serves as a surrogate for untested mysid species, including members of the genus *Siriella*, residing in North America (Heard et al. 2006).

NMED Exhibit 63

3.1.1.2.2 Second most sensitive estuarine/marine genus: Mytilus (mussel)

The acute toxicity of PFOA (purity not provided) on the Mediterranean mussel, *Mytilus galloprovincialis*, which occurs in California and other parts of the Pacific Northwest (Green 2014), was evaluated by **Fabbri et al. (2014)**. The endpoint was the percent reduction of normal D-larvae in each well. Authors noted that controls had ≥80% normal D-larvae across all tests, meeting the >75% acceptability threshold outlined by ASTM (2004). PFOA was only measured once in one treatment which was similar to the nominal concentration. The percentage of normal D-larva decreased with increasing test concentrations. The NOEC and LOEC reported for the study were 0.00001 and 0.0001 mg/L, respectively. Although authors report ~27% effect at the LOEC (i.e., 0.0001 mg/L), the test concentrations failed to elicit 50% malformations in the highest test concentration, and an EC_{50} was not determined. Therefore, the EC_{50} for the study was greater than the highest test concentration (1 mg/L). The 48-hour EC_{50} based on malformation of >1 mg/L was quantitatively acceptable.

Hayman et al. (2021) reported the results of a 48-hour static, measured acute PFOA (CAS # 335-67-1, 95% purity, purchased from Sigma-Aldrich, St. Louis, MO) test on the Mediterranean mussel, *Mytilus galloprovincialis*. Authors note that tests followed U.S. EPA (1995b) and ASTM (2004) protocols. Six test solutions were made in 0.45 µm filtered seawater (North San Diego Bay, CA) with PFOA dissolved in methanol. The highest concentration of methanol was 0.02% (v/v) and each treatment solution contained five replicates. At test termination (48 hours), larvae were enumerated for total number of larvae that were alive at the end of the test (normally or abnormally developed) as well as number of normally-developed (in the prodissoconch "D-shaped" stage) larvae. There were no significant differences between solvent control and filtered seawater, suggesting no adverse effects of methanol. The author

NMED Exhibit 63

reported 48-hour EC_{50}, based on normal larvae survival was 9.98 mg/L PFOA. The EPA-calculated 48-hour EC_{50} value was 17.58 mg/L, which was acceptable for quantitative use.

Although the 48-hour EC_{50} based on malformation of >1 mg/L from Fabbri et el. (2014) met the EPA's data quantitatively objectives, it was not used directly in the calculation of the *M. galloprovincialis* SMAV because it was a "greater than LC_{50}" value and a definitive LC_{50} was available for the same species as reported by Hayman et al. (2021). The definitive LC_{50} value from Hayman et al. (2021) of 17.58 mg/L served directly as the *Mytilus galloprovincialis* SMAV and as the *Mytilus* GMAV.

3.1.1.2.3 Third most sensitive estuarine/marine genus: Strongylocentrotus (urchin)

Hayman et al. (2021) reported the results of a 96-hour static, measured PFOA (CAS # 335-67-1, 95% purity, purchased from Sigma-Aldrich, St. Louis, MO) test with the purple sea urchin, *Strongylocentrotus purpuratus*. Authors note that tests followed U.S. EPA (1995b) and ASTM (2004) protocols. Six test solutions were made in 0.45 µm filtered seawater (North San Diego Bay, CA) with PFOA dissolved in methanol and each treatment was replicated five times. The highest concentration of methanol was 0.02% (v/v). At test termination (96 hours), the first 100 larvae were enumerated and observed for normal development (organisms distinguished as being in the four arm pluteus stage). There were no significant differences between solvent control and filtered seawater, suggesting no adverse effects of methanol. The author reported 96-hour EC_{50}, based on normal development, was 19 mg/L PFOA. The EPA-calculated 96-hour EC_{50} value was 20.63 mg/L, which was acceptable for quantitative use. The EC_{50} value of 20.63 mg/L was the only acceptable acute value for *Strongylocentrotus purpuratus* or any members of the genus *Strongylocentrotus*. Therefore, it served directly as the *Strongylocentrotus purpuratus* SMAV and the *Strongylocentrotus* GMAV.

NMED Exhibit 63

3.1.1.2.4 Fourth most sensitive estuarine/marine genus: Americamysis (mysid)

Hayman et al. (2021) conducted a 96-hour static, measured test to assess effects of PFOA (CAS # 335-67-1, 95% purity, purchased from Sigma-Aldrich, St. Louis, MO) on the mysid, *Americamysis bahia*. Authors note that tests followed U.S. EPA (2002) protocols. Six test solutions were made in 0.45 µm filtered seawater (North San Diego Bay, CA) with PFOA dissolved in methanol. The highest concentration of methanol was 0.02% (v/v) and each test solution was replicated six times with five mysids per replicate. There were no significant differences between solvent control and filtered seawater, suggesting no adverse effects of methanol. No organisms were found dead in the controls at test termination. The EPA was unable to fit a concentration-response model with significant parameters and relied on the author-reported 96-hour LC_{50} of 24 mg/L PFOA as the quantitatively acceptable acute value. The LC_{50} value of 24 mg/L was the only acceptable acute value for *Americamysis bahia* or any members of the genus *Americamysis.* Therefore, it served directly as the *Americamysis bahia* SMAV and the *Americamysis* GMAV.

The estuarine/marine acute data set for PFOA contained four genera (Figure 3-2) representing only three of the eight taxonomic MDR groups. The missing MDR groups included two families in the phylum Chordata, two families in a phylum other than Chordata, and any other family not already represented (Table 3-5). As noted above, the EPA used the available acute toxicity data and ORD's peer-reviewed web-ICE tool to develop aquatic life benchmarks for consideration by states and Tribes (see Appendix L).

NMED Exhibit 63

Table 3-5. Ranked Estuarine/Marine Genus Mean Acute Values.

Rank[a]	GMAV (mg/L PFOA)	MDR Group[c]	Genus	Species	SMAV[b] (mg/L PFOA)
1	15.5	C	*Siriella*	Mysid, *Siriella armata*	15.5
2	17.58	D	*Mytilus*	Mediterranean mussel, *Mytilus galloprovincialis*	17.58
3	20.63	F	*Strongylocentrotus*	Purple sea urchin, *Strongylocentrotus purpuratus*	20.63
4	24	C	*Americamysis*	Mysid, *Americamysis bahia*	24

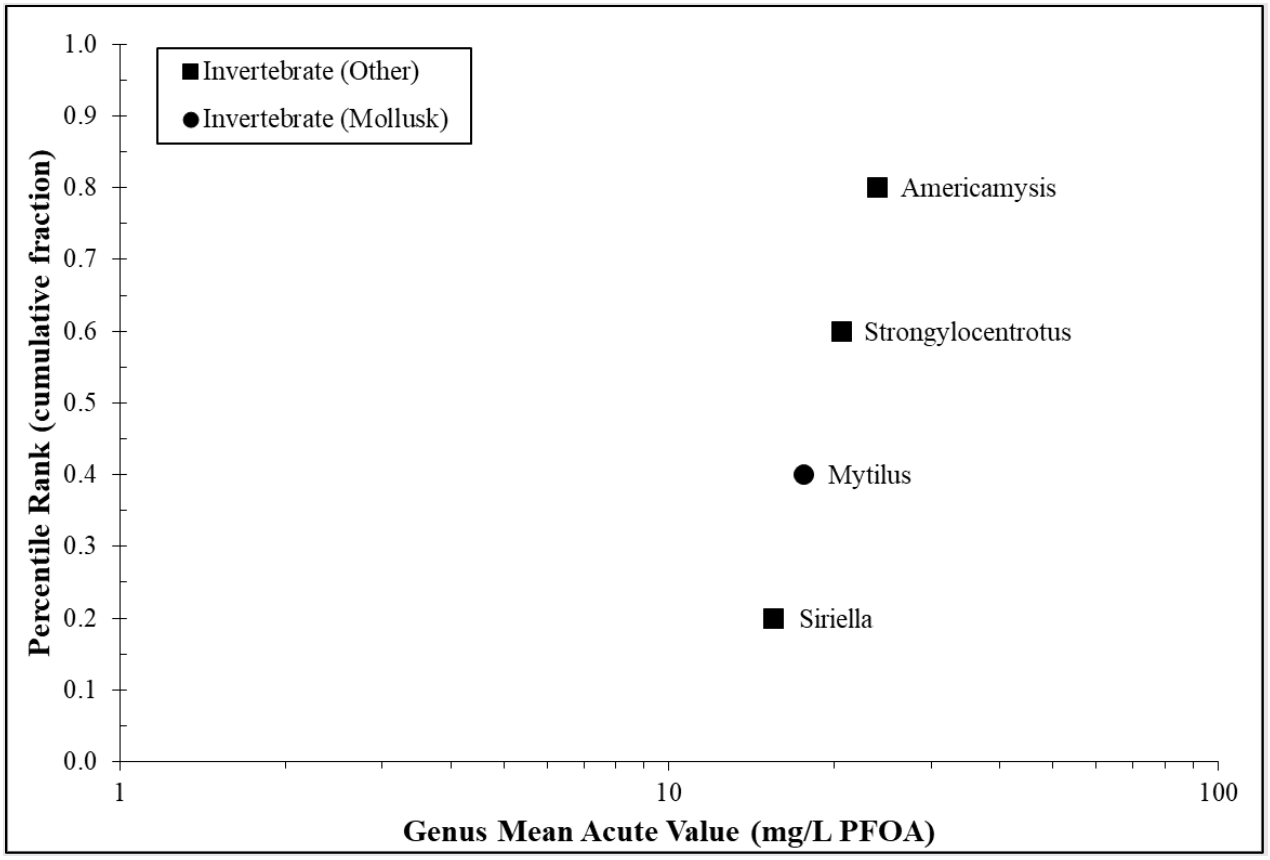

Figure 3-2. Acceptable Estuarine/Marine GMAVs.

3.1.1.3 Summary of Chronic PFOA Toxicity Studies Used to Derive the Freshwater Aquatic Life Criterion

Acceptable chronic PFOA toxicity data in freshwater were available for a total of 13 species representing 12 genera and ten families in three phyla. All eight of the required MDRs were fulfilled. The following section provides information and summaries of studies for the sensitive taxa with effect values used in the quantitative calculation of the chronic freshwater PFOA criterion (Table 3-6). The chronic data set for PFOA based on quantitatively acceptable data contains 12 genera representing all eight taxonomic MDR groups (Table 3-7).

Table 3-6. The Most Sensitive Genera Used in Calculating the Chronic Freshwater Water Column Criterion (Sensitivity Rank 1-4).

Ranked Below from Most to Least Sensitive

Rank	Genus	GMCV (mg/L)	Species
1	*Hyalella*	0.147	Amphipod (*Hyalella azteca*)
2	*Lithobates*	0.288	American bullfrog (*Lithobates catesbeiana*)
3	*Daphnia*	0.3695	Cladoceran (*Daphnia carinata*)[a]
			Cladoceran (*Daphnia magna*)
4	*Brachionus*	0.7647	Rotifer (*Brachionus calyciflorus*)

[a] Not a North American resident but in same genus as resident species.

3.1.1.3.1 Most chronically sensitive genus: Hyalella (amphipod)

Bartlett et al. (2021) evaluated the chronic effects of PFOA (CAS# 335-67-1, 96% purity, solubility in water at 20,000 mg/L, purchased from Sigma-Aldrich) on *Hyalella azteca* via a 42-day static-renewal, measured study. Methods for this study were adapted from Borgmann et al. (2007), and organisms were two to nine days old at the test initiation. A 100 mg/L stock solution was prepared to yield measured test concentrations of 0 (control), 0.84, 3.3,

NMED Exhibit 63

8.9, 29 and 97 mg/L PFOA. Two separate tests were performed with five replicates per concentration and 20 amphipods per replicate. At test termination (day 42), adults were sexed and weighed, as well as their young counted. The 42-day author-reported LC_{10} value for survival was 23.2 mg/L PFOA. The author-reported EC_{10} values for growth and reproduction were 0.160 mg/L and 0.0265 mg/L, respectively. The EPA only performed C-R analysis for the growth and reproduction-based endpoints for this test, given the apparent tolerance of the survival-based endpoint. The EPA calculated EC_{10} values for the 42-day growth endpoint (i.e., control normalized wet weight/amphipod) and the 42-day reproduction endpoint (i.e., number of juveniles per female). The 42-day growth-based EC_{10} of 0.488 mg/L was not selected as the primary endpoint from this test because it was more tolerant than the reproduction-based EC_{10} of 0.147 mg/L, which was acceptable for qualitative use. The EC_{10} value of 0.147 mg/L was the only acceptable chronic value for *Hyalella azteca* or any members of the genus *Hyalella.* Therefore, it served directly as the *Hyalella azteca* Species Mean Chronic Value (SMCV) and the *Hyalella* Genus Mean Chronic Value (GMCV).

3.1.1.3.2 Second most chronically sensitive genus: Lithobates (frog)

Flynn et al. (2019) evaluated the chronic effects of PFOA (CAS# 335-67-1, purchased from Sigma-Aldrich) on the American bullfrog (*Lithobates catesbeiana,* formerly, *Rana catesbeiana*) during a 72-day static-renewal unmeasured exposure. The authors tested a negative control and two treatment concentrations (i.e., 0.144 and 0.288 mg/L), which were the only three PFOA-only treatments within the larger factorially-designed experiment. Each treatment contained 10 tadpoles (Gosner stage 25) and treatments were replicated four times. On day 72 of the experiment, all tadpoles were euthanized and measured (snout vent length and mass). The most sensitive chronic endpoint was growth (snout-vent length), with a 72-day NOEC and LOEC of 0.144 mg/L and 0.288 mg/L, respectively. The EPA could not independently calculate an EC_{10}

NMED Exhibit 63

value because there were minimal effects observed across the limited number of treatment concentrations tested. Consequently, the EPA used the LOEC of 0.288 mg/L as the chronic value from this chronic test. The LOEC was used preferentially to the MATC from this test because a ~7% reduction in snout-vent length relative to control responses was observed at the LOEC (i.e., 0.288 mg/L), which is a similar effect level to the chronic 10% effect level (i.e., EC_{10}) used preferentially to derive the chronic criterion. The LOEC value of 0.288 mg/L was the only acceptable chronic value for *Lithobates catesbeiana* or any members of the genus *Lithobates.* Therefore, it served directly as the *Lithobates catesbeiana* SMCV and the *Lithobates* GMCV.

3.1.1.3.3 Third most chronically sensitive genus: Daphnia (cladoceran)

Logeshwaran et al. (2021) conducted a static-renewal unmeasured PFOA (95% purity, purchased from Sigma-Aldrich Australia) chronic toxicity test with the cladoceran, *Daphnia carinata*. Authors stated the chronic test protocol followed OECD guidelines (2012). Authors tested a negative control and five PFOA concentrations (i.e., 0.001, 0.01, 0.1, 1.0 and 10 mg/L PFOA). Each test treatment was replicated 10 times with one daphnid (six to12 hours old) per treatment. At test termination (21 days) test endpoints included survival, days to first brood, average offspring in each brood and total live offspring. No mortality occurred in the controls or lowest test concentration. Of the three endpoints measured, average offspring in each brood and total live offspring were the more sensitive endpoints with 21-day NOEC and LOEC values of 0.01 and 0.1 mg/L PFOA, respectively. The EPA was unable to calculate statistically robust EC_{10} estimates from C-R models for these endpoints, largely because of the 10X dilution series across five orders of magnitude. The LOECs for these endpoints were not selected as the chronic value because the LOECs produced a 29.23% reduction in the average number of offspring per brood relative to controls and a 39.89% reduction in the total living offspring relative to controls. Therefore, the MATC (i.e., 0.03162 mg/L) was selected as the quantitatively acceptable chronic

NMED Exhibit 63

value from this test. The MATC value of 0.03162 mg/L was the only acceptable chronic value for *Daphnia carinata,* and it served directly as the *Daphnia carinata* SMCV.

Centre International de Toxicologie (2003) and **Colombo et al. (2008)** conducted a 21-day renewal measured chronic test on PFOA with the daphnid, *Daphnia magna*. Authors stated that the toxicity test conducted followed OECD test guideline 211. Average number of live young was the most sensitive endpoint reported by Colombo et al. (2008), with a NOEC of 20 mg/L. The author-reported NOEC for the average number of live young was 20 mg/L, the LOEC was 44.2 mg/L and the MATC was 29.73 mg/L. The EPA performed C-R analysis for each reported endpoint. The most sensitive endpoint with an acceptable C-R curve was the average number of live young per starting adult, with an EPA-calculated EC_{10} of 20.26 mg/L PFOA and was acceptable for quantitative use.

Ji et al. (2008) conducted a chronic life-cycle test on the effects of PFOA with *Daphnia magna*. Authors stated that the *D. magna* test followed OECD 211 (1998). The most sensitive endpoint for *D. magna* reported in the publication was days to first brood with a 21-day NOEC of 6.25 mg/L (LOEC = 12.5 mg/L; MATC = 8.839 mg/L); however, number of young per starting female (an endpoint not reported in the publication, which only assessed number of young per surviving female) was calculated by the EPA and considered to be a more sensitive endpoint with an EPA-calculated EC_{10} of 7.853 mg/L. Therefore, the EPA-calculated EC_{10} of 7.853 mg/L PFOA for *D. magna* (number of young per starting female) was considered quantitatively acceptable.

Li (2010) conducted an unmeasured chronic life cycle 21-day test on the effects of PFOA on *Daphnia magna*. Authors stated the test followed OECD 211 (1998). The *D. magna* 21-day NOEC (reproduction as number of young per female, broods per female, and mean brood size)

NMED Exhibit 63

was 10 mg/L (LOEC = 32 mg/L; calculated MATC = 17.89 mg/L). The EPA performed C-R analysis for each reported endpoint. The EPA also revaluated all endpoints that were based on number of surviving females to be based on the number of starting females. This recalculation was done with the intent to account for starting females that were unable to contribute to the population as reproduction/female due to mortality. The most sensitive endpoint with an acceptable C-R curve was the number of young per starting female with an EPA-calculated EC_{10} of 12.89 mg/L PFOA and was acceptable for quantitative use.

Yang et al. (2014) evaluated the chronic 21-day renewal, measured test of PFOA with *Daphnia magna*, following ASTM E729 (1993). The author-reported *D. magna* 21-day EC_{10} for reproduction (total number of spawning) was 7.02 mg/L. The EPA performed C-R analysis for each reported endpoint. Both chronic survival and reproduction endpoints resulted in acceptable C-R curves. The EPA-calculated EC_{10} for reproduction as total number of spawning events was 6.922 mg/L, similar to the EC_{10} reported by the authors (i.e., 7.02 mg/L). Chronic survival was more sensitive than reproduction, with an EPA-calculated EC_{10} of 5.458 mg/L PFOA. Therefore, the survival based EC_{10} calculated by the EPA (i.e., 5.458 mg/L) was acceptable for quantitative use.

Lu et al. (2016) evaluated the chronic toxicity of PFOA (CAS# 335-67-1, 98% purity, purchased from Tokyo Chemical Industry Co., Ltd., Tokyo, Japan) on *Daphnia magna* immobilization, growth and reproduction in a 21-day semi-static test with unmeasured treatment solutions. Authors stated the test protocol followed OECD Test Method 211. Neonates (<24 h old) were exposed to PFOA in one of six PFOA treatments (i.e., 0 [control] 0.032, 0.16, 0.8, 4 and 20 mg/L), with 20 replicates for each treatment. The 21-day growth and reproductive NOEC and LOEC values were 0.032 and 0.16 mg/L PFOA, respectively. The EPA was unable to fit a

NMED Exhibit 63

C-R model with significant parameters to the chronic data associated with reproduction from this test. The EPA-calculated EC_{10} values for mean intrinsic rate of increase (r; population-level endpoint that accounts for births and deaths over time) and growth (as length) were 0.0173 mg/L and 0.0124 mg/L, respectively. Both EC_{10} values were nearly two times lower than the NOEC for both endpoints (i.e., 0.032 mg/L) and four times lower than the LOEC values (i.e., 0.16 mg/L) for both endpoints, where a 15.2% reduction in intrinsic rate of natural increase ® and an 11.9% reduction in length were observed. As a result, the MATC of 0.0716 mg/L for growth and reproduction was selected as the most appropriate chronic value for quantitative use to in deriving the chronic water column-based criterion.

Yang et al. (2019) evaluated the chronic effects of PFOA (CAS# 335-67-1, purchased from Sigma-Aldrich in St. Louis, MO) on *Daphnia magna* via a 21-day unmeasured, static-renewal test that assessed reproductive effects. The protocol for testing followed OECD Guideline 211. Authors tested a negative control and four PFOA treatment concentrations (6.708, 10.10, 15.11, and 22.61 mg/L), with each treatment replicated 10 times and each replicate containing one neonate (12–24 hours old) in a 100 mL glass beaker. The reproductive NOEC and LOEC values were 6.708 and 10.10 mg/L PFOA, respectively. The EPA performed C-R analysis for the test. The EPA-calculated EC_{10} based on mean offspring at 21-days as a proportion of the control response was 8.084 mg/L and was used quantitatively to derive the chronic water column criterion.

The chronic values from Centre International de Toxicologie/Colombo et al. (2003/2008; EC_{10} = 20.26 mg/L; endpoint = average number of live young), Ji et al. (2008; EC_{10} = 7.853 mg/L; endpoint = number of live young per starting female), Li (2010; EC_{10} =12.89 mg/L; endpoint = number of young per starting female), Yang et al. (2014; EC_{10} = 5.458 mg/L;

NMED Exhibit 63

endpoint = survival), Lu et al. (2016; MATC = 0.0716 mg/L; endpoint = length and rate of natural increase), and Yang et al. (2019; EC_{10} = 8.084 mg/L; endpoint = mean offspring as a proportion of control response) were taken together as a geometric mean to serve as the *Daphnia magna* SMCV (i.e., 4.317 mg/L).

The *D. carinata* SMCV (i.e., 0.03162 mg/L) and the *D. magna* SMCV (i.e., 4.317 mg/L) were used to calculate the *Daphnia* GMCV of 0.3695 mg/L. Exclusion of the *D. carinata* SMCV under the basis of it being an overly sensitive outlier (relative to *D. magna* and the overall quantitatively acceptable chronic data) would have resulted in the *Daphnia* GMCV being potentially underprotective. Conversely, excluding the *D. magna* SMCV under the basis of being a tolerant outlier (relative to *D. carinata*) would result in the *Daphnia* GMCV being highly influenced by a single test/species with a relatively sensitive chronic value. The *D. carinata* chronic value was also an MATC, calculated as the geometric mean of the NOEC (0.01 mg/L) and LOEC (0.1 mg/L) from a 10X dilution series, meaning the MATC was influenced by a relatively low NOEC and broadly spaced dosing. However, the corresponding LOEC (i.e., 0.1 mg/L) remains relatively sensitive and produced effects of 29.23% to 39.89%, depending on the specific offspring-based endpoint. Using both the *D. magna* and *D. carinata* SMAVs resulted in a *Daphnia* GMCV (0.3695 mg/L) that was among the four most sensitive genera and in the general range of the data overall.

3.1.1.3.4 Fourth most chronically sensitive genus: Brachionus (rotifer)

Zhang et al. (2013a) conducted a chronic life-cycle renewal test of PFOA (CAS # 335-67-1, 96% purity) with *Brachionus calyciflorus*. The test consisted of a negative control and four PFOA concentrations (0.25, 0.5, 1.0, 2.0 mg/L PFOA). For each treatment level, fifteen amictic rotifers were placed individually into culture plate wells containing two mL of test solution that was renewed daily. Numbers of eggs produced and starting rotifer lifetimes were recorded for

NMED Exhibit 63

every individual, and the test was conducted until every starting rotifer from every treatment level died, which occurred around 200 hours after test initiation. Data from this test were used to construct survivorship and fertility tables using conventional life-history techniques, which were used to calculate net reproductive rate, generation time, and intrinsic rate of natural increase. The EPA calculated EC_{10} values from C-R data reported in the publication, and the most sensitive endpoint with an acceptable C-R curve was the intrinsic rate of natural increase, with an EC_{10} of 0.5015 mg/L PFOA.

The intrinsic rate of natural increase (d^{-1}) is a population-level endpoint that accounts for births and deaths over time. In Zhang et al. (2013a), the intrinsic rate of natural increase was calculated as the natural log of the lifetime net reproductive rate for all individuals within a population (defined here as a PFOA treatment level) divided by the average generation time of those individuals.

The EC_{10} calculated for the intrinsic rate of natural increase was similar to the EC_{10} value for average net reproductive rate (0.514 mg/L). Zhang et al. (2013a) also reported significant reductions in egg size, with an EPA-calculated EC_{10} = 0.193 mg/L. However, this endpoint displayed a relatively poor concentration response relationship and may not be relevant for assessing population level effects. For these reasons, it was not selected as the primary effect concentration from this study. Zhang et al. (2013a) also reported effects to average juvenile period, which was a relatively tolerant endpoint. Juvenile period decreased with increasing exposure concentration, with the average juvenile period being about 16% faster than the control responses in the highest treatment concentration (2.0 mg/L). Effects to chronic apical endpoints in this publication and Zhang et al. (2014b) generally appear as a threshold effect from 0.25 mg/L to 1.0 mg/L, providing further support for selection of the EC_{10} value (i.e., 0.5015 mg/L)

NMED Exhibit 63

based on rate of natural increase as the primary chronic value for quantitative use from Zhang et al. (2013a).

In addition to the life cycle exposure, Zhang et al. (2013a) also conducted a second multi-generational 28-day study to measure effects of PFOA on growth patterns, population density, and population dynamics. The 28-day test consisted of a negative control and two PFOA concentrations (0.25, and 2.0 mg/L PFOA). Population densities were lower than controls at both PFOA treatment levels; however, because this study was limited to two treatment levels, it was considered to be of secondary importance compared to the life-cycle test.

Zhang et al. (2014b) describes the results of three experiments involving *Brachionus calyciflorus* exposures to PFOA (CAS # 335-67-1, 96% purity). The effects of PFOA concentration on mictic ratios of *B. calyciflorus* was examined by placing individual neonates in culture plate wells with two mL of medium containing of two PFOA concentrations (0.25 mg/L and 2.0 mg/L) plus a control. Each treatment level, as well as the control, was replicated three times. All eggs produced by these exposed individuals were individually incubated in culture wells with one mL control medium. The mature F_1 offspring were subsequently identified as producing mictic or amictic eggs, and these data were used to calculate mictic ratios. The proportions of mictic eggs increased with increasing PFOA concentration (0.56 – control, 0.72 – 0.25 mg/L, 0.75 – 2.0 mg/L), and the results were statistically significant ($p<0.05$). In contrast, mictic ratios were not affected by PFOA concentrations in Zhang et al. (2013a). Because of the inconsistent result in the mictic ratio endpoint between Zhang et al. (2013a) and Zhang et al. (2014b), it was not selected as the representative endpoint from either publication.

The effects of PFOA concentration on resting egg production of *B. Calyciflorus* was examined by exposing rotifers to one of five PFOA concentrations (plus control) in the dark for

NMED Exhibit 63

six days. Resting eggs were collected on the sixth day and then hatched in control medium 30 days later. Resting egg production decreased with increasing PFOA concentration. The EPA-calculated EC_{10} calculated from C-R data reported in Figure 1 of Zhang et al. (2014b) was 0.076 mg/L. Because there was only one replicate (as implied by lack of error bars in Figure 1 of the publication, no clear description of replicates in the methods section, and no author-reported statistical analysis of this endpoint), resting egg production from this study was not considered quantitatively acceptable but was retained for qualitative use. In a second resting egg exposure study, resting eggs were produced under control conditions, then allowed to hatch while exposed to one of five PFOA concentrations plus a control. In this study, the effects of PFOA exposure on resting egg hatching rate were not statistically significant.

Finally, the effects of PFOA concentration on *B. calyciflorus* population growth was examined during a four-day study in which 10 neonates were placed into chambers with 10 mL of medium containing one of eight PFOA concentrations, plus a control. Each treatment level, as well as the control, was replicated at least six times. After four days, the total numbers of rotifers in each chamber were counted, and these data were used to calculate the intrinsic rate of natural increase (d^{-1}), the most sensitive acceptable endpoint from this study, with an EPA-calculated EC_{10} of 1.166 mg/L. Beyond Zhang et al. (2013a) and Zhang et al. (2014b), no other quantitatively acceptable chronic tests were available for *Brachionus calyciflorus*. The EPA-calculated EC_{10} values from Zhang et al. (2013a) (i.e., 0.5015 mg/L; endpoint = rate of natural increase) and Zhang et al. (2014b) (i.e., 1.166 mg/L; endpoint = rate of natural increase) were taken together as a geometric mean to serve as the *Brachionus calyciflorus* SMCV (i.e., 0.7647 mg/L). No other quantitatively acceptable chronic toxicity data were available for other members

NMED Exhibit 63

of the genus *Brachionus* and the *Brachionus calyciflorus* SMCV (i.e., 0.7647 mg/L) served directly as the *Brachionus* GMCV.

Table 3-7. Ranked Freshwater Genus Mean Chronic Values.

NMED Exhibit 63

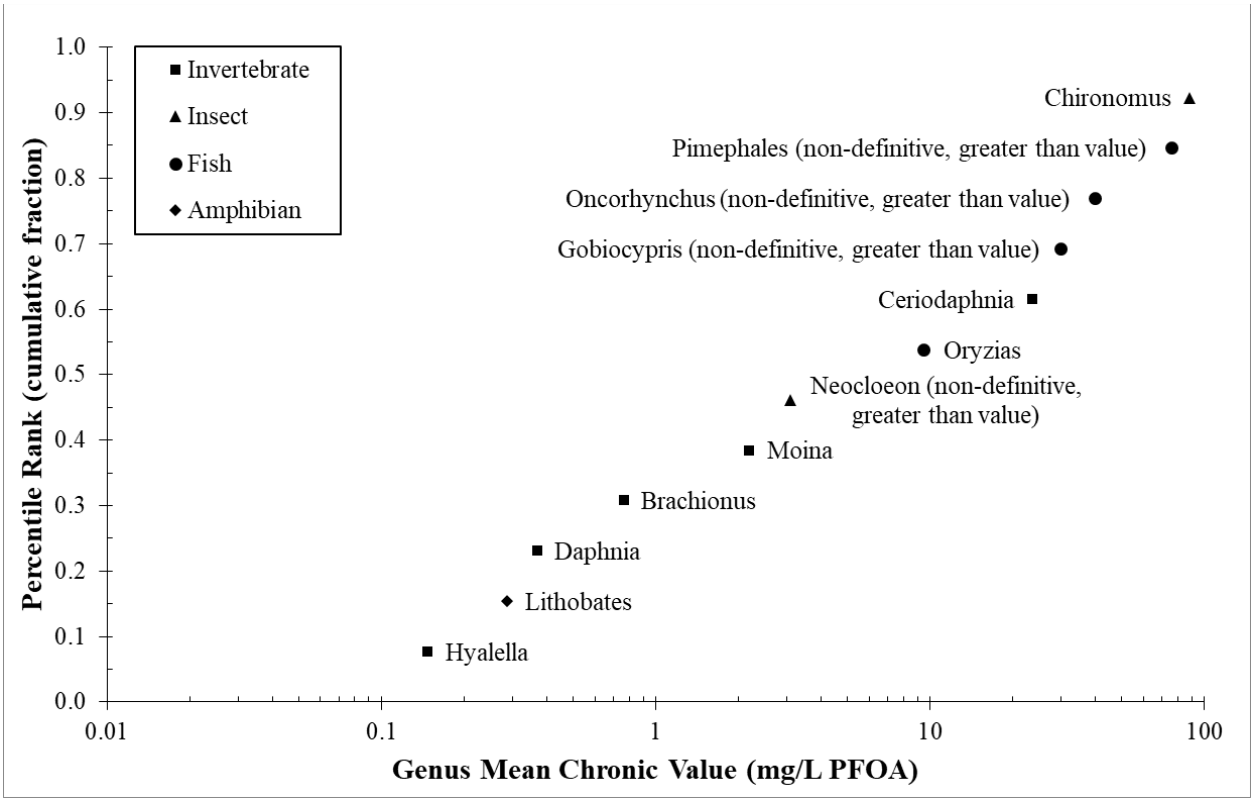

Figure 3-3. Freshwater Genus Mean Chronic Values for PFOA.

3.1.1.4 Summary of Chronic PFOA Toxicity Studies Used to Derive the Estuarine/Marine Aquatic Life Criterion

Quantitatively-acceptable empirical data for chronic PFOA toxicity were available for two estuarine/marine species, fulfilling two of the eight MDRs (Table 3-8).

3.1.1.4.1 Most chronically sensitive estuarine/marine species: Oryzias (fish)

Oh et al. (2013) evaluated the chronic toxicity of PFOA on the Japanese medaka, *Oryzias latipes*, in a 30-day static exposure. Prior to test initiation, the fish were acclimated to a seawater environment. Fish were exposed for 30 days to one PFOA concentration (1.0 mg/L), a 0.22 µm filtered seawater control, and a DMSO carrier solvent control. The 30-day condition factor NOEC of 1.0 mg/L PFOA was selected as the primary endpoint from this study. The methods section of Oh. et al. (2013) also stated, "In our preliminary study, fish mortality was altered 30 days after perfluorinated compound exposure, suggesting that repeated exposure to

NMED Exhibit 63

PFCs for 30 days at 1 µg/mL [1 mg/L] causes adverse effect on *O. latipes*." The statement about mortality-based effects in their preliminary test is in direct conflict with the condition-based results from the primary test that was the focus of the publication. Few details are provided about the preliminary test. Results of the final test (i.e., condition factor NOEC of 1.0 mg/L reported in Table 1 of Oh et al. 2013) were retained as quantitatively acceptable because they provide chronic estuarine/marine data that were otherwise limited.

3.1.1.4.2 Second most chronically sensitive estuarine/marine species: Paracentrotus (sea urchin)

Savoca et al. (2022) tested chronic toxicity of perfluorooctanoic acid (PFOA, >98% purity) to sea urchins (*Paracentrotus lividus*) in a 28-day measured, static experiment. Four sea urchins were placed into one of nine aquariums containing 15 L of seawater at nominal concentrations (0 [control], 10, and 100 mg/L), with three replicates per concentration treatment. The average recovery of PFOA was stable and close to nominal across all treatments throughout the experiment, and PFOA in control water was less than 10 ng/L. Coelomic fluid was sampled from all individuals weekly to measure PFOA uptake. During the exposure period, sea urchins at the highest test concentration showed sublethal signs of toxicity, including reduced spine mobility, spine loss, and reduced ability to remain anchored to the bottom of the test vessels. Mortality was only observed at the highest test concentration. Adult mortality, adult PFOA accumulation in coelomic fluid, percentage of normal and abnormal embryos, and gene expression in embryos were measured. The NOEC and LOEC for adult mortality were 10 mg/L and 100 mg/L, respectively, and the MATC of 31.62 mg/L was determined to be acceptable for quantitative use.

NMED Exhibit 63

Table 3-8. Ranked Estuarine/Marine Genus Mean Chronic Values.

Rank[a]	GMCV[b] (mg/L PFOA)	MDR Group[c]	Genus	Species	SMCV[b] (mg/L PFOA)

3.2 Derivation of the PFOA Aquatic Life Criteria

3.2.1 Derivation of Water Column-based Criteria

3.2.1.1 Derivation of Acute Water Criterion for Freshwater

The acute data set for PFOA contains 19 genera representing all eight taxonomic MDR groups. GMAVs for the four most sensitive genera were within a factor of 16.1 of each other.

NMED Exhibit 63

The freshwater Final Acute Value (FAV) (i.e., the 5th percentile of the genus sensitivity distribution, intended to address 95 percent of the genera) for PFOA is 6.237 mg/L, calculated using the procedures described in the 1985 Guidelines (Table 3-9). The FAV is lower than all the GMAVs for the tested species. The FAV was then divided by two to obtain a concentration yielding a minimal effect acute criterion value. Based on the above, the FAV/2, which is the freshwater acute criterion water column magnitude (criterion maximum concentration, CMC), is 3.1 mg/L PFOA (rounded to two significant figures) and is expected to be protective of 95% of freshwater genera exposed to PFOA under short-term conditions of one-hour of duration, if the one-hour average magnitude is not exceeded more than once in three years (Figure 3-5).

Table 3-9. Freshwater Final Acute Value and Criterion Maximum Concentration.

Calculated Freshwater FAV based on 4 lowest values: Total Number of GMAVs in Data Set = 19						
Rank	**Genus**	**GMAV (mg/L)**	**ln(GMAV)**	**ln(GMAV)^2**	**P=R/(N+1)**	**sqrt(P)**
1	*Moina*	8.885	2.18	4.77	0.050	0.224
2	*Neocloeon*	13.05	2.57	6.60	0.100	0.316
3	*Chydorus*	93.17	4.53	20.56	0.150	0.387
4	*Daphnia*	142.8	4.96	24.61	0.200	0.447
		Σ (Sum):	**14.25**	**56.54**	**0.50**	**1.37**

S^2 =	208.28	S = slope
L =	-1.396	L = X-axis intercept
A =	1.831	A = lnFAV
FAV =	6.237	P = cumulative probability
CMC =	**3.1 mg/L PFOA** (rounded to two significant figures)	

NMED Exhibit 63

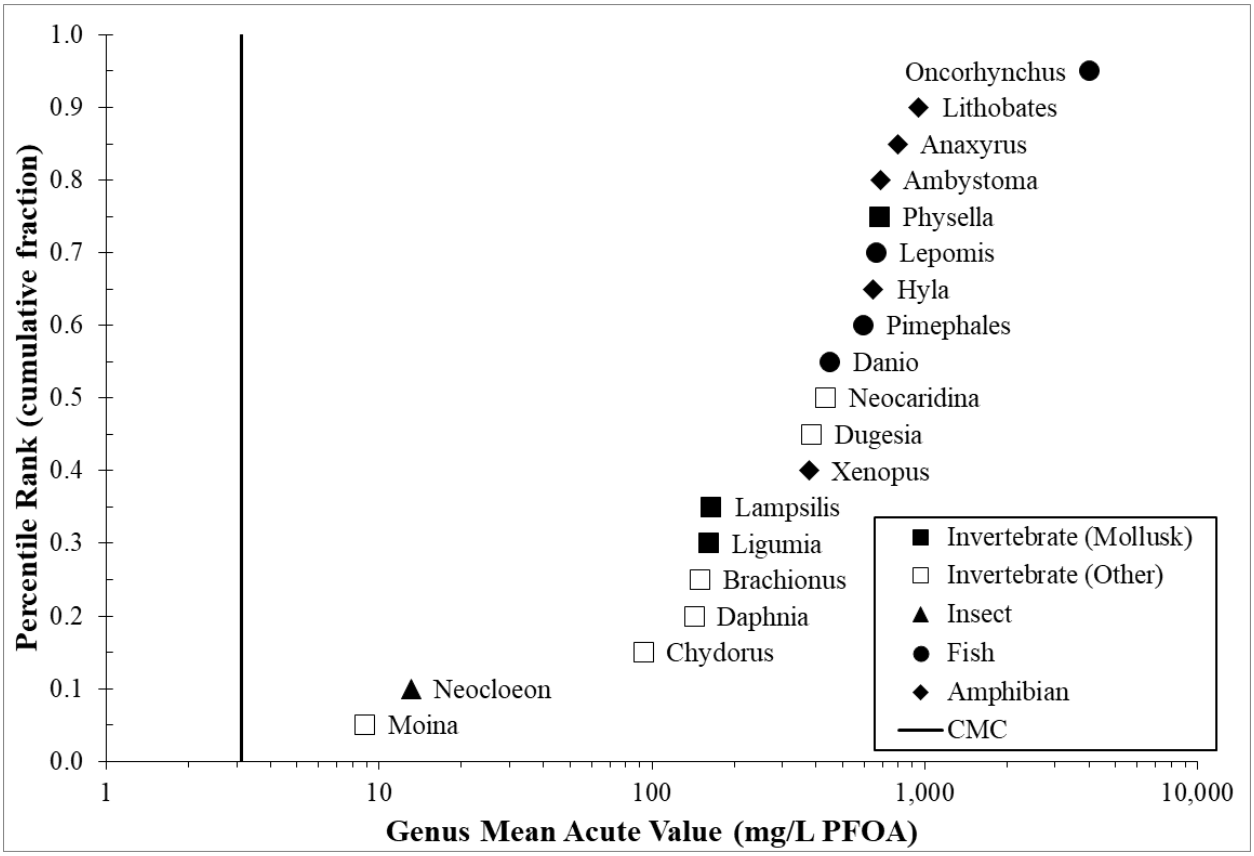

Figure 3-5. Ranked Freshwater Acute PFOA GMAVs and CMC.

3.2.1.2 Derivation of Acute Water Criterion for Estuarine/Marine Water

The 1985 Guidelines state that data from a minimum of eight families are needed to calculate an estuarine/marine FAV. Insufficient data exist to fulfill all eight of the taxonomic MDR groups. Notably, no acceptable test data on fish species were available. Since data were available for only three families, an estuarine/marine FAV could not be derived, and consequently, the EPA cannot derive an estuarine/marine acute criterion. The EPA has, however, developed an estuarine/marine acute benchmark value using available empirical data and the EPA/ORD's web-ICE tool to estimate missing data. The acute estuarine/marine benchmark is provided in Appendix L.

