## INTRODUCTION

Biological monitoring was initiated in 1997 to evaluate the effects of open pit mining operations and waste rock dumps over a 30-year period on aquatic biota (i.e., fish and benthic invertebrate populations) in the Red River upstream, adjacent to, and downstream of the Questa Molybdenum Mine (Chadwick Ecological Consultants, Inc.[CEC] 1997, 1998). Our original report discussed the approach and scope of our evaluation in detail (CEC 1997). That discussion is not repeated here. The purpose of this report is to present data on fish and benthic invertebrate populations, and sediments collected in 2000 to further evaluate the trends identified in previous monitoring reports (CEC 1997, 1998, 1999, 2000), and to monitor the current status of aquatic