NMED Exhibit 63

3.2.1.3 Derivation of Chronic Water Criterion for Freshwater

The freshwater Final Chronic Value (FCV) (i.e., the 5th percentile of the genus sensitivity distribution, intended to address 95 percent of the genera) for PFOA is 0.1041 mg/L, calculated using the procedures described in the 1985 Guidelines (Table 3-10). The freshwater chronic criterion water column magnitude (CCC) is the FCV rounded to two significant figures, or 0.10 mg/L PFOA, and is expected to be protective of 95% of freshwater genera potentially exposed to PFOA if the four-day average magnitude is not exceeded more than once in three years.

Table 3-10. Freshwater Final Chronic Value and Criterion Continuous Concentration.

Calculated Freshwater FCV based on 4 lowest values: Total Number of GMCVs in Data Set = 12						
Rank	**Genus**	**GMCV (mg/L)**	**ln(GMCV)**	**ln(GMCV)^2**	**P=R/(N+1)**	**sqrt(P)**
1	*Hyalella*	0.147	-1.917	3.676	0.077	0.277

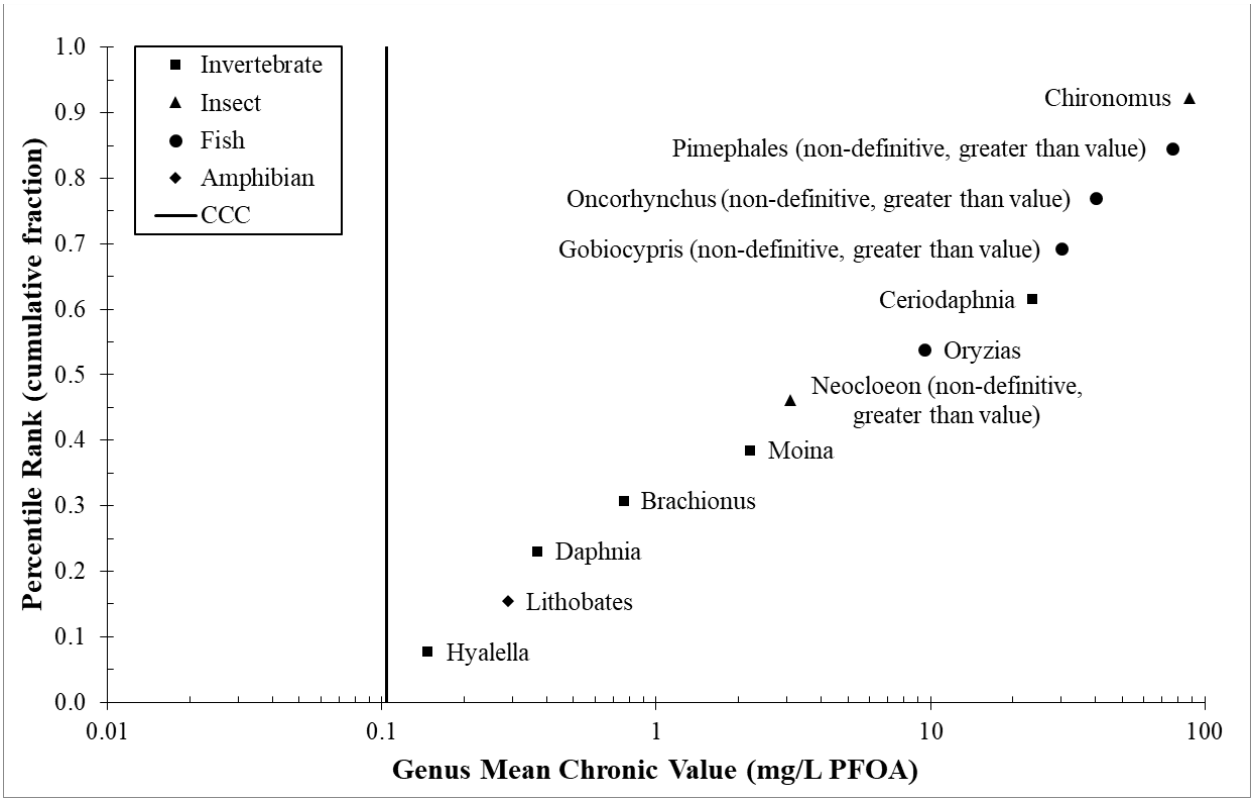

Figure 3-6. Freshwater Quantitative GMCVs and CCC.

3.2.1.4 Deriving A Protective Duration Component of the Water Column-Based Chronic Criterion

The EPA 1985 Guidelines set the standard chronic duration at four days for two primary reasons. The 1985 Guidelines state, "*An averaging period of four days seems appropriate for use with the CCC for two reasons. First, it is substantially shorter than the 20 to 30 days that is obviously unacceptable. Second, for some species it appears that the results of chronic tests are due to the existence of a sensitive life stage at some time during the test.*"

Among tests with chronically sensitive genera, Bartlett et al. (2021) measured effects of PFOA on *H. azteca* (the most chronically sensitive GMCV) survival at 7, 14, 21, 28, 35, and 42 days and concluded, "Toxicity increased approximately two-fold over the duration of exposure, with LC_{50}s of 110 mg/L after seven days and 51 mg/L after 42 days." Based on Table S6 of Bartlett et al. (2021), LC_{50} values decreased from seven to 21-days and remained generally stable from 28 to 42 days, suggesting the chronic PFOA LC_{50} value became time-independent between 21 and 28 days. Although *H. azteca* survival was tolerant at seven days, clear time-dependent toxicity may not occur for more sensitive endpoints such as reproduction.

Bartlett et al. (2021) determined effects to reproduction to be more sensitive than long-term survival, but only measured effects to reproduction after 42 days of exposure, which is substantially longer than the four-day chronic duration. Bartlett et al. (2021) noted, effects to amphipod reproduction are typically the result of effects to growth under the premise, "larger amphipods have a greater reproductive output" and "reduced growth delays sexual maturity." However, results observed in Bartlett et al. (2021), suggested "the effects on reproduction may also have occurred independently of growth." Therefore, the reproductive-specific effects observed by Bartlett et al. (2021) may not have been caused by the long-term effects of reduced growth but were possibly the result of a sexually-developing and uniquely-sensitive life stage

NMED Exhibit 63

that existed during a relatively brief duration within the longer 42-day test. Such instances are among the two primary reasons why the 1985 Guidelines prescribed the standard four-day chronic duration.

PFOA effects observed for other chronically sensitive and short-lived species further suggests a four-day chronic duration was appropriate. For example, the SMCV for *Brachionus calyciflorus* and the *Brachionus* GMCV (fourth most sensitive genus) are both the geometric mean of a full life-cycle test (i.e., up to 200 hours) test by Zhang et al. (2013a) and a four-day test by Zhang et al. (2014b). Chronic values for both studies correspond to the effect on population intrinsic growth rate. The full life-cycle test lasted up to 200 hours and yielded an EPA-calculated EC_{10} of 0.5015 mg/L. The four-day test yielded an EPA-calculated EC_{10} of 1.166 mg/L, suggesting chronic PFOA effects to short-lived species may occur after four days and increase with exposure duration.

Similarly, the SMCV for *Moina macrocopa* and the *Moina* GMCV (fifth most sensitive genus) are based on a seven-day life-cycle test by Ji et al. (2008), which also suggested reproductive effects (endpoint of number of young per starting female) occur in as little as seven days.

Overall, no chronic PFOA toxicity tests systematically evaluated time-to-effect, reported effect data at time intervals at a high enough resolution to model the speed of toxic action, assessed time variable PFOA exposures, or assessed the potential for latent toxicity. However, chronic tests, including life cycle tests with relatively short-lived species suggest chronic effects may occur at durations shorter than those of standard toxicity tests (e.g., 28 days) and a chronic four-day duration component of the water column criterion was considered protective for these species/genera. Therefore, the EPA has set the duration component of the PFOA chronic water

NMED Exhibit 63

column criterion at four days to reflect the chronic criterion duration recommended in the 1985 Guidelines. This four-day duration component of the chronic water column criterion is also consistent with U.S. EPA (1991), which considered the default four-day chronic averaging period as "the shortest duration in which chronic effects are sometimes observed for certain species and toxicants," and concludes that four-day averaging "should be fully protective even for the fastest acting toxicants."

3.2.1.5 Derivation of Chronic Water Criterion for Estuarine/Marine Water

The 1985 Guidelines recommend that data from a minimum of eight families are needed to calculate an estuarine/marine FCV or sufficient data to transform an estuarine/marine FAV to a CCC through the use of an ACR. Insufficient data exist to fulfill all eight of the taxonomic MDR groups. There are only two quantitatively acceptable GMCVs for estuarine/marine genera and no estuarine/marine ACRs. Consequently, the EPA could not derive an estuarine/marine chronic criterion (see Appendix L for derivation of acute estuarine/marine benchmarks).

3.2.2 Derivation of Tissue-Based Criteria

Chronic PFOA toxicity data with measured tissue concentrations were limited. There were no aquatic life tissue-based toxicity studies considered acceptable for quantitative use. Therefore, there were not sufficient data to derive chronic tissue criteria using a sensitivity distribution approach. Instead, the water column chronic criterion was transformed into corresponding tissue-based criteria through a BAF approach, as outlined in Section 2.11.3. The chronic PFOA tissue-based criteria were derived by translating the chronic freshwater column criterion (i.e., 0.10 mg/L; see equation *1* in Section 3.2.1.3) into corresponding tissue-based criteria. The resulting tissue criterion corresponded to the tissue type from the 20th percentile BAF used in the equation (see Section 2.11.3). The 20th centile BAF was used to derive tissue-

NMED Exhibit 63

based criteria as a relatively conservative BAF estimate in order to protect species across taxa and across water bodies with variable bioaccumulation conditions. That is, use of the 20th centile BAF protects species and conditions where the bioaccumulation of PFOA and resultant tissue-based exposures is relatively low as well as those conditions with the bioaccumulation potential of PFOA is relatively high.

3.2.2.1 PFOA Bioaccumulation Factors (BAFs)

Section 2.11.3.1 above summarizes the literature search, calculation, and evaluation of the PFOA BAFs for aquatic life. These BAFs were compiled by and can be found in Burkhard (2021). BAFs used in the derivation of the PFOA tissue-based criteria consisted of two or more water and organism samples each and were collected within one year and 2 km distance of one another. In order to derive more protective tissue criteria across and within water bodies, the distributions of BAFs used to derive tissue criteria were based on the lowest species-level BAF reported at a site. When more than one BAF was available for the same species within the same waterbody, the species-level BAF was calculated as the geometric mean of all BAFs for that species at that site. Summary statistics for the PFOA BAFs used in derivation of the tissue-based criteria are presented in Table 3-11 and individual BAFs are provided in Appendix O.

Table 3-11. Summary Statistics for PFOA BAFs in Invertebrate Tissues and Various Fish Tissues[1].

Category	n	Geometric Mean BAF (L/kg-wet weight)	Median BAF (L/kg-wet weight)	20th Centile BAF (L/kg-wet weight)	Minimum (L/kg-wet weight)	Maximum (L/kg-wet weight)
Invertebrates	21	105.3	84.8	11.76	0.985	9,680
Fish Muscle	17	7.152	7.94	1.331	0.292	656
Fish Whole Body	25	198.6	219	64.93	1	16,273

[1] Based on the lowest species-level BAF measured at a site (i.e., when two or more BAFs were available for the same species at the same site, the species-level geometric mean BAF was calculated, and the lowest species-level BAF was used to represent that site).

NMED Exhibit 63

3.2.2.2 Deriving Tissue-Based Criteria from the Chronic Water Column Criterion

Invertebrate whole-body, fish whole-body, and fish muscle tissue criteria were derived separately by multiplying the freshwater chronic water column criterion by the respective 20th centile of the distribution of BAFs described in Section 3.2.2.1, using Equation *1* from Section 2.11.3. The use of a 20th centile BAF results in more protective tissue criteria than those derived from a BAF based on a central tendency measure (e.g., geometric mean or median), which would only be protective on average or approximately 50% of the time.

The invertebrate whole-body tissue chronic criterion was calculated by multiplying the 20th centile BAF of 11.76 L/kg wet weight and the PFOA freshwater chronic water criterion of 0.10 mg/L, which resulted in a chronic invertebrate whole-body tissue criterion of 1.18 mg/kg wet weight. The fish muscle tissue chronic criterion was calculated by multiplying the 20th centile BAF of 1.331 L/kg wet weight and the PFOA freshwater chronic water criterion of 0.10 mg/L, which resulted in a chronic fish muscle-based chronic criterion of 0.133 mg/kg wet weight. The fish whole-body tissue chronic criterion was calculated by multiplying the 20th centile BAF of 64.93 L/kg wet weight and the PFOA freshwater chronic water criterion of 0.10 mg/L, which resulted in a chronic fish whole-body tissue criterion of 6.49 mg/kg wet weight. The chronic tissue-based criteria are expected to be protective of 95% of freshwater genera potentially exposed to PFOA under long-term exposures if the tissue-based criteria magnitudes are not exceeded.

The EPA acknowledges that there is uncertainty in deriving protective tissue criteria magnitudes by transforming the chronic water column criterion (which was based on tests that only added PFOA to the water column) into tissue concentrations through field-measured bioaccumulation data of paired water and tissue concentrations in waterbodies. Nevertheless, the

NMED Exhibit 63

chronic water column criterion is based on chronic toxicity tests that fed test organisms. In these tests, PFOA can directly affect species based on direct water column exposure and/or sorb to added food that is consumed by test organisms before eliciting chronic effects from dietary exposure. Therefore, the chronic water column criterion magnitude accounts for water column-based and, to a possible lesser extent, dietary-based effects, while the field-based BAFs account for water column-based and dietary-based PFOA exposure in tissues.

The tissue criteria will provide information to states, Tribes, and stakeholders on potential effects to aquatic organisms based on aquatic tissue monitoring data. No available quantitatively acceptable data on the effects of dietary exposures to aquatic species were available, thus the EPA elected to develop protective values for aquatic organism tissues based on the observed relationship between water column concentrations and tissue concentrations and observed PFOA toxicity in chronic tests where PFOA was only added directly to the water column.

3.2.2.3 Deriving Protective Duration and Exceedance Frequencies for the Tissue-based Chronic Criteria

3.2.2.3.1 Duration: Chronic Tissue-Based Criteria

PFOA concentrations in tissues are generally expected to change only gradually over time in response to environmental fluctuations. The chronic tissue-based criteria averaging periods, or duration components, were therefore specified as instantaneous, because tissue data provide point, or instantaneous, measurements that reflect integrative accumulation of PFOA over time and space in population(s) at a given site.

3.2.2.3.2 Frequency: Chronic Tissue-Based Criteria

The PFOA tissue-based criteria frequencies are set as “not to be exceeded” to ensure protection of aquatic life populations. This frequency accounts for the many variables influencing ecological recovery and the uncertainty in PFAS-specific ecological recovery time due to the lack of case studies on recovery rates following elevated PFOA concentrations in

NMED Exhibit 63

aquatic biota. Ecological recovery times following chemical disturbances are context-dependent, being largely dependent on: (1) biological variables such as the presence of nearby source populations or generational time of taxa affected, (2) physical variables such as lentic and lotic habitat considerations where recovery rates in lentic systems may be slower than lotic systems where the pollutant may be quickly flushed downstream, and (3) chemical variables such as the persistence of a chemical and potential for residual effects.

PFOA-specific case studies are unavailable to directly inform rates of ecological recovery following elevated concentrations in fish and aquatic invertebrates. Metals and other chemical pollutants may be retained in the sediment and biota, where they can result in residual effects over time that further delay recovery. Few studies are available concerning PFOA elimination or depuration half-life in aquatic animals, however the data that exist indicate a short half-life. For example, the elimination half-life for PFOA in adult rainbow trout exposed to PFOS for 28 days via the diet followed by 28 days depuration was estimated to be seven days in muscle tissue (Falk et al. 2015), while the terminal half-life in rainbow trout receiving a one-time intra-arterial injection of PFOA was 12.6 days (Consoer et al. 2014). Additionally, the depuration half-life in northern leopard frog tadpoles via 40-day aqueous exposure to 0.10 mg/L PFOA was estimated to be only 2.6 days (Hoover et al. 2017). It's unclear whether PFOA half-life in aquatic organism tissues is the mechanistic result of rapid depuration via gills or an artifact of these measurements that are taken during relatively short testing times (e.g., 28 days) where a steady state condition between PFOA and water and tissues has not occurred. Long-term uptake and subsequent excretion rates of PFOA have been extensively studied in humans relative to aquatic life. For example, Li et al. (2017) reported a median PFOA half-life of 2.7 years in human serum

NMED Exhibit 63

following exposure to PFOA in drinking water, which authors stated was in the range of previously published estimates.

Due to chemical retention in both the environment and tissues, ecosystems impacted by discharges of bioaccumulative pollutants (such as selenium) recover from chemical disturbances at relatively slow rates. For example, Lemly (1997) concluded that although water quality in Belews Lake, North Carolina, (a freshwater reservoir) had recovered significantly in the decade since selenium discharges were halted in 1985, the threat to fish had not been eliminated. The effects of selenium that led to severe reproductive failure and deformities in fish, were still measurable (as fish deformities) in 1992 (seven years later) and in 1996 (ten years later). Lemly (1997, pg. 280) estimated based on these data that "*the timeframe necessary for complete recovery from selenium contamination from freshwater reservoirs can be on the order of decades.*"

Beyond bioaccumulation, chemical-specific considerations such as degradation vs. persistence may also provide a mechanism influencing ecological recovery rates. The persistence of PFOA has been attributed to the strong C-F bond, with no known biodegradation or abiotic degradation processes for PFOA (see Section 2.3). Similarly, metals do not degrade and may persist in aquatic systems following elevated discharge. The persistence of metals may explain why metals had the second longest median recovery time of any disturbance described in a systematic review of aquatic ecosystem recovery (Gergs et al. 2016). Gergs et al. (2016) showed recovery times following metal disturbances ranged from roughly six months to eight years (median recovery time = one year; 75^{th} centile ~ three years; n = 20). Unlike metals, however, PFOA is not naturally-occurring and aquatic organisms possess no evolved detoxification mechanisms to aid in recovery at the individual level. Furthermore, the degradation of other

NMED Exhibit 63

PFAS into PFOA may represent a continued source of PFOA in aquatic systems that further delays recovery.

The persistence and bioaccumulative/human-made nature of PFOA in aquatic systems, in combination with the documented recovery times of pollutants with similar chemical attributes (Lemly 1997; Gergs et al. 2016; Mebane 2022), suggests aquatic systems may recover from PFOA tissue criteria exceedances on the order of five to 10 years. However, recovery times could be longer if the source of PFOA and other PFAS that degrade into PFOA is not removed. There is a large amount of uncertainty in specifying a time interval associated with ecological recovery from PFOA tissue criteria exceedances given the lack of PFOA-specific examples of ecological recovery and the many situational-specific factors influencing recovery (Mebane et al. 2020). For example, the lack of PFOA degradation in the environment, and the fact that other PFAS in the environment can degrade into PFOA could act as ongoing PFOA sources that further delay recovery. Given these uncertainties, the PFOA tissue-based criteria frequencies are set as "not to be exceeded" to ensure protection of aquatic life populations. Moreover, if tissue-based criteria were exceeded, then PFOA has likely built up through the food web and PFOA source reservoirs are likely to exist, representing a broad level of PFOA contamination throughout the aquatic ecosystem.

The "not to exceed" frequency components of the tissue-based criteria do not suggest aquatic ecosystems could never recover from PFOA tissue-based criteria exceedance, under the right conditions. For example, ecological recovery from such an exceedance could begin once PFOA sources are decreased or eliminated, PFOA source reservoirs existing within the ecosystem (including other PFAS that degrade into PFOA), became permanently isolated from possible uptake by the ecosystem (e.g., long-term burial with no benthic disturbances), and

NMED Exhibit 63

unaffected organisms were able to repopulate the system through immigration and/or reproductive events producing generations that are no longer exposed to PFOA.

Evaluation of PFOA concentrations in tissues would likely include evaluating the central tendency of tissue concentrations of samples for a given species, collected at a specific site and time. Considering a measure of central tendency to assess tissue-based exposures in the field relative to the criteria is appropriate because the criteria are intended to protect aquatic life populations.

3.3 Summary of Freshwater PFOA Aquatic Life Criteria and the Acute Estuarine/Marine Benchmark

This Aquatic Life Ambient Water Quality Criteria for PFOA document includes water column based acute and chronic criteria and tissue-based criteria for fresh waters. Acute and chronic water column criteria magnitudes for estuarine/marine waters could not be derived at this time due to data limitations; however, an acute estuarine/marine benchmark is provided for states/authorized tribal consideration (see Appendix L). The freshwater acute water column-based criterion magnitude is 3.1 mg/L, and the chronic water column-based chronic criterion magnitude is 0.10 mg/L. The fish whole-body tissue criterion magnitude is 6.49 mg/kg wet weight, the fish muscle tissue criterion magnitude is 0.133 mg/kg wet weight and the invertebrate whole-body tissue criterion magnitude is 1.18 mg/kg wet weight (Table 3-12). The assessment of the available data for fish, invertebrates, amphibians, and plants indicates these criteria will protect the freshwater aquatic community.

The freshwater chronic water column criterion is more strongly supported than the chronic tissue-based criteria because the water column-based chronic criterion was derived directly from the results of empirical toxicity tests. The chronic tissue-based criteria are relatively less certain because they were derived by transforming the chronic water column

NMED Exhibit 63

criterion into tissue concentrations through BAFs, with any uncertainty and variability in the underlying BAFs then propagating into the resultant tissue-based criteria magnitudes.

Table 3-12. Recommended Perfluorooctanoic acid (PFOA) Ambient Water Quality Criteria for the Protection of Aquatic Life in Freshwater.

Type/Media	Acute Water Column (CMC)[1,4]	Chronic Water Column (CCC)[1,5]	Invertebrate Whole-Body[1,2]	Fish Whole-Body[1,2]	Fish Muscle[1,2]
Magnitude	3.1 mg/L	0.10 mg/L	1.18 mg/kg ww	6.49 mg/kg ww	0.133 mg/kg ww
Duration	One-hour average	Four-day average	Instantaneous[3]		
Frequency	Not to be exceeded more than once in three years on average	Not to be exceeded more than once in three years on average	Not to be exceeded[6]		

[1] All five of these water column and tissue criteria are intended to be independently applicable and no one criterion takes primacy. All of the above recommended criteria (acute and chronic water column and tissue criteria) are intended to be protective of aquatic life. These criteria are applicable throughout the year.
[2] Tissue criteria derived from the chronic water column concentration (CCC) with the use of bioaccumulation factors and are expressed as wet weight (ww) concentrations.
[3] Tissue data provide instantaneous point measurements that reflect integrative accumulation of PFOA over time and space in aquatic life population(s) at a given site.
[4] Criterion Maximum Concentration; applicable throughout the water column.
[5] Criterion Continuous Concentration; applicable throughout the water column.
[6] PFOA chronic freshwater tissue-based criteria should not be exceeded, based on measured tissue concentrations representing the central tendency of samples collected at a given site and time.

This Aquatic Life Ambient Water Quality Criteria and Acute Saltwater Benchmark for PFOA document includes a water column based acute benchmark for estuarine/marine waters. The derivation of this benchmark is described in detail in Appendix L. The saltwater acute benchmark 7.0 mg/L (magnitude component), expressed as a one-hour average (duration component), that is not to be exceeded more than once in three years on average (Table 3-13).

Aquatic life benchmarks, developed under 304(a)(2) of the CWA, are informational values that the EPA generates when there are limited high quality toxicity data available and data gaps exist for several aquatic organism families. The EPA develops aquatic life benchmarks to provide information that states and Tribes may consider in their water quality protection programs. In developing aquatic life benchmarks, data gaps may be filled using new approach

NMED Exhibit 63

methods (NAMs), such as computer-based toxicity estimation tools (e.g., the EPA's Web-ICE) or other new approach methods intended to reduce reliance on additional animal testing (https://www.epa.gov/chemical-research/epa-new-approach-methods-work-plan-reducing-use-vertebrate-animals-chemical), including the use of read-across estimates based on other chemicals with similar structures. The EPA's aquatic life benchmark values are not regulatory, nor do they automatically become part of a state's water quality standards.

Table 3-13. Acute Perfluorooctanoic Acid (PFOA) Benchmark for the Protection of Aquatic Life in Estuarine/Marine Waters.

Type/Media	Acute Water Column Benchmark
Magnitude	7.0 mg/L
Duration	One hour average
Frequency	Not to be exceeded more than once in three years on average

NMED Exhibit 63

4 EFFECTS CHARACTERIZATION FOR AQUATIC LIFE

This section describes supporting information for the derivation of these PFOA aquatic life criteria. Specifically, this chapter: (1) assesses the influence of including non-North American resident species in criteria derivation (Section 4.1), (2) considers relatively sensitive toxicity data from qualitatively acceptable studies that were used as supporting information (Section 4.2), (3) describes the available PFOA ACRs (Section 4.3), (4) compares the tissue-based criteria magnitudes to the empirical tissue-based effect concentrations available (Section 4.4), (5) evaluates aquatic plant tolerance to PFOA exposures (Section 4.5), and (6) evaluates the tolerance of threatened and endangered species to PFOA exposures (Section 4.6).

4.1 Influence of Using Non-North American Resident Species on PFOA Criteria

The EPA conducted an additional analysis of the water column-based criteria by limiting the toxicity datasets to organisms that are residents to the conterminous United States that have established populations to evaluate the influence of including non-North American resident species in criteria derivation.

4.1.1 Freshwater Acute Water Criterion with Resident Organisms

Three species, the green neon shrimp (*Neocaridina denticulata*), the cladoceran (*Daphnia carinata*) and the planarian (*Dugesia japonica*), are not resident or reproducing in the conterminous United States, while it remains uncertain if there are established resident zebrafish (*Danio rerio*) populations in the conterminous United States (U.S. FWS 2018). Nevertheless, zebrafish are common ecotoxicity test organisms that serve as taxonomic surrogates for untested fish species and are also considered in effects assessments conducted under the Toxic Substances Control Act (TSCA) and the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). Removal of the green neon shrimp, *Daphnia carinata*, and *Dugesia japonica*, while retaining

NMED Exhibit 63

zebrafish truncated the freshwater acute dataset to 24 species representing 17 genera (Table 4-1). The freshwater acute dataset truncated to North American resident species only was missing one MDR group (a benthic crustacean). The *Daphnia carinata* SMAV was the third most sensitive; however, its removal along with the removal of the other non-North American resident species had limited impact on the exploratory FAV and subsequent acute water column concentration (Table 4-2). The acute water column concentration based on North American resident species only, including zebrafish, was 2.6 mg/L PFOA, which was slightly lower than the chronic criteria CMC (CMC of 3.1 mg/L) based on both North American and non-North American species. Had zebrafish also been removed from the exploratory FAV and acute water column concentration based on North American resident species only, the four most sensitive genera would have remained the same, but the number of genera in the dataset would have decreased by one, which causes the resulting exploratory FAV (i.e., 4.793 mg/L) and acute water column concentration (i.e., 2.4 mg/L) to decrease slightly. The exploratory FAV and CMC based on North American resident species only with zebrafish excluded were both similar to the FAV and CMC described in Section 3.2.1.1.

Table 4-1. Ranked Freshwater Genus Mean Acute Values with North American Resident Organisms.

Rank[a]	GMAV (mg/L PFOA)	MDR Group[c]	Genus	Species	SMAV[b] (mg/L PFOA)
1	8.885	D	*Moina*	Cladoceran, *Moina macrocopa*	166.3

4.1.2 Freshwater Chronic Water Criterion with North American Resident Organisms

Three species, the cladoceran (*Daphnia carinata*), the rare minnow (*Gobiocypris rarus*) and the medaka (*Oryzias latipes*), are not resident or reproducing in the conterminous United States. Removal of these species truncated the freshwater chronic dataset to ten species representing ten genera (Table 4-3). The freshwater chronic dataset truncated to North American resident species fulfilled all MDR groups. Calculating the FCV based on the chronic GSD comprised of North American resident species only resulted in an exploratory FCV of 0.05857 mg/L and a chronic water column criterion of 0.059 mg/L (rounded to two significant figures; Table 4-4). The exploratory chronic water column concentration CCC (0.059 mg/L PFOA) based on North American species only was about half of the CCC based on North American and non-North American species (0.10 mg/L PFOA) and is lower than all of the quantitatively-acceptable GMCVs (Table 3-7). The reduction in the exploratory FCV based on North American resident species only was primarily an artifact of the FCV calculation procedure rather than inclusion of more sensitive toxicity data. That is, the reduced "*n*" used in the exploratory criterion calculation

NMED Exhibit 63

and the increase in the *Daphnid* GMCV (which was the result of excluding *D. carinata* SMCV), increased the slope of the GSD which decreased the extrapolated FCV. The EPA retained the chronic water column criterion which includes North American and non-North American species, with a magnitude of 0.10 mg/L, to ensure the fullest, high-quality dataset available is used to represent the thousands of untested aquatic taxa present in U.S. ecosystems when deriving the chronic criterion for PFOA.

Table 4-3. Ranked Freshwater Genus Mean Chronic Values with Resident Organisms.

Rank[a]	GMCV[b] (mg/L PFOA)	MDR Group[c,d]	Genus	Species	SMCV[b] (mg/L PFOA)
1	0.147	E	*Hyalella*	Amphipod, *Hyalella azteca*	0.147
2	0.288	C	*Lithobates*	American bullfrog, *Lithobates catesbeiana*	0.288
3	0.7647	G	*Brachionus*	Rotifer, *Brachionus calyciflorus*	0.7647
4	2.194	D	*Moina*	Cladoceran, *Moina macrocopa*	2.194
5	>3.085	H	*Neocloeon*	Mayfly, *Neocloeon triangulifer*	>3.085
6	4.317	D	*Daphnia*	Cladoceran, *Daphnia magna*	4.317
7	23.56	D	*Ceriodaphnia*	Cladoceran, *Ceriodaphnia dubia*	23.56
8	>40	A	*Oncorhynchus*	Rainbow trout, *Oncorhynchus mykiss*	>40
9	>76	B	*Pimephales*	Fathead minnow, *Pimephales promelas*	>76
10	88.32	F	*Chironomus*	Midge, *Chironomus dilutus*	88.32

4.2 Consideration of Relatively Sensitive Qualitatively Acceptable Water Column-Based Toxicity Data

A multitude of studies were identified as not meeting the EPA's data quality guidelines for inclusion in the criteria derivation; however, these studies were used qualitatively as supporting information to the PFOA criteria derived to protect aquatic life and provide additional evidence of the observed toxicity and effects of PFOA, including the relative sensitivities. Most of these studies produced relatively tolerant effect concentrations relative to the criteria and are listed in Appendix G. The key studies used qualitatively in the derivation of the PFOA criteria were identified as being from either relatively sensitive genera or relatively sensitive tests and are described below. That is, qualitatively acceptable data for tests with species among the four most sensitive genera that were used to derive the criteria magnitudes are discussed. Qualitatively acceptable tests with relevant exposure durations and apical effects that also observed effect concentrations less than or similar to (e.g., factor of two) the corresponding criteria magnitude are discussed. Qualitatively acceptable studies described below were separated by acute (Section 4.2.1) and chronic (Section 4.2.2) data and only included those

NMED Exhibit 63

studies that reported apical endpoints. The toxicity values summarized as part of this Effects Characterization were not used in any quantitative analyses or in the numerical derivation of the PFOA aquatic life criteria.

4.2.1 Consideration of Qualitatively Acceptable Acute Data

4.2.1.1 Qualitatively Acceptable Acute Data for Species Among the Four Most Sensitive Genera Used to Derive the Acute Water Column Criterion

4.2.1.1.1 Most acutely sensitive genus, Moina

There were no qualitatively acceptable acute tests for species within the genus, *Moina*.

4.2.1.1.2 Second most acutely sensitive genus, Neocloeon

There were no qualitatively acceptable acute tests for species within the genus, *Neocloeon*.

4.2.1.1.3 Third most acutely sensitive genus, Chydorus

There were no qualitatively acceptable acute tests for species within the genus, *Chydorus*.

4.2.1.1.4 Fourth most acutely sensitive genus, Daphnia

3M Co. (2000a) exposed *D. magna* to PFOA (CAS # 335-67-1) in a 48-hour static, unmeasured acute toxicity test that followed USEPA-TSCA Guideline 797.1300. The toxicant was part of the 3M production lot number 269 and was characterized as mixture of PFOA (96.5-100% of the compound) and C_6, C_7 and C_9 perfluoro homologue compounds (0-3.5% of the compound). The 48-hour reported EC_{50}, based on death/immobility, was 360 mg/L PFOA. This test was not acceptable for quantitative use because of possible mixture effects from other perfluoro homologue compounds in the test substance, the amount of isopropanol and missing exposure details, but was retained for qualitative use.

3M Co. (2000a) summarized four 48-hour static, unmeasured APFO (CAS # 3825-26-1) acute toxicity tests with the cladoceran, *Daphnia magna* and APFO. The toxicant was part of the 3M production lot number 37 and was characterized as a mixture of APFO (96.5-100% of the compound) and C_6, C_7 and C_9 perfluoro analogue compounds (0-3.5% of the compound). The

NMED Exhibit 63

48-hour EC_{50} determined from tests conducted in May 1982, based on death/immobility, was >1,000 mg/L APFO, while the EC_{50} for a subsequent test in June 1982 was reported to be 126 mg/L APFO. Possible mixture effects of other perfluoro analogue compounds, and the authors indication that the tests may have included food, did not make these tests acceptable for quantitative use and they were retained for qualitative use.

3M Co. (2000a) summarized a 48-hour static, unmeasured acute toxicity test with the cladoceran, *Daphnia magna* and APFO (CAS # 3825-26-1). The toxicant was part of the 3M production lot number 390 and was characterized as a mixture of APFO (78-93% of the compound) and C_5, C_6 and C_7 perfluoro analogue compounds (7-22% of the compound). The author-reported 48-hour EC_{50}, based on mortality, was 221 mg/L APFO. The possible mixture effects of APFO with other perfluoro analogue compounds in the test material and possible low (<80%) test substance purity did not make this test acceptable for quantitative use. This test was retained for qualitative use only.

3M Co. (2000a) summarized a 48-hour static, unmeasured acute toxicity test with the cladoceran, *Daphnia magna* and APFO (CAS # 3825-26-1). The acute test followed USEPA-TSCA Guideline 797.1300 protocol. The toxicant was part of the 3M production lot number HOGE 205 and was not sufficiently characterized but was considered a mixture of APFO (30% of the compound) and water (80% of the compound). The author-reported 48-hour EC_{50}, based on mortality, was 1,200 mg/L test substance. The authors reported that the test substance was considered a mixture of APFO (with unreported purity) and other impurities, so the EC_{50} does not accurately reflect the toxicity of APFO and therefore the value was not acceptable for quantitative use but was retained for qualitative use.

NMED Exhibit 63

3M Co. (2000a) summarized a 48-hour static, unmeasured acute toxicity test with the cladoceran, *Daphnia magna* and APFO (CAS # 3825-26-1). The acute test followed test guidance from OECD 202. The toxicant was part of the 3M production lot number 2327 and was characterized as a mixture of APFO (<45% of the compound), water (50% of the compound), inert perfluorinated compound (<3% of test substance), and C_5 and C_7 perfluoro analogue compounds (1-2% of the compound). The author-reported 48-hour EC_{50}, based on death/immobility, was 584 mg/L test substance. Because of the possible mixture effects of the inert perfluorinated compounds, other perfluoro analogue compounds and unreported test substance purity, the test was not acceptable for quantitative use but was retained for qualitative use.

3M Co. (2000a) summarized a 21-day static-renewal, unmeasured chronic toxicity test with the cladoceran, *Daphnia magna,* and APFO (CAS # 3825-26-1) and also briefly described a corresponding acute test with a reported 48-hour EC_{50} of 266 mg/L APFO. Very few details were provided about the acute test methodology. The test compound was assumed to be that of the chronic test, where the toxicant was part of the 3M production lot number 37 and was characterized as a mixture of APFO (96.5-100% of the compound) and C_6, C_7 and C_9 perfluoro analogue compounds (0-3.5% of the compound). The 48-hour EC_{50} from this test was not used quantitatively because of missing study details and the possible presence of additional PFAS, but the study was retained for qualitative use.

Overall, these *D. magna* acute effect concentrations were all greater than the FAV (i.e., 6.237 mg/L) and the acute criterion magnitude (i.e., 3.1 mg/L). These additional data suggest the *Daphnia* GMAV (i.e., 142.8 mg/L) used to derive the acute criterion was sufficiently protective.

NMED Exhibit 63

4.2.1.2 Consideration of Relatively Sensitive Freshwater Tests based on Qualitatively Acceptable Data

This section focuses on qualitatively acceptable tests that were most relevant to informing the appropriateness of the acute freshwater criterion. Specifically, those tests used to qualitatively inform the acute freshwater criterion magnitude were identified as most relevant if they met all parameters listed below:

1. reported effect concentrations that were less than or similar to (e.g., factor of two) the acute criterion magnitude;
2. evaluated an animal species;
3. conducted the test for a relevant acute exposure duration (e.g., ~48 hours to ~96 hours);
4. evaluated apical effects (i.e., acute mortality/inhibition), and;
5. not already discussed in the previous section (i.e., not a species discussed among the four most sensitive genera).

The toxicity values summarized below were not used quantitatively to derive the acute PFOA criterion. Results of each individual study (as well as the rationale why a study was not quantitatively acceptable) were considered relative to the acute criterion magnitude to ensure the acute PFOA criterion was not underprotective and to provide additional supporting evidence of the potential toxicity of PFOA to aquatic organisms.

4.2.1.2.1 Genus: Danio (zebrafish)

Truong et al. (2014) evaluated the sub-chronic effects of 1,060 compounds (U.S. EPA ToxCast phase 1 and 2) on zebrafish, *Danio rerio*, through the use of high-throughput characterization of multidimensional *in vivo* effects. The effects of APFO and PFOA on mortality, growth, behavior, morphology, histology and physiology were observed until 120 hours post fertilization (hpf) (114-hour exposure duration) with the water quality conditions not reported. The most sensitive endpoint was mortality with a reported LOEC of 0.02759 mg/L APFO. There were no effects of PFOA on mortality for zebrafish embryos with a reported NOEC of 26.50 mg/L PFOA. This test was not used quantitatively and retained for qualitative

NMED Exhibit 63

use only because the exposure durations were too long for an acute test and too short for a chronic test.

Han et al. (2021) evaluated the bioconcentration factors and phenotypic toxicities of 74 PFAS in zebrafish after five days of exposure. Toxicity tests followed OECD test guidance with minor modifications. Embryos (64-cell stage) were exposed to one measured PFAS concentration or DMSO solvent controls with solutions renewed daily. At test termination no mortality effects were observed at 3.94 µM PFOA (1.631 mg/L) and 3.67 µM APFO (1.582 mg/L). This test was not used quantitatively and retained for qualitative use only because the exposure durations were too long for an acute test and too short for a chronic test with no effects observed.

Rericha et al. (2021) conducted a 114-hour static unmeasured PFOA toxicity test with the zebrafish, *Danio rerio.* The authors reported a 114-hour mortality NOEC of 0.60 µM, or 0.2484 mg/L PFOA, based on a molecular weight of 414.07 g/mol. This test was not acceptable for quantitative use as the exposure duration was too long to be an acute test and too short to be a chronic test. Additionally, the authors only tested one exposure concentration that produced a relatively low NOEC. Although relatively low, the NOEC of 0.2484 mg/L does not suggest *D. rerio* early life stages are sensitive to sub-chronic PFOA exposures.

Haimbaugh et al. (2022) evaluated the acute toxic effects of low-level (≤700 ng/L) PFOA on zebrafish from zero to five days post fertilization. Unmeasured test concentrations (7, 70, or 700 ng/L PFOA) were renewed daily. At test termination, the highest test concentration (700 ng/L or 0.0007 mg/L) had no effects on mortality or abnormal development. This test was not used quantitatively and retained for qualitative use only because the exposure durations were too long for an acute test and too short for a chronic test with no effects observed.

NMED Exhibit 63

Yu et al. (2022) evaluated the sub-chronic effects of PFOA on embryonic *Danio rerio*. Exposure to PFOA concentrations up to 0.100 mg/L had no effect on growth/length, mortality/hatch, or survival of larvae. The 70-hour growth, mortality, and hatch NOECs of 0.100 mg/L PFOA were not acceptable for quantitative use because of the short exposure duration, especially in the context of other available tests for this species that were of a sufficient exposure duration. Yu et al. (2022) also reported that heartbeat (at 48 hpf) and locomotor behavior (at 120 hpf) were significantly decreased by PFOA at 0.025 mg/L; however, these effects did not translate to effects on growth, mortality, or hatch at nominal test concentrations that were four times greater.

Liu et al. (2023b) evaluated the acute effects of PFOA on zebrafish embryos (5 hpf) exposed to one of five test concentrations (1, 2, 5, 10, and 20 mg/L). Test concentrations were renewed daily and test concentrations were measured with hatching rate, mortality and deformity recorded at test termination (96 hpf). The author reported that the 91-hour LC_{50} was approximately 2 mg/L PFOA. This test was not acceptable for quantitative use because the exposure duration was not a 96-hour exposure duration and other quantitatively acceptable data suggests the relatively-sensitive LC_{50} reported here (~2 mg/L) is an outlier, with the *Danio* SMAV being 450.4 mg/L.

Wang et al. (2023) evaluated the acute effects of PFOA on zebrafish embryos (2 hpf) exposed to 5 or 500 µg/L up to 120 hours post fertilization. Test concentrations were renewed daily and PFOA concentrations were measured using high-performance liquid chromatography-tandem mass spectrometry. At 96 hpf, there were no effects observed on mortality or abnormal development at 491.5 µg/L (0.4915 mg/L PFOA). Since this exposure was shorter than the

NMED Exhibit 63

recommended 96 hour exposure (only 94 hours) and no effects were observed, the test was only used qualitatively.

Quantitatively acceptable acute tests used to calculate the SMAV (Ye et al. 2007; Hagenaars et al. 2011; Zhao et al. 2016; Godfrey et al. 2017a; Stengel et al. 2017, 2018) suggested *D. rerio* is relatively tolerant to acute PFOA exposures with a *D. rerio* SMAV of 450.4 mg/L. Another quantitatively acceptable acute test with the zebrafish was conducted by Corrales et al. (2017). However, the LC_{50} value from this test was excluded from the SMAV calculation because a comparative assessment between this LC_{50} value and the other seven quantitatively-acceptable values available indicated the LC_{50} was an outlier, about 5 times lower than the other lowest LC_{50} value. It is expected that *D. rerio* will be tolerant to acute PFOA exposures.

4.2.2 Consideration of Qualitatively Acceptable Chronic Data

4.2.2.1 Qualitatively Acceptable Chronic Data for Species Among the Four Most Sensitive Genera Used to Derive the Chronic Water Column Criterion

4.2.2.1.1 Most chronically sensitive genus, Hyalella

Kadlec et al. (2024) tested the sub-chronic toxicity of PFOA (96-99% purity) to *Hyalella azteca* for seven days in a measured, static-renewal experiment. Testing protocols followed ASTM methodologies (ASTM 2002) with a shortened exposure period. The test was conducted with a 0.5x dilution series of measured PFOA concentrations, with four replicates of each concentration, and ~10 organisms per replicate (note: some replicates were overstocked and included 11 test organisms). Mean test concentrations were 0.53 (control), 5.3, 11, 21, 41 and 83 mg/L. Amphipods were placed in 100 mL glass beakers with two holes (covered by stainless-steel mesh) on opposite sides and filed with 60 mL of test solution. Beakers also included 2.5 mL of silica sand substrate to fully cover the bottoms of each chamber and each test chamber was renewed daily. Little to no mortality was observed in any treatment with survival ranging from

NMED Exhibit 63

98-100% at test termination. The author reported EC_{20} for biomass was 5.0 mg/L. The EPA did not recalculate an EC_{10} from this study since the exposure duration was too short for a chronic exposure. However, this value is much larger than the 42-day exposure (Bartlett et al. 2021) with an EPA-calculated EC_{10}, based on reproduction, of 0.147 mg/L PFOA.

4.2.2.1.2 Second most chronically sensitive genus, Lithobates

Hoover et al. (2017) tested PFOA (96% purity) toxicity on the northern leopard frog, *Lithobates pipiens* (formerly, *Rana pipiens*) in a chronic renewal toxicity test using measured PFOA treatment concentrations. The 40-day NOEC was ≥1.0 mg/L PFOA based on Gosner stage reached at test termination and snout-vent length. The test used water renewals rather than the required flow-through design for chronic ALC development; however, leopard frogs commonly do not tolerate flow-through test systems and the use of renewal system was appropriate for this study organism. Also, PFOA was detected in the control organisms at concentrations three orders of magnitude lower than any PFOA treatment groups, indicating the trace contamination in controls may not be considered a significant issue. The 40-day NOEC of ≥1.0 mg/L was classified as acceptable for quantitative use based on meeting data quality objectives; however, it was not used to derive the chronic criterion because the study showed no adverse effects at the highest treatment concentrations (i.e., 1.0 mg/L). Because the highest treatment group that showed no effects was a relatively low treatment concentration, including this NOEC value in the criterion calculation would have resulted in the criterion magnitude being influenced by the relatively low-test concentration selected by study investigators (that did not produce an adverse response), rather than a concentration-response relationship. Therefore, this test was not used quantitatively and was considered qualitatively acceptable for use in criterion derivation.

NMED Exhibit 63

Flynn et al. (2021) evaluated the chronic effects of PFOA (CAS # 335-67-1, ≥96% purity, purchased from Sigma-Aldrich) on northern leopard frogs, *Lithobates pipiens* (formerly *Rana pipiens*), via a 30-day sediment-spiked, static outdoor mesocosm study. At test termination (30 days) there was no effect on survival or growth (snout-vent length and weight). The 30-day NOEC, based on survival and growth, was 0.066 mg/L. However, on test-day five and at test termination all frogs in the spiked sediment mesocosm were less developed, based on Gosner stage, than the control mesocosms. The study was not acceptable for quantitative use because the test design was an outdoor spiked sediment mesocosm exposure with algal and zooplankton communities present and because of the relatively low NOEC value that did not quantitatively inform criteria derivation based on an exposure-response effect.

Flynn et al. (2022) evaluated the chronic effects of PFOA on the northern leopard frog [*Lithobates* (formerly *Rana*) *pipiens*] during a 30-day measured renewal exposure. Animals were monitored daily for mortality and abnormalities and sampled to quantify snout–vent length (SVL), body mass, and developmental stage. The SVL and body mass were used to calculate the scaled mass index (SMI). The NOEC for SVL was >1.376 mg/L and not used quantitatively because of a lack of a clear dose-response relationship and high variability in organismal responses despite a 10X dilution series. The NOEC and LOEC for growth (as mass) were 0.1251 and 1.376 mg/L resulting in a MATC of 0.4149 mg/L, which was also not used quantitatively for the same reasons. The effects of PFOA on SMI and Gosner stage were also not quantitatively acceptable because, while the highest test concentration was over 100X greater than the lowest, the response in the highest test concentration did not differ from control responses. Results of this test were retained for qualitative use.

NMED Exhibit 63

Overall, these three studies showed minimal effects to the northern leopard frog at the concentrations tested, while the indoor laboratory test by Flynn et al. (2019; used to derive the *Lithobates catesbeiana* SMCV) showed a ~7% reduction in SVL after 72-day exposures at 0.288 mg/L. Although Hoover et al. (2017) reported a NOEC of 1.0 mg/L, the tests only consisted of a 40-day exposure, which may not have been long enough to elicit the chronic effects to SVL observed by Flynn et al. (2019) after 72 days. For example, Flynn et al. (2019) reported effects of PFOS on *Lithobates catesbeiana* tadpole mass after 21, 42, 56, 63, 70, and 72 days, with PFOS dose-dependent effects only becoming apparent at 56 days. Results of Flynn et al. (2021) could not meaningfully inform the appropriateness of the chronic criterion or the *Lithobates catesbeiana* SMCV (0.288 mg/L) because Flynn et al. (2021) did not observe effects of PFOA on *Lithobates pipiens*, with a relatively low NOEC of 0.066 mg/L. Similarly, results of Flynn et al. (2022) did not suggest the *Lithobates* GMAV value was underprotective, as Flynn et al. (2022) did not observe obvious PFOA effects with increasing exposure concentrations.

4.2.2.1.3 Third most chronically sensitive genus, Daphnia

3M Co. (2000a) summarized a 21-day static-renewal, unmeasured chronic toxicity test with the cladoceran, *Daphnia magna*, and APFO (CAS # 3825-26-1). The toxicant was part of the 3M production lot number 37 and was characterized as a mixture of APFO (96.5-100% of the compound) and C_6, C_7 and C_9 perfluoro analogue compounds (0-3.5% of the compound). The test followed U.S. EPA (1982) and OECD (1997) test protocols. The 21-day NOEC and LOEC, based on reproduction and survival were 22 and 36 mg/L APFO, respectively with a corresponding MATC of 28.14 mg/L. This test was acceptable for qualitative use only because of the possible mixture effects of other perfluoro analogue compounds and missing exposure details but does not suggest *D. magna* will be chronically sensitive relative to the chronic freshwater criterion.

NMED Exhibit 63

Seyoum et al. (2020) evaluated the chronic effects of PFOA (CAS# 335-67-1, >99%, purchased from Sigma) on *Daphnia magna* neonates via a 21-day unmeasured, static-renewal study. The study authors did not report following any specific protocol. The 21-day reproductive (fecundity) LOEC of 0.4141 mg/L PFOA was reported by the study authors, where a ~38.25% reduction in mean number of daphnids relative to the control was observed. The EPA was unable to fit a model with significant parameters to the reproduction-based concentration-response data due to a lack of clear concentration-dependent effects beyond the LOEC. The reproduction-based LOEC (i.e., 0.4141 mg/L) was selected as the chronic value from this test; however, it was not considered acceptable for quantitative use because chronic responses in this test did not display concentration-dependent effects beyond the LOEC despite a 25X increase in treatment concentrations. Moreover, additional EC_{10} values from other, quantitatively acceptable tests, were available to inform the chronic sensitivity of *Daphnia magna* in criteria derivation.

4.2.2.1.4 Fourth most chronically sensitive genus, Brachionus

The qualitatively acceptable chronic value for *Brachionus* from **Zhang et al. (2014b)** was discussed in greater detail in Section 3.1.1.3.4. Briefly, Zhang et al. (2014b) conducted a full life-cycle test using renewal conditions for approximately four days on the rotifer, *Brachionus calyciflorus*. Zhang et al. (2014b) reported several endpoints, including intrinsic rate of natural increase, which was selected as the primary endpoint for criterion derivation. Zhang et al. (2014b) also observed effects to resting egg production. Resting egg production is an ecologically important endpoint for this species because it represents the final result of sexual reproduction. NOEC and LOEC values were not reported for resting egg production, but 0.25 mg/L PFOA produced more than a 50% reduction in resting egg production. Based on the authors description of results in the text, it was assumed the *B. calyciflorus* four-day NOEC for resting egg production was 0.125 mg/L and the LOEC was 0.25 mg/L and the calculated MATC

NMED Exhibit 63

was 0.1768 mg/L, suggesting resting egg production may be a relatively sensitive endpoint. Because there was only one replicate (as implied by lack of error bars in Figure 1 of the publication, no clear description of replicates in the methods section, and no author-reported statistical analysis of this endpoint), resting egg production from this study was not considered quantitatively acceptable and was instead considered in a qualitative manner. Overall, effects to chronic apical endpoints for this genus, reported in this publication and Zhang et al. (2013a), generally appear as a threshold effect from 0.25 mg/L to 1.0 mg/L, providing support for the endpoint and effect level selected for quantitative use in criterion derivation (i.e., intrinsic rate of natural increase), and further suggests the chronic criterion magnitude is adequately protective of the genus, *Brachionus*.

4.2.2.2 Consideration of Relatively Sensitive Freshwater Tests based on Qualitatively Acceptable Data

This section focuses on qualitatively acceptable chronic tests that were most relevant to informing the appropriateness of the chronic freshwater criterion. Specifically, those tests used to qualitatively inform the chronic freshwater criterion magnitude were identified as most relevant if they met all parameters listed below:

1. reported effect concentrations that were less than or similar to (e.g., factor of two) the chronic freshwater criterion magnitude;
2. evaluated an animal species;
3. conducted the test for a non-acute exposure duration (e.g., greater than seven days);
4. evaluated apical effects (i.e., long-term survival, growth, and/or reproduction), and;
5. not already discussed in the previous section (i.e., not a species discussed among the four most sensitive genera).

The toxicity values summarized below were not used quantitatively to derive the chronic PFOA freshwater criterion. Results of each individual study (as well as the rationale why a study was not quantitatively acceptable) were considered relative to the chronic criterion magnitude to

NMED Exhibit 63

ensure the chronic PFOA criterion was not underprotective and to provide additional supporting evidence of the potential toxicity of PFOA to aquatic organisms.

4.2.2.2.1 Genus: Chironomus (midge)

Stefani et al. (2014) conducted a chronic (10 generation) test of PFOA with a midge, *Chironomus riparius*. The 10 generations (each approximately 20 to 28 days) were tested under static conditions. The NOEC for the study, based on effect on emergence, reproduction or sex ratio at the only concentration tested, was 0.0089 mg/L PFOA. **Marziali et al. (2019)** provides further analysis of the same chronic test conducted by Stefani et al. (2014; reported in Table G.1) by reporting measurements of alterative endpoints/responses. The LOEC based on developmental time, adult weight was 0.0098 mg/L (time-weighted average; NOEC <0.0098 mg/L). While Stefani et al. (2014) reported no effects across the chronic test, Marziali et al. (2019) reported effects to select generations. Overall, however, effects were sporadic with reductions in growth observed in several generations. There were no effects on "survival, development, or reproduction" and Marziali et al. (2019) concluded "no effects at population level (population growth rate) were proved, thus a toxicity risk in real ecosystems at the tested concentrations seems unlikely." The results from these studies were deemed not acceptable for quantitative use because of limited test concentrations assessed, and uncertainty pertaining to sediment characteristics, as well as poor control survival in four of the 10 generations.

Zhai et al. (2016) exposed *Chironomus plumosus* larvae to PFOA (perfluorooctanoic acid, obtained from Acros Organics, Morris Plains, NJ, 96% purity) spiked in sediment for 10.3 days. The sediment was collected from the upstream region of the Yongding River in Beijing, China. Sediments were physically mixed with a steel blender at 60 rpm for 24 hours in the darkness at room temperature. Then, 1 mL of PFOA methanol solution (20 mg/L) was added to obtain a concentration of 100 ng/g PFOA, and the sample was thoroughly mixed in a fume hood.

NMED Exhibit 63

When the methanol had evaporated, 300 mL of distilled water was added to each beaker. Finally, the beakers were sealed, kept in the darkness at 25℃, and aged for 60 days before test initiation. The midge larvae used in this study were collected from the uncontaminated upstream area of the Yangliuqing River in the outer suburbs of Tianjin, China. Male larvae in the third or fourth instars of similar size were chosen and placed in pure water to purify their guts for more than 48 hours in the laboratory. There were 20 larvae in each 500 mL beaker containing sediment and 300 mL of solution and three replicates per concentration (9.8 ng PFOA/g sediment) and control (pure water). The static measured exposure lasted 10 days without food supply and involved a 16:8 hour (light:dark) photoperiod at 25 ± 1℃. At the end of the experiment, the surviving larvae were counted. The 10-day mortality NOEC was 9.8 ng/g, the only concentration tested. The test was not acceptable for quantitative use because: (1) exposures were spiked sediments rather than water only, (2) test duration (~10 days) was sub-chronic, too long for an acute test and too short for a chronic test, and (3) no effects were observed at the highest concentration tested which produced a relatively low "> NOEC" value that did not provide information on the sensitivity of this species to PFOA at concentrations consistent with criteria magnitudes. Results of this test were retained for qualitative use.

Quantitatively acceptable midge data (McCarthy et al. 2021) were available to derive the chronic PFOA freshwater criterion and these chronic data further suggest *Chironomus* is relatively tolerant to chronic PFOA exposures.

4.2.2.2.2 Genus: Salmo (Atlantic salmon)

Spachmo and Arukwe (2012) exposed Atlantic salmon (*Salmo salar*) to PFOA (95% purity) in a 52-day flow-through test with unmeasured treatment concentrations. The 52-day growth NOEC and LOEC were 0.10 and >0.10 mg/L PFOA, respectively. These data were acceptable for quantitative use based on meeting data quality objectives; however, were not used

NMED Exhibit 63

in deriving the chronic criterion because the study only included one treatment group that showed no adverse effects. Because the one treatment group that showed no effects was a relatively low treatment concentration, including this NOEC value in the criterion calculation would have resulted in the criterion magnitude being strongly influenced by the low test concentration selected by study investigators (that did not produce an adverse response), rather than a concentration-response relationship.

Arukwe et al. (2013) exposed Atlantic salmon (*Salmo salar*) embryos to PFOA at 100 µg/L for 49 days. This test was not used quantitatively because of the lack of effects in the one treatment group tested. The 49-day growth-based NOEC of 0.1 mg/L PFOS was selected as the most sensitive and relevant endpoint. However, given there was only one treatment group and that the test concentration was a relatively low concentration (at 0.1 mg/L) compared to the other PFOA data, resulting in a > low value, this test was not informative enough for quantitative use in the derivation of the PFOA aquatic life criteria. Results of this test were retained for qualitative consideration.

4.2.2.2.3 Genus: Cyprinus (carp)

Petre et al. (2023) evaluated the bioconcentration and biotransformation of PFOA in common carp (*Cyprinus carpio*) through a 14-week exposure and 3-week depuration period. Carp (30-40 g) were exposed to one of two PFOA treatments (10 and 100 µg/L) in a static renewal measured experiment with solutions renewed every 48 hours. After 14 weeks, the fish were visually analyzed, measured, and weighed. No mortalities or visible physiological were observed in any treatment. Therefore, the 14-week NOEC, based on mortality, weight and length, was >92.1 µg/L (>0.0921 mg/L). The test not acceptable for quantitative use because the chronic value was a "greater than" NOEC which would have influenced the criterion magnitude despite no effects observed at the chronic value.

NMED Exhibit 63

4.2.2.2.4 Genus: Danio (zebrafish)

Jantzen et al. (2017a) evaluated the effects of PFOA on the morphometric, behavioral and gene expression in *D. rerio* exposed via five-day static unmeasured exposures. Zebrafish embryos were exposed at 3-hpf to PFOA for 120 hours in what is equivalent to a rapid early-life stage test. The observation period in clean water was extended beyond the exposure time points from 120 hpf to 14 days post fertilization (dpf) to assess possible latent effects. The five-day (plus nine days for observation) chronic value for growth-based endpoints, including body length, was an MATC of 0.6325 mg/L (NOEC = 0.2 mg/L; LOEC = 2.0 mg/L), but the MATC for swimming activity, a non-apical endpoint, was reported as 0.06325 mg/L (NOEC = 0.02 mg/L; LOEC = 0.2 mg/L). The reported chronic values based on growth and swimming activity were not considered quantitatively acceptable because of the relatively brief chronic (i.e., 5-day) exposure duration compared to other acceptable acute exposures that indicated *D. rerio* was tolerant to brief (i.e., 96-hours) PFOA exposures.

4.2.2.2.5 Genus: Oryzias (medaka)

Ji et al. (2008) evaluated the chronic toxicity of PFOA (CAS # 335-67-1, purity not provided) to the Japanese medaka, *Oryzias latipes*, via renewal unmeasured exposures. For the F0 fish exposure study, breeding medaka pairs were exposed to PFOA for 14 days. Eggs were counted every day, and the eggs spawned on the seventh day were saved for the F1 generation exposure study. For the F1 fish exposure study, fertilized eggs collected from F0 fish were exposed until all living embryos had hatched. Newly hatched larvae were then randomly transferred to 100 mL beakers and observed daily for swim-up success and survival for an additional two weeks. Larvae were fed *Artemia nauplii ad libitum* twice daily. After 14 days, replicates from each treatment group were transferred to beakers without PFOA for observation through 100 days post hatch. The F0 (parental generation) adult survival, condition factor and

NMED Exhibit 63

adult male and female GSI and HSI 14-day LOECs were all >10 mg/L PFOA. For the F1 (progeny generation), the LOEC for larval survival was 0.1 mg/L, while the corresponding NOEC was considered <0.1 because effects were observed in the lowest concentration tested. This test was not used quantitatively because uncertainties associated with the responses across the range of concentrations tested. In many instances, the authors did not report increasing chronic effects with increasing concentrations that differed by an order of magnitude. Additionally, endpoints associated with longer term effects to juveniles were also rejected because of pseudoreplication resulting from a lack of replicates in the hatching stage. Since this test is a static-renewal unmeasured test, the EPA chose to rely exclusively on the test by Lee et al. (2017) to derive the SMCV for this species since Lee et al. (2017) was a flow-through measured test with fewer concerns pertaining to test design (i.e., no pseudoreplication) and results (lack of increasing effects despite a 10-fold increase in exposure concentrations).

4.3 Acute to Chronic Ratios

When sufficient empirical data are not available, the 1985 Guidelines allow the use of a Final Acute-to-Chronic Ratio (FACR) to convert the FAV to a FCV as an alternative approach to derive the chronic criterion (U.S.EPA 1985). An ACR approach was not used for the derivation of the chronic freshwater PFOA criterion, which was derived from empirical chronic data with all of the eight MDRs met. For illustrative purposes only, 11 individual ACRs for five invertebrate species, and one amphibian could be calculated from the quantitatively acceptable acute and chronic toxicity data (Appendix A and Appendix C). Appendix I includes the ACRs for freshwater aquatic species with quantitatively acceptable acute values for which comparable quantitatively acceptable chronic values were reported from the same study or same investigator and laboratory combination. For each species where more than a single ACR was calculated,

NMED Exhibit 63

Species Mean Acute-Chronic Ratios (SMACRs) were also calculated as the geometric mean value of individual ACRs. In the case of a single ACR within a species, that ACR was the SMACR.

Individual ACRs ranged from <4.229 to 3,493 across all species and SMACRs ranged from <4.299 to 3,493. Except for *D. magna*, all SMACRs consisted of a single ACR. *Lithobates catesbeiana* had the largest ACR (i.e., 3,493). The denominator of the *L. catesbeiana* ACR was a LOEC where authors reported a significant effect to snout vent length (SVL) despite a reduction of only ~7% relative to control responses (Flynn et al. 2019). The ~7% decrease to SVL observed at the LOEC was a relatively mild effect level compared to the denominator (i.e., chronic value) of most other PFOA ACRs, with chronic effect levels typically being EC_{10} values or MATCs that had corresponding LOECs that produced a >10% effect. Consequently, the relatively mild effect to SVL observed by Flynn et al. (2019) may have contributed to an artificially high ACR relative to the other PFOA ACRs available.

Daphnia carinata had the second highest ACR (2,113) and the denominator was based on a MATC, with the corresponding NOEC and LOEC (which reduced reproduction by ~40%) that differed by a factor of 10 (Logeshwaren et al. 2021). The 10X difference between the *D. carinata* NOEC and LOEC published by Logeshwaran et al. (2021) likely contributed to an artificially low MATC that, in turn, produced an artificially high ACR.

The mayfly, *Neocloeon triangulifer*, had the lowest non-definitive ACR (<4.229). The 96-hour LC_{50} of 13.05 mg/L was divided by the highest chronic test concentration from Soucek et al. (2023) that did not result in any adverse survival, weight or emergence effects at test termination (i.e., NOEC > 3.085 mg/L). The relatively high acute sensitivity of this species produced a low ACR compared to other test organisms.

NMED Exhibit 63

Four out of the five *D. magna* ACRs ranged from 14.50 to 69.08, with the remaining ACR from Lu et al. (2016) being 1,602. The *D. magna* ACR from Lu et al. (2016) was removed from the SMACR calculation because it was an order of magnitude greater than other ACRs for the species. Overall, the range of SMACRs was greater than a factor of 100 and there was not an apparent relationship between SMACRs and SMAVs. The 1985 Guidelines do not provide for calculation of a FACR under these circumstances.

4.4 Tissue-based Toxicity Studies Compared to the Chronic Tissue-based Criteria

Tissue-based PFOA toxicity data were reported for four species (three fish and one frog species) across five publications, all of which were classified as qualitatively acceptable. Feng et al. (2015) conducted a 96-hour study with juvenile goldfish (*Carassius auratus*) and observed no effects of PFOA on mortality or antioxidant enzyme activity in the highest aqueous PFOA treatment concentration (4.931 mg/L, measured), which corresponded to liver, gill, and muscle PFOA concentrations of 17.11, 35.13, and 6.07 mg/kg dry weight, respectively.

Giari et al. (2016) measured PFOA in several tissues of two-year-old common carp (*Cyprinus carpio*) exposed to nominal PFOA water concentrations of 0.0002 mg/L and 2 mg/L, plus a control, for 56 days. Corresponding tissue PFOA average concentrations in blood, liver, and muscle in fish from the 2 mg/L treatment after 56 days were 0.0649, 0.0281, and 0.0075 mg/kg wet weight, respectively. No effects of mortality, condition factor, hepatic somatic index (HSI) or gonadal somatic index (GSI) were observed. Manera et al. (2017) performed a separate study that replicated the study design of Giari et al. (2016), in which two-year-old common carp (*Cyprinus carpio*) were exposed to nominal PFOA water concentrations of 0.0002 mg/L and 2 mg/L, plus a control, for 56 days. PFOA was measured in liver, and average concentrations in fish exposed to 2 mg/L for 56 days was 0.0284 mg/kg wet weight, similar to Giari et al. (2016).

NMED Exhibit 63

PFOA in the livers of fish exposed to 0.0002 mg/L and the control were below detection (<0.0002 mg/kg ww). No apical endpoints were reported; however, evidence of degenerative liver morphology in PFOA exposed fish was observed.

Hagenaars et al. (2013) exposed adult zebrafish (*D. rerio*) to aqueous PFOA for 28 days. Several reproductive and biochemical endpoints were measured. Whole-body PFOA concentrations in the highest concentration (1 mg/L PFOA, nominal) after 28 days averaged 0.550 mg/kg wet weight in males and 0.301 mg/kg wet weight in females. No statistically significant differences were observed in reproductive endpoints (total egg production, fertilized egg production, and hatching rate) for any treatment levels compared to controls. Statistically significant effects were observed among non-apical endpoints. Decreased whole body glycogen content was lower in male and female fish across all exposure treatments, and liver mitochondrial electron transport activity was lower in males exposed to the highest PFOA concentration. Differences in several liver proteins of PFOA exposed males and females were also observed.

Hoover et al. (2017) exposed juvenile (Gosner stage 26) northern leopard frogs (*Lithobates pipiens*, formerly, *Rana pipiens*) to three PFOA concentrations (0.011, 0.109, and 1.11 mg/L PFOA, respectively) for 40 days. Survival, growth (snout-vent length), and developmental time were measured. Whole body PFOA concentrations in frogs exposed to the highest aqueous treatment level averaged 3.61 mg/kg dry weight after 40 days. Tadpole moisture content was not reported. In order to convert the reported dry weight concentrations to wet weight concentrations, so that they would be more directly comparable to the whole-body fish tissue criterion, a whole-body moisture content of 72.1% was applied, calculated as the average for all fish collected as part of the USGS National Contaminant Biomonitoring Program (NCBP

NMED Exhibit 63

Fish Database). The resulting whole-body concentration at the highest treatment level after 40 days was 1.01 mg/kg wet weight. No effects of PFOA on mortality, growth, or development time were reported.

Tissue PFOA concentrations reported in all but one of the qualitative studies were lower than the chronic freshwater tissue-based criteria (i.e., invertebrate whole-body criterion = 1.18 mg/kg ww; fish whole-body criterion = 6.49 mg/kg ww; fish muscle criterion = 0.133 mg/kg ww). The exception was reported by Feng et al. (2015), where the 96-hour muscle-based NOEC (i.e., 6.07 mg/kg dw) was greater than the muscle tissue criterion magnitude of 0.133 mg/kg. However, the liver- and muscle-based NOECs reported by Feng et al. (2015) were from an acute duration (96-hour exposure), whereas the tissue-based values were derived to protect species from longer-term chronic exposures, where effects to sensitive species at concentrations lower than the whole body-based NOEC reported by Feng et al. (2015) may occur. In addition, the tissue concentrations were reported by Feng et al. (2015) as dry weight, as tissue specific percent moisture contents were not available. Had the values in Feng et al. (2015) been expressed as wet weight, the magnitude of the differences would have been smaller.

Although all other tissue-based concentrations were lower than the corresponding tissue-based criteria, no statistically significant effects of apical endpoints were observed in any of these studies. Results of these studies do not provide any evidence that the aquatic community will experience unacceptable chronic effects at tissue-based criteria magnitudes.

4.5 Effects on Aquatic Plants

Available data for aquatic plants and algae were reviewed to determine if aquatic plants were likely to be adversely affected by PFOA and if they were likely to be more sensitive to PFOA than aquatic animals (see Section 4 and Appendix E: Acceptable Freshwater Plant PFOA

NMED Exhibit 63

Toxicity Studies). Toxicity values for freshwater plants reported in Appendix E were all greater than the chronic freshwater criterion (i.e., 0.10 mg/L PFOA). The lowest effect concentrations reported were all NOECs for the green alga (*Chlorella pyrenoidosa*). All of these were relatively low NOEC values, which do not provide meaningful information about the sensitivity of this alga relative to the chronic water column criterion. However, a definitive EC_{50} for the same species of 190.99 mg/L (Xu et al. 2013) suggests the PFOA criteria magnitudes are protective of *C. pyrenoidosa*. Excluding the relatively low NOECs, effect concentrations for freshwater plants and algae ranged from 5 to 745.7 mg/L relative to animal chronic values of 0.03162 to 88.32 mg/L (Appendix C). Therefore, it was not necessary to develop a criterion based on the toxicity of PFOA to aquatic plants and the PFOA freshwater criteria are expected to be protective of freshwater plants.

4.6 Protection of Threatened and Endangered Species

The PFOA acute and chronic datasets include some data representing species that are listed as threatened or endangered by the U.S. Fish and Wildlife Service and/or National Oceanic and Atmospheric Administration (NOAA) Fisheries. Summaries are provided here describing the available PFOA toxicity data for listed species indicating that the PFOA criteria are protective of these listed species, based on available scientific data.

4.6.1 Quantitatively Acceptable Acute Toxicity Data for Listed Species

Quantitatively acceptable acute toxicity test data evaluating the effects of PFOA on threatened and endangered freshwater species were available for rainbow trout (*Oncorhynchus mykiss*) with a SMAV of 4,001 mg/L PFOA (DuPont Haskill Laboratory 2000). The rainbow trout SMAV is more than 1,290 times greater than the recommended acute criterion (CMC) of 3.1 mg/L, indicating the acute criterion is protective of rainbow trout and expected to be

NMED Exhibit 63

protective of other listed salmonid species. There were no acceptable acute toxicity data for endangered or threatened estuarine/marine aquatic species.

4.6.2 Quantitatively Acceptable Chronic Toxicity Data for Listed Species

Quantitatively acceptable chronic toxicity test data evaluating the effects of PFOA on threatened and endangered freshwater species were available for rainbow trout (*Oncorhynchus mykiss*) with a SMCV of >40 mg/L PFOA (Centre International de Toxicologie 2004; Colombo et al. 2008). The rainbow trout SMCV is 400 times greater than the recommended chronic criterion (CCC) of 0.10 mg/L, indicating the chronic criteria are protective of rainbow trout and other listed salmonid species. There are no acceptable chronic toxicity data for endangered or threatened estuarine/marine aquatic species.

4.6.3 Qualitatively Acceptable Toxicity Data for Listed Species

Focusing on qualitatively acceptable tests with apical endpoints and water column exposures, there available data for the listed Atlantic salmon (*Salmo salar*). Spachmo and Arukwe (2012) and Arukwe et al. (2013) observed no adverse effects for growth at the highest treatment concentration (0.1 mg/L PFOA) following 49-day and 53-day exposures, respectively. For both exposures, the qualitatively-acceptable NOECs were greater than the recommended acute criterion (CCC) of 0.10 mg/L, which further indicates that the chronic criteria are protective of listed salmonid species. There were no qualitative acute or chronic toxicity data for endangered or threatened estuarine/marine aquatic species.

4.7 Summary of the PFOA Aquatic Life Criteria and the Supporting Information

The PFOA aquatic life criteria were developed to protect aquatic life against adverse effects, such as mortality, altered growth, and reproductive impairments associated with acute and chronic exposure to PFOA. This Aquatic Life Ambient Water Quality Criteria for

NMED Exhibit 63

Perfluorooctanoic acid (PFOA) document includes water column based acute and chronic criteria and tissue-based criteria for fresh waters. Acute and chronic water column criteria magnitudes for estuarine/marine waters could not be derived at this time due to data limitations; however acute estuarine/marine benchmarks are provided in Appendix L. The freshwater acute water column-based criterion magnitude is 3.1 mg/L, and the chronic water column-based chronic criterion magnitude is 0.10 mg/L. The fish whole-body tissue criterion magnitude is 6.49 mg/kg wet weight, the fish muscle tissue criterion magnitude is 0.133 mg/kg wet weight and the invertebrate whole-body tissue criterion magnitude is 1.18 mg/kg wet weight (Table 3-12). Although empirical PFOA toxicity data for estuarine/marine species were not available to fulfill the eight MDRs directly, the EPA included an acute aquatic life benchmark for estuarine/marine environments in Appendix L, using available estuarine/marine species toxicity data and a NAM application of ORD's peer-reviewed webICE tool. The estuarine/marine acute water column-based benchmark magnitude is 7.0 mg/L; this value provides information on a concentration that should be protective of aquatic estuarine/marine life from acute PFOA exposures. As noted earlier, the benchmark value has greater uncertainty than the freshwater PFOA criteria, due to the paucity of empirical data of PFOA effects on estuarine/marine organisms.

The EPA evaluated the influence of including non-North American resident species on the acute and chronic criteria magnitudes and concluded their inclusion did not substantiality affect the criteria magnitudes. These PFOA aquatic life criteria are expected to be protective of aquatic life, such as fish and aquatic invertebrates, on a national basis.

a S=static, R=renewal, F=flow-through, U=unmeasured, M=measured, T=total, D=dissolved, Diet=dietary, MT=maternal transfer

b Chemical concentrations made in a side-test representative of exposure and verified stability of concentrations of PFOA in the range of concentrations tested under similar conditions. Daily renewal of test solutions.

c Reported in moles converted to milligram based on a molecular weight of 414.07 mg/mmol.

d Concentration of APFO in publication indirectly determined through quantification of the anion (PFO-).

e Values in bold used in the SMAV calculation.

f Only the most sensitive life-stage used in the SMAV calculation.

g Value is considered an outlier and not used in SMAV calculation.

h Author pooled test of life stages.

NMED Exhibit 63

A.2 Detailed PFOA Acute Toxicity Study Summaries and Corresponding Concentration-Response Curves (when calculated)

The purpose of this section is to present detailed study summaries for tests that were considered quantitatively acceptable for criterion derivation, with summaries grouped and ordered by genus sensitivity. C-R models developed by the EPA that were used to determine acute toxicity values used for criterion derivation are also presented. C-R models included here with study summaries were those for the four most sensitive genera. In many cases, authors did not report concentration-response data in the publication/supplemental materials and/or did not provide concentration-response data upon request by the EPA. In such cases, the EPA did not independently calculate toxicity values and the author-reported effect concentrations were used to derive the criterion.

A.2.1 Most acutely sensitive genus – *Moina*

Ji et al. (2008) performed a 48-hour static, unmeasured acute test of PFOA (CAS # 335-67-1, purity unreported; obtained from Sigma Aldrich, St. Louis, MO) with *Moina macrocopa*. Authors stated the test followed U.S. EPA/600/4-90/027F (2002). *M. macrocopa* used for testing were obtained from brood stock cultured at the Environmental Toxicology Laboratory at Seoul National University, Korea. Test organisms were less than 24-hours old at test initiation. Dilution water was moderately hard reconstituted water (total hardness typically 80-100 mg/L as $CaCO_3$). Experiments were conducted in glass jars of unspecified size and fill volume. Photoperiod was assumed as 16-hour:8-hour, light:dark, the same conditions as the daphnid cultures. Preparation of test solutions was not described. The test involved four replicates of five daphnids each in five unmeasured test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 62.5, 125, 250, 500 and 1,000 mg/L. Test temperature was maintained at 25 ± 1°C. Authors noted water quality parameters (pH, temperature, conductivity, and dissolved oxygen)

NMED Exhibit 63

were measured 48-hours after exposure, but the information was not reported. Survival of daphnids in the negative control was not reported, although EPA/600/4-90/027F requires at least 90% survival for test acceptability. The author-reported 48-hour EC_{50} for the study was 199.51 mg/L (95% C.I. = 163.9 – 245.1). The EPA performed C-R analysis for the test. The EPA-calculated EC_{50} was 166.3 mg/L PFOA (95% C.I. = 138.6 – 194.1 mg/L) and was acceptable for quantitative use.

Razak et al. (2023) tested the acute toxicity of perfluorooctanoic acid (PFOA) to *Moina micrura* in a 48 hour static measured experiment. In addition to acute toxicity, the effects of PFOA on heart rate, heart size, and individual size were also examined. PFOA (≥98% purity) analytical standards were purchased from Dr. Ehrenstorfer GmbH (Augsburg, Germany), and PFOA and solvents for making test solutions were purchased from Fisher Scientific (New Jersey, USA). Organisms were obtained from the Aquatic Animal Health and Therapeutics Laboratory (Aquahealth) at the Institute of Bioscience, Universiti Putra Malaysia. Culturing procedures followed International Organisation for Standardization (ISO) procedure 6341:2012. Cultures were kept under a 12:12 light:dark cycle at 27±1°C. Culture water was renewed every two weeks, and culture organisms were fed green algae (*Chlorella vulgaris*) three times weekly. Both culture and test water was filtered (0.2 µm) surface lake water. A stock solution of 100 mg/L PFOA with filtered surface lake water was made just before testing began. Testing methods followed OECD 202 (OECD 2004) with nominal testing concentrations of 10, 25, 50, 75, 100, 250, 500, 750, 1,000, 2,500, 5,000, 7,500, and 10,000 µg/L, plus a control, with four replicates per treatment. Measured concentrations were not reported, but the authors noted they were 94.3±6.1% of nominal on average. Each replicate consisted of 10 neonates (<48 hours old) in 50 mL of solution in a 100 mL beaker, and organisms were not fed during the study. Nonparametric

NMED Exhibit 63

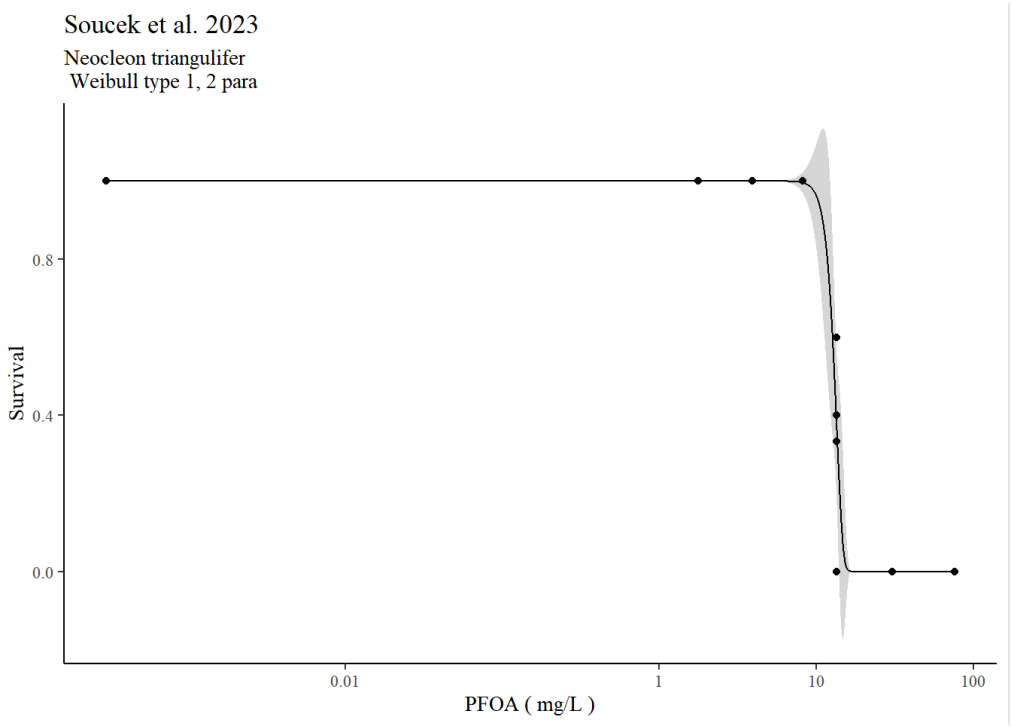
Kruskal-Wallace tests followed by post-hoc tests were used to calculate significant ($P<0.05$) differences between controls and treatment concentrations for all endpoints. The lethal effect concentrations (LC_{10}, LC_{50}, LC_{75}, LC_{90}) were calculated using Probit analysis, and the 48-hour LC_{50} value of 474.7 µg/L, or 0.4747 mg/L was determined to be acceptable for quantitative use. C-R data could not be obtained for this test (beyond the visual presentation in the Razak et al. (2023), so the EPA was unable to perform independent C-R analysis.

A.2.2 Second most acutely sensitive genus – *Neocloeon*

Soucek et al. (2023) exposed the parthenogenetic mayfly, *Neocloeon triangulifer*, to PFOA (CAS # 335-67-1, 95% purity) in a 96-hour acute toxicity test. The test was performed under static, non-renewal conditions beginning with <24-hour old larvae. Exposures consisted of five mayfly nymphs per 30 mL polypropylene cup filled with 20 mL test solution. The control and each of six PFOA test concentrations were replicated five times for a total of 25 test organisms per treatment. Nominal test concentrations were 0.0 (control), 1.25, 2.5, 5.0, 10, and 20 mg/L PFOA. Mean measured PFOA concentrations (EPA Analytical Method 1633; LC-MC/MS) were 0.0003 (control), 1.765, 3.896, 8.137, 13.39 and 30.40 mg/L PFOA, respectively. Mayflies were exposed at 23 ± 1°C under a 16:8-hour light:dark cycle and fed live diatom biofilm scraping beginning on day 0. Feeding only occurred on day 0, and the authors indicated that test organisms required food to survive the entire 96-hour exposure, with previous studies demonstrating greater than 80% mortality at 48 hours with no food (Soucek and Dickinson 2015). Percent survival in the control treatment after 96 hours was 100%. A steep concentration-response relationship between percent survival and increasing PFOA test concentration was observed. Survival decreased from 100% at 8.137 mg/L PFOA to 38.5% at 13.39 mg/L, and to 0% at 30.40 mg/L. The EPA-calculated acute LC_{50} (i.e., 13.045 mg/L) was similar to the author-

NMED Exhibit 63

reported LC_{50} of 13.451 mg/L. The EPA-calculated LC_{50} value (i.e., 13.045 mg/L) was acceptable for quantitative use in deriving the acute freshwater PFOA criterion.



Recent research has led to the development of successful culturing methods for mayflies that are used in laboratory-based toxicity studies (Soucek and Dickinson 2015; Soucek et al. 2023). These resulting toxicity studies have shown that mayflies (including *Neocloeon triangulifer*) are commonly among the most sensitive taxa to different chemical exposures, including PFOA, PFOS, major geochemical ions, pesticides, and heavy metals (Johnson et al. 2015; Kim et al. 2012; Raby et al. 2018; Soucek and Dickinson 2015; Soucek et al. 2020; Soucek et al. 2023; Wesner et al. 2014). The high sensitivity of mayflies to contaminant exposures has also been observed In mesocosm-based experiments (Mebane et al. 2020) and field-based surveys (U.S. EPA 2011). Many of these laboratory-based toxicity tests used mayflies capable of adapting to laboratory settings. It is hypothesized that mayfly species unable to survive in laboratory settings may also be more sensitive to contaminant exposures than the relatively hardy mayfly species (e.g., *N. triangulifer*) commonly used for toxicity testing.

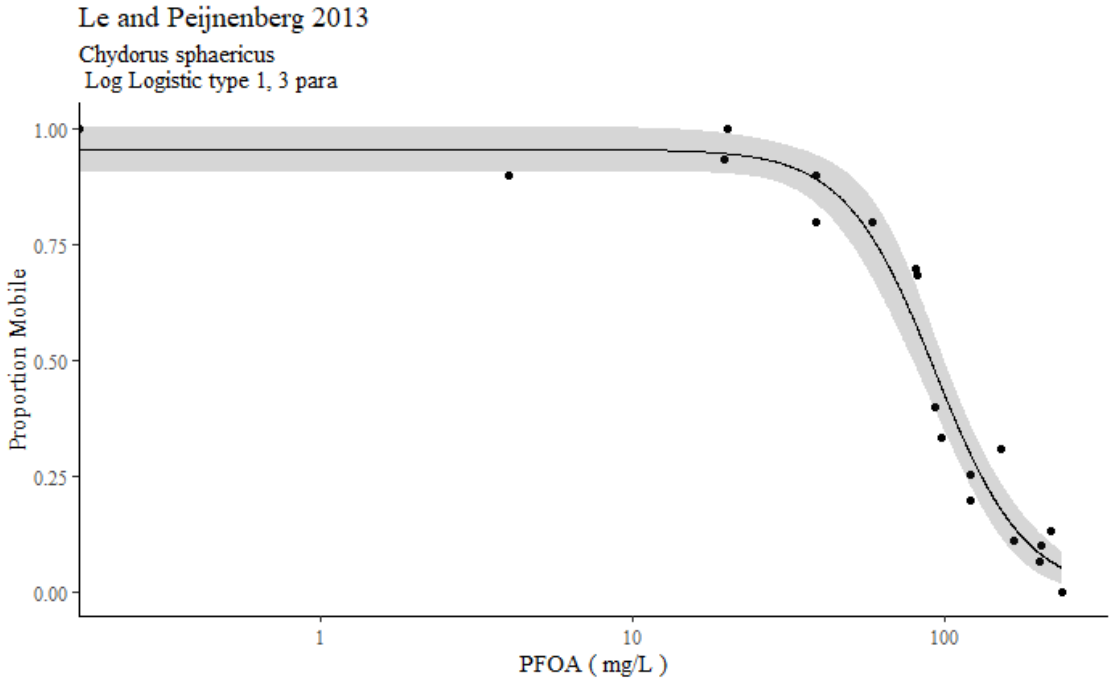
Concentration-Response Model Fit:

A.2.3 Third most acutely sensitive genus – *Chydorus*

Le and Peijnenburg (2013) performed a 48-hour static unmeasured test on PFOA (unreported purity) with the cladoceran, *Chydorus sphaericus*. Authors stated the test followed the protocol of the "Chydotox toxicity test" developed by the National Institute for Public Health and the Environment, The Netherlands. In-house cultures of neonates (<24 hours) were exposed to 250 ML of test solutions in 2 ML vials of unreported material. Each vial contained five neonates and each test concentration was replicated four times. No solvent was used in the test solutions with 18-20 test concentrations. *C. sphaericus* was cultured at 20 ± 1°C and a cycle of 16-hour:8-hour light:dark without the addition of food. At test termination vials were shaken slightly and the mobility of the neonates was determined. The author-reported 48-hour EC_{50} was 0.22 MM PFOA (91.10 mg/L). The EPA performed concentration-response (C-R) analysis for



NMED Exhibit 63

the test and calculated a LC_{50} of 93.17 mg/L PFOA (95% C.I. = 82.52 – 103.8 mg/L) that was acceptable for quantitative use.

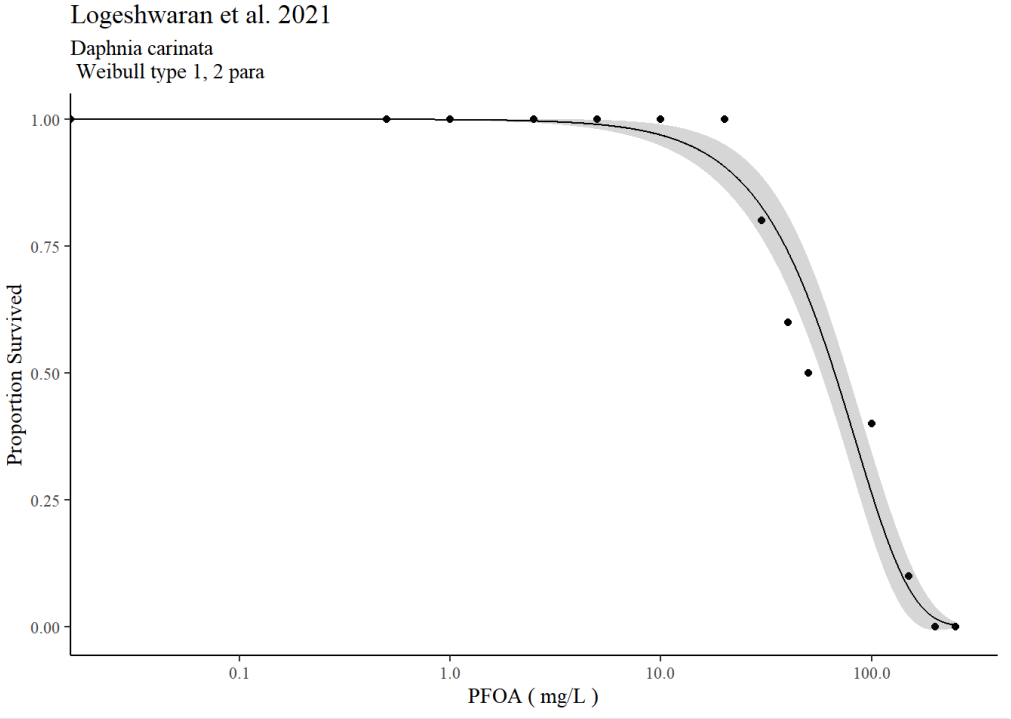
Concentration-Response Model Fit:

A.2.4 Fourth most acutely sensitive genus – *Daphnia*

Logeshwaran et al. (2021) conducted acute and chronic toxicity tests with the cladoceran, *Daphnia carinata*, and PFOA (95% purity, purchased from Sigma-Aldrich Australia). In-house cultures of daphnids were maintained in 2 L glass bottles with 30% natural spring water in deionized water, 21°C and a 16-hour:8-hour light:dark photoperiod. The acute test protocol followed OECD guidelines (2000) with slight modifications. A PFOA stock



NMED Exhibit 63

solution (100 mg/L) was prepared in deionized water. Cladoceran culture medium was used to prepare the PFOA stock and test solutions. Ten daphnids (six to 12 hours old) were transferred to polypropylene containers containing one of 14 nominal test concentrations (0, 0.5, 1, 2.5, 5, 10, 20, 30, 40, 50, 100, 150, 200 and 250 mg/L PFOA). Each test treatment was replicated three times and held under the same conditions as culturing. At test termination (48 hours) immobility was determined after 15 seconds of gentle stirring. No mortality occurred in the controls. The author-reported 48-hour EC_{50} was 78.2 mg/L PFOA. The EPA-calculated 48-hour EC_{50} value was 66.80 mg/L (95% C.I. = 57.10 – 76.50 mg/L), which was acceptable for quantitative use.

Concentration-Response Model Fit:

Boudreau (2002) performed a 48-hour static unmeasured test on PFOA (CAS # 335-67-1, ≥97% purity) with *Daphnia magna* and *Daphnia pulicaria* as part of a Master's thesis at the University of Guelph, Ontario, Canada. The results were subsequently published in the open literature (Boudreau et al. 2003). Authors stated the test followed ASTM E729-96 (1999). Daphnids used for testing were less than 24-hours old at test initiation. *D. magna* were obtained from a brood stock (Dm99-23) at ESG International (Guelph, ON, Canada). *D. pulicaria* were acquired from a brood stock maintained in the Department of Zoology at the University of Guelph. Dilution water was clean well water obtained from ESG International. Total hardness was softened by addition of distilled deionized water to achieve a range of 200-225 mg/L of $CaCO_3$. Photoperiod was 16-hours of illumination under cool-white, fluorescent light between 380 and 480 lux. Laboratory-grade distilled water was used for all solutions with maximum concentrations derived from stock solutions no greater than 450 mg/L. Test vessels consisted of 225 mL polypropylene disposable containers containing 150 mL of test solution. All toxicity testing involved three to four replicates of 10 daphnids each in five unmeasured test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 26.3, 52.6, 105, 210 and 420 mg/L. Experiments were conducted in environmental chambers at a test temperature of 21 ± 1°C. Authors note that temperature and pH were measured at the beginning and end of the study, but this information is not reported. Mortality of daphnids in the negative control was also not reported, although ASTM E729-96 requires at least 90% survival for test acceptability. The 48-hour *D. magna* EC_{50} reported in the publication was 223.6 mg/L. The 48-hour *D. pulicaria* EC_{50} reported in the publication was 203.7 mg/L.

Colombo et al. (2008) conducted a 48-hour static unmeasured acute test on ammonium perfluorooctanoate (APFO, CAS # 3825-26-1, 99.7% purity) with the daphnid, *Daphnia magna*. The authors stated that the toxicity test was conducted following OECD test guideline 202 (1992). Neonates, six to 24-hours old, were acclimated to test conditions for six-hours before test initiation with test solutions made in reconstituted M4 media. There were four replicates for each test treatment containing five animals each. Exposure vessel material and size were not reported. Based on loading, exposure vessels contained at least 100 mL test solution. Nominal test concentrations were used based on the known stability of the test substance in water. The nominal test concentrations included control, 100, 178, 316, 562 and 1,000 mg/L. Dissolved oxygen was >60% saturation and temperature were maintained between 18-22°C. Illumination involved 16-hours of light with an unreported intensity. No mortality was observed in the controls. C-R data were available for this acute test; however, the EPA was unable to fit a model with significant parameters and relied on the 48-hour EC_{50} reported in the study of 480 mg/L, which was acceptable for quantitative use. The authors note the contribution of ammonia from APFO exposure indicates that un-ionized ammonia could be a potential contributor to the observed acute toxicity of APFO. The EPA believes ammonia does not contribute substantively to the acute toxicity to *D. magna* in this test based on the following rationale. U.S. EPA (2013)

NMED Exhibit 63

derived a SMAV of 157.7 mg N/L at pH=7 and temperature of 20°C for *D. magna*. Using the EPA equations, this translates to approximately 30.36 mg N/L at the authors' assumed acute test pH=8.1 (from their Table 7) and their midrange test temperature of 20°C, which in turn translates to an un-ionized ammonia concentration of approximately 1.76 mg un-ionized ammonia/L at this pH and temperature. The authors' Table 7 lists the un-ionized ammonia concentration at their APFO EC_{50} as 0.73 mg un-ionized ammonia/L, which is 2.4-fold lower than the EPA's SMAV for D. *magna* re-expressed as an un-ionized ammonia concentration for the test condition. Therefore, it is unlikely that ammonia contributes substantively to the acute toxicity of APFO to *D. magna* in this test, and therefore, the 48-hour EC_{50} is used in the calculation of the SMAV for this species.

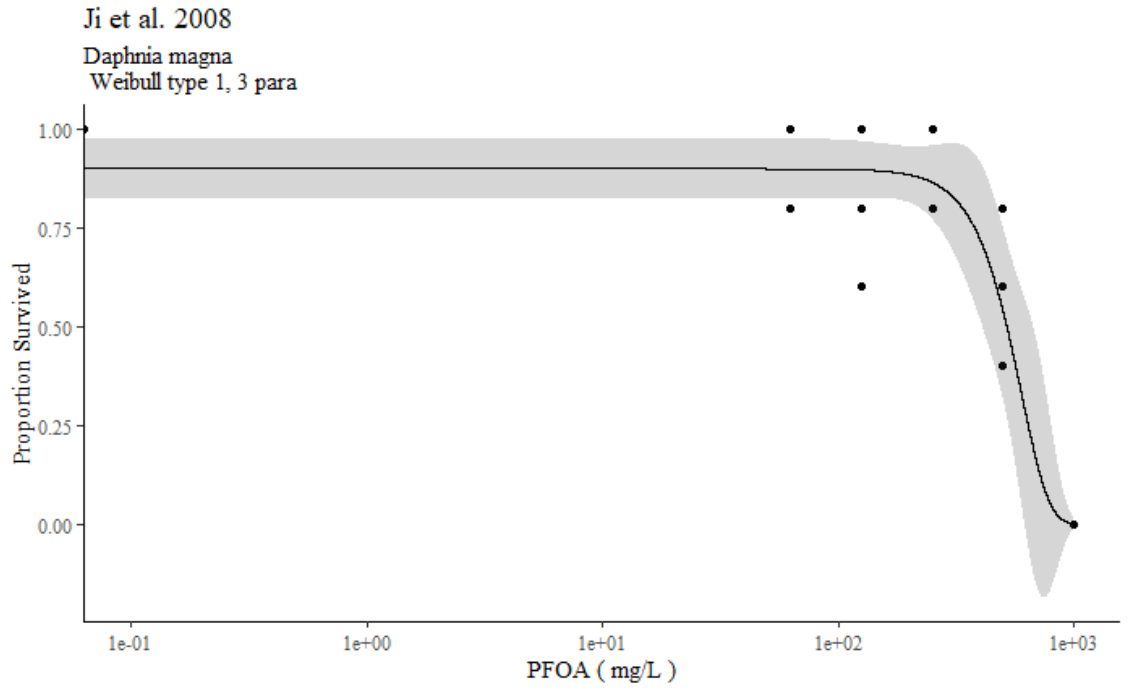
Concentration-Response Model Fit: Not Applicable

Ji et al. (2008) also performed a 48-hour static, unmeasured acute test of PFOA (CAS # 335-67-1, purity unreported; obtained from Sigma Aldrich, St. Louis, MO) with *D. magna*. Authors stated that the test followed U.S. EPA/600/4-90/027F (2002). *D. magna* used for testing were obtained from brood stock cultured at the Environmental Toxicology Laboratory at Seoul National University, Korea. Test organisms were less than 24-hours old at test initiation. Dilution water was moderately hard reconstituted water (total hardness typically 80-100 mg/L as $CaCO_3$). Experiments were conducted in glass jars of unspecified size and fill volume. Photoperiod was assumed as 16-hour:8-hour, light:dark, the same conditions as the daphnid cultures. Preparation of test solutions was not described. The test involved four replicates of five daphnids each in five unmeasured test concentrations plus a negative control. Nominal concentrations were 0 (negative

NMED Exhibit 63



control), 62.5, 125, 250, 500 and 1,000 mg/L. Test temperature was maintained at 21 ± 1°C. The authors noted that water quality parameters (Ph, temperature, conductivity, and dissolved oxygen) were measured 48-hours after exposure, but the information was not reported. Mortality of daphnids in the negative control was not reported, although EPA/600/4-90/027F requires at least 90% survival for test acceptability. The author-reported 48-hour EC_{50} for the study was 476.52 mg/L (95% C.I. = 375.3 – 577.7 mg/L). The EPA performed C-R analysis for the test. The EPA-calculated EC_{50} was 542.5 mg/L PFOA (95% C.I. = 461.1 – 623.8 mg/L), which was acceptable for quantitative use.

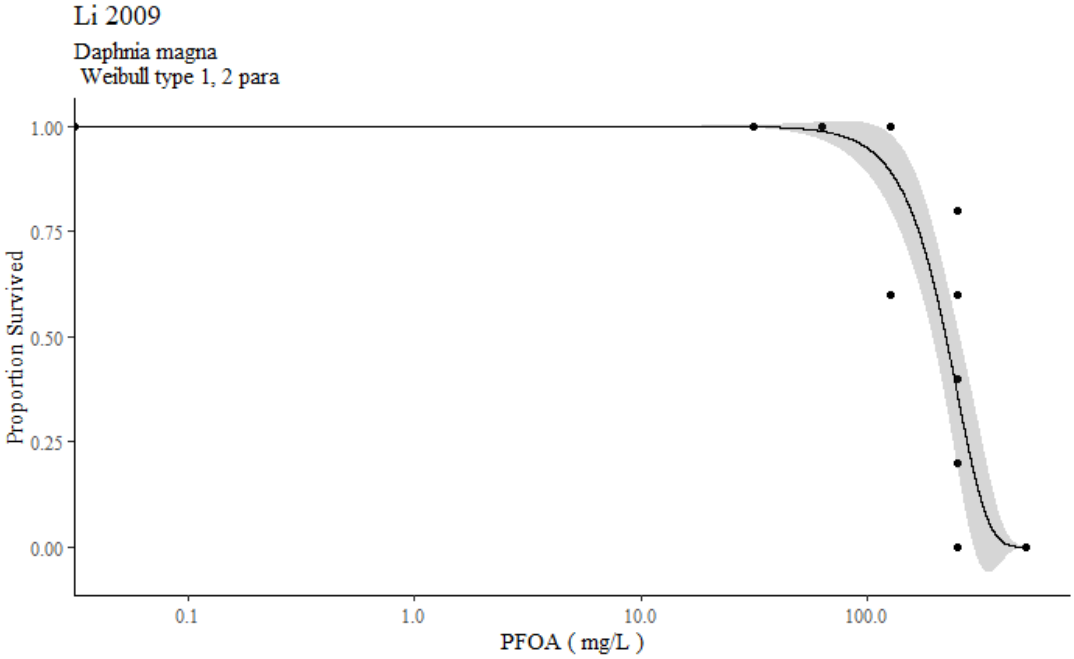
Concentration-Response Model Fit:

Li (2009) conducted a 48-hour static unmeasured acute test on PFOA (ammonium salt, >98% purity) with *Daphnia magna*. The authors stated that the test followed OECD 202 (1984) with slight modifications. *D. magna* used for the test were less than 24-hours old at test initiation. Dilution water was dechlorinated tap water. The photoperiod consisted of 12-hours of illumination at an unreported light intensity. A primary stock solution was prepared in dilution water and did not exceed 400 mg/L. Exposure vessels were polypropylene of unreported dimensions and 50 Ml fill volume. The test employed five replicates of six daphnids each in five

NMED Exhibit 63



test concentrations plus a negative control. Based on water solubility of test chemicals and preliminary toxicity results, nominal test concentrations were in the range of 31-250 mg/L for PFOA. The test was conducted in a temperature incubator at 25 ± 2°C. Water quality parameters including water Ph, conductivity, and dissolved oxygen were measured at the beginning and at the end of each test. Initial values of Ph were 7.82 ± 0.12 and 7.91 ± 0.03 after 48-hours. At the start of the bioassays, dissolved oxygen and specific conductivity were 67.7 ± 6.8% saturation and 101.8 ± 6.8 µS/cm, respectively. After the 48-hour testing period, dissolved oxygen and specific conductivity were 55.6 ± 1.26% saturation (implying 4.56 mg/L) and 109.1 ± 3.5 µS/cm, respectively. None of the control animals became immobile at the end of the test. The author-reported 48-hour EC_{50} for the study was 181 mg/L (95% C.I.: 166-198 mg/L) which was averaged across three tests. The EPA performed C-R analysis for each individual test. All three tests had acceptable curves with the EPA-calculated EC_{50} values of 220.8 mg/L (95% C.I. = 191.8 – 250.0 mg/L), 157.9 mg/L (95% C.I. = 135.9 – 180.0 mg/L), and 207.3 mg/L (95% C.I. = 176.1 – 238.5 mg/L), which were acceptable for quantitative use.

Concentration-Response Model Fit:

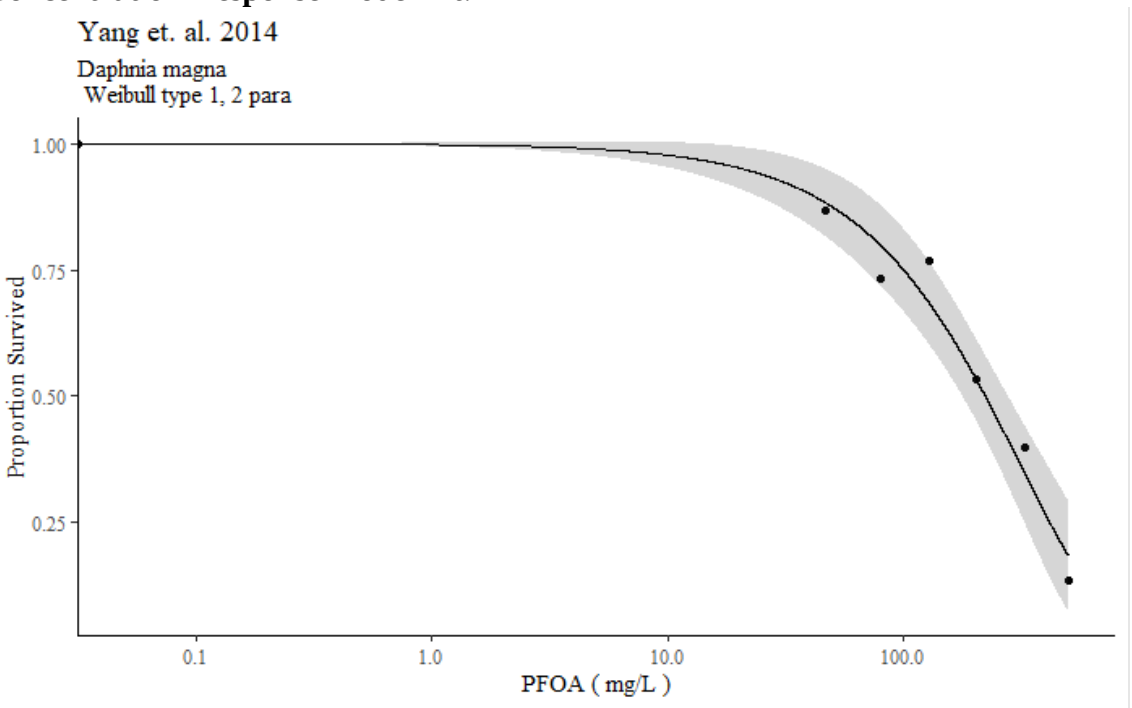
Yang et al. (2014) conducted a 48-hour measured acute test of PFOA (CAS # 335-67-1, 99% purity) with *Daphnia magna*, following ASTM E729 (1993). Although the authors termed the test conditions "static", they also mentioned PFOA measurements before and after renewal; based on this distinction the test was assumed to be renewed at least once. Daphnids used for the test were donated by the Chinese Research Academy of Environmental Sciences. The daphnids were less than 24-hours old at test initiation. Dilution water was dechlorinated tap water (pH, 7.0 ± 0.5; dissolved oxygen, 7.0 ± 0.5 mg/L; total organic carbon, 0.02 mg/L; and total hardness, 190.0 ± 0.1 mg/L as $CaCO_3$). The photoperiod consisted of 12-hours of illumination at an

NMED Exhibit 63



unreported intensity. A primary stock solution was prepared by dissolving PFOA in deionized water and solvent, DMSO, and proportionally diluted with dilution water to prepare the test concentrations. Exposure vessels were 200 mL beakers of unreported material type containing 100 mL of test solution. The test employed three replicates of 10 daphnids each in six test concentrations (measured in low and high treatments only) plus a negative and solvent control. Nominal concentrations were 0 (negative and solvent controls), 50, 80, 128, 204.8, 327.68 and 524.29 mg/L. The authors provided mean measured concentrations before and after renewal: 49.62 and 43.93 mg/L (lowest concentration) and 526.9 and 476.41 mg/L (highest concentration). Analyses of test solutions were performed using HPLC/MS and negative electrospray ionization. The concentration of PFOA was calculated from standard curves (linear in the concentration range of 1-800 ng/mL), and the average extraction efficiency was in the range of 70-83%. The concentrations and chromatographic peak areas exhibited a significant positive correlation ($r = 0.9987$, $p < 0.01$), and the water sample-spiked recovery was 99%. The temperature, D.O., and pH were reported as having been measured every day during the acute test, but results were not reported. Negative control and solvent control mortality were 0% each. The author-reported 48-hour LC_{50} for the study was 201.85 mg/L (95% C.I. = 134.7 - 302.5 mg/L). The EPA performed C-R analysis for the test and had an acceptable curve with an EPA-calculated LC_{50} of 222.0 mg/L PFOA (95% C.I. = 190.5 – 253.5 mg/L). The acute value was acceptable for quantitative use.

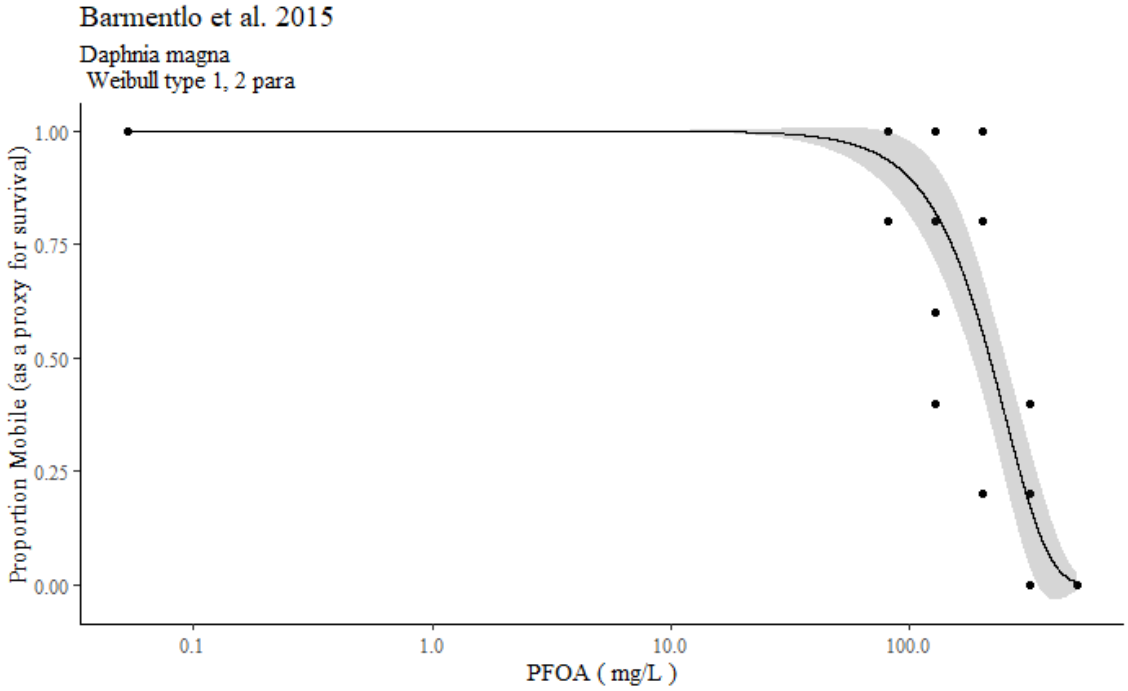
Concentration-Response Model Fit:

Barmentlo et al. (2015) performed a 48-hour static, measured acute test of PFOA (CAS # 335-67-1, >96%) with *Daphnia magna*. The authors stated the test followed OECD 202 (2004) guidelines for testing. *D. magna* used for testing were obtained from Grontmij, Amsterdam, and cultured in M4 media according to OECD 211 (2012). Test organisms were less than 24-hours old at test initiation. Dilution water was ISO medium. Experiments were conducted in 50 Ml polypropylene tubes with 20 Ml of test solution. The photoperiod consisted of 16-hours of illumination at an unreported intensity. PFOA stock was made with demineralized water. The test involved four to six replicates of five daphnids each in five test concentrations plus a

NMED Exhibit 63



negative control. Nominal concentrations were not provided, but PFOA was measured in the control, lowest and highest test concentrations. Based on these measurements, the authors interpolated all test concentrations, 0.053 (negative control), 81, 128, 202, 318 and 503 mg/L. Test temperature was maintained at 20 ± 1°C, Ph ranged from 7.00-7.82, and D.O. ranged from 8.54-9.42 mg/L. Mortality of daphnids in the negative control was not reported. The author-reported 48-hour EC_{50} for the study was 239 mg/L (95% C.I.: 190 – 287 mg/L). The EPA performed C-R analysis for the test and had an acceptable curve with an EPA-calculated EC_{50} of 215.6 mg/L PFOA (95% C.I. = 181.7 – 249.5 mg/L). The acute value was acceptable for quantitative use.

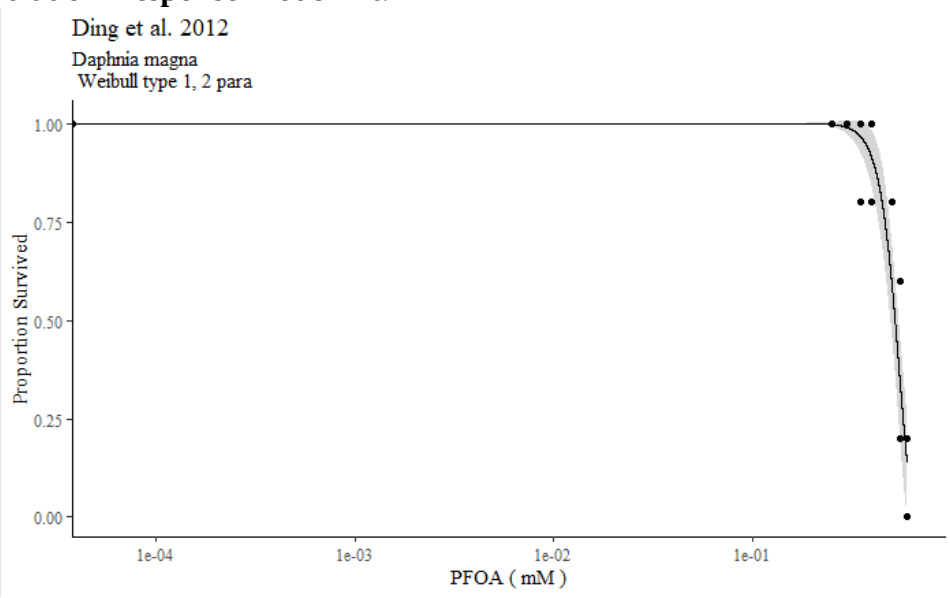
Concentration-Response Model Fit:

Ding et al. (2012a) conducted a 48-hour static, partially measured acute test on PFOA (CAS # 335-67-1; 96% purity from Sigma Aldrich) with *D. magna*. The test was performed following OECD test guideline 202 (2004) with slight modifications. *D. magna* used for testing were purchased from local suppliers and cultured for two months prior to use. Test organisms were less than 24-hours old at test initiation. Dilution water was M4 solution prepared following the OECD test guideline. The photoperiod consisted of a 16 hour:8-hour light:dark cycle at an unreported light intensity. A primary stock solution was prepared in dilution (reconstituted M4)

NMED Exhibit 63

water. Exposure vessels were 50 Ml polypropylene disposable tubes containing 20 Ml of test solution. The test involved four replicates of five daphnids each in six test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 0.35, 0.4, 0.45, 0.5, 0.55 and 0.6 Mm PFOA, or 0, 144.9, 165.6, 186.3, 207.0, 227.7 and 248.4 mg/L, respectively, after conversion by multiplying the Mm concentration by a molecular weight of 414.07 g/mol for PFOA. The subsequent concentrations are reported in the converted units of mg/L. Concentrations of PFOA were confirmed in the highest and lowest concentrations, though only nominal concentrations were reported. It was stated that the verified concentration was "well in line with nominal concentrations". Test temperature was maintained at 20 ± 1°C. Observations were made at 24-hours and 48-hours after test initiation. EC_{50} values were reported for both observational time periods. The 48-hour EC_{50} was reported as 211.6 mg/L with the 95% confidence levels of 184.7 - 255.5 mg/L and a NOEC of 207.0 mg/L. The EPA performed C-R analysis for the test. The EPA-calculated EC_{50} was 216.1 mg/L PFOA (95% C.I. = 206.1 – 225.9 mg/L) for *D. magna*, which was acceptable for quantitative use.



(It should be noted that these authors also conducted and reported on a similar acute toxicity test with *Chydorus sphaericus.* However, this test was not used qualitatively or quantitatively because personal correspondence with the authors indicated high control mortality. Raw data provided by the authors did not clearly show 24- and 48-hour EC_{50} data reported in the publication. Data provided by the authors contained many PFOA C-R datasets for *C. sphaericus*. Of these, the C-R dataset with nominal concentrations and 24- and 48-hour EC_{50} values that best matched those in the publication indicated high mortality in control responses. Therefore, the results of this test were not included in the PFOA aquatic life criteria document.)

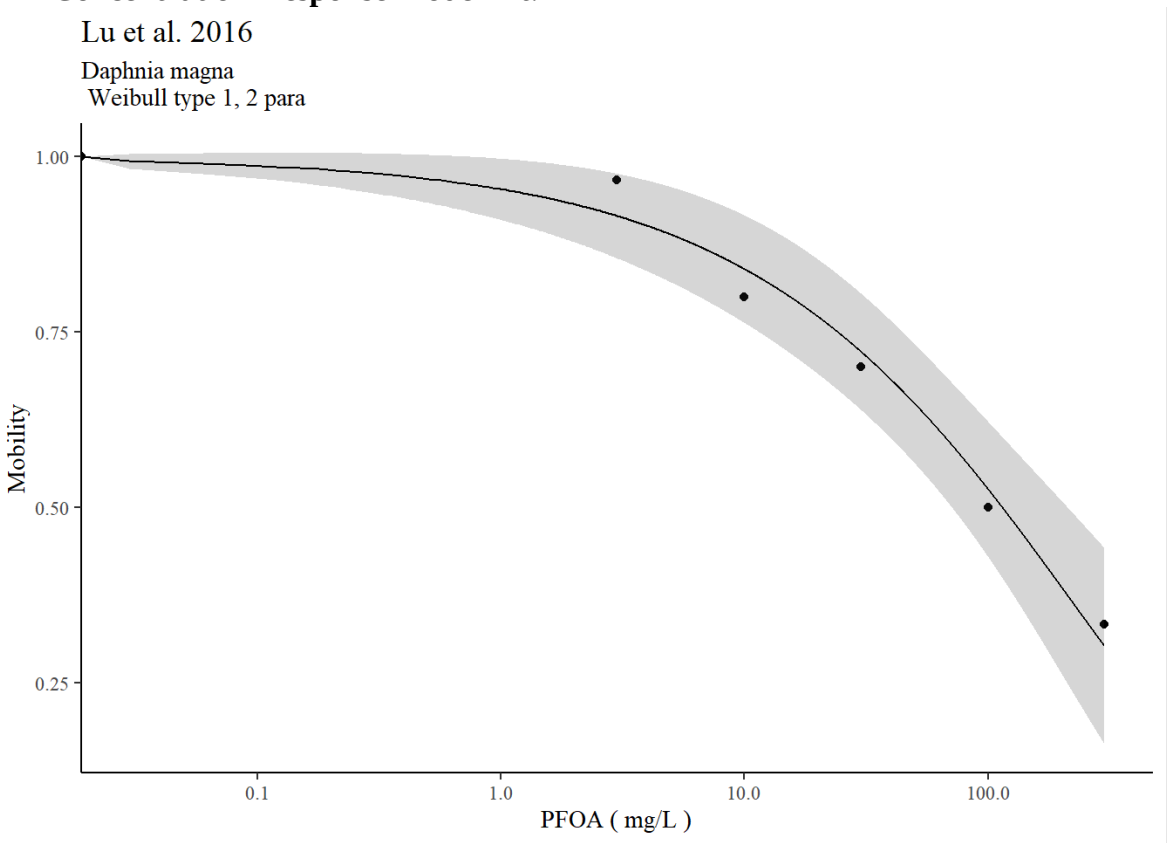
Concentration-Response Model Fit:

Lu et al. (2016) evaluated the acute toxicity of PFOA (CAS# 335-67-1, 98% purity, purchased from Tokyo Chemical Industry Co., Ltd., Tokyo, Japan) on *Daphnia magna* immobilization. Reconstituted daphnia culture media was used for both culturing and test solution preparation as described in OECD Test Guideline 202. *D. magna* cultures (originally obtained from the Chinese Center for Disease Control and Prevention (Beijing, China) were fed with the green algae *Scenedesmus obliquus* daily, maintained at 20°C and a light/dark photoperiod of 16-hour/8-hour and the medium renewed three times weekly. The 48-hour static unmeasured acute test was conducted via a modified OECD standard test procedure 202, whereby five concentration treatments (3, 10, 30, 100 and 300 mg/L) plus a blank control were

NMED Exhibit 63



employed. Ten neonates (<24-hours old) from a designated brood were placed in a 100 Ml glass beaker containing 45 Ml test solution for each test concentration and control. Test daphnids were not fed during the testing period and each treatment was replicated three times. The status of immobilization and mortality was checked at 48 hours (daphnids unable to swim within 15 seconds after gentle agitation of the test container are considered to be immobile and those animals whose heartbeats have stopped are considered dead). The authors reported immobility/ survival to be a more sensitive endpoint than survival alone. The author-reported 48-hour EC_{50} for immobility/survival was 110.7 mg/L and the EPA-calculated 48-hour EC_{50} was 114.595 mg/L (95% C.I. = 93.71 – 135.5 mg/L).

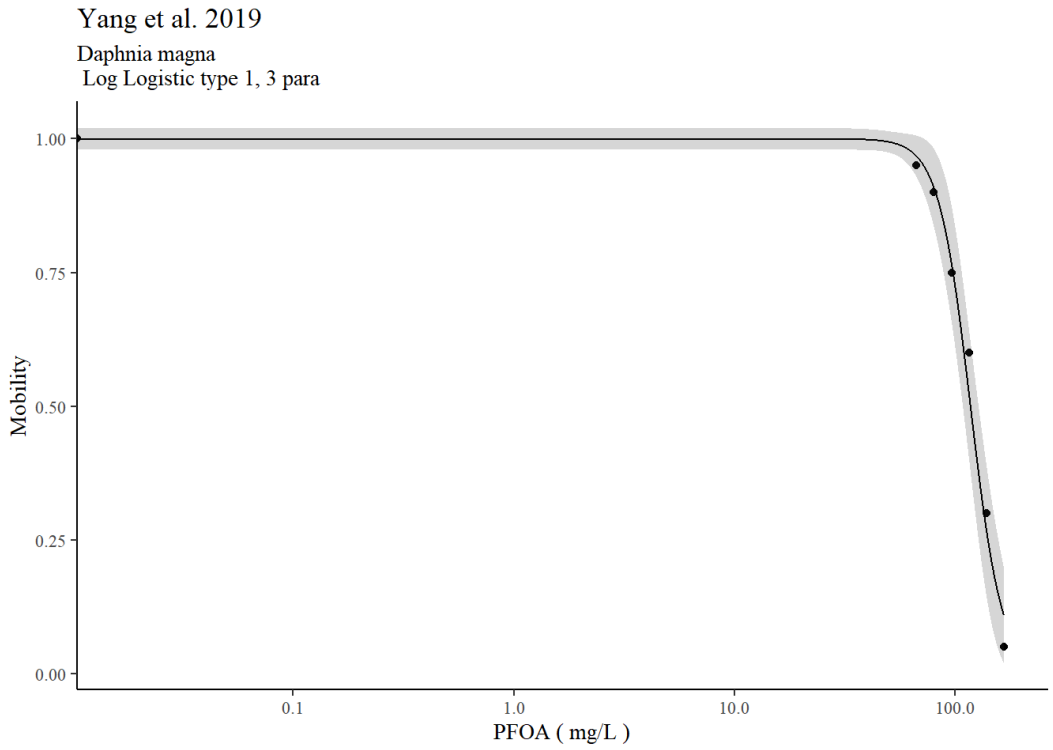
Concentration-Response Model Fit:

Yang et al. (2019) evaluated the acute effects of PFOA (CAS# 335-67-1, purchased from Sigma-Aldrich in St. Louis, MO) on *Daphnia magna* via a 48-hour unmeasured static exposure. *D. magna* cultures were originally obtained from the Institute of Hydrobiology of Chinese Academy of Science in Wuhan, China. Organisms were cultured in Daphnia Culture Medium according to the parameters specified in OECD Guideline 202. Protocol for all testing followed OECD Guideline 202. Cladocerans were cultured in artificial freshwater maintained at 20 ± 1°C

NMED Exhibit 63



under a 16-hour:8-hour light:dark photoperiod and a light intensity of 1,000-1,500 lux at the surface of the water. Cultures were fed *Scenedesmus obliquus* daily and the water was changed twice weekly. Reported water quality parameters include total hardness of 140-250 mg/L as $CaCO_3$ and Ph of 6-8.5. Acute test concentrations included 0 (control), 0.000161, 0.000193, 0.000232, 0.000278, 0.000334 and 0.000401 mol/L (or 0 (control), 66.67, 79.92, 96.06, 115.1, 138.3 and 166.0 mg/L, respectively, given the molecular weight of the form of PFOA used in the study, CAS # 335-67-1, of 414.07 g/mol). Five neonates (12-24 hours old) were placed randomly in 100 Ml glass beakers filled with 60 Ml test solution, with four replicates per concentration. Organisms were observed for mortality at 48 hours, and the authors reported a LC_{50} of 0.000292 mol/L, or 120.9 mg/L PFOA. The EPA-calculated 48-hour LC_{50} was 117.192 mg/L (95% C.I. = 112.2 – 122.2 mg/L).

e	117.1921	4.8691	24.0685	$< 2.2\ e^{-16}$

Concentration-Response Model Fit:

Chen et al. (2022) tested the acute toxicity of ammonium perfluorooctanoic acid (APFO) to *Daphnia magna* in a 48-hour unmeasured, static experiment. In addition, the authors tested the acute effects of pristine and aged polystyrene particles, and the combined effects of these microplastics and AFPO, but only the results of the AFPO exposure are summarized here. AFPO (≥98% purity) was purchased from Shanghai Aladdin Biochemical Technology Co., Ltd., China. Organisms were purchased from Everbright Algae Species Co., China. They were housed in

NMED Exhibit 63

culture medium described in method OECD 202 (OECD 2004) at 20±1°C under a 12:12 light:dark cycle at 2000±200 lux. Culture medium was renewed twice a week, and organisms were fed green algae daily. The acute APFO exposure generally followed test method OECD 202 (OECD 2004). Stock solution of 50 g/L APFO was prepared by mixing the chemical with ultrapure laboratory water. For each replicate, 10 neonates were exposed to 50 Ml of test solutions with nominal concentrations of 0, 10, 50, 100, 200, and 500 mg/L APFO, made by diluting the stock solution with culture medium. There were three replicates per treatment, and test vessels were housed on a bath oscillator rotating at 150 rpm. Test organisms were not fed during the experiment. A reference toxicity test was performed with K_2CrO_7. Control mortality was less than 10% in the AFPO and reference toxicity tests. The LC_{50} and EC_{50} values were calculated using a logistic model in GraphPad Prism, version 9.2.0, and the 48-hour EC_{50} for immobility was 156.9 mg/L, which was determined to be acceptable for quantitative use.

A.2.5 Fifth most acutely sensitive genus – *Brachionus*

Zhang et al. (2013a) performed a 24-hour static test of PFOA (CAS # 335-67-1, 96% purity) with *Brachionus calyciflorus*. Organisms were neonates less than two-hours old at test initiation. All animals were parthenogenetically-produced offspring of one individual from a single resting egg collected from a natural lake in Houhai Park (Beijing, China). The rotifers were cultured in an artificial inorganic medium at 20°C (16-hour:8-hour, light:dark; 3,000 lux) for more than six months before toxicity testing to acclimate to the experimental conditions. All toxicity tests were carried out in the same medium and under the same conditions as during culture (i.e., Ph, temperature, illumination). Solvent-free stock solutions of PFOA (1,000 mg/L) were prepared by dissolving the solid in deionized water via sonication. After mixing, the primary stock was proportionally diluted with dilution water to prepare the test concentrations. Exposures were in 15 Ml, six-well cell culture plates (assumed plastic) each containing at total of

NMED Exhibit 63

10 Ml of test solution. The test employed seven measured test concentrations plus a negative control. Each treatment consisted of one replicate plate of 10 rotifers each in individual cells and repeated six times. Nominal concentrations were 0 (negative control), 60, 80, 100, 120, 140, 160, and 180 mg/L. PFOA concentrations were not measured in the rotifer exposures, but rather, in a side experiment using HPLC/MS. The side experiment showed that the concentration of PFOA measured every eight-hours over a 24-hour period in rotifer medium with green algae incurs minimal change in the concentration range from 0.25 to 2.0 mg/L. The acute test was conducted without green algae added to the exposure medium. Although this rotifer species has a short life span, a 24-hour unfed test is not expected to cause starvation and 0% mortality was observed at test termination in the negative control. The study reported 24-hour LC_{50} was 150.0 mg/L. The acute value was acceptable for quantitative use.

Publication: Zhang et al. (2013a)
Species: Rotifer (*Brachionus calyciflorus*)
Genus: *Brachionus*
EPA-Calculated LC_{50}: Not calculable, concentration-response data not available
Concentration-Response Model Fit: Not Applicable

A.2.6 Sixth and seventh most acutely sensitive genera – *Ligumia* and *Lampsilis* (mussels)

Hazelton (2013) and Hazelton et al. (2012) evaluated the acute effects of PFOA (96% purity) on two freshwater mussels: *Lampsilis siliquoidea* and *Ligumia recta*. Acute toxicity was observed under static conditions over a 24-hour period (<24-hour old glochidia) or renewal conditions over a 96-hour period (four to six-week-old juveniles). The authors stated that the tests followed ASTM E2455-06 (2006). Dilution water was hard reconstituted water. Photoperiod and light intensity were not reported. No details were provided regarding primary stock solution and test solution preparation. Experiments were conducted in 3.8 L glass jars of unspecified fill volume. The test employed three replicates of 150 glochidia or seven juvenile mussels each in six measured test concentrations plus a negative control (10 juveniles for the

NMED Exhibit 63

control treatment). Nominal concentrations were 0 (negative control), 0.005, 0.05, 0.5, 5, 50 and 500 mg/L, while corresponding mean measured concentrations were less than the limit of quantification (LOQ, specifics not provided), 0.0051, 0.0484, 0.490, 4.8, 51 and 476 mg/L PFOA, respectively. Analyses of test solutions were performed at the U.S. EPA National Exposure Research Laboratory in Research Triangle Park, NC using HPLC/MS. Measured test concentrations of PFOA were within 10% of target in water from acute tests. Recovery of PFOA standards ranged from 91.2-108%. For all acute tests, alkalinity ranged from 97 to 110 mg/L as $CaCO_3$ with a mean of 104.4 mg/L; total hardness ranged from 132 to 162 mg/L as $CaCO_3$ with a mean of 149.6 mg/L; conductivity ranged from 514 to 643 µS/cm with a mean of 556.5 µS/cm; Ph ranged from 8.05 to 8.56 with a mean of 8.46; and dissolved oxygen ranged from 8.16 to 9.46 mg/L with a mean of 8.62 mg/L (n = 12 for alkalinity and total hardness, n = 55 for all other parameters). Exposures were conducted at 20°C. Mortality of mussels in the negative control was <10% in all exposures. The 24-hour EC_{50} reported for glochidia of *L. siliquoidea* was 164.4 mg/L (95% C.I.: 116.0 – 232.8 mg/L) and for *L. recta*, 161.0 mg/L (95% C.I.: 135.0 – 192.7 mg/L). The 96-hour LC_{50} values for the juvenile *L. siliquoidea* and *L. recta* were greater than the highest test concentration (500 mg/L). The study reported 24-hour EC_{50}s for *L. siliquoidea* and for *L. recta* represent acute values acceptable for quantitative use for the two mussel species. The juvenile life stage is less sensitive, such that its LC_{50}s were not used quantitatively in SMAVs.

A.2.7 Eighth most acutely sensitive genus – *Xenopus*

Kim et al. (2013) conducted a 96-hour renewal unmeasured assay with perfluorooctanoic acid (PFOA) using the frog embryo teratogenesis assay – *Xenopus* (FETAX). PFOA stock solutions were prepared by dissolving PFOA in dimethyl sulfoxide (DMSO), and then diluting in FETAX medium for exposure solutions (DMSO did not exceed 0.15%). Adult *Xenopus* were purchased from Nasco (Fort Atkinson, WI) and housed in clear plastic aquariums with

NMED Exhibit 63

dechlorinated tap water at 18 ± 2°C with a 12-hour light cycle and fed three times a week. Ovulation was induced by injecting 1,000 IU of human chorionic gonadotropin just under the skin of a female in the evening. The next day, females laid eggs in 60 mm plastic dishes. The eggs were immediately fertilized in 0.1X modified Barth solution (MBS) (*Xenopus* testes were obtained from sacrificed males). Following successful fertilization, the jelly coat was removed by swirling the embryos in a 2% L-cysteine solution. The embryos were then transferred to 1X MBS containing 3% Ficoll 400. Unfertilized eggs and dead embryos were removed and maintained at 22 ± 0.5°C. Finely cleaved embryos in the blastula stage (stage 8.5) were selected, with 20-25 embryos used per concentration (nominal concentrations of 100, 500, 750, 1000 and 1,250 µM PFOA, or 41.4, 207.0, 310.6, 414.1 and 517.6 mg/L PFOA, respectively). DMSO alone (0.1%) and FETAX medium alone were used as controls. Embryos were incubated at 23°C until the end of the assay. The media were changed every day, and dead embryos were removed. At the end of the experiments, embryo mortality was recorded and surviving embryos were fixed in 4% formaldehyde to check for malformation. Head-tail lengths and malformations were analyzed to measure growth inhibition. The authors reported a 96-hour LC_{50} of 377 mg/L PFOA and the value was acceptable for quantitative use.

A.2.8 Ninth most acutely sensitive genus – *Dugesia*

Li (2008) conducted a 96-hour static, unmeasured acute toxicity test on PFOA (CAS # 3825-26-1, >98% purity) with the planarian, *Dugesia japonica* (a non-North American species). The test organisms were originally collected from Nan-shi stream located in Wu-lai, Taipei County, Taiwan in 2004 and maintained in the laboratory in dechlorinated tap water. The planarians had a body length of 0.9 ± 0.1 cm at test initiation. The dilution water was dechlorinated tap water and a primary stock solution of PFOA was prepared in the same dilution water. The photoperiod consisted of 12-hours of illumination at an unreported intensity.

NMED Exhibit 63

Exposure vessels were polypropylene beakers of unreported dimensions with a 50 Ml fill volume. The test employed five replicates of five planarians each in at least five test concentrations plus a negative control. Nominal test concentrations were in the range of 100-750 mg/L PFOA. The test temperature was maintained at 25 ± 1°C. No other water quality parameters were reported for test solutions. Survival of negative control animals was not reported. The study reported a 96-hour LC_{50} was 458 mg/L (95% C.I. = 427 – 491 mg/L). The acute value was acceptable for quantitative use.

Li (2009) conducted a second 96-hour static, unmeasured acute test of PFOA (ammonium salt, >98% purity) with *Dugesia japonica.* Again, the tested individuals were originally collected from Nan-shi stream located in Wu-lai, Taipei County, Taiwan in 2004 and maintained in the laboratory in dechlorinated tap water. The planarians had a body length of 0.9 ± 0.1 cm at test initiation. The dilution water was dechlorinated tap water and a primary stock solution of PFOA was prepared in the same dilution water. The photoperiod consisted of 12-hours of illumination at an unreported intensity. Exposure vessels were made of polyethylene with unreported dimensions and 50 Ml fill volume. The test employed three replicates of 10 planarians each in at least five test concentrations plus a negative control. The test was repeated three times with different test concentrations. Nominal test concentrations were in the range of 150-750 mg/L PFOA. The test temperature was maintained at 25 ± 2°C. Water quality parameters including Ph, conductivity, and D.O. were reported as having been measured at the beginning and end of each test, but the information was not provided. Organisms were not fed, and no mortality was observed in the control groups in any of the three tests. The author-reported 96-hour LC_{50} was 337 mg/L (95% C.I. = 318-357 mg/L) which was averaged across the three tests. The EPA performed C-R analysis for each individual test. Two of the tests had acceptable

NMED Exhibit 63

curves with the EPA-calculated LC_{50} values of 321.8 mg/L PFOA (95% C.I. = 290.6 – 353.1 mg/L) and 383.0 mg/L PFOA (95% C.I. = 347.8 – 418.2 mg/L) which were acceptable for quantitative use. The third curve had a poor concentration response and the LC_{50} (427.7 mg/L; 95% C.I. = 251.4 – 604.1 mg/L) was, therefore, not used quantitatively but considered for qualitative use only.

A.2.9 Tenth most acutely sensitive genus – *Neocaridina*

Li (2009) conducted a 96-hour acute test on PFOA (ammonium salt, >98% purity) with the freshwater shrimp species, *Neocaridina denticulata* (a non-North American species). Test conditions were static (no solution renewal), and test concentrations were unmeasured. Test organisms were obtained from an unspecified local supplier and acclimated in the laboratory for at least seven days prior to the experiments. *N. denticulata* of unspecified age were used at test initiation and were reported to be 1.3 ± 0.2 cm long. Dilution water was dechlorinated tap water. The photoperiod consisted of 12-hours of illumination at an unreported light intensity. A primary stock solution was prepared in dilution water. Exposure vessels were polypropylene beakers of unreported dimensions and 1 L fill volume. The test employed five replicates of six organisms each in at least five test concentrations plus a negative control. Each treatment was tested three different times. Nominal test concentrations were in the range of 50-1,000 mg/L PFOA. The test temperature was maintained at 25 ± 2°C. Water quality parameters including Ph, conductivity, and D.O. were reported as having been measured at the beginning and end of each test, but the information is not reported. Mortality of negative control animals was 10% for one treatment, but 0% in others. The author-reported 96-hour LC_{50} reported in the study was 454 mg/L (95% C.I.: 418-494 mg/L) which was averaged across three tests. The EPA performed C-R analysis for each individual test. All three tests had acceptable curves with the EPA-calculated LC_{50}s of 499.7

NMED Exhibit 63

mg/L (95% C.I. = 457.4 – 542.1 mg/L), 428.1 mg/L (95% C.I. = 396.3 – 459.9 mg/L), and 375.5 mg/L (95% C.I. = 296.5 – 454.4 mg/L), which were acceptable for quantitative use.

A.2.10 Eleventh most acutely sensitive genus – *Danio*

The acute effects of PFOA on the zebrafish, *Danio rerio*, have been reported by numerous researchers. **Ye et al. (2007)** evaluated the acute effects of perfluorooctanoic acid (PFOA, purity not reported) on *D. rerio* in a 96-hour static-renewal test with unmeasured treatment concentrations. The PFOA stock solution of 1,500 mg/L was maintained at a Ph of 8.2 with phosphate buffer and test substances were agitated in the reconstituted water by ultrasonification. The solutions were stored at 4 ± 1°C. No added solvents were used to formulate test concentrations from the stock solution. Test fish (AB strain) were obtained from the School of Life Sciences at Fandan University, Shanghai, China. Breeding fish (1.5 years old) were fed live brine shrimp twice daily and kept with a light:dark period of 14:10 in aquaria containing aerated natural water. The Ph ranged from 7 to 8.5 and water temperature was maintained at 26 ±1°C in test solutions. Embryos were obtained from spawning adults, usually five male and three female. For each toxicant concentration, 48 embryos were randomly distributed into each well of 24-well polystyrene multi-well plates, with four eggs per well. Each well was filled with 2.5 mL of test solution, which was totally renewed daily by transferring embryos in newly cleaned wells. Nominal exposure concentrations were 0 (control), 1.5, 45, 100, 400, 800 and 1,500 mg/L PFOA. The multi-well plates were kept at 26 ± 1°C, with a photoperiod of 16:8-hour light:dark. The observations of embryos were made at distinct stages, which represent important steps of zebrafish development. The author reported 96-hour LC_{50} was 499 mg/L PFOA. The EPA could not calculate an LC_{50} value because sufficient C-R data were not reported by Ye et al. (2007). The author-reported LC_{50} value (i.e., 499 mg/L) was acceptable for quantitative use in deriving the freshwater acute PFOA criterion.

NMED Exhibit 63

Hagenaars et al. (2011) exposed *D. rerio* embryos to PFOA (CAS #335-67-1, purity ≥97%) under static unmeasured conditions for 120 hours. The PFOA was dissolved in medium-hard reconstituted laboratory water, which was aerated and kept at 26°C until use (no solvent). Adult wildtype zebrafish (breeding stock) were obtained from a commercial supplier (Aqua hobby, Heist-op-den-berg, Belgium) and kept in aerated and biologically filtered medium-hard reconstituted freshwater. Four males and four females were used for egg production, with fertilized eggs collected in egg traps within 30 minutes of spawning. Eggs were transferred to the test solutions within 60 minutes after spawning. Eggs with anomalies or damaged membranes were discarded, and fertilized eggs were separated from the non-fertilized eggs using a stereomicroscope. Twenty normally shaped fertilized eggs per exposure concentration were divided over a 24-well plastic plate and each embryo was placed individually in 2 mL of the test solution. The remaining four wells were filled with clean water and used for the control eggs. Two replicate plates were used for each exposure concentration resulting in 40 embryos per exposure condition at the beginning of the experiment. The 24-well plates were covered with a self-adhesive foil, placed in an incubation chamber at 26 ± 0.3°C, Ph 7.2-7.5 and subjected to a 14-hour:10-hour, light:dark cycle. A test was considered valid if more than 90% of the controls successfully hatched and showed neither sublethal nor lethal effects. The authors reported a 96-hour LC_{50} of >500 mg/L PFOA and was classified as quantitative.

Zhao et al. (2016) performed a 96-hour static acute PFOA (98% purity; obtained from J&K Scientific) test on zebrafish, *D. rerio*. Authors stated that the test followed OECD Guideline 203. Zebrafish were obtained from Wuhan Institute of Hydrobiology at the Chinese Academy of Science. Test organisms were three months old and 2.5-3.0 cm in length at test initiation. The dilution water used for testing was not provided. Experiments were conducted in 5-liter glass fish

NMED Exhibit 63

tanks filled with three liters of solution. The photoperiod and preparation of test solutions was not described. The test involved 10 fish in five unmeasured test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 72.3, 86.8, 104.2, 125.0 and 150.0 mg/L. However, nominal concentrations of 50, 100, 200 mg/L PFOA were confirmed by HPLC in a side study without organisms. Measured concentrations in the side study were 80-120 percent of nominal. Test temperature was maintained at 23 ± 2°C, but other water quality parameters were not reported. There was no mortality in the negative control at the end of the exposure period. The author-reported 96-hour LC_{50} was 118.82 mg/L (95% C.I. = 107.46 – 134.33 mg/L). The EPA performed C-R analysis for the test and calculated an LC_{50} of 122.5 mg/L PFOA (95% C.I. = 119.1 – 125.8 mg/L), which was acceptable for quantitative use in deriving the acute PFOA freshwater criterion. *D. rerio* embryos (4 hours post-fertilization; hpf) were also subjected to PFOA by **Godfrey et al. (2017a)** in a 96-hour acute toxicity test using static renewal exposures that were not analytically confirmed. Stock solutions were prepared by dissolving PFOA in 1 L of reverse osmosis (RO) water containing 12.5 µL Replenish (Seachem Laboratories Inc.) and then adjusted to neutral Ph (7-7.5). Adult zebrafish, AB wild-type, were maintained at a water temperature of 28 ± 1°C and a photoperiod of 14-h L:10-h D. Fish were fed twice daily, *Artemia* nauplii in the morning and Tetramin in the afternoon, and genders were kept separate overnight at a ratio of 2 males:1 female. Randomly collected embryos (20 per concentration, gastrula stage, 4-hpf) were placed in plastic petri dishes containing 25 Ml of exposure solution for 96-hours at 28°C. Each test consisted of a minimum of two replicates per dose and test solutions were renewed daily (nominal exposure solutions ranged from 250-1,000 mg/L PFOA). The author-reported 96-hour LC_{50} was 473.0 mg/L PFOA which was averaged across four tests. The EPA performed C-R analysis for each individual test. Three tests had

NMED Exhibit 63

acceptable curves with the EPA-calculated LC_{50}s of 548.0 mg/L (95% C.I. = 530.6 – 565.5 mg/L), 508.5 mg/L (95% C.I. = 471.4 – 545.6 mg/L), and 547.0 mg/L (95% C.I. = 516.0 – 578.0 mg/L), which were acceptable for quantitative use. The fourth test had an unacceptable curve and therefore the EPA-calculated LC_{50} of 560.1 mg/L PFOA (95% C.I. = 556.4 – 563.8 mg/L) was not used.

Stengel et al. (2017, 2018) exposed *D. rerio* embryos to PFOA for 96-hours using renewal unmeasured procedures as specified in OECD (2013) guidelines. PFOA stock and exposure solutions were prepared in reconstituted laboratory water. All adult zebrafish used for breeding were wild-type descendants of the "Westaquarium" strain and obtained from the Aquatic Ecology and Toxicology breeding facilities at the University of Heidelberg. Details of zebrafish maintenance, egg production and embryo rearing are provided as described previously (Kimmel et al. 1995, 1988; Nagel 2002; Spence et al. 2006; Wixon 2000) and have been updated for the purpose of the zebrafish embryo toxicity test by Lammer et al. (2009). Embryos were exposed at the latest from 1 hpf in glass vessels, which had been preincubated (saturated) for at least 24 hours, to a series of nominal PFOA dilutions (0, 400, 512, 640, 800 and 1,000 mg/L). After verifying fertilization success, embryos were individually transferred to the wells of 24-well plates, which had been pre-incubated with 2 mL of the test solution per well for 24 hours prior to the test start and kept in an incubator at 26.0 ± 1.0°C under a 14-hour:10-hour light:dark regime. In order to prevent evaporation or cross-contamination between the wells, the plates were sealed with self-adhesive foil. Embryo tests were classified as valid if the mortality in the negative control was ≤10%, and if the positive control (3,4-dichloroaniline) showed mortalities between 20% and 80%. All fish embryo tests were run in three independent replicates. The author-reported 96-hour LC_{50} was 759 mg/L PFOA. The EPA performed C-R analysis for the

NMED Exhibit 63

test and had an acceptable curve with an EPA-calculated LC_{50} of 806.6 mg/L (95% C.I. = 773.6 – 839.6 mg/L) and was determined to be quantitatively acceptable for criterion derivation.

Corrales et al. (2017) exposed *D. rerio* embryos to PFOA for 96-hours employing static unmeasured procedures (U.S. EPA 2002, OECD 2013). Tropical 5D wild type adult zebrafish were kept at a density of less than four fish per liter in a z-mod recirculating system with water (Ph 7.0, 260 ppm Instant Ocean) maintained at 26-28°C and a 16-hour:8-hour light/dark cycle. Zebrafish were fed twice daily with brine shrimp (*Artemia sp*. Nauplii) and once per day with TetraMin Tropical Flakes. Sexually mature fish were bred to produce embryos for toxicity studies. Glass beakers were used as experimental units; 15 zebrafish embryos in 100 Ml beakers containing 30 ml test solution. Before the start of each experiment, all solutions were titrated to Ph 7.5 following standard methods. General water chemistry measures (e.g., alkalinity, total hardness, dissolved oxygen, and temperature) were also routinely monitored (assume same culture and test physico-chemical test conditions). The author-reported 96-hour LC_{50} was 24.6 mg/L PFOA. The EPA-calculated LC_{50} was 22.77 mg/L PFOA (95% C.I. = 13.30 – 32.20 mg/L), which was acceptable for quantitative use. This LC_{50} value, however, was excluded from derivation of the acute criterion because a comparative assessment between this LC_{50} value and the other seven quantitatively-acceptable zebrafish LC_{50} values available (Ye et al. 2007; Zhao et al. 2016; Godfrey et al. 2017a; Hagenaars et al. 2011; Stengel et al. 2017, 2018), indicated that the LC_{50} reported by Corrales et al. (2017) was an outlier, falling out more than five times lower than the next lowest *D. rerio* LC_{50} value (Zhao et al. 2016) and nearly 20 times lower than the final *D. rerio* SMAV.

A.2.11 Twelfth most acutely sensitive genus – *Pimephales*

The **3M Company (2000a)** conducted a 96-hour static, unmeasured acute toxicity test with the fathead minnow, *Pimephales promelas*, and PFOA (CAS # 335-67-1). The toxicant was

NMED Exhibit 63

part of the 3M production and was characterized as a mixture of PFOA (95-98% of the compound) and perfluorochemical inert compounds (1-5% of the compound). No specific test protocol was identified. A stock of PFOA was made by dissolving the test substance with NaOH and diluting the stock with carbon-filtered well water to make five test concentrations (690, 750, 810, 870 and 930 mg/L) plus a control (well water only). Exposures were conducted in glass beakers with 5 L of test solution and five fish per beaker (0.5 g/L fish loading). There were two replicates for each treatment. Test conditions throughout the experiment varied little (D.O.: 6.1-7.7 mg/L; Ph: 7.5-7.7; 19-20℃). No mortality occurred in the control and PFOA treatments ≤750 mg/L. The author-reported 96-hour LC_{50} was 843 mg/L. The EPA performed C-R analysis for the test. The EPA-calculated LC_{50} was 852.7 mg/L PFOA (95% C.I. = 834.4 – 870.9 mg/L), which was acceptable for quantitative use and was used for criterion derivation.

Corrales et al. (2017) also evaluated the acute toxicity of PFOA to the fathead minnow (*Pimephales promelas*). Embryos were exposed to PFOA for 96-hours employing static unmeasured procedures (U.S. EPA 2002, OECD 2013). Fish were housed in a flow-through system supplied with aged, dechlorinated tap water at a constant temperature of 25 ±1°C under a 16-hour:8-hour light/dark photoperiod. They were fed twice daily with brine shrimp (*Artemia sp*. Nauplii) and TetraMin Tropical Flakes. Individuals were aged to at least 120 days before breeding at which time they were placed in tanks in a 1:4-5 male to female ratio. Embryos were collected, and within 24 hours post hatched larvae were used for toxicity studies. Glass beakers were used as experimental units; 10 fathead minnow larvae were placed in each 500 Ml beaker containing 200 ml test solution. Before the start of each experiment, all solutions were titrated to Ph 7.5 following standard methods. General water chemistry measures (e.g., alkalinity, total hardness, dissolved oxygen, and temperature) were also routinely monitored (assume same

NMED Exhibit 63

culture and test physico-chemical test conditions). The reported 96-hour LC_{50} was 413.2 mg/L PFOA and was determined to be quantitatively acceptable for criterion derivation.

A.2.12 Thirteenth most acutely sensitive genus – *Hyla*

Tornabene et al. (2021) conducted an acute PFOA (purchased from Sigma Aldrich, Catalog # 171468-25G; purity not provided) toxicity test with the gray treefrog, *Hyla versicolor*. The acute test followed standard 96-hour acute toxicity test guidance (U.S. EPA 2002; ASTM 2017). Frog egg masses were collected from the field in the wetlands of Indiana near the campus of Purdue University. Collected egg masses were raised outdoors in 200 L polyethylene tanks filled with well water. Experiments began when frogs reached Gosner stage 26, defined as when larvae are free swimming and feeding. Before test initiation larvae were acclimated to test conditions (21℃ and 12-hour:12-hour light:dark photoperiod) for 24 hours. A stock solution of PFOA (2,000 mg/L) was made in UV-filtered well water and diluted with well water to reach test concentrations (ranged from 0-2,000 mg/L PFOA). Test concentrations were not measured in test solutions based on previous research that demonstrated limited degradation under similar conditions. Larva were transferred individually to 250 Ml plastic cups with 200 Ml of test solution and were not fed during the exposure period. There were nine to 10 replicates for each treatment and no mortality occurred in the controls. The author reported 96-hour LC_{50} was 557 mg/L and the EPA-calculated 96-hour LC_{50} values was 646.2 mg/L (95% C.I. = 588.0 – 704.4 mg/L), which was acceptable for quantitative use. Note, the authors also reported a qualitatively acceptable test for the same species (Gosner stage 40) that is described in Table G.1.

A.2.13 Fourteenth most acutely sensitive genus – *Lepomis*

The **DuPont Haskell Laboratory (2000)** evaluated the acute toxicity of ammonium perfluorooctanoate (APFO, 99% purity) to the bluegill sunfish, *Lepomis macrochirus*. The static unmeasured GLP study exposed 2.1 cm fish for 96 hours (dilution water not identified). Fish

NMED Exhibit 63

used in this study were not fed approximately 24-hours prior to and during the test. Bluegill sunfish were assigned to the test chambers using random numbers. Nominal APFO concentrations were 262, 328, 410, 512, 640, 800 and 1,000 mg/L. Glass aquaria (20L) containing 10 L of test solution were employed. Positions of test chambers in the water bath used to maintain constant temperature were assigned using random numbers. Ten fish were added to each replicate using random numbers (2 replicates per concentration; total 20 fish per concentration). A photoperiod of 16 hours light (312-344 lux) versus eight hours darkness was employed with 25 minutes of transitional light (<2.15 lux) preceding and following the 16-hour light interval. Observations for mortality and behavioral effects were made daily. All chemical and physical parameters were within expected ranges. Total alkalinity and EDTA total hardness of the dilution water control were 79 mg/L $CaCO_3$ and 76 mg/L $CaCO_3$, respectively. During the test, dissolved oxygen concentrations ranged from 6.7-8.5 mg/L, Ph ranged from 6.9-7.4, and temperature ranged from 21.4-22.1°C. No fish died in the controls. The authors reported a 96-hour LC_{50} of 634 mg/L APFO. The EPA performed C-R analysis for the test and had an acceptable curve with an EPA-calculated LC_{50} of 664.0 mg/L (95% C.I. = 631.4 – 696.7 mg/L), which was determined to be quantitatively acceptable for criterion derivation.

A.2.14 Fifteenth most acutely sensitive genus – *Physella*

Li (2009) conducted a 96-hour static unmeasured acute test on PFOA (ammonium salt, >98% purity) with the snail species, *Physella acuta* (Note: formerly called *Physa acuta*). The test organisms were collected from a ditch located in Shilin of Taipei City in June 2005. Snails were fed with lettuce and half of the culture medium was changed with dechlorinated water every two weeks, implying a holding time of greater than two weeks. Snails of mixed ages (shell length 0.6 ± 0.2 cm) were used at test initiation. The dilution water was dechlorinated tap water, and a primary stock solution of PFOA was prepared in the same dilution water. The photoperiod

NMED Exhibit 63

consisted of 12-hours of illumination at an unreported intensity. Exposure vessels were made of polyethylene with unreported dimensions and 1 L fill volume. The test employed five replicates of six snails each in at least five test concentrations plus a negative control. Nominal test concentrations were in the range of 100-1,000 mg/L PFOA. The test temperature was maintained at 25 ± 2°C. Water quality parameters including pH, conductivity, and D.O. were reported as having been measured at the beginning and end of each test, but the information is not reported. Organisms were not fed, and no animals died in the control groups. The author-reported 96-hour LC_{50} was 672 mg/L (95% C.I.: 635-711 mg/L) which was averaged across three tests. The EPA performed C-R analysis for each individual test. All three tests had acceptable curves with the EPA-calculated LC_{50}s of 762.0 mg/L (95% C.I. = 706.1 – 817.9 mg/L), 659.9 mg/L (95% C.I. = 607.9 – 711.8 mg/L), and 628.3 mg/L (95% C.I. = 582.9 – 673.7 mg/L), which were acceptable for quantitative use.

A.2.15 Sixteenth most acutely sensitive genus – *Ambystoma*

Tornabene et al. (2021) conducted acute toxicity tests with three species of salamanders in the genus *Ambystoma* and PFOA (purchased from Sigma Aldrich, Catalog # 171468-25G; purity not provided). Acute tests followed standard 96-hour acute toxicity test guidance (U.S. EPA 2002; ASTM 2017). The three test species (Jefferson salamander, *Ambystoma jeffersonianum*; small-mouthed salamander, *A. texanum*; eastern tiger salamander, *A. tigrinum*) were collected from the field in the wetlands of Indiana near the campus of Purdue University. Collected egg masses were raised outdoors in 200 L polyethylene tanks filled with well water. Experiments began when salamanders reached Harrison stage 40, defined as when larvae are free swimming and feeding. Before test initiation larvae were acclimated to test conditions (21°C and 12-hour:12-hour light:dark photoperiod) for 24 hours. An additional acute test with Harrison stage 45 small-mouthed salamanders was run to determine if toxicity varied between life stages.

NMED Exhibit 63

A stock solution of PFOA (2,000 mg/L) was made in UV-filtered well water and diluted with well water to reach test concentrations (ranged from 0-2,000 mg/L PFOA). Test concentrations were not measured in test solutions based on previous research that demonstrated limited degradation under similar conditions. Larva were transferred individually to 250 Ml plastic cups with 200 Ml of test solution and were not fed during the exposure period. The number of replicates varied by species, life stage and treatment; five replicates per treatment for Jefferson salamander and Harrison stage 45 small-mouthed salamander, five to seven replicates per treatment for Harrison stage 40 small-mouthed salamander, and 20 replicates in the control and 10 replicates in each treatment for eastern tiger salamander. Only one salamander larva died in the controls across all tests (eastern tiger salamander test). acute values from the four tests include:

- **Jefferson salamander**: The author-reported 96-hour LC_{50} was 1,070 mg/L. The EPA was unable to fit a C-R model with significant parameters and relied on the author reported value as quantitatively acceptable.
- **Harrison stage 40 small-mouthed salamander**: The author-reported 96-hour LC_{50} was 474 mg/L. The EPA-calculated LC_{50} was 407.3 mg/L (95% C.I. = 303.7 – 0.510.9 mg/L), which was acceptable for quantitative use.
- **Harrison stage 45 small-mouthed salamander**: The author-reported 96-hour LC_{50} was 1,000 mg/L. The EPA was unable to fit a C-R model with significant parameters and relied on the author-reported value as quantitatively acceptable; however, the LC_{50} from this test was more than two times greater than the Harrison stage 40 small-mouthed salamander indicating the Harrison stage 45 was a relatively tolerant life stage. As a result, the LC_{50} from this test was not used in the SMAV calculation for *A. texanum*.
- **Eastern tiger salamander**: The author-reported 96-hour LC_{50} was 752 mg/L. Concentration-response data from this test lacked partial effects and the EPA was

NMED Exhibit 63

unable to fit a C-R model with significant parameters and relied on the author reported value as quantitatively acceptable.

A.2.16 Seventeenth most acutely sensitive genus – *Anaxyrus*

Tornabene et al. (2021) conducted acute PFOA (purchased from Sigma Aldrich, Catalog # 171468-25G; purity not provided) toxicity tests with the American toad, *Anaxyrus americanus*. The acute tests followed standard 96-hour acute toxicity test guidance (U.S. EPA 2002; ASTM 2017). The toad egg masses were collected from the field in the wetlands of Indiana near the campus of Purdue University. Collected egg masses were raised outdoors in 200 L polyethylene tanks filled with well water. Experiments began when frogs reached Gosner stage 26, defined as when larvae are free swimming and feeding. An additional acute test with Gosner stage 41 was conducted to determine if toxicity varied between life stages. Before test initiation larvae were acclimated to test conditions (21℃ and 12-hour:12-hour light:dark photoperiod) for 24 hours. A stock solution of PFOA (2,000 mg/L) was made in UV-filtered well water and diluted with well water to reach test concentrations (ranged from 0-2,000 mg/L PFOA). Test concentrations were not measured in test solutions based on previous research that demonstrated limited degradation under similar conditions. Larva were transferred individually to 250 Ml plastic cups with 200 Ml of test solution and were not fed during the exposure period. The number of replicates varied by treatment for both tests; 10 replicates for each treatment except the 1,750 mg/L PFOA exposure which had nine replicates. No mortality occurred in any of the control groups. The authors did not find a significant difference between the life stages of the American toad, so results of the two tests were pooled to determine the 96-hour author-reported LC_{50} of 711 mg/L. The EPA-calculated 96-hour LC_{50} value was 781.4 mg/L (95% C.I. = 748.3 – 814.4 mg/L) for the Gosner stage 26 test and was 806.6 (95% C.I. = 760.6 – 852.6 mg/L) mg/L for the Gosner stage 41 test, both of which were quantitatively acceptable for use.

NMED Exhibit 63

A.2.17 Eighteenth most acutely sensitive genus – *Lithobates*

Flynn et al. (2019) evaluated the acute effects of PFOA (CAS# 335-67-1, purchased from Sigma-Aldrich) on the American bullfrog (*Lithobates catesbeiana*, formerly, *Rana catesbeiana*) during a 96-hour static unmeasured study. Testing followed Purdue University's Institutional Animal Care and Use Committee Guidelines Protocol #16010013551. American bullfrog eggs were taken from a permanent pond in the Martell Forest outside of West Lafayette, Indiana. The eggs from a single egg mass were acclimated in 100 L outdoor tanks filled with 70 L of aged well water and covered with a 70% shade cloth. Once hatched, tadpoles were fed rabbit chow and TetraMin *ad libitum* and were acclimated to laboratory conditions for 24 hours before testing (21ºC and a 12-hour:12-hour light:dark photoperiod). A 2,000 mg/L PFOA stock solution was prepared with reverse osmosis water to produce 12 nominal test concentrations of PFOA [0 (control), 10, 100, 250, 500, 750, 1,000, 1,250, 1,500, 1,750, 2,000 and 2,500 mg/L]. Each test treatment contained 10 replicates with one Gosner Stage 25 tadpole in each 250 Ml plastic tub. Mortality was monitored twice daily. The author reported a 96-hour LC_{50} value of 1,004 mg/L PFOA. The EPA performed C-R analysis for the test and the EPA-calculated 96-hour LC_{50} was 1,006 mg/L (95% C.I. = 992.8 – 1,018 mg/L).

Tornabene et al. (2021) conducted acute PFOA (purchased from Sigma Aldrich, Catalog # 171468-25G; purity not provided) toxicity tests with four species of frogs in the genus *Lithobates* (formerly, *Rana*). Acute tests followed standard 96-hour guidance (U.S. EPA 2002; ASTM 2017). The four test species (American bullfrog, *Lithobates catesbeiana*; green frog, *L. clamitans*; northern leopard frog, *L. pipiens*; wood frog, *L. sylvatica*) were collected from a field in the wetlands of Indiana near the campus of Purdue University. Collected egg masses were raised outdoors in 200 L polyethylene tanks filled with well water. Experiments began when frogs reached Gosner stage 26, defined as when larvae are free swimming and feeding. Before

NMED Exhibit 63

test initiation larvae were acclimated to test conditions (21℃ and 12-hour:12-hour light:dark photoperiod) for 24 hours. A stock solution of PFOA (2,000 mg/L) was made in UV-filtered well water and diluted with well water to reach test concentrations (ranged from 0-2,000 mg/L PFOA). Test concentrations were not measured in test solutions based on previous research that demonstrated limited degradation under similar conditions. Larva were transferred individually to 250 mL plastic cups with 200 mL of test solution and were not fed during the exposure period. The number of replicates varied by species and treatment; 30 replicates in the control and five to 20 replicates in each treatment for American bullfrog, 10 replicates for each treatment for green frog, northern leopard frog and wood frog. No mortality occurred in any of the control groups. Acute values from the four tests include:

- **American bullfrog**: The author-reported 96-hour LC_{50} was 1,060 mg/L. The EPA-calculated LC_{50} was 1,035 mg/L (95% C.I. = 1,020 – 1,049 mg/L), which was acceptable for quantitative use.
- **Green frog**: The author-reported 96-hour LC_{50} was 1,070 mg/L. The EPA was unable to fit a C-R model with significant parameters and relied on the author reported value as quantitatively acceptable.
- **Northern leopard frog**: The author-reported 96-hour LC_{50} was 752 mg/L. The EPA-calculated LC_{50} was 751.7 mg/L (95% C.I. = 713.0 – 790.5 mg/L), which was acceptable for quantitative use.
- **Wood frog**: The author-reported 96-hour LC_{50} was 999 mg/L. The EPA was unable to fit a C-R model with significant parameters and relied on the author reported value as quantitatively acceptable.

A.2.18 Nineteenth most acutely sensitive genus – *Oncorhynchus*

The acute effects of ammonium perfluorooctanoate (APFO, 99.4% purity) to *Oncorhynchus mykiss* were investigated by researchers at the **DuPont Haskell Laboratory (2000)**. The static measured GLP study exposed 2.8 cm fish for 96-hours (dilution water not

NMED Exhibit 63

identified). Rainbow trout used in this study were not fed approximately 29-hours prior to and during the test. Rainbow trout were assigned to the test chambers using random numbers. The addition of fish to the test solutions was initiated approximately 41 minutes after test solution mixing was completed. Mean measured concentrations of ammonium perfluorooctanoate were 554, 1,090, 2,280, 4,560 and 9,360 for the 625, 1,250, 2,500, 5,000 and 10,000 mg/L nominal dose levels, respectively (measured directly by high performance liquid chromatography/tandem mass spectrometry). Control solutions showed no detectable concentrations of ammonium perfluorooctanoate. All test substance solutions were clear and colorless with no insoluble test substance present during the test. Test chambers were stainless steel aquaria that held approximately 9 L of test solution. Two replicate test chambers were used per test concentration with 10 fish in each chamber (total of 20 fish per concentration). Each chamber was covered with a glass plate to prevent fish from escaping. Mortality and behavioral observations were made at test start, every 24-hours thereafter, and at test end. All chemical and physical parameters for the definitive test were within expected ranges. Total alkalinity and EDTA total hardness of the dilution water control were 49 mg/L $CaCO_3$ and 122 mg/L $CaCO_3$, respectively. During the test, dissolved oxygen concentrations ranged from 7.5-11.2 mg/L, pH ranged from 7.1-7.2, and mean temperature was 11.8°C (range 11.6-12.1°C). A photoperiod of 16 hours light (approximately 199-450 lux) and eight hours darkness was employed, which included 30 minutes of transitional light (11-157 lux) preceding and following the 16-hour light interval. The authors reported a 96-hour LC_{50} of 4,001 mg/L APFO and no mortality or sublethal effects were observed at concentrations ≤2,500 mg/L APFO. Unlike Colombo et al. (2008), DuPont Haskell Laboratory (2000) did not observe any ammonia toxicity resulting from the APFO test salt, perhaps a result of the relatively lower pH and temperature used by DuPont Haskell Laboratory

NMED Exhibit 63

(2000), which decreased the proportion of un-ionized ammonia. Results of this study were considered quantitatively acceptable for use in criterion derivation.

Appendix B Acceptable Estuarine/Marine Acute PFOA Toxicity Studies

B.1 Summary Table of Acceptable Quantitative Estuarine/Marine Acute PFOA Toxicity Studies

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Effect	Author Reported Effect Conc. (mg/L)	EPA Calculated Effect Conc. (mg/L)	Final Effect Conc. (mg/L)[e]	Species Mean Acute Value (mg/L)	Reference
Purple sea urchin (embryo), *Strongylocentrotus purpuratus*	S, M	96 hours	PFOA 95%	-	15	30	EC50 (normal development)	19	20.63	**20.63**	20.63	Hayman et al. 2021
Mediterranean mussel (larva), *Mytilus galloprovincialis*	S, U	48 hours	PFOA Unreported	7.9-8.1	16	36	EC50 (malformation)	>1	-	>1[c]	-	Fabbri et al. 2014

NMED Exhibit 63

B.2 Detailed Study Summaries of Acute Saltwater PFOA Toxicity Studies Considered for Use in Saltwater Criterion Derivation

The purpose of this section is to present detailed study summaries for acute estuarine/marine tests that were considered quantitatively acceptable for criterion derivation, with summaries grouped and ordered by genus sensitivity. Unlike Appendix A.2 and Appendix C.2, the EPA-calculated C-R models were not presented below for the four most sensitive estuarine/marine genera because an estuarine/marine criterion was not developed exclusively based on these empirical data. Rather, an estuarine/marine benchmark was derived using a NAM, which is further described in Appendix L.

B.2.1 Most acutely sensitive estuarine/marine genera – *Siriella* (mysid)

Mhadhbi et al. (2012) performed a 96-hour static, unmeasured acute test with PFOA (96% purity) on the mysid, *Siriella armata*. A stock solution of PFOA was made either with filtered sea water from the Ria of Vigo (Iberian Peninsula) for low exposure concentrations, or with DMSO for high PFOA concentrations (a final maximum DMSO concentration of 0.01% (v/v) in the test medium). However, the authors do not indicate what is considered a high-test concentration, so it is unclear which test concentrations actually used DMSO as a solvent. If DMSO was used, a solvent control was also included. Mysids were exposed to one of ten nominal PFOA treatments (0.1, 0.5, 1, 2, 5, 10, 20, 30, 40 and 80 mg/L). Mysids were also collected from the same source as the dilution water and quarantined before use in 100 L plastic tanks with circulating sand-filtered seawater. The adult stock was fed daily and maintained at laboratory conditions (17-18°C, salinity between 34.4-35.9 ppt, and oxygen 6 mg/L). Twenty neonates (<24-hours old) were used per each treatment. To prevent cannibalism, a single individual was added to each glass vial with 2-4 Ml of test solution. Vials were incubated at 20°C with a 16-hour light period. Neonates were fed 10-15 *Artemia salina* nauplii daily and

NMED Exhibit 63

mortality was recorded after 96 hours. The 96-hour LC_{50} reported in the study was 15.5 mg/L PFOA and was acceptable for quantitative use.

B.2.2 Second most acutely sensitive estuarine/marine genus – *Mytilus* (mussel)

The acute toxicity of perfluorooctanoic acid (PFOA, purity not provided) on the Mediterranean mussel, *Mytilus galloprovincialis,* which occurs in California and other parts of the Pacific Northwest (Green 2014), was evaluated by **Fabbri et al. (2014)**. Sexually mature mussels were purchased from an aquaculture farm in the Ligurian Sea (La Spezia, Italy) and held for two days for gamete collection. Gametes were held in artificial sea water (ASW) made of analytical grade salts and at a constant temperature of 16 ± 1°C. It is assumed that the gametes were held at the same environmental conditions as the adults, so test salinity was assumed to be 36 ppt with a Ph of 7.9-8.1. Embryos were transferred to 96-well microplates with a minimum of 40 embryos/well. Each treatment had six replicates. Embryos were incubated with a 16-hour:8-hour light:dark photoperiod and exposed to one of six nominal PFOA concentrations (0.00001, 0.0001, 0.001, 0.01, 0.1 and 1 mg/L) or controls. The PFOA stock was made with ethanol, and ASW control samples run in parallel. This included ethanol at the maximal final concentration of 0.01%. Each experiment was repeated four times. At test termination (48 hours), the endpoint was the percentage of normal D-larvae in each well, including malformed larvae and pre-D stages. The acceptability of test results was based on controls for a percentage of normal D-shell stage larvae of >75% (ASTM 2004). Authors noted that controls had ≥80% normal D-larvae across all tests. PFOA was only measured once in one treatment which was similar to the nominal concentration, 0.000081 mg/L versus the nominal concentration of 0.0001 mg/L. PFOA was below the limit of detection in the control ASW (0.04 ng/L). The percentage of normal D-larva decreased with increasing test concentrations. The NOEC and LOEC reported for the study were 0.00001 and 0.0001 mg/L, respectively. However, the test concentrations failed to elicit

NMED Exhibit 63

50% malformations in the highest test concentration, and an EC_{50} was not determined. Therefore, the EC_{50} for the study was greater than the highest test concentration (1 mg/L). The 48-hour EC_{50} based on malformation of >1 mg/L was acceptable for quantitative use.

Hayman et al. (2021) report the results of a 48-hour static, measured test on the effects of PFOA (CAS # 335-67-1, 95% purity, purchased from Sigma-Aldrich, St. Louis, MO) on the Mediterranean mussel, *Mytilus galloprovincialis*. The authors note that the tests followed U.S. EPA (1995b) and ASTM (2004) protocols. Mussels were collected in the field (Sand Diego Bay, CA) and conditioned in a flow-through system at 15℃. Mussels were induced to spawn by heat-shock and approximately 250 embryos (2-cell stage) were added to 20 Ml borosilicate glass scintillation vials with 10 Ml of test solution. There were five replicates per test concentration. Test conditions were 30 ppt, 15℃ and a 16-hour:8-hour light:dark photoperiod. Six test solutions were made in 0.45 µm filtered seawater (North San Diego Bay, CA) with PFOA dissolved in methanol. The highest concentration of methanol was 0.02% (v/v). Measured test concentrations ranged from 1.5-52 mg/L. Controls were made in the same seawater and the acute test also included a solvent control. At test termination (48 hours), larvae were enumerated for total number of larvae that were alive at the end of the test (normally or abnormally developed) as well as number of normally-developed (in the prodissoconch "D-shaped" stage) larvae. There were no significant differences between solvent control and filtered seawater, suggesting no adverse effects of methanol. The author reported 48-hour EC_{50}, based on normal survival larvae, was 9.98 mg/L PFOA. The EPA-calculated 48-hour EC_{50} value was 17.58 mg/L (95% C.I. = 13.73 – 21.43 mg/L), which was acceptable for quantitative use.

B.2.3 Third most acutely sensitive estuarine/marine genus – *Strongylocentrotus* (sea urchin)

Hayman et al. (2021) report the results of a 96-hour static, measured test on the effects of PFOA (CAS # 335-67-1, 95% purity, purchased from Sigma-Aldrich, St. Louis, MO) on the

NMED Exhibit 63

purple sea urchin, *Strongylocentrotus purpuratus*. The authors noted that tests followed U.S. EPA (1995b) and ASTM (2004) protocols. Sea urchins were collected in the field (Sand Diego Bay, CA) and conditioned in a flow-through system at 15°C. They were induced to spawn by KCl injection and approximately 250 embryos (2-cell stage) were added to 20 Ml borosilicate glass scintillation vials with 10 Ml of test solution. There were five replicates per test concentration. Test conditions were 30 ppt, 15°C and a 16-hour:8-hour light:dark photoperiod. Six test solutions were made in 0.45 µm filtered seawater (North San Diego Bay, CA) with PFOA dissolved in methanol. The highest concentration of methanol was 0.02% (v/v). Measured test concentrations ranged from 1.5-52 mg/L. Controls were made in the same seawater and the acute test also included a solvent control. At test termination (96 hours), the first 100 larvae were enumerated and observed for normal development (four-arm pluteus stage). There were no significant differences between solvent control and filtered seawater, suggesting no adverse effects of methanol. The author reported 96-hour EC_{50}, based on normal development, was 19 mg/L PFOA. The EPA-calculated 96-hour EC_{50} value was 20.63 mg/L (95% C.I. = 19.74 – 21.52 mg/L), which was acceptable for quantitative use.

B.2.4 Fourth most acutely sensitive estuarine/marine genus – *Americamysis* (mysid)

Hayman et al. (2021) conducted a 96-hour static, measured test to assess effects of PFOA (CAS # 335-67-1, 95% purity, purchased from Sigma-Aldrich, St. Louis, MO) on the mysid, *Americamysis bahia*. The authors noted that tests followed U.S. EPA (2002) protocols. Mysids were purchased from a commercial supplier (Aquatic Research Organisms, Hampton, NH) and acclimated to test conditions (30 ppt, 20°C and a 16-hour:8-hour light:dark photoperiod). Six test solutions were made in 0.45 µm filtered seawater (North San Diego Bay, CA) with PFOA dissolved in methanol. The highest concentration of methanol was 0.02% (v/v). Measured test concentrations ranged from 1.1-29 mg/L. The highest test concentration (61.7

NMED Exhibit 63

mg/L) was reported as nominal only because the sample was mistakenly not sent to the lab for verification. Controls were made in the same seawater and the acute test also included a solvent control. Five mysids (three-days old) were added to 120 Ml polypropylene cups and 100 Ml of test solution with six replicates per treatment. Living mysids were counted and dead organisms were removed daily. There were no significant differences between solvent control and filtered seawater, suggesting no adverse effects of methanol. No organisms were found dead in the controls at test termination. The EPA was unable to fit a concentration-response model with significant parameters and relied on the author-reported 96-hour LC_{50} of 24 mg/L PFOA as the quantitatively acceptable acute value.

NMED Exhibit 63

Appendix C Acceptable Freshwater Chronic PFOA Toxicity Studies

C.1 Summary Table of Acceptable Quantitative Freshwater Chronic PFOA Toxicity Studies

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Chronic Value Endpoint	Author Reported Chronic Value (mg/L)	EPA Calculated Chronic Value (mg/L)	Final Chronic Value (mg/L)[c]	Species Mean Chronic Value (mg/L)	Reference

C.2 Detailed PFOA Chronic Toxicity Study Summaries and Corresponding Concentration-Response Curves (when calculated)

The purpose of this section is to present detailed study summaries for tests that were considered quantitatively acceptable for criteria derivation, with summaries grouped and ordered by genus sensitivity. C-R models developed by the EPA that were used to determine chronic toxicity values used for criterion derivation are also presented. C-R models included here with study summaries were those for the four most sensitive genera. In many cases, authors did not report concentration-response data in the publication/supplemental materials and/or did not provide concentration-response data upon request by the EPA. In such cases, the EPA did not independently calculate toxicity values and the author-reported effect concentrations were used to derive the criterion.

C.2.1 Most chronically sensitive genus – *Hyalella*

Bartlett et al. (2021) evaluated the chronic effects of PFOA (CAS# 335-67-1, 96% purity, solubility in water at 20,000 mg/L, purchased from Sigma-Aldrich) on *Hyalella azteca* via a 42-day static-renewal, measured study. Methods for this study were adapted from Borgmann et al. (2007), and organisms were two to nine days old at the test initiation. Experiments were conducted in standard artificial media with water quality characteristics of 52 to 60 mg/L alkalinity as $CaCO_3$, average specific conductivity of 0.41 Ms/cm, dissolved oxygen of 5.2 to 8.8 mg/L, total hardness of 120 to 140 mg/L $CaCO_3$, average Ph of 8.1 and average temperature of 25ºC. A 100 mg/L stock solution was prepared to yield measured test concentrations of 0 (control), 0.84, 3.3, 8.9, 29 and 97 mg/L PFOA. Two separate tests were performed with five replicates per concentration and 20 amphipods per replicate in 2-L HDPE containers filled with 1 L of testing solution, 2.5 mg of ground TetraMin and one piece of 5x5 cm cotton gauze. Test organisms were fed 2.5 mg TetraMin three times a week during weeks one

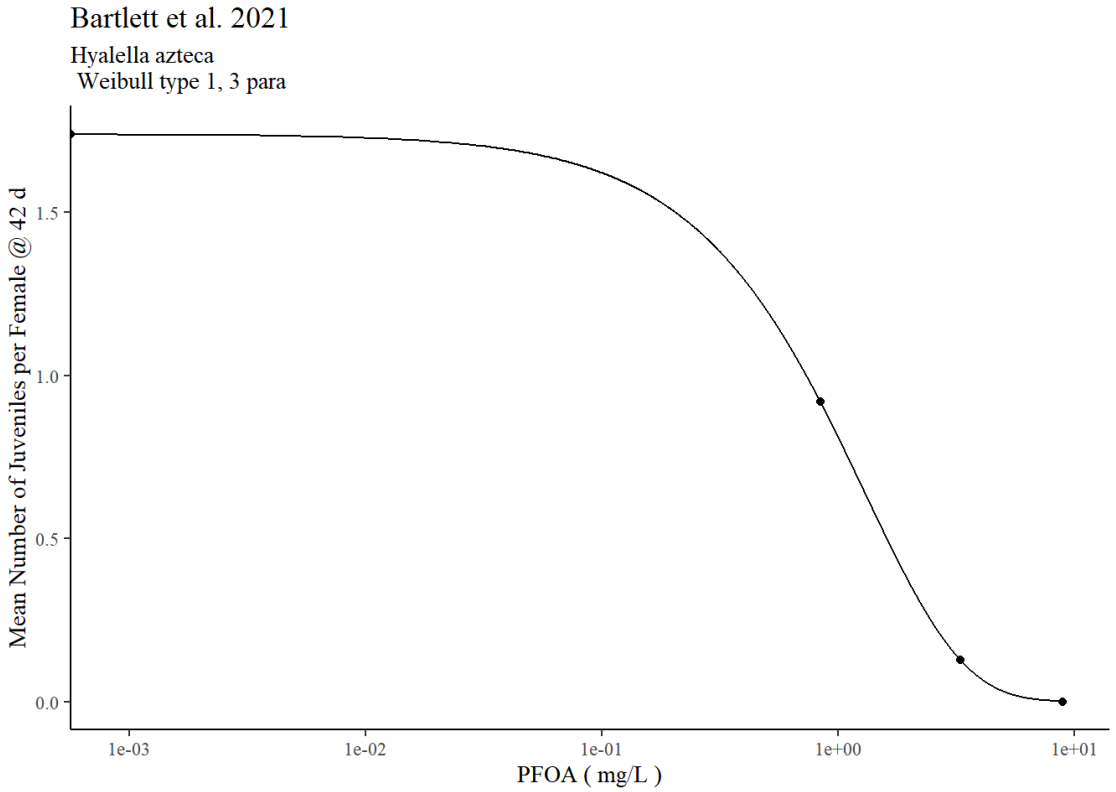
NMED Exhibit 63

and two, 5 mg TetraMin three times a week during weeks three and four, and 5 mg TetraMin five times a week during weeks five and six. At test termination (day 42), adults were sexed and weighed, as well as their young counted. The 42-day author-reported LC_{10} value for survival was 23.2 mg/L PFOA. The author-reported EC_{10} values for growth and reproduction were 0.160 mg/L and 0.0265 mg/L, respectively. The EPA only performed C-R analysis for the growth and reproduction-based endpoints for this test, given the apparent tolerance of the survival-based endpoint. The EPA calculated EC_{10} values for the 42-day growth endpoint (i.e., control normalized wet weight/amphipod) and the 42-day reproduction endpoint (i.e., number of juveniles per female). The 42-day growth-based EC_{10} of 0.488 mg/L (95% C.I. = 0.319 – 0.657 mg/L) was not selected as the primary endpoint from this test because it was more tolerant than the reproduction-based EC_{10} of 0.147 mg/L (95% C.I. = 0.147 – 0.147 mg/L). The EPA-calculated EC_{10} was 0.147 mg/L with a corresponding EC_{50} of 0.911 mg/L. While the EC_{10} was relatively uncertain due to a lack of partial effects around the 10% effect level, the EC_{50} estimate remained relatively certain given the 47% effect observed in the lowest treatment concentration. EC_{50} to EC_{10} ratios from all quantitatively acceptable chronic concentration-response curves with similar species (i.e., small members of the subphylum Crustacea) and endpoints (i.e., offspring/female) were evaluated to understand the variability in the EC_{50}:EC_{10} ratios and provide further context to the reasonableness of the *H. azteca* EC_{10} estimate. Overall, three quantitatively acceptable chronic concentration-response curves with similar species/endpoints were available. See Table C-1 below for a description of the individual C-R curves and resultant EC_{50}:EC_{10} ratios from each C-R curve.

NMED Exhibit 63

Table C-1. EC_{50} to EC_{10} ratios from all quantitatively acceptable chronic concentration-response curves with species similar to *H. azteca* (i.e., small members of the subphylum Crustacea) and with endpoints that were based on reproduction per female.

Citation	Species	Endpoint	EPA-Calculated EC_{50} (mg/L)	EPA-Calculated EC_{10} (mg/L)	EC_{50}:EC_{10} Ratio
Ji et al. 2008	*Daphnia magna*	(# young/starting female)	61.67	7.853	7.853
Li 2008	*Daphnia magna*	(# young/starting female)	40.75	12.89	3.161
Ji et al. 2008	*Moina macrocopa*	(# young/starting female)	12.77	2.194	5.819



EC_{50}:EC_{10} ratios from the three tests with similar species/endpoints ranged from 3.161 to 7.852 with a geometric mean ration of 5.247. Dividing the *H. azteca* reproduction-based EC_{50} (i.e., 0.911 mg/L) by the geometric mean EC_{50}:EC_{10} ratio (i.e., 5.247) produced an estimated *H. azteca* EC_{10} of 0.174 mg/L, which was similar to EC_{10} value calculated directly from the *H. azteca* C-R curve (i.e., 0.147 mg/L). The EC_{10} value calculated directly from the *H. azteca* C-R dataset was, therefore, hypothesized to provide a robust estimate of a 10% reproductive-based effect concentration despite the lack of partial low-level effects observed along the C-R curve. The 42-day average number of young per female EC_{10} value of 0.147 mg/L (95% C.I. = 0.147 – 0.147 mg/L) calculated from C-R data reported by Bartlett et al. 2021 was retained for quantitative use.

Concentration-Response Model Fit:

C.2.2 Second most chronically sensitive genus – *Lithobates*

Flynn et al. (2019) evaluated the chronic effects of PFOA (CAS# 335-67-1, purchased from Sigma-Aldrich) on the American bullfrog (*Lithobates catesbeiana*, formerly, *Rana catesbeiana*) during a 72-day static-renewal unmeasured exposure. Testing followed Purdue University's Institutional Animal Care and Use Committee Guidelines Protocol #16010013551. American bullfrog eggs were taken from a permanent pond in the Martell Forest outside of West

NMED Exhibit 63

Lafayette, Indiana. The eggs from a single egg mass were acclimated in 100 L outdoor tanks filled with 70 L of aged well water and covered with a 70% shade cloth. Once hatched, tadpoles were fed rabbit chow and TetraMin *ad libitum* and were acclimated to laboratory conditions for 24 hours before testing (21ºC and a 12-hour:12-hour light:dark photoperiod). A 2,000 mg/L PFOA stock solution was prepared with RO water to produce three concentrations for the chronic test (0, 0.144 and 0.288 mg/L). Each chronic test treatment contained 10 tadpoles (Gosner stage 25), replicated four times, in 15-L plastic tubs filled with 10 L of aged UV-irradiated, filtered well water. Complete water changes were performed every three to four days, at which time chemical treatments were reapplied. Each experimental unit was fed daily at a constant rate (10% per capita) based on tadpole wet biomass in the control treatment to assure that food was not limiting. On day 72 of the experiment, all tadpoles were euthanized, measured (snout vent length and mass) and staged. The most sensitive chronic endpoint was growth (snout-vent length), with a 72-day NOEC and LOEC of 0.144 mg/L and 0.288 mg/L, respectively. The EPA could not independently calculate an EC_{10} value because there were minimal effects observed across the limited number of treatment concentrations tested. Consequently, the EPA used the LOEC of 0.288 mg/L as the chronic value from this chronic test. The LOEC was used preferentially to the MATC from this test because a ~7% reduction in snout-vent length relative to control responses was observed at the LOEC (i.e., 0.288 mg/L).

EPA-Calculated EC_{10}: Not calculable, unable to fit a model with significant parameters
Concentration-Response Model Fit: Not Applicable

NMED Exhibit 63

C.2.3 Third most chronically sensitive genus – *Daphnia*

Logeshwaran et al. (2021) conducted a PFOA (95% purity, purchased from Sigma-Aldrich Australia) chronic toxicity test with the cladoceran, *Daphnia carinata*. In-house cultures of daphnids were maintained in 2 L glass bottles with 30% natural spring water in deionized water, 21℃ and a 16-hour:8-hour light:dark photoperiod. The chronic test protocol followed OECD guidelines (2012). A PFOA stock solution (100 mg/L) was prepared in deionized water. Cladoceran culture medium was used to prepare the PFOA stock and test solutions. One daphnid (6-12 hours old) was transferred to each 100 Ml polypropylene container containing 50 Ml of the nominal test solution (0, 0.001, 0.01, 0.1, 1.0 and 10 mg/L PFOA). Each test treatment was replicated 10 times with test solutions renewed and daphnids fed daily. At test termination (21 days) test endpoints included survival, days to first brood, average offspring in each brood and total live offspring. No mortality occurred in the controls or lowest test concentration. Of the three endpoints measured, average offspring in each brood and total live offspring were the more sensitive endpoints with 21-day NOEC and LOEC values of 0.01 and 0.1 mg/L PFOA, respectively. The EPA was unable to calculate statistically robust EC_{10} estimates from C-R models for these endpoints, largely because of the 10X dilution series across five orders of magnitude. The LOECs for these endpoints were not selected as the chronic value because the LOECs produced a 29.23% reduction in the average number of offspring per brood relative to controls and a 39.89% reduction in the total living offspring relative to controls. Therefore, the MATC (i.e., 0.03162 mg/L) was selected as the quantitatively acceptable chronic value form this test.

Publication: Logeshwaran et al. (2021)

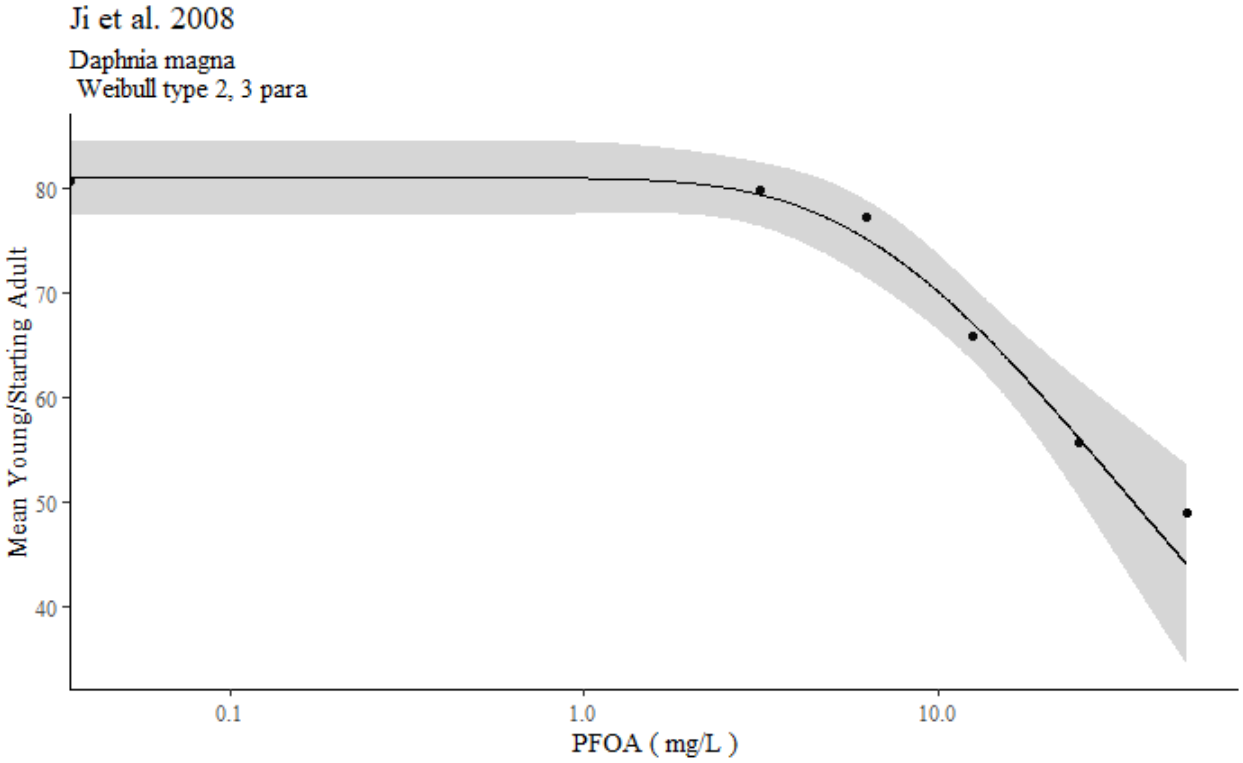
Genus: *Daphnia*
EPA-Calculated EC_{10}: Not used, unable to fit a statistically robust model
Concentration-Response Model Fit: Not Applicable

NMED Exhibit 63

Ji et al. (2008) conducted a chronic life-cycle test on the effects of PFOA (CAS # 335-67-1, purity was not reported; obtained from Sigma Aldrich, St. Louis, MO, USA) with *Daphnia magna*. The test was done under renewal conditions over a 21-day period and test solutions were not analytically confirmed. Authors stated that the *D. magna* test followed OECD 211 (1998). *D. magna* used for testing were obtained from brood stock cultured at the Environmental Toxicology Laboratory at Seoul National University, Korea. Test organisms were less than 24-hours old at test initiation. Dilution water was moderately hard reconstituted water (total hardness typically 80-100 mg/L as $CaCO_3$). Experiments were conducted in glass jars of unspecified size and fill volume. Photoperiod was assumed to be 16-hours of illumination, the same conditions as the daphnid cultures used as the source of the experimental organisms. Preparation of test solutions was not described. The test involved 10 replicates of one daphnid each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 3.125, 6.25, 12.5, 25 and 50 mg/L and test solutions were renewed three times per week. Test temperature was 21 ± 1°C for the *D. magna* test. Authors note that the water quality parameters (pH, temperature, conductivity, and dissolved oxygen) were measured after changing the medium, but the information is not reported. Survival of daphnids in the negative control was 100%. The most sensitive endpoint for *D. magna* reported in the publication was days to first brood with a 21-day NOEC of 6.25 mg/L (LOEC = 12.5 mg/L; MATC = 8.839 mg/L); however, number of young per starting female (an endpoint not reported in the publication, which only assessed number of young per surviving female) was calculated by the EPA and considered to be a more sensitive endpoint with an EPA-calculated EC_{10} of 7.853 mg/L



NMED Exhibit 63

(95% C.I. = 4.253 – 11.45 mg/L). Therefore, the EPA-calculated EC_{10} of 7.853 mg/L PFOA for D. *magna* (number of young per starting female) was considered quantitatively acceptable.

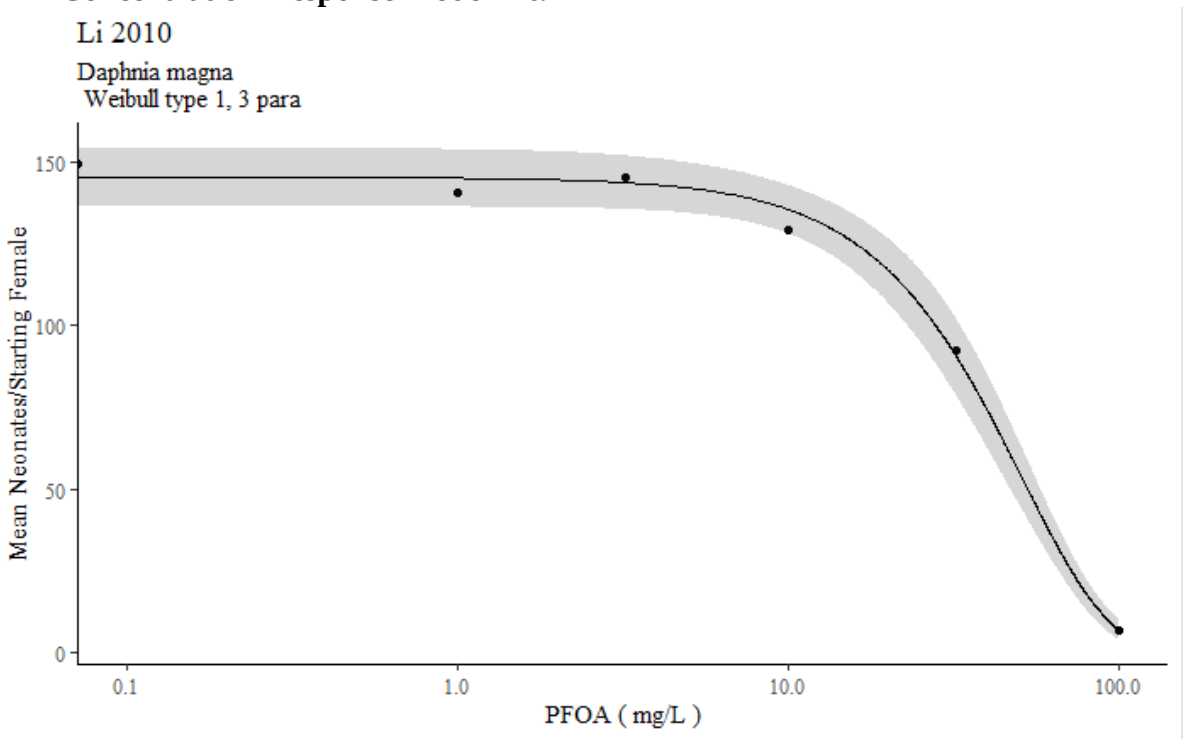
e	37.5761	6.5642	5.7244	0.0106

Concentration-Response Model Fit:

Li (2010) conducted an unmeasured chronic life cycle 21-day test on the effects of PFOA (ammonium salt, >98% purity) on *Daphnia magna*. The authors stated that the test followed OECD 211 (1998). *D. magna* used for the test were maintained in the laboratory for more than one year and were less than 24-hours old at test initiation. Dilution water was distilled water with

NMED Exhibit 63



ASTM medium salts added (0.12 g/L $CaSO_4.2H_2O$, 0.12 g/L $MgSO_4$, 0.192 g/L $NaHCO_3$, and 0.008 g/L KCl). The calculated total hardness was 169 mg/L as $CaCO_3$. The photoperiod had 16-hours of illumination with an unreported light intensity. A primary stock solution (1,000 mg/L) was prepared in ASTM medium. Exposure vessels were 50 Ml polypropylene culture tubes with 50 Ml fill volume. The test involved 10 replicates of one daphnid each in five nominal test concentrations plus a negative control and each test was repeated three times. Nominal concentrations were 0 (negative control), 1, 3.2, 10, 32 and 100 mg/L. Test temperature was maintained at 20 ± 1°C. Water quality parameters measured in test solutions were not reported. Survival of daphnids in the negative control was 96.7% across all three tests. The *D. magna* 21-day NOEC (reproduction as number of young per female, broods per female, and mean brood size) was 10 mg/L (LOEC = 32 mg/L; calculated MATC = 17.89 mg/L). The EPA performed C-R analysis for each reported endpoint. The EPA also revaluated all endpoints that were based on number of surviving females to be based on the number of starting females. This recalculation was done with the intent to account for starting females that were unable to contribute to the population as reproduction/female due to mortality. The most sensitive endpoint with an acceptable C-R curve was the number of young per starting female with an EPA-calculated EC_{10} of 12.89 mg/L PFOA (95% C.I. = 8.292 – 17.49 mg/L) and was acceptable for quantitative use.

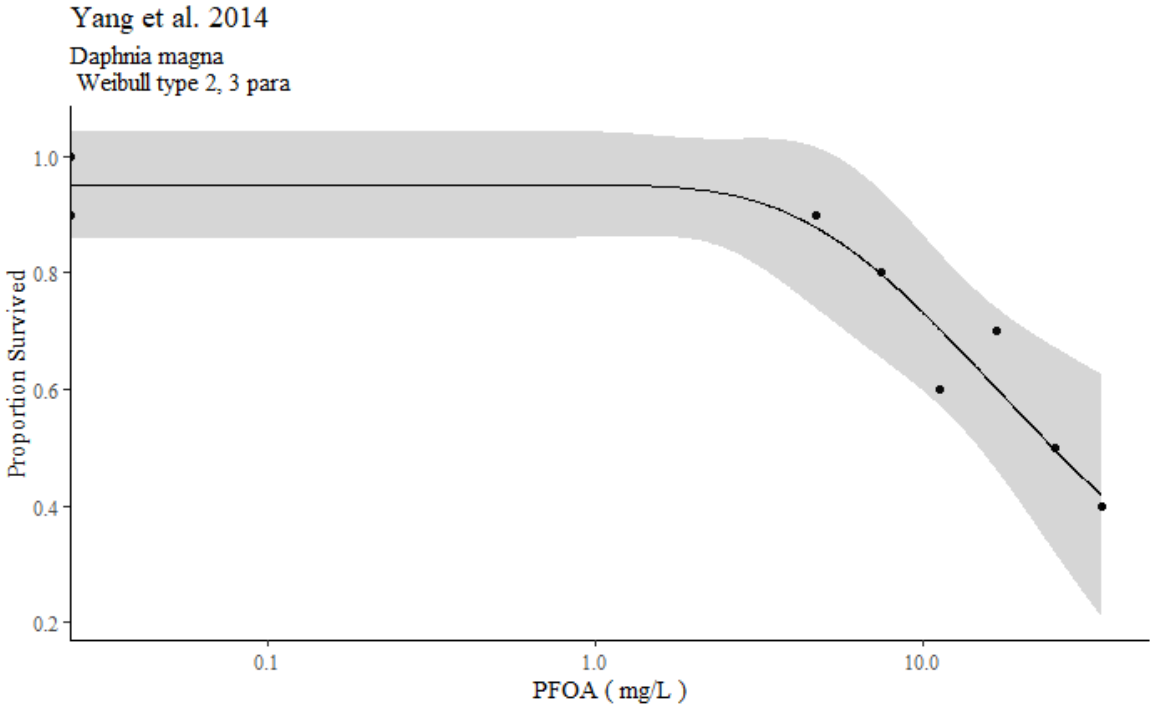
Concentration-Response Model Fit:

Yang et al. (2014) evaluated the chronic 21-day renewal, measured test of PFOA (CAS # 335-67-1, 99% purity) with *Daphnia magna*, following ASTM E729 (1993). Daphnids used for the test were donated by the Chinese Research Academy of Environmental Sciences. The daphnids were less than 24-hours old at test initiation. Dilution water was dechlorinated tap water (Ph, 7.0 ± 0.5; dissolved oxygen, 7.0 ± 0.5 mg/L; total organic carbon, 0.02 mg/L; and total hardness, 190.0 ± 0.1 mg/L as $CaCO_3$). The photoperiod consisted of 12-hours of illumination at an unreported intensity. A primary stock solution was prepared by dissolving

NMED Exhibit 63



PFOA in deionized water and DMSO solvent, and proportionally diluted with dilution water to prepare the test concentrations. Exposure vessels were 200 Ml beakers of unreported material type containing 100 Ml of test solution. The test employed ten replicates of one daphnid each in six test concentrations plus a negative and solvent control. Nominal concentrations were 0 (negative and solvent controls), 5, 7.5, 11.25, 16.88, 25.31 and 37.97 mg/L and were renewed at 48-hour intervals. Test concentrations were measured in low and high treatments only. The authors provided mean measured concentrations before and after renewal: 4.96 and 4.49 mg/L (lowest concentration) and 37.66 and 32.88 mg/L (highest concentration). Analyses of test solutions were performed using HPLC/MS and negative electrospray ionization. The concentration of PFOA was calculated from standard curves (linear in the concentration range of 1-800 ng/Ml), and the average extraction efficiency was in the range of 70-83%. The concentrations and chromatographic peak areas exhibited a significant positive correlation ($r = 0.9987$, $p < 0.01$), and the water sample-spiked recovery was 99%. The temperature, DO, and Ph were reported as having been measured every day during the test, but results are not provided. Negative control and solvent control survival were 90% and 100%, respectively. The author-reported *D. magna* 21-day EC_{10} for reproduction (total number of spawning) was 7.02 mg/L. The EPA performed C-R analysis for each reported endpoint. Both chronic survival and reproduction endpoints resulted in acceptable C-R curves. The EPA-calculated EC_{10} for reproduction as total number of spawning events was 6.922 mg/L (95% C.I. = 4.865 – 8.979 mg/L), similar to the EC_{10} reported by the authors (i.e., 7.02 mg/L). Chronic survival was more sensitive than reproduction, with an EPA-calculated EC_{10} of 5.458 mg/L PFOA (95% C.I. = 3.172 – 7.743 mg/L). Therefore, the survival based EC_{10} calculated by the EPA (i.e., 5.458 mg/L) was acceptable for quantitative use.

Concentration-Response Model Fit:

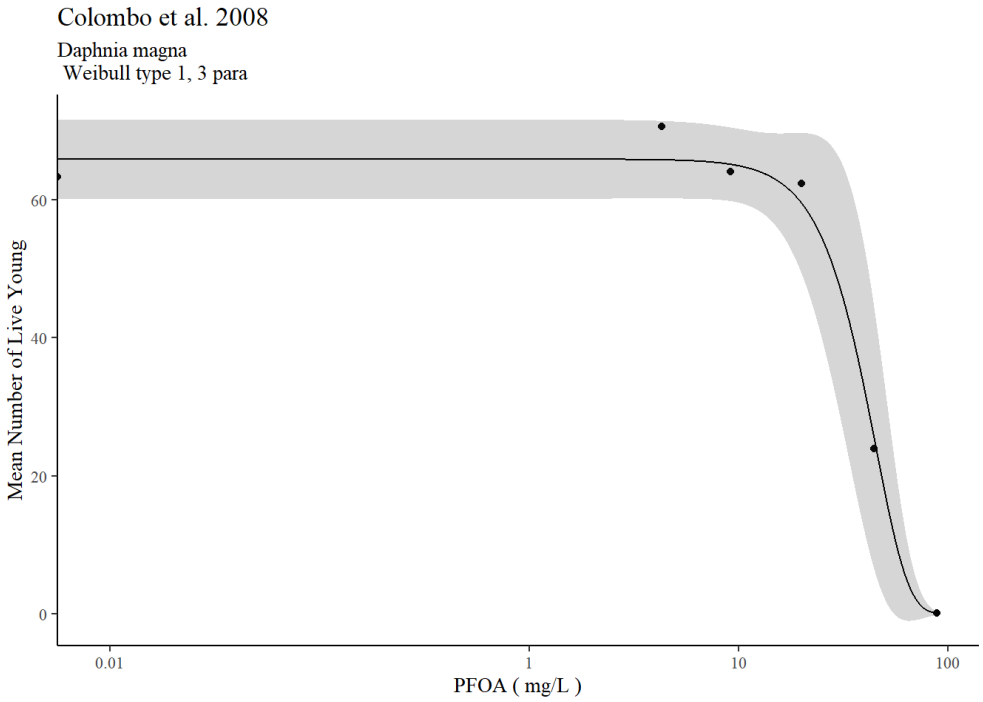
Centre International de Toxicologie (2003) and **Colombo et al. (2008)** conducted a 21-day renewal measured chronic test on ammonium perfluorooctanoate (APFO CAS # 3825-26-1, 99.7% purity) with the daphnid, *Daphnia magna*. The authors stated that the toxicity test was conducted followed OECD test guideline 211. There were 10 replicates for each test treatment containing one neonate, six to 24-hours old, each. Exposure vessel material and size were not reported but filled with 50 Ml of test solution. Stock solutions of APFO were prepared by dissolving the test substance directly in M4 media. The stock was diluted with M4 media to

NMED Exhibit 63

make the nominal test concentrations: control, 6.25, 12.5, 25, 50 and 100 mg/L. Test solutions were analyzed by ion chromatography with electrochemical detection. Measured concentrations were <LOQ, 4.31, 9.16, 20, 44.2 and 88.6 mg/L. Dissolved oxygen was >60% saturation and temperature were maintained between 18-22°C. Illumination included 16-hours of light with an unreported intensity. Test solutions were typically renewed every three days and daphnids were fed daily. Control survival met the minimum survival guidance (80%). Average number of live young was the most sensitive endpoint reported by Colombo et al. (2008), with a NOEC of 20 mg/L. Based on the author-reported EC_{50} for the average number of live young, the LOEC was 44.2 mg/L and the MATC was 29.73 mg/L. The EPA performed C-R analysis for each reported endpoint. The most sensitive endpoint with an acceptable C-R curve was the average number of live young, with an EPA-calculated EC_{10} of 20.26 mg/L PFOA (95% C.I. = -75.48 – 116.0 mg/L), which was acceptable for quantitative use. Although the *D. magna* C-R curve from Colombo et al. (2008) displayed relatively wide 95% confidence bands, the C-R curve was retained for use because the EC_{10} is just beyond the NOEC, where effects quickly increase from 0% to nearly 100%. Although there is a lack of partial effects, there appears to be a threshold effect that occurs above the NOEC. Note, Colombo et al. (2008) reported treatment-mean C-R data for the number of offspring per starting adult. In contrast, Centre International de Toxicologie (2004) reported replicate-level C-R data for number of offspring per surviving adult (producing an EPA-calculated EC_{10} of 21.25 mg/L; Model = Weibull Type 1, 3 parameters). Basing the number of offspring on starting adult (as reported by Colombo et al. [2008]) rather than per surviving adult (as reported by Centre International de Toxicologie [2003]), produces a more sensitive endpoint that accounts for those parents that could not contribute to the overall offspring count as a result of their own mortality. Because Colombo et al. 2008 and Centre

NMED Exhibit 63

International de Toxicologie (2003) both reported only treatment-mean C-R survivorship data, the number of offspring per starting adult was based on treatment mean data rather than replicate-level data.



The authors note that the contribution of ammonia from APFO exposure in this test indicates that un-ionized ammonia could be a potential contributor to the observed chronic toxicity of APFO. The EPA believes ammonia does not contribute substantively to the chronic toxicity to *D. magna* in this test based on the following rationale. US EPA (2013) derived a GMCV of 41.46 mg N/L at pH=7 and temperature of 20°C for *D. magna*. Using the EPA equations, this translates to 12.6 mg N/L at the authors' assumed acute test pH=8.2 (from their Table 7) and the midrange reported test temperature (20°C). This in turn translates to an un-ionized ammonia concentration of approximately 0.91 mg un-ionized ammonia/L at this pH and temperature. Table 7 of Colombo et al. (2008) lists un-ionized ammonia concentration at the APFO 21-day reproductive NOEC as 0.048 mg un-ionized ammonia/L, which is almost twenty times lower than the EPA's SMAV for D. *magna* re-expressed as an un-ionized ammonia concentration for the test condition. Therefore, it is highly unlikely that ammonia contributed to the chronic toxicity of APFO to *D. Magna* in this test, and therefore, the EPA-calculated EC_{10} of 20.26 mg/L APFO is used in the calculation of the GMCV for this species.

Concentration-Response Model Fit:

Lu et al. (2016) evaluated the chronic toxicity of PFOA (CAS# 335-67-1, 98% purity, purchased from Tokyo Chemical Industry Co., Ltd., Tokyo, Japan) on *Daphnia magna* immobilization, growth and reproduction. Reconstituted daphnia culture media was used for both culturing and test solution preparation as described in OECD Test Guideline 202. *D. magna* cultures (originally obtained from the Chinese Center for Disease Control and Prevention (Beijing, China) were fed with the green algae *Scenedesmus obliquus* daily, maintained at 20°C and a light/dark photoperiod of 16-hours/8-hours and the medium renewed three times weekly. The 21-day chronic test endpoints were assessed by a semi-static unmeasured test according to OECD Test Method 211. Neonates (<24-hours old) were exposed to six concentrations of PFOA [0 (control), 0.032, 0.16, 0.8, 4 and 20 mg/L] maintained at 20 ± 1°C. One test organism was exposed in a 100 mL glass beaker filled with 45 mL of test solution, and there were 20 replicates for each exposure concentration. The daphnids were fed 1×10^6 cells of *Scenedesmus obliquus* per animal per day, and the test solution was renewed every other day. Survival, growth and

NMED Exhibit 63

reproduction (fecundity) was determined during the 21-day exposure. The 21-day growth and reproductive NOEC and LOEC were 0.032 and 0.16 mg/L PFOA, respectively. The EPA was unable to fit a C-R model with significant parameters to the chronic data associated with reproduction from this test. The EPA-calculated EC_{10} values for mean intrinsic rate of increase ® and growth (as length) were 0.0173 mg/L (95% C.I. = 0.0170 – 0.0177 mg/L) and 0.0124 mg/L (95% C.I. = 0.0048 – 0.0200 mg/L), respectively. Both EC_{10} values were nearly two times lower than the NOEC of 0.032 mg/L and four times lower than the LOEC value (i.e., 0.16 mg/L) where only 15.2% and 11.9% reductions in intrinsic rate of natural increase (r) and length were observed, respectively. As a result, the MATC of 0.07155 mg/L for growth and reproduction was selected as the most appropriate chronic value for quantitative use to in deriving the chronic water column-based criterion.

Publication: Lu et al. (2016)

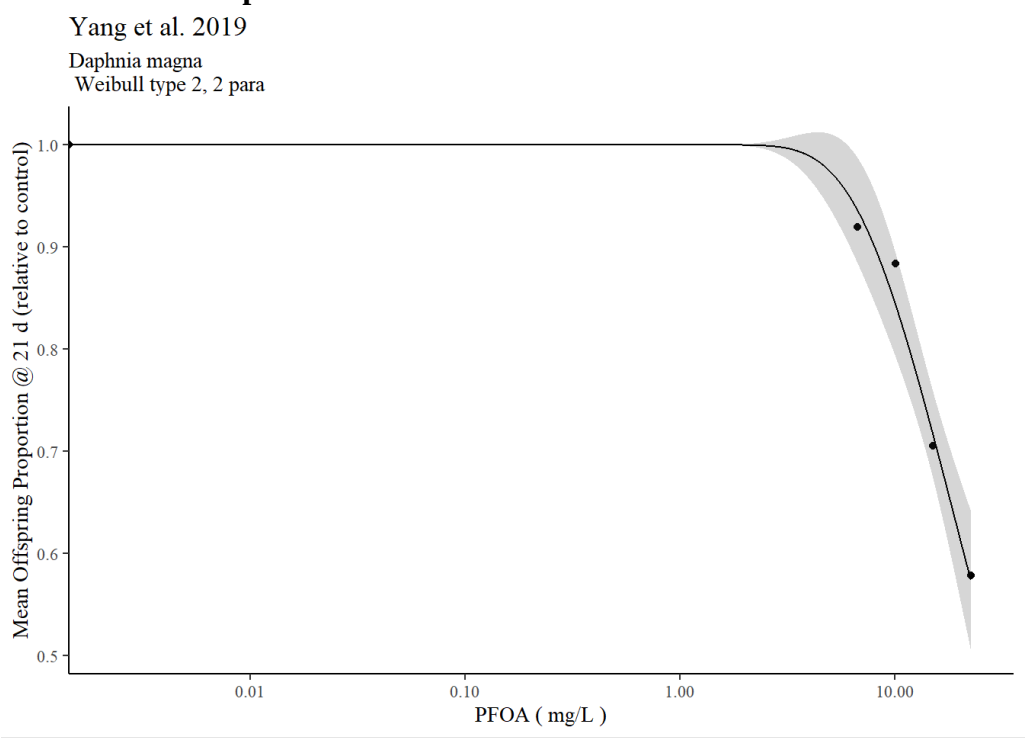
Concentration-Response Model Fit: Not Applicable

Yang et al. (2019) evaluated the chronic effects of PFOA (CAS# 335-67-1, purchased from Sigma-Aldrich in St. Louis, MO) on *Daphnia magna* via a 21-day unmeasured, static-renewal test that assessed reproductive effects. *D. magna* cultures were originally obtained from the Institute of Hydrobiology of Chinese Academy of Science in Wuhan, China. Organisms were cultured in Daphnia Culture Medium according to the parameters specified in OECD Guideline 202. Protocol for all testing followed OECD Guideline 211. Cladocerans were cultured in artificial freshwater maintained at 20 ± 1°C under a 16-hour:8-hour light:dark photoperiod and a light intensity of 1,000-1,500 lux at the surface of the water. Cultures were fed *Scenedesmus obliquus* daily and the water was changed twice weekly. Reported water quality parameters

NMED Exhibit 63



include total hardness of 140-250 mg/L as $CaCO_3$ and pH of 6-8.5. The 21-day chronic study had nominal concentrations of 0 (control), 0.0000162, 0.0000244, 0.0000365 and 0.0000546 mol/L (or 0 (control), 6.708, 10.10, 15.11 and 22.61 mg/L, respectively, given the molecular weight of the form of PFOA used in the study, CAS # 335-67-1, of 414.07 g/mol). One neonate (12–24 hours old) was placed in A 100 mL glass beaker, replicated 10 times, and each container filled wiTH 80 mL of test solution maintained at 20 ± 1ºC and a 16-hour:8-hour light:dark photoperiod with a light intensity of 1,000-1,500 lux. *D. magna* were fed *S. obliquus* and test solutions were renewed every 72 hours. Test organisms were counted daily, with any young removed. The reproductive NOEC and LOEC were 0.0000162 and 0.0000244 mol/L, or 6.708 and 10.10 mg/L PFOA, respectively. The EPA performed C-R analysis for the test. The EPA-calculated EC_{10} based on mean offspring at 21-days as a proportion of the control response was 8.084 mg/L (95% C.I. = 7.830 – 8.334 mg/L) and was used quantitatively to derive the chronic water column criterion.

Concentration-Response Model Fit:

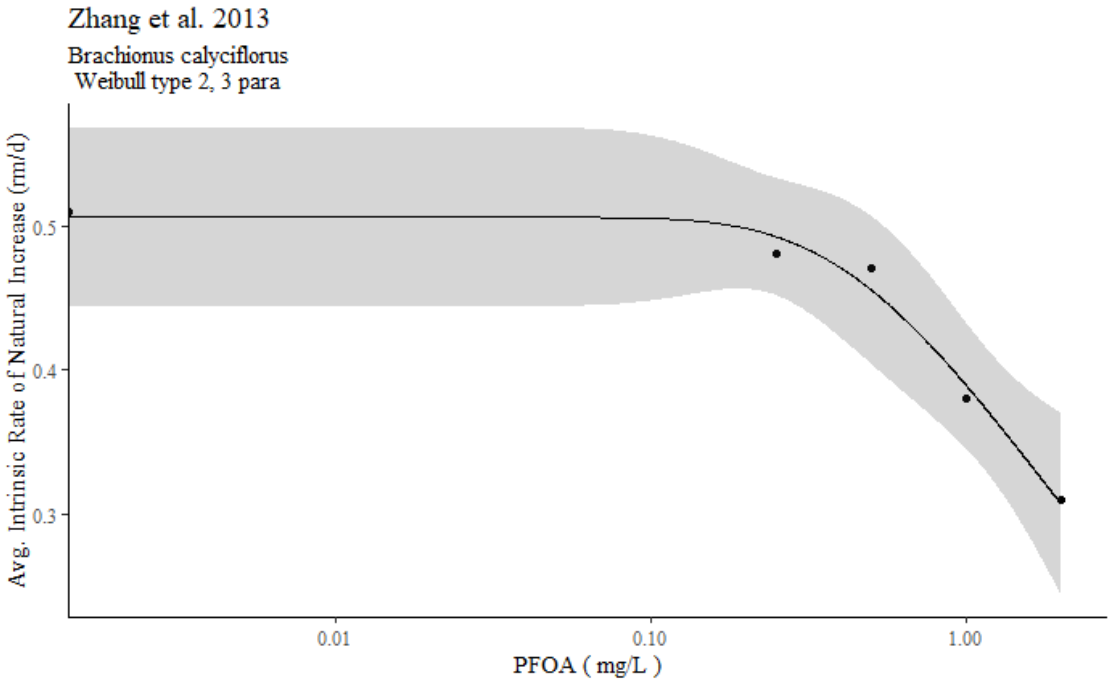
C.2.4 Fourth most chronically sensitive genus – *Brachionus*

Zhang et al. (2013a) conducted a chronic life-cycle renewal test of PFOA (CAS # 335-67-1, 96% purity) with *Brachionus calyciflorus*. The test duration was up to 200-hours in a full-life cycle test (primary emphasis), and 28 days in a population growth test (secondary emphasis: only two concentrations plus a control). Test organisms were less than two-hours old at test initiation. All animals were parthenogenetically-produced offspring of one individual from a single resting egg collected from a natural lake in Houhai Park (Beijing, China). The rotifers

NMED Exhibit 63

were cultured in an artificial inorganic medium at 20°C (16-hours:8-hours, light:dark; 3,000 lux) for more than six months before toxicity testing to acclimate to the experimental conditions. Culture medium was an artificial inorganic medium and all toxicity tests were carried out in the same culture medium and under the same conditions as during culture (i.e., pH, temperature, illumination). Solvent-free stock solutions of PFOA (1,000 mg/L) were prepared by dissolving the solid in deionized water via sonication. After mixing, the primary stock was proportionally diluted with dilution water to prepare the test concentrations. Exposures were carried out in 24-well cell culture plates (assumed plastic) containing 2 mL of test solution per cell. The test employed four measured test concentrations plus a negative control. Each treatment consisted of one replicate plate of 15 rotifers, with one rotifer per cell. Treatments were repeated six times. Nominal concentrations were 0 (negative control), 0.25, 0.5, 1.0 and 2.0 mg/L. PFOA concentrations were not measured in the rotifer exposures, but rather, in a side experiment using HPLC/MS. The side experiment showed that the concentration of PFOA measured every 8 hours over a 24-hour period in rotifer medium with green algae incurs minimal change in the concentration range from 0.25 to 2.0 mg/L. One hundred percent survival was observed at 24 hours in the negative control in the corresponding acute test, but survival information is not provided for the life-cycle test. Zhang et al. (2013a) demonstrated rotifer body size and mictic ratio after 28-days were relatively tolerant endpoints with reported NOECs of ≥ 1.0 mg/L and 2.0 mg/L, respectively. The EPA performed C-R analysis for the remaining reported endpoints from C-R data reported in the publication. The most sensitive endpoint with an acceptable C-R curve was the intrinsic rate of natural increase with an EPA-calculated EC_{10} of 0.5015 mg/L PFOA (95% C.I. = 0.1458 – 0.8572 mg/L), which was acceptable for quantitative use. The intrinsic rate of natural increase (d^{-1}) is a population level endpoint that accounts for births and deaths over

NMED Exhibit 63



time. In this study, the intrinsic rate of natural increase was defined as the natural log of the lifetime net reproductive rate for all individuals within a population (defined here as a PFOA treatment level) divided by the average generation time of those individuals. The effect associated with intrinsic rate of natural increase is similar to other chronic apical effects reported by Zhang et al. (2013a). For example, Zhang et al. (2013a) also reported net reproductive rate and juvenile period which produced an EPA-calculated EC_{10} value of 0.514 mg/L (95% C.I. = 0.1958 – 0.8329 mg/L). Zhang et al. (2013a) also reported effects to average juvenile period, which was a relatively tolerant endpoint. Juvenile period decreased with increasing exposure concentration, with the average juvenile period being about 16% faster than the control responses in the highest treatment concentration (2.0 mg/L; the EPA was unable to fit a statistically-robust C-R model for this endpoint). Zhang et al. (2013a) reported significant reductions in egg size with an EPA-calculated EC_{10} = 0.193 (95% C.I. = -0.1606 – 0.5466 mg/L); however, this endpoint displayed a relatively poor concentration response relationship and may not be relevant for assessing population level effects and was, therefore, not selected as the primary effect concentration from this test. Effects to chronic apical endpoints in this publication and Zhang et al. (2014b) generally appear as a threshold effect from 0.25 mg/L to 1.0 mg/L, providing further support for the endpoint and effect level selected for quantitative use from Zhang et al. (2013a).

Concentration-Response Model Fit:

Zhang et al. (2014b) reports the results of a similar chronic life-cycle test of PFOA (CAS # 335-67-1, 96% purity) with *Brachionus calyciflorus*. The full life-cycle test used renewal conditions for approximately four days. *B. calyciflorus* used for the test were less than two-hours old at test initiation. All animals were parthenogenetically-produced offspring of one individual from a single resting egg collected from a natural lake in Houhai Park (Beijing, China). The rotifers were cultured in an artificial inorganic medium at 20°C (16-hours:8-hours, light:dark; 3000 lux) for more than six months before toxicity testing to acclimate to the experimental

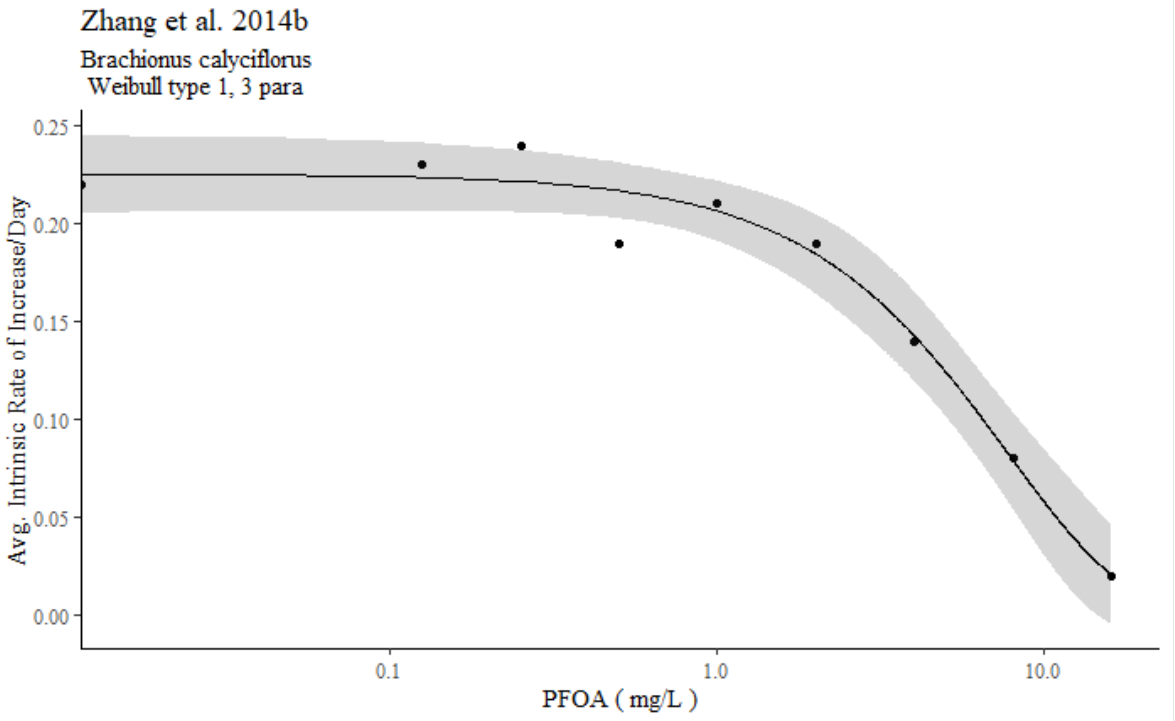
NMED Exhibit 63

conditions. Culture medium was an artificial inorganic medium and all toxicity tests were carried out in the same culture medium and under the same conditions as during culture (i.e., Ph, temperature, illumination). Solvent-free stock solutions of PFOA (1,000 mg/L) were prepared by dissolving the solid in deionized water via sonication. After mixing, the primary stock was proportionally diluted with dilution water to prepare the test concentrations. Exposure vessels and size were not reported for the four-day reproductive assay but were likely 6-well cell culture plates (assumed plastic) each containing at total of 10 Ml of test solution. The test employed eight test concentrations plus a negative control. Each treatment consisted of six replicates of 10 rotifers each in individual cells. The numbers of living rotifers were counted after four days for each treatment level. Nominal concentrations were 0 (negative control), 0.125, 0.25, 0.50, 1.0, 2.0, 4.0, 8.0 and 16.0 mg/L. PFOA concentrations were not measured in the rotifer exposures, but rather in a side experiment using HPLC/MS. The side experiment showed that the concentration of PFOA measured every eight-hours over a 24-hour period in rotifer medium with green algae incurs minimal change in the concentration, ranging from 0.25 to 2.0 mg/L. Negative control survival was not provided for the life-cycle test.

Resting egg production is an ecologically important endpoint for this species because it represents the final result of sexual reproduction. Based on authors description of results in the text, “PFOA exposure significantly reduced resting egg production of *B. calyciflorus* females during the three-day period.” NOEC and LOEC values were not reported, but 0.25 mg/L PFOA produced more than a 50% reduction in resting egg production. Therefore, it is assumed The *B. calyciflorus* four-day NOEC for resting egg production was 0.125 mg/L and the LOEC was 0.25 mg/L, with a calculated MATC is 0.1768 mg/L. Concentration response data from Figure 1 of

NMED Exhibit 63

Zhang et al. (2014b) were estimated (WebPlotDigitizer[1]) and used to derive an EPA-calculated EC_{10} of 0.076 mg/L (95% C.I. = 0.054 – 0.098 mg/L), further suggesting resting egg production may be a relatively sensitive endpoint. Because there was only one replicate (as implied by lack of error bars in Figure 1 of the publication, no clear description of replicates in the methods section, and no author-reported statistical analysis of this endpoint), resting egg production from this study was not considered quantitatively acceptable but was retained for qualitative use. Beyond resting egg production, PFOA did not clearly affect hatching rate of resting eggs when exposed to PFOA during the formation or hatching period, enhanced hatching rate relative to controls in most treatments (nominal test concentration range = 0 – 2.0 mg/L; see figures 3 and 4 of Zhang et al. 2014b) and displayed no clear concentration-response relationship, suggesting rotifer hatching rate was a relatively tolerant endpoint from this publication. In contrast to Zhang et al. (2013a), which observed no effect of PFOA on mictic ratio after 28 days at a nominal concentration as high as 2.0 mg/L PFOA, Zhang et al. (2014b) stated PFOA significantly increased the F1 mictic ratio from 0.56 in the control treatment to 0.75 and 0.72 in nominal PFOA test concentrations of 0.25 mg/L and 2.0 mg/L, respectively. Given conflicting results of PFOA on rotifer mictic ratio, it was not selected as the primary endpoint from Zhang et al. (2014b). The most sensitive quantitatively acceptable endpoint was the intrinsic rate of natural increase. The intrinsic rate of natural increase (d^{-1}) is a population level endpoint that accounts for births and deaths over time. In this study, the intrinsic rate of natural increase was defined as the natural log of the net increase in the number of rotifers (surviving parents and offspring) for each PFOA treatment level over a four-day exposure period. This endpoint was conceptually



[1] WebPlotDigitizer is an online application used to convert values shown in figures to numerical values. This application was used to obtain numerical concentration-response data when they were only reported in figures. The application is free and available online (WebPlotDigitizer - Extract data from plots, images, and maps (automeris.io)).

equivalent to the intrinsic rate of natural increase endpoint calculated by Zhang et al. (2013a) but was a simplification of the calculations performed in Zhang et al. (2013b), in that it only applied to the four-day observational period, whereas the intrinsic rate of natural increase calculated in Zhang et al. (2013a) represented the full lifetimes of all individuals within each population (i.e., exposure concentration). The EPA-calculated EC_{10} for this endpoint was 1.166 mg/L (95% C.I. = 0.7720 – 1.559 mg/L).

Publication: Zhang et al. (2014b)
Species: Rotifer (*Brachionus calyciflorus*)
Genus: *Brachionus*
EPA-Calculated EC_{10}: 1.166 mg/L (95% C.I. = 0.7720 – 1.559 mg/L)
Concentration-Response Model Estimates:

Parameter	Estimate	Std. Error	t-stat	p-value
b	1.1913	0.2118	5.6236	0.0014
d	0.2253	0.0081	27.9366	$1.392\ e^{-7}$
e	7.7080	0.8191	9.4102	$8.183\ e^{-5}$

Concentration-Response Model Fit:

C.2.5 Fifth most chronically sensitive genus – *Moina*

Ji et al. (2008) conducted a chronic life-cycle test on the effects of PFOA (CAS # 335-67-1, purity unreported; obtained from Sigma Aldrich, St. Louis, MO, USA) with *Moina macrocopa*. Tests were done under renewal conditions over a seven-day period and test solutions were not analytically confirmed. Authors stated that the *M. macrocopa* test followed a protocol developed and reported by S.R. Oh (2007) (Master's thesis, Seoul National University, Seoul, Korea), which is similar to OECD 211 (1998), but with slight modification (i.e., shorter test duration, exposure temperature and different feeding regime: 100 µL yeast:cerophyll:Tetramin mixture and 200 µL algae suspension per day). *M. macrocopa* used for testing were obtained from brood stock cultured at the Environmental Toxicology Laboratory at Seoul National University, Korea. Test organisms were less than 24 hours old at test initiation. Dilution water was moderately hard reconstituted water (total hardness typically 80-100 mg/L as $CaCO_3$). Experiments were conducted in glass jars of unspecified size and fill volume. Photoperiod for the test was not reported but was assumed to be 16-hours of illumination, the same conditions as the daphnid cultures reported in this same publication. Preparation of test solutions was not described. The test involved ten replicates of one individual each in five nominal test concentrations plus a negative control. Nominal concentrations were 0 (negative control), 3.125, 6.25, 12.5, 25 and 50 mg/L and test solutions were renewed three times per week. Test temperature was 25 ± 1°C for *M. macrocopa*. Authors note that the water quality parameters (Ph, temperature, conductivity, and dissolved oxygen) were measured after changing the medium, but the information was not reported. Survival of daphnids in the negative control was 100%. The *M. macrocopa* seven-day NOEC (reproduction: number of young per adult) was 3.125 mg/L, the LOEC was 6.25 mg/L and the MATC is 4.419 mg/L. The EPA performed C-R analysis for this study. The most sensitive endpoint with an acceptable C-R curve was the number of young per

NMED Exhibit 63

starting female. The EPA-calculated EC_{10} was 2.194 mg/L PFOA (95% C.I. = -0.7120 – 5.010 mg/L) for *M. macrocopa*. The lowest treatment concentration produced a greater than a 10% effect which forced the EC_{10} calculation to extrapolate beyond the lowest treatment concentration (i.e., not the control, but the nominal treatment of 3.25 mg/L). However, the resultant EC_{10} value (i.e., 2.194 mg/L) was considered acceptable for quantitative use because it was largely in agreement with the 14.3% effect observed at the test concentration of 3.125 mg/L.

C.2.6 Sixth most chronically sensitive genus – *Neocloeon*

Soucek et al. (2023) conducted a chronic life-cycle test to determine the effects of PFOA (CAS # 335-67-1, 95% purity) on the parthenogenetic mayfly, *Neocloeon triangulifer*. The test was performed under renewal conditions over 28 days beginning with <24-hour old nymphs. Single mayfly exposures were static without renewal for the first four days due to the small size of starting organisms and renewed three times per week thereafter by transferring organisms to new exposure chambers. From day 0 to 14, mayflies were exposed in 30 Ml polypropylene cups with 20 Ml exposure water. Organisms were transferred after 14 days into 250 Ml glass beakers with 100 or 150 Ml of test water (or control) and to 300 Ml tall form beakers for emergence. At test initiation, there were 16 replicates per test concentration and control. Nominal test concentrations were 0.0 (control), 0.047, 0.094, 0.375, 0.750, 1.500 and 3.000 mg/L PFOA. Mean measured PFOA concentrations (EPA Analytical Method 1633; LC-MC/MS) were 0.000176 (control), 0.043, 0.078, 0.419, 0.672, 1.739 and 3.085 mg/L PFOA, respectively. Mayflies were exposed at 23 ± 1°C under a 16:8-hour light:dark cycle and fed 0.2 Ml diatom slurry plus small scraping on test days 0 and 4 followed by live diatom biofilm scraping after day 4 on solution renewal days. Percent survival in the control after 14 days was 94%. Percent survival of mayflies after 14 days in the remaining seven test concentrations ranged from 75 to 100%. On test day 14, replicates one through eight were destructively sampled to evaluate 14-

NMED Exhibit 63

day weight. Replicates 9-18 were maintained under test conditions until test day 23. No clear effects of PFOA on 14-day weight or survival were observed in any of the treatments. Similarly, after 28-days of exposure, no clear effects of PFOA were observed on survival to pre-emergent nymph (PEN) stage, survival to emergence, number of days to emergence, imago live weight, or survival to subimago. The relatively high >NOEC (i.e., >3.085 mg/L) suggests *N. triangulifer* is relatively tolerant to chronic PFOA exposures and does not occur among the four most sensitive genera. The >NOEC (i.e., >3.085 mg/L) was acceptable for quantitative use in deriving the chronic freshwater PFOA criterion.

C.2.7 Seventh most chronically sensitive genus – *Oryzias*

Lee et al. (2017) conducted a multiple generation exposure to determine the effects of PFOA (CAS # 335-67-1, purity was not reported) on the reproductive toxicity and metabolic disturbances to *Oryzias latipes*. Fish were originally received from the Department of Risk Assessment of the National Institute of Environmental Research (NIER; South Korea) and maintained according to the following conditions: dissolved oxygen 7-8 mg/L, Ph 7.5 ± 0.2, water temperature 25 ± 1°C, 16-hour light, 8-hour dark photoperiod and total hardness 55-57 mg/L (as $CaCO_3$). *O. latipes* were fed *Artemia salina* once daily, based on the OECD test guideline 240 feeding schedule. Adults (about 13 weeks old, when genders could be visually differentiated) through the F2 generation were exposed to three nominal concentrations of PFOA (0.3, 3 and 30 mg/L PFOA) for a total exposure period of 259 days. At test initiation, four pairs of both genders were introduced into the test chambers (8 L glass tank) of a flow-through exposure system. PFOA solutions were replenished five times daily to keep the same water quality as fish maintaining condition. PFOA exposure continued for three weeks, during which eggs produced by mating of F0 fish were removed from test chamber and counted daily for fecundity. During test week four, (spawning period), the F1 generation eggs (n = 192) were

NMED Exhibit 63

obtained per concentration. Right after the spawning period was finished, F0 fish were used to evaluate metabolism disturbance. The F1 eggs were pooled and redistributed into an incubation chamber containing PFOA solution. After the hatching was completed, the test organisms were returned into test chambers and raised under flow-through PFOA exposure conditions until they reached adult stage (at about 13 weeks old), during which sac-fry survival rate, hatching rate, and abnormality of F1 were analyzed. When F1 fish reached the adult stage, sex ratio of total F1 fish was determined and 32 individuals of F1 fish were used to analyze gonadosomatic (GSI), hepatosomatic (HSI), condition factor (K), VTG expression, and histological alterations. In addition, other F1 fish (32 male and female fish) were used for obtaining the F2 generation eggs same as the F0 generation. The exposure conditions to F2 fish were carried out in the same manner as F1 fish. Consequently, F0 fish were exposed to PFOA for four weeks and F1 and F2 fish were exposed to PFOA across all life cycle stages without exposure pause. The exposure regime was applied equally in all test groups. The 259-day MATC of 9.487 mg/L PFOA was reported for F2 sac-fry survival and fecundity for the F0, F1 and F2 generations and represented the most sensitive endpoints from the study. Reproductive responses reported by Lee et al. (2017) appear to be control normalized; however, use of control normalized data in this study does not alter conclusions from hypothesis-based testing (i.e., use of a NOEC, LOEC, or MATC). Beyond F2 survival (which had control mortality), the EPA attempted C-R analysis for all endpoints reported by Lee et al. (2017). Given the large dilution factor between PFOA treatments, C-R models could either not be fit, or when models could be fit, they performed poorly on statistical metrics and were not used. Therefore, the 259-day MATC of 9.487 mg/L PFOA was considered to be quantitatively acceptable for criterion derivation. The large dilution

NMED Exhibit 63

factor from this test does not support concentration response modeling, consequently EPA relied on an MATC (i.e., 9.487 mg/L) as the chronic effect level from this test.

C.2.8 Eighth most chronically sensitive genus – *Ceriodaphnia*

Kadlec et al. (2024) tested the chronic toxicity of pefluorooctanoic acid (PFOA) to *Ceriodaphnia dubia* for seven days in three measured, renewal experiments. Similar chronic tests were also performed with *Chironomus dilutus* and *Hyallela azteca*, but this summary is limited to the results of the *C. dubia* tests. Test chemicals were obtained from Sigma, Alfa Aesar, Synquest, and Toronto Research Chemical (purity 96-99%). Test organisms were obtained from in-house cultures maintained following ASTM and EPA protocols. Test water was UV-treated and sand-filtered Lake Superior water supplemented with Na_2SO_4, NaCl, KCl, $CaCl_2$ x $2H_2O$, and $MgCl_2$ x $6H_2O$. Testing protocols followed species-specific ASTM methodologies (ASTM 2002). Three separate tests were conducted, each with a 0.5x dilution series of measured PFOA concentrations, with ten replicates of each concentration, and one organism per replicate. Test 1 mean concentrations were 0.019 (control), 0.19, 0.31, 0.62, 1.3, 2.7, 5.5, 11, 22, 44 and 91 mg/L. Test 2 mean concentrations were 0.67 (control), 6.7, 14, 28, 55, and 109 mg/L. Test 3 mean concentrations were 0.35 (control), 3.5, 6.8, 14, 30 and 57 mg/L. *C. dubia* neonates (<8-hour) were placed in one ounce polystyrene cups filled with 15 mL of test solution. Dissolved oxygen and pH were measured twice in each exposure per treatment and twice in the stock solutions. Test chambers were placed in a water bath to maintain a steady temperature under a 16:8 light:dark cycle. Study authors reported average water quality measurements of 24.7°C, 8.6 mg/L DO, 7.8 pH, 52 mg/L as $CaCO_3$ hardness, 41 mg/L as $CaCO_3$ alkalinity, and 145 µmhos/cm conductivity. Testing solutions were renewed daily, and organisms were fed daily with 100 µg/L YCT and algae. Control survival was 96.8% with a mean reproduction of 26.8 offspring per surviving female. EC_{20}s and EC_{50}s for survival and young per surviving female were calculated

NMED Exhibit 63

following methods described in Mount et al. (2016), using custom software written with Intel Visual Fortran Compiler Xe (Intel Corporation) and Winteracter 13.0 (Interactive Software Services). The author reported EC_{20}s for young per surviving female for tests 1, 2, and 3 were 26.2, 25.1, and 33.8 mg/L, respectively. Concentration-response data were reported for these tests, allowing the EPA to independently model concentration-response curves using the dose-response curve package in R. The EPA-calculated EC_{10} values for tests 1, 2, and 3 were 20.42, 21.69, and 29.54 mg/L, respectively, which were determined to be acceptable for quantitative use.

C.2.9 Ninth most chronically sensitive genus – *Gobiocypris*

The chronic toxicity of PFOA (98% purity) on the rare minnow (*Gobiocypris rarus*; not North American resident species) was investigated by **Wei et al. (2007)** using flow-through unmeasured exposure conditions. Two hundred and forty mature male and female rare minnows (about nine months old, 1.4 ± 0.4 g, 47.7 ± 3.6 mm) were obtained from a laboratory hatchery and randomly assigned to eight 20 L glass tanks (30 individuals per tank). Fish were supplied with dechlorinated tap water under continuous flow-through conditions at 25 ± 2°C and a photoperiod of 16-hours:8-hours light:dark. During the 28-day exposure period, fish were fed a commercial granular food (Tetra) at a daily rate of 0.1% body weight. Waste and uneaten food were removed daily. After a one-week acclimation period, 30 randomly selected male and 30 female rare minnows (gender determined by observing the shape of the abdomen and the distance between the abdomen fin and the stern fin) were assigned to one of the four nominal PFOA exposures (0, 3, 10 or 30 mg/L PFOA). Each treatment was performed in duplicate tanks. The flow rate of the test solution was 8 L/hour, and actual PFOA concentrations in the tanks were not verified by chemical analysis. During the exposure period, there were separate inputs for water and PFOA and the mixer helped mix PFOA and water before flowing into the tanks.

NMED Exhibit 63

The concentration of mixed solution flowing out from the mixer were kept at 3, 10 or 30 mg/L PFOA by adjusting the input flow rate of concentrated PFOA and water, respectively. After 14-day and 28-day exposure periods, fish were anesthetized on ice, and liver samples were taken and immediately frozen in liquid nitrogen and stored at -80°C until analyzed. No mortality was observed in any treatments. The 28-day LOEC (survival) was >30 mg/L PFOA and was acceptable for use as a high-unbounded value from a high-quality study which provides relevant sensitivity information for this fish species.

C.2.10 Tenth most chronically sensitive genus - *Oncorhynchus*

Centre International de Toxicologie (2004) and **Colombo et al. (2008)** evaluated the chronic effects of ammonium perfluorooctanoate (APFO, CAS #3825-26-1, 99.7% purity) to embryos of the rainbow trout, *Oncorhynchus mykiss*. Stock solutions of APFO were prepared by dissolving the test substance directly in the test media or dilution water and then diluting the stock solution to provide a geometric series of test concentrations (nominal concentrations of 3.13, 6.25, 12.5, 25 and 50 mg/L APFO). The early-life-stage (ELS) test was performed under flow-through conditions and in compliance with OECD test guideline 210. Unfertilized trout eggs and sperm were received from a commercial supplier and the eggs were fertilized in the laboratory. One hundred and eighty newly fertilized eggs were randomly selected and allocated, 60 eggs per replicate, to the three replicate test vessels for each control and test concentration. Authors stated that the number of surviving fish was reduced randomly to 30 per replicate just after the end of the hatching period (day 26) in the control. The number of surviving fish was again reduced randomly to 15 per replicate when swim-up and feeding began on day 50. Actively feeding juveniles were fed trout chow two to four times per day, corresponding to approximately 4% of their body weight per day, from day 50 to the end of the 85-day test. Test solutions were continuously renewed during the study by pumping the stock solutions into

NMED Exhibit 63

flowing dilution water with a peristaltic pump system at a replacement rate of 5.76 times the test vessel volume per day. Dilution water pH was 6.0-8.5, total hardness was 150 mg/L as $CaCO_3$, and water temperature was kept between 11.1 and 12.5°C for embryos and between 11.6 and 14.4°C for larvae and juvenile fish. The dissolved oxygen concentration was greater than 60% air saturation, the light/dark cycle was maintained at constant darkness until seven days after hatching, then 16 hours light and eight hours dark through test end. Observations were made daily as follows: eggs-marked loss of translucency and change in coloration, white opaque appearance; embryos-absence of body movement or heartbeat; larvae and juvenile fish-immobility, absence of respiratory movement or heartbeat, white opaque coloration of the central nervous system, lack of reaction to mechanical stimulus, and abnormalities. The reported 85-day growth and mortality NOEC was 40 mg/L PFO^-; however, the authors' note that the contribution of ammonia from APFO exposure indicates that un-ionized ammonia could be a potential contributor to the observed toxicity of APFO. Although the authors cite U.S. EPA (1999) for un-ionized ammonia toxicity values, that document (and the subsequent U.S. EPA [2013] criteria document) expressed toxicity in terms of a relationship between total ammonia nitrogen and pH and temperature. For rainbow trout, U.S. EPA (1999) declined to specify a chronic value, due to inconsistencies between tests. However, U.S. EPA (2013) set the rainbow trout chronic value at 6.66 mg TAN/L (Total Ammonia Nitrogen/L) at pH = 7. Using the normalization equations in U.S. EPA (2013), the rainbow trout chronic value translated to 3.60 mg N/L at the authors' assumed chronic test pH of 7.8 (see table 7 of Colombo et al. [2008]), which in turn translated to a rainbow trout chronic value as un-ionized ammonia of 0.064 mg un-ionized ammonia/L at pH 7.8 and a reported test of temperature (13°C). Table 7 of Colombo et al. (2008) listed the un-ionized ammonia concentration at their APFO NOEC as 0.013 mg un-ionized ammonia/L, which

NMED Exhibit 63

is 4.9-fold lower than the EPA's chronic value for rainbow trout re-expressed as an un-ionized ammonia concentration for the test condition. Therefore, the EPA does not believe ammonia was a confounding factor in this test and the study was determined to be quantitatively acceptable for criterion derivation.

C.2.11 Eleventh most chronically sensitive genus – *Pimephales*

Bartlett et al. (2021) also evaluated the chronic effects of PFOA (CAS# 335-67-1, 96% purity, solubility in water at 20,000 mg/L, purchased from Sigma-Aldrich) on fathead minnows (*Pimephales promelas*) via a 21-day early-life stage static-renewal, measured study. The authors followed OECD Test Guideline 210, except that the test ended at 16 days post-hatch (dph) compared to 28 dph for the standard OECD test. Test water (i.e., stock solutions, exposure solutions and controls) was charcoal-filtered UV-sterilized Burlington City water from Lake Ontario (total hardness 120–130 mg/L, alkalinity 89–93 mg/L, Ph 7.4–7.8), and was maintained in a header tank prior to use in testing. Fathead minnow eggs (<18-hour post fertilization) were purchased from Aquatox Labs (Guelph, ON) and exposed to nine nominal PFOA concentrations: 0.01, 0.032, 0.1, 0.32, 1, 3.2, 10, 32 and 100 mg/L. The tests were divided into low concentration (0.01-10 mg/L) and high concentration (32-100 mg/L) tests, with five days in the egg stage and 16 days in the larval fish stage. Tests were initiated with eggs from five to ten egg batches (from different fathead minnow breeding groups) to maximize genetic diversity and variability. There were 20 eggs per beaker, with eight replicates of controls and four replicates of each PFOA concentration in each of the two tests. Embryos and larvae were held in glass, Nitex mesh bottomed (mesh size 500 µm) egg cups within 800-Ml HDPE beakers filled to 700 Ml with test solution. Beakers containing fathead minnow eggs/larvae were aerated, loosely covered, and held in a 25°C incubator with a photoperiod of 16 hours light and 8 hours dark. Larvae were fed 10 µL/fish (0–9 dph) and 20 µL/fish (9–16 dph) of newly hatched brine shrimp slurry per day. The

NMED Exhibit 63

first feeding (half of the daily aliquot) was two hours prior to the daily solution changeover (to remove excess food and waste), and the second feeding (the other half of the daily aliquot) was after solution changeover, so that food was available at all times during the tests. Endpoints evaluated were survival to hatch, time to hatch, hatching success, deformities at hatch, uninflated swim bladder, survival from the egg until nine and 16 dph, and weight, length, tail length, and condition factor of larvae at nine and 16 dph. The reported 21-day NOEC for mortality, weight, length, and condition factor was 76 mg/L PFOA. The EPA could not independently calculate an EC_{10} value because no effects were observed across the range of concentrations tests. Because the NOEC of 76 mg/L was a relatively tolerant NOEC value it was considered quantitatively acceptable for criteria derivation.

C.2.12 Twelfth most chronically sensitive genus - *Chironomus*

McCarthy et al. (2021) conducted a 19-day "abbreviated full life cycle" PFOA (97% purity, purchased from Sigma-Aldrich) toxicity test on the midge, *Chironomus dilutus*. The PFOA stock solution was dissolved in reconstituted moderately hard water without the use of a solvent and stored in polyethylene at room temperature until use. Authors reported that they followed standard protocols (ASTM 2005; U.S. EPA 2000) with slight modifications. Exposure vessels for both experiments were 1 L high-density polyethylene beakers containing natural field-collected sediment with 60 mL of sediment and 105 mL of test solution. PFOA test solutions were added via pipette to the beakers with the tip just above the sediment substrate. Nominal test concentrations were 0, 26, 87, 149, 210 and 272 mg/L PFOA, respectively. Test concentrations were based on the results of a 10-day range finding test conducted by McCarthy et al. (2021). Egg cases were obtained from Aquatic Biosystems or USGS Columbia Environmental Research Center and held as free-swimming hatched embryos (<24 hour after hatch) before testing. Each beaker held 12 organisms with five replicates per exposure treatment.

NMED Exhibit 63

Solutions were renewed every 48 hours. PFOA treatment concentrations were measured on days 10, 15 and 20 in the 20-day exposure. Mean measured PFOA concentrations in the 20-day exposure were 0 (control), 19.9, 59.4, 145, 172 and 227 mg/L PFOA. Percent survival in the control treatment was 82%. The most sensitive endpoint was survival with an author reported 19-day EC_{10} of 89.8 mg/L PFOA. The EPA-calculated survival-based EC_{10} was 88.32 mg/L (95% C.I. = 15.40 – 161.3 mg/L), which was acceptable for quantitative use.

NMED Exhibit 63

Appendix D Acceptable Estuarine/Marine Chronic PFOA Toxicity Studies

D.1 Summary Table of Acceptable Quantitative Estuarine/Marine Chronic PFOA Toxicity Studies

Species (lifestage)	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Salinity (ppt)	Chronic Value Endpoint	Author Reported Chronic Value (mg/L)	EPA Calculated Chronic Value (mg/L)	Final Chronic Value (mg/L)[b]	Species Mean Chronic Value (mg/L)	Reference
Purple sea urchin (adult), *Paracentrotus lividus*	S, M	28 days	PFOA >98%	-	17.00	35	MATC (survival)	31.62	-	**31.62**	31.62	Savoca et al. 2022
Japanese medaka, *Oryzias latipes*	S, U	30 days	Perfluoro-octanoate 96%	7.72	24.82	34.52	NOEC (growth - condition factor)	1.0	-	**>1.0**	>1.0	Oh et al. 2013

NMED Exhibit 63

D.2 Detailed Study Summaries of Chronic Saltwater PFOA Toxicity Studies Considered for Use in Saltwater Criterion Derivation

The purpose of this section is to present detailed study summaries for chronic estuarine/marine tests that were considered quantitatively acceptable for criterion derivation, with summaries grouped and ordered by genus sensitivity. Unlike Appendix A.2 and Appendix C.2, the EPA-calculated C-R models were not presented below for the four most sensitive estuarine/marine genera because a chronic estuarine/marine criterion or benchmark was not developed.

D.2.1 Most chronically sensitive estuarine/marine genera – *Oryzias*

Oh et al. (2013) evaluated the chronic toxicity of PFOA on the Japanese medaka, *Oryzias latipes,* in a 30-day static exposure. PFOA (96% pure, CAS No. 335-67-1) was dissolved in filtered seawater with a minimal concentration (<0.001%) of DMSO used as a vehicle to prevent cellular damage to the fish. Only nominal concentrations were used throughout the study. Prior to test initiation, the fish were acclimated to a seawater environment. The fish were maintained at 25°C under a constant photoperiod of 16:8 hour (light:dark) and water quality was monitored by measuring the pH, dissolved oxygen, and temperature. Fish from the 3rd generation of *O. latipes* (n = 7/group) that had acclimated to seawater for over one month were used in the exposure experiments. Fish were exposed for 30 days to one PFOA concentration (1.0 mg/L), a 0.22 µm filtered seawater control, and a DMSO carrier solvent control. Test conditions were maintained at an average temperature of 24.82°C, pH of 7.72, dissolved oxygen of 6.04 mg/L, and salinity of 34.52 practical salinity units, with fish fed daily. The 30-day condition factor NOEC of 1.0 mg/L PFOA was selected as the primary endpoint from this study. In the methods section, Oh et al. (2013) also stated, "In our preliminary study, fish mortality was altered 30 days after perfluorinated compound exposure, suggesting that repeated exposure to PFCs for 30 days

NMED Exhibit 63

at 1 µg/mL [1 mg/L] causes adverse effect on *O. latipes*." The statement about mortality-based effects in their preliminary test is in direct conflict with the condition factor-based results from the primary test described in the publication. Few details are provided about the preliminary test. Results of the final test (i.e., condition factor NOEC of 1.0 mg/L; reported in Table 1 of Oh et al. 2013) were retained as quantitatively acceptable because they provide chronic estuarine/marine data that were otherwise limited.

D.2.2 Second most chronically sensitive estuarine/marine genera – *Paracentrotus*

Savoca et al. (2022) tested chronic toxicity of perfluorooctanoic acid (PFOA) to sea urchins (*Paracentrotus lividus*) in a 28-day measured, static experiment. Analytical grade PFOA (>98% purity) was obtained from Sigma-Aldrich. Thirty-six adult sea urchins were collected off the coast near Capo Zafferano, Italy, a site where little to no PFOA exposure was expected, and were acclimated in the laboratory for eight days in 200 L of filtered (30 µm) seawater. Four sea urchins were placed into one of nine aquariums containing 15 L of seawater at nominal concentrations (0 (control), 10, and 100 mg/L), with three replicates per concentration treatment. Organisms were kept at 17±1°C with a 35±1% salinity under a 12:12 light:dark cycle. To avoid PFOA uptake, organisms were not fed during the experiment and tanks did not have filtration. Instead, continuous aeration was employed, and PFOA in test water was monitored weekly in each tank. The average recovery of PFOA was stable and close to nominal across all treatments throughout the experiment, and PFOA in control water was less than 10 ng/L. Coelomic fluid was sampled from all individuals weekly to measure PFOA uptake. During the exposure period, sea urchins at the highest test concentration showed sublethal signs of toxicity, including reduced spine mobility, spine loss, and reduced ability to remain anchored to the bottom of the test vessels. Mortality was only observed at the highest test concentration. After the exposure, or in the case of urchins exposed to the highest PFOA concentrations, after the onset of adverse

NMED Exhibit 63

effects, egg samples were dissected from the gonads of each organism, fertilized, and held at 18±1°C for 48 hours. Adult mortality, adult PFOA accumulation in coelomic fluid, percentage of normal and abnormal embryos, and gene expression in embryos were measured. Adverse effects of PFOA were observed for all endpoints. ANOVA or Kruskal-Wallis tests were used to assess significant differences in PFOA treatments compared to controls. The NOEC and LOEC for adult mortality were 10 mg/L and 100 mg/L, respectively, and the MATC of 31.62 mg/L was determined to be acceptable for quantitative use.

NMED Exhibit 63

Appendix E Acceptable Freshwater Plant PFOA Toxicity Studies

E.1 Summary Table of Acceptable Quantitative Freshwater Plant PFOA Toxicity Studies

Species	Method[a]	Test Duration	Chemical / Purity	pH	Temp. (°C)	Effect	Reported Effect Concentration (mg/L)	Reference
Cyanobacteria, *Microcystis aeruginosa*	S, U	12 days	PFOA ≥95%	-	25	MATC (population abundance – cell density)	15.81	Hu et al. 2023
Green alga, *Chlamydomonas reinhardtii*	S, U	96 hours	PFOA >96%	6.8	25	EC_{50} (growth)	51.9	Hu et al. 2014
Green alga, *Chlamydomonas reinhardtii*	S, U	8 days	PFOA >96%	6.8	25	MATC (cell number)	28.28	Hu et al. 2014
Green alga, *Chlamydomonas sorokiniana*	S, U	96 hours	PFOA ≥96%	7.1	25	EC_{50} (population abundance inhibition rate)	140.59	Zhao et al. 2023
Green alga (7.0×10^5 cells/mL), *Chlorella pyrenoidosa*	S, M	96 hours	PFOA >98%	-	25	EC_{50} (growth)	190.99	Xu et al. 2013
Green alga, *Chlorella pyrenoidosa*	S, M	10 days	PFOA >98%	7.1	23	NOEC (biomass)	0.73	Hu et al. 2020
Green alga, *Chlorella pyrenoidosa*	S, M	10 days	PFOA >98%	7.1	23	NOEC (biomass)	0.95	Hu et al. 2020
Green alga, *Chlorella pyrenoidosa*	S, M	10 days	PFOA >98%	7.1	23	NOEC (biomass)	0.95	Hu et al. 2020
Green alga, *Chlorella pyrenoidosa*	S, M	10 days	PFOA >98%	7.1	23	NOEC (biomass)	0.86	Hu et al. 2020
Green alga, *Chlorella pyrenoidosa*	S, M	10 days	PFOA >98%	7.1	23	NOEC (biomass)	0.84	Hu et al. 2020
Green alga, *Chlorella pyrenoidosa*	S, M	10 days	PFOA >98%	7.1	23	NOEC (biomass)	0.97	Hu et al. 2020
Green alga, *Chlorella pyrenoidosa*	S, M	10 days	PFOA >98%	7.1	23	NOEC (biomass)	0.94	Hu et al. 2020
Green alga, *Chlorella pyrenoidosa*	S, M	10 days	PFOA >98%	7.1	23	NOEC (biomass)	0.95	Hu et al. 2020
Green alga, *Chlorella pyrenoidosa*	S, M	10 days	PFOA >98%	7.1	23	NOEC (biomass)	0.83	Hu et al. 2020
Green alga (9×10^5 cells/mL), *Chlorella pyrenoidosa*	S, U	96 hours	PFOA ≥95%	-	25	NOEC (growth)	0.1	Li et al. 2021b

NMED Exhibit 63

E.2 Summary of Quantitatively Acceptable Plant PFOA Toxicity Studies

E.2.1 Cyanobacteria, *Microcystis aeruginosa*

Hu et al. (2023) tested perfluorooctanoic acid (PFOA) on *Microcystis aeruginosa* for 12 days in a static, unmeasured experiment. PFOA (≥95% purity) was purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA). Test organisms were obtained from the Freshwater Algae Culture Collection at the Institute of Hydrobiology in Wuhan, China, and were cultured in BG-11 medium within Erlenmeyer flasks at 25°C and 30µmol $m^{-2}s^{-1}$ photosynthetic photon flux density. *M. aeruginosa* in the exponential growth phase were added to 250 mL Erlenmeyer flasks containing 100 mL of test solution at a density of approximately $1.45x10^6$ cells/mL. The experimental design consisted of nominal concentrations of 0 (control), 1, 10, 25, and 50 mg/L PFOA, diluted from a PFOA stock solution of 1,000 mg/L prepared in BG-11 medium. All concentrations were repeated in triplicate, and each Erlenmeyer flask was manually shaken twice daily during the 12-day experiment. One mL of algal-test chemical solution was sampled from each flask daily to measure cell density. Chlorophyll *a*, photosynthesis, respiration, cellular ROS production, growth inhibition, enzyme activity, emission spectra, carbohydrate content, and total RNA were also measured. Statistical differences between treatments and controls were assessed using ANOVA and Dunnett's tests ($P<0.05$). Algal cells began showing signs of growth inhibition after two days of exposure, and decreased cell density in the highest PFOA concentration after four days. Starting on day five, cell density was significantly lower than controls in the 25 and 50 mg/L treatments. The 12-day NOEC and LOEC for cell density were 10 and 25 mg/L, and the MATC of 15.81 was determined to be acceptable for quantitative use.

E.2.2 Green alga, *Chlamydomonas reinhardtii*

Hu et al. (2014) evaluated the growth inhibition of PFOA (>96% purity) with *Chlamydomonas reinhardtii* in 96-hour and eight-day static exposures. Authors stated that the

NMED Exhibit 63

tests followed OECD test guidance 201 (OECD 2006). *Chlamydomonas reinhardtii* were supplied by UTEX Culture Collection of Algae, University of Texas at Austin. Dilution medium was described as modified high-salt media at a pH of 6.8. Algae in exponential growth phase were exposed to nominal concentrations of 0 (negative control), 1, 3.16, 10, 31.6, 100, 316 and 1,000 mg/L in the 96-hour exposure, and 0, 5, 10, 20 and 40 mg/L in the eight-day exposure. Experiments were initiated by inoculating equal cell numbers of $1x10^4$ cells/mL in the 96-hour exposure and $5x10^6$ cells/mL in the eight-day exposure into 250 mL flasks containing a total volume of 100 mL of algal cell suspension per flask. There were five replicates per treatment in the 96-hour exposure and three replicates in the eight-day exposure. Algae were incubated at 25°C under cool-white fluorescence lights at 85-90 µmol photons/[m^2 x s] irradiance with a 16-hour:8-hour light:dark cycle. The 96-hour growth EC_{50} (inhibition based on optical density) was 51.9 mg/L. The 8-day MATC based on cell number was 28.28 mg/L (NOEC and LOEC are 20 and 40 mg/L, respectively). The plant values from the study were acceptable for quantitative use.

E.2.3 Green alga, *Chlamydomonas sorokiniana*

Zhao et al. (2023) tested perfluorooctanoic acid (PFOA) on *Chlorella sorokiniana* for 96 hours in a 96-hour, static, unmeasured experiment. The study also investigated the effects of polystyrene microplastics on *C. sorokiniana,* both independently and in combination with PFOA, but only the independent effects of PFOA are summarized here. PFOA (≥96% purity) was purchased from Aladdin (Shanghai, China). Algae were purchased from the Freshwater Algae Culture Collection at the Institute of Hydrobiology in Wuhan, China. Before the experiment, the algae were cultured in BG-11 media in an illumination incubator at 25±1°C on a 12:12 hour light-dark cycle at a light intensity of 2,000±50 lux. Algal cultures were shaken three times daily. *C. sorokiniana* in the exponential growth phase were added to test vessels containing test solution at a density of approximately $1.0x10^6$ cells/mL. The experimental design consisted of

NMED Exhibit 63

nominal concentrations of 0 (control), 0.05, 0.5, and 5.0 mg/L PFOA, diluted from a PFOA stock solution of 500 mg/L prepared in BG-11 medium, with three replicates per treatment. Cell density and chlorophyll *a* were measured every 24 hours, and population growth inhibition rate was calculated after 96 hours. Several additional endpoints related to morphology and oxidative stress were also measured after 96 hours. Statistically significant ($p<0.05$) differences between treatment were assessed using ANOVA and least significant different tests. The EC_{50} for population growth inhibition rate was calculated using SPSS 19 software. The 96-hour EC_{50} value of 140.59 mg/L for population growth inhibition rate was determined to be acceptable for quantitative use.

E.2.4 Green alga, *Chlorella pyrenoidosa*

Xu et al. (2013) performed a 96-hour static, measured algal growth inhibition test on PFOA (>98% purity) with *Chlorella pyrenoidosa*. Algae were obtained from the Aquatic Organism Research Institute of the Chinese Academy of Science and precultured for three generations prior to initiating the test. Dilution medium consisted of number one culture medium supplemented with aquatic number four nutrient solution (Zhou and Zhang 1989). Algae in logarithmic growth phase (7.0×10^5 cells/mL) were inoculated in medium containing PFOA at 0 (negative control), 30, 60, 90, 120, 150, 180, 240, 300 and 360 mg/L. Tests were conducted in 100 mL conical flasks with 50 mL of solution with each concentration replicated three times. Exposure concentrations were verified via UHPLC-MS/MS using the Agilent 1290 Infinity UHPLC system interfaced with an Agilent 646-0 Triple Quadrupole mass. Algae were exposed under a 12-hour:12-hour light:dark cycle at 3,000-4,000 lux and 25°C. Chlorophyll concentration and permeability of cell membranes was determined after 96-hours of exposure. The reported 96-hour growth EC_{50} (inhibition based on optical density) was 190.99 mg/L and was considered to be acceptable for quantitative use.

NMED Exhibit 63

Hu et al. (2020) also evaluated the toxic effects of PFOA (>98% purity) on the green alga, *Chlorella pyrenoidosa,* in both nutrient rich and nutrient limited media. PFOA was dissolved in deionized water to make stock solutions. Green algae were purchased from the Chinese Academy of Sciences and cultivated in sterile blue-green medium (BG11) with a 14-hour photoperiod and pH of 7.1, at 23 ± 1°C. Algae in the cultures were in the logarithmic growth phase before they were used for testing. Nominal PFOA test concentrations in standard growth media (BG11) were 0.05, 0.2, 0.5 and 1.0 mg/L. In the eight nutrient-limited, -enriched, or -starved tests only one PFOA test concentration (1.0 mg/L) was examined. All experiments included controls, lasted for 10 days and were replicated three times. The initial cell density for each treatment was 1.0 x 10^6 cells/mL and followed OECD test guidelines (OECD 2011). PFOA was measured in all test treatments at test termination. After exposure day 10, cell density, dry biomass, chlorophyll content, malondialdehyde content, catalase/peroxidase activities, and cell membrane property of algae were measured. In all tests there was no effect on plant biomass compared to the controls at the highest or only test concentration. The 10-day biomass NOECs for the study were 0.73, 0.95, 0.95, 0.86, 0.84, 0.97, 0.94, 0.95 and 0.83 mg/L PFOA for the BG11 media, N,P-limited, N-limited, P-limited, N,P-enriched, N,P-starved, N-starved, P-starved and N,P-enriched tests, respectively. All these NOECs were considered acceptable for quantitative use. Although these NOEC values are relatively low compared to the other plants and animals tested, they represent NOEC values and, therefore, do not suggest effects are expected to occur at these relatively low concentrations.

Li et al. (2021b) conducted a 12-day static, unmeasured toxicity test with PFOA (≥95% purity, purchased from Sigma-Aldrich) on the green alga, *Chlorella pyrenoidosa*. The FACHB-9 strain of the green alga was purchased from the Institute of Hydrobiology, Chinese Academy of

NMED Exhibit 63

Sciences. The alga was cultured in BG-11 medium at 25℃ under a 12-hour:12-hour light:dark photoperiod (2,000 lux) and shaken manually every 12 hours. Two PFOA solutions (0.100 and 100 µg/L) were prepared in sterile water and control solutions were sterile water only. Test solutions were added to flasks containing an initial density of 9 x 10^5 cells/mL growing in BG-11 medium, with three flasks for each treatment. The variation in algal density was observed every day over the 12-day exposure period and chlorophyll pigment content and photosynthetic activity was observed on days 3, 6, 9 and 12. During the first half of the test there was no significant difference in growth of PFOA treatments and the control. On day 12, the growth was reduced by 6.76 and 14.4% relative to the control, in the 0.1 and 100 µg/L PFOA treatments, respectively. Later time points (i.e., > 4 – 12 days of exposure) were not used quantitatively use because the exposure duration was too long (U.S. EPA 2012). The four-day cell density-based endpoint with a NOEC of 0.1 mg/L was acceptable for quantitative use.

E.2.5 Green alga, *Chlorella vulgaris*

Boudreau (2002) performed a 96-hour static algal growth inhibition test on PFOA (acid form, CAS # 335-67-1, 95% purity) with *Chlorella vulgaris* as part of a Master's thesis at the University of Guelph, Ontario, Canada. The author stated that the algal growth inhibition tests followed protocols found in ASTM E 1218-97a (ASTM 1999) and Geis et al. (2000). *Chlorella vulgaris* (UTCC 266 strain) used for testing were obtained as slants from the University of Toronto Culture Collection (UTCC; Toronto, Canada). Stock concentrations were prepared in laboratory-grade distilled water with a maximum concentration that did not exceed the critical micelle concentration for PFOA of 450 mg/L. Dilution medium was Bristol's algal growing media. Toxicity testing consisted of a range-finder test and at least two definitive tests. Nominal test concentrations were 0 (negative control), 6.7, 12.5, 25, 50, 100, 200 and 400 mg/L. Tests were conducted in 60 x 15 mm polyethylene disposable Petri dishes containing 20 mL of test

NMED Exhibit 63

solution. Each Petri dish was inoculated with 1.5 x 10^4 cells/mL at initiation and replicated four times per test concentration. Tests were continuously illuminated with cool-white, fluorescent light between 3,800 and 4,200 lux and incubated at 23 ± 1°C. Replicate Petri dishes were manually shaken twice a day during testing. Toxicity test endpoints included cell density and chlorophyll-*a* content. The reported IC_{10}, IC_{25} and IC_{50} based on growth inhibition (measured as either chlorophyll-*a* or cell density) were 0.014 M (95% Confidence Interval, C.I.: 0.013-0.016), 0.034 M (95% C.I.: 0.032-0.040) and 0.279 M (95% C.I.: 0.249-0.320). Note that the Icx's for PFOA were reported in molar (M) units, but the EPA judged the units were misreported and were actually millimolar (mM) units. This judgement was based on the reported test concentrations in Table 3.1 of the publication and the reported effect concentrations (ICx) would not fall within this range unless the values were in mM units. Accordingly, the Icx reported as mM were converted to mg/L by multiplying the mM concentration by a molecular weight of 414.07 g/mol for PFOA. The calculated 96-hour IC_{10}, IC_{25} and IC_{50} expressed as mg/L from the study were 5.797, 14.07 and 115.5, respectively and acceptable for quantitative use.

E.2.6 Green alga, *Raphidocelis subcapitata*
(formerly known as *Selenastrum capricornutum* and *Pseudokirchneriella subcapitata*)

Elnabarawy (1981) and **3M Company (2000a)** provide the results of four separate toxicity tests completed with the green alga, *Raphidocelis subcapitata* (formerly *Selenastrum capricornutum*), and APFO (CAS # 3825-26-1). The toxicant was part of the 3M production lot number 37 and was characterized as a mixture of APFO (96.5-100% of the compound) and C_6, C_7 and C_9 perfluoro analogue compounds (0-3.5% of the compound). The toxicity tests followed a protocol modified from U.S. EPA-600/9-78-018 (1978) and ASTM-E-35.23 (1981). There were four separate exposure regimes: 1) a four-day exposure + 10-day recovery period, 2) a seven-day exposure + seven-day recovery period, 3) a 10-day exposure + four-day recovery

NMED Exhibit 63

period, and 4) a 14-day continuous exposure. Only the results of the continuous exposure are presented here due to the confusion if reported effect concentrations are reported before or after the recovery period. A bacteria-free culture of the alga was obtained from the USEPA (Corvallis, OR) and stored in the dark until testing. Seven-day old stock cultures with an initial density of 1 x 10^4 cells/mL were placed in 250 mL flasks with 50 mL of test solution. There were three replicates for each of the six nominal test concentrations (100, 180, 320, 560, 1000 and 1800 mg/L) and control. Nutrient medium was used as the dilution media for all test treatments and were not renewed during the exposure. Algae were grown at 23°C and continuously shaken at 100 rpm. The author-reported EC_{10}, based on cell counts, was 5 mg/L for the 14-day exposure and is acceptable for quantitative use.

Boudreau (2002) also performed a 96-hour static algal growth inhibition test on PFOA (acid form, CAS # 335-67-1, 95% purity) with *Raphidocelis subcapitata* as part of the Master's thesis at the University of Guelph, Ontario, Canada. The author stated that the algal growth inhibition test with *R. subcapitata* similarly followed protocols found in ASTM E 1218-97a (ASTM 1999) and Geis et al. (2000). *R. subcapitata* (UTCC 37 strain) used for testing were obtained as slants from the University of Toronto Culture Collection (UTCC; Toronto, Canada). Stock concentrations were prepared in laboratory-grade distilled water with a maximum concentration that did not exceed the critical micelle concentration for PFOA of 450 mg/L. Dilution medium was Bristol's algal growing media. Toxicity testing consisted of a range-finder test and at least two definitive tests. Nominal test concentrations were 0 (negative control), 6.7, 12.5, 25, 50, 100, 200 and 400 mg/L. Tests were conducted in 60 x 15 mm polyethylene disposable Petri dishes with 20 mL of test solution. Each Petri dish was inoculated with 1.5 x 10^4 cells/mL at initiation and replicated four times per test concentration. Tests were continuously

NMED Exhibit 63

illuminated with cool-white, fluorescent light between 3,800 and 4,200 lux and incubated at 23 ±1°C. Replicate Petri dishes were manually shaken twice a day during testing. Toxicity test endpoints included cell density and chlorophyll-*a* content. The reported IC_{10}, IC_{25} and IC_{50} based on growth inhibition (measured as either chlorophyll-*a* or cell density) were 0.130 M (95% C.I.: 0.020-0.162), 0.197 M (95% C.I.: 0.166-0.231) and 0.298 M (95% C.I.: 0.274-0.317). As noted above, although the Icx for PFOA were reported in molar (M) units in the thesis, the EPA judged the units were misreported and were actually millimolar (mM). This judgement was based on the reported test concentrations in Table 3.1 of the publication and the reported effect concentrations (ICx) would not fall within this range unless the values were in mM units. Accordingly, the Icx reported as mM were converted to mg/L by multiplying the mM concentration by a molecular weight of 414.07 g/mol. The calculated 96-hour IC_{10}, IC_{25} and IC_{50} expressed as mg/L from the study were 53.83, 81.57 and 123.4, respectively and acceptable for quantitative use.

More recently, **Xu et al. (2013)** conducted a 96-hour static, measured algal growth inhibition test on PFOA (acid form, >98% purity) with *Raphidocelis subcapitata*. Algae were obtained from the Aquatic Organism Research Institute of the Chinese Academy of Science and precultured for three generations prior to initiating the test. Dilution medium consisted of number one culture medium supplemented with aquatic number four nutrient solution (Zhou and Zhang 1989). Algae in logarithmic growth phase (7.0×10^5 cells/mL) were inoculated in medium containing nominal concentrations of PFOA at 0 (negative control), 30, 60, 90, 120, 150, 180, 240, 300 and 360 mg/L. Tests were conducted in 100 mL conical flasks with 50 mL of solution. Each test concentration and the control were replicated three times. Exposure concentrations were verified via UHPLC-MS/MS using the Agilent 1290 Infinity UHPLC system interfaced with an Agilent 646-0 Triple Quadrupole mass. Algae were exposed under a 12-hour:12-hour

NMED Exhibit 63

light:dark cycle at 3,000-4,000 lux and 25°C. Chlorophyll concentration and permeability of cell membranes was determined after 96 hours of exposure. The reported 96-hour growth EC_{50} (inhibition based on optical density) was 207.46 mg/L and was considered to be acceptable for quantitative use.

Colombo et al. (2008) evaluated growth inhibition with *Raphidocelis subcapitata* on ammonium perfluorooctanoate (APFO, the ammonium salt of PFOA, CAS # 3825-26-1, 99.7% purity). Authors stated that the 96-hour algal growth inhibition test followed OECD test guidance 201 and European Commission directive 92/69/EEC. The source of *R. subcapitata* used for testing was not reported, but presumably from an in-house culture as the medium reported to be used for both culturing and testing was reconstituted water recommended via the French algae test guideline (AFNOR T 90-304). The media differs slightly from the OECD recommended media with regard to concentrations of P, N, and chelators. Stock solutions of APFO were prepared by dissolving the test substance directly in the test media and diluting to provide a geometric series of test concentrations. A range-finding and two definitive tests were conducted. Definitive tests included six negative control replicates and three replicates at each PFOA concentration. Tests were initiated via inoculation with 1×10^4 cells/mL from an algal culture in log phase growth and carried out under continuous illumination with approximately 2,000 lux and at 21-25°C. Test solutions were agitated to keep algae in suspension during the 96-hour exposure and growth was determined at 24-hour intervals by counting an aliquot of test solution from each replicate test chamber. Test concentrations measured in the second definitive algal test and were 0 (negative control), 5.76, 11.37, 22.70, 46.33, 95.87, 180.67 and 369.67 mg/L. APFO was determined as PFOA from a calibration curve of peak area against APFO concentrations in standard solutions. The limit of quantification (LOQ) of the analytical method was 1 mg/L.

NMED Exhibit 63

Linearity was checked with a resulting coefficient of determination for the calibration curve of greater than 0.999 in the range of 1-100 mg/L. Accuracy and precision were demonstrated by analyzing six solutions containing nominal concentrations of 2.03 and 50.7 mg/L APFO in Milli-Q water. The mean measured concentrations were 2.02 and 53.7 mg/L, respectively, with calculated precision of 6% and 2% and accuracy of 99% and 106%, respectively. The reported 96-hour NOEC, based on biomass and growth rate, was 11.37 mg/L. The reported 96-hour LOEC was 22.70 mg/L. The calculated MATC was 16.07 mg/L and was considered to be acceptable for quantitative use.

E.2.7 Green alga, *Scenedesmus obliquus*

Hu et al. (2014) evaluated algal growth inhibition of PFOA (>96% purity) with *Scenedesmus obliquus* in both a 96-hour and eight-day static unmeasured exposures. Authors stated that the tests followed OECD test guidance 201 (OECD 2006). *S. obliquus* were supplied by UTEX Culture Collection of Algae, University of Texas at Austin. Dilution medium was HB-4 media adjusted to a pH of 6.8. Algae in exponential growth phase were exposed to nominal concentrations of 0 (negative control), 1, 3.16, 10, 31.6, 100, 316 and 1,000 mg/L in the 96-hour exposure, and 0, 5, 10, 20 and 40 mg/L in the eight-day exposure. Experiments were initiated by inoculating equal cell numbers of 5×10^3 cells/mL in the 96-hour exposure and 5×10^6 cells/mL in the eight-day exposure into 250 mL flasks containing a total volume of 100 mL of algal cell suspension per flask. There were five replicates per treatment in the 96-hour exposure and three replicates in the eight-day exposure. Algae were incubated at 25°C under cool-white fluorescence lights at 85-90 µmol photons/[m^2 x s] irradiance with a 16-hour:8-hour light:dark cycle. The 96-hour growth EC_{50} (inhibition based on optical density) was 44.0 mg/L. The eight-day NOEC based on cell number was 40 mg/L (the highest test concentration). The plant values from the study were acceptable for quantitative use.

NMED Exhibit 63

E.2.8 Green alga, *Scenedesmus quadricauda*

Yang et al. (2014) conducted a 96-hour renewal, measured test on the growth effects of PFOA (acid form, CAS #335-67-1, 99% purity) with the green alga, *Scenedesmus quadricauda*. Algae were obtained from in-house cultures originally supplied by the Chinese Research Academy of Environmental Sciences. The algae used for testing were inoculated at a cell density equal to 2.0×10^4 cells/mL in 50 mL beakers. PFOA was dissolved in deionized water and DMSO (amount not provided) and then diluted with M4 medium. Algae in logarithmic growth phase were exposed to 0 (solvent control), 80.00, 128.00, 204.80, 327.68, 524.29 and 838.86 mg/L. Each treatment was replicated three times. Measured concentrations ranged from 75.68 mg/L (before renewal) to 78.8 mg/L (after renewal) in the lowest treatment, and from 764.13 (before renewal) to 831.45 mg/L (after renewal) in the highest treatment. The experiments were conducted at 22 ± 2°C with a 12-hour:12-hour light:dark cycle. The initial pH of the test solution was 7.0 ± 0.5, total hardness was 190 ± 0.1 mg/L as $CaCO_3$, and total organic carbon was 0.02 mg/L. Algae concentrations in the beakers were measured daily with a microscope. The 96-hour growth inhibition EC_{50} was reported as 269.63 mg/L and was acceptable for quantitative use.

E.2.9 Duckweed, *Lemna minor*

Wu et al. (2023) tested perfluorooctanoic acid (PFOA) on duckweed, *Lemna minor*, for 96 hours in a static, measured experiment. PFOA (≥97.6% purity) was obtained from Dr. Ehrenstorfer GmbH (Augsburg, Germany). DMSO solvent (≥ 99.9% purity) was obtained from Merck (Germany). Duckweed was obtained from in house cultures that had been grown in a modified Swedish Standards Institute (SIS) medium. Duckweed cultures were housed in 150 mm petri dishes with 100 mL SIS medium that was changed every two weeks. SIS medium pH was adjusted to 6.5 by using NaOH or HCl. Plants were cultured at 25±1°C and 60% humidity under a 12:12 light dark cycle at 2,000 lux. Duckweed was precultured for 1 week in clean SIS media

NMED Exhibit 63

for seven days prior to testing. Duckweed experiments were conducted in 6-well poly-propylene plates to avoid PFOA sorption to container walls. Each replicate well contained 10 mL of test material and two colonies approximately the same size of a 3-frond *L. minor*. Nominal test concentrations were 0 (control), 0.001, 0.1, and 10 mg/L PFOA. All test chambers included DMSO solvent, and each treatment had three duplicates. PFOA concentrations measured on day 0 were 0.93±0.04, 97.2±0.89, and 9,478±4.74 µg/L. PFOA in solvent controls were not reported for day 0 but was below detection levels when measured after 96 hours. The number of fronds in each treatment well were counted after 48 and 96 hours. In addition, Fourier-transform infrared spectroscopy (FTIR) was performed on a subset of fronds from each treatment at the end of the 96-hour exposure to examine responses to PFOA at the biochemical level. Statistically significant ($p<0.05$) differences between treatment groups were assessed with one-way ANOVA followed by Dunnett's tests using SPSS Statistics 26. No statistically significant differences in frond number were observed. However, FTIR analysis revealed structural and functional alterations in response to PFOA at the biochemical level. The reported NOEC of 9.478 mg/L for population growth rate was determined to be acceptable for quantitative use.

E.2.10 Watermilfoil, *Myriophyllum sp.*

Hanson et al. (2005) conducted a 35-day microcosm study on PFOA (sodium salt donated by 3M Co., purity not provided) with the submerged watermilfoils, *Myriophyllum spicatum* and *M. sibiricum*. The study was conducted in 12,000 L outdoor microcosms at the University of Guelph Microcosm Facility located in Ontario, Canada using in-house cultures of *Myriophyllum* spp. Each microcosm was below ground and was flush with the surface. Plastic trays filled with sediment (1:1:1 mixture of sand, loam and organic matter, mostly manure) were placed in the bottom of each microcosm. The total carbon content of the sediment was 16.3%. Ten apical shoots, 4 cm in length, from in-house cultures using the same sediment were

NMED Exhibit 63

transferred to each microcosm, with three separate microcosms used for each treatment (nominal concentrations 0, 0.3, 10, 30 and 100 mg/L). Endpoints of toxicity that were monitored on days 14, 21 and 35 of the study included growth in plant length, root number, root length, longest root, node number, wet mass, dry mass and chlorophyll-*a* and -*b* content. PFOA treatments were dissolved in the same water (well water) used to supply the microcosms. Results showed that measured concentrations remained similar to nominal concentrations throughout the entire exposure period and did not change appreciably over the course of the study. The time-weighted average measured concentrations were 0 (negative control), 0.27, 0.65, 23.9 and 74.1 mg/L. Water quality over the length of the 35-day microcosm experiment was: dissolved oxygen: 7.3-8.5 mg/L; temperature: 17.8-22.0°C; pH: 8.3-8.7; total hardness: 217.5 mg/L as $CaCO_3$. The light:dark cycle was outdoor ambient cycles beginning June 13, 2000 (Guelph, Ontario). The watermilfoil species were equally sensitive to PFOA. The 35-day EC_{10} (based on weight) was 21.6 mg/L for *M. sibiricum* and 19.7 mg/L for *M. spicatum*. The plant values were acceptable for quantitative use.

E.2.11 Lettuce, *Lactuca sativa*

Ding et al. (2012b) conducted a microcosm study where water lettuce, *Lactuca sativa,* was exposed to PFOA (CAS# 335-67-1, 96% purity) for 5 days. Authors stated the test protocols followed U.S. EPA (1996). Test vessels were plastic and test solutions were static and unmeasured. The test employed six exposure concentrations and a negative control, with each treatment being replicated three times. Petri dishes containing lettuce seeds were placed in a plant test chamber with a constant room temperature of 18°C ±2°C and a photoperiod or 16-hours light and 8-hours dark. After 5 days, the number of germinated seeds was counted, and the length of the roots was measured with a ruler to the closest millimeter. The author reported EC_{50}

NMED Exhibit 63

(endpoint = root elongation) was 1.801 mM, which was converted to 745.7 mg/L and was retained for quantitative use.

F.1 Summary of Quantitatively Acceptable Plant PFOA Toxicity Studies

F.1.1 Green alga, *Chlorella sp.*

Mao et al. (2023) tested perfluorooctanoic acid (PFOA) on an estuarine/marine *Chlorella sp.* For seven days in a static, unmeasured experiment. PFOA (>98% purity) was obtained from Tokyo Chemical Industry Co. Ltd. Algae were obtained from the Freshwater Algae Culture Collection at the Institute of Hydrobiology in Wuhan, China. Algae were obtained from the Algae Culture Collection at the Institute of Hydrobiology in Wuhan, China. Algae were cultured in Erdschreiber medium within a conical flask inside an illumination incubator at 23±1°C under a 12:12 light:dark cycle at 5,000 lux. Algae were shaken three times per day to prevent sticking to the sides of the flask, and inoculated once every two weeks to maintain optimal growth. *Chlorella sp.* In the exponential growth phase were added to test vessels containing test solution at a density of approximately $5.0x10^4$ cells/mL. The experimental design consisted of nominal concentrations of 0 (control), 5, 10, 20, 40, 80, 160, and 320 mg/L PFOA. Testing protocols followed OECD guidelines, and all experiments were performed in triplicate. Statistical analysis included one-way ANOVA, using SPSS version 26 software. Algal cell density and size were measured daily, and algal growth inhibition was calculated using the equation provided in the OECD guidelines. Chlorophyll *a*, maximum quantal yield, cell membrane integrity, esterase activity relative to control, relative electron transfer rate, and reactive oxygen species were reported after 1, 3, 5, and 7 days, respectively. Algae exhibited maximum growth at 20 mg/L, but growth significantly declined at 80 mg/L and higher concentrations. Increasing PFOA concentrations also inhibited chlorophyll *a*, and increased oxidative stress. The 96-hour EC_{50} for algal growth inhibition was 127.35 mg/L, and was determined to be acceptable for quantitative use.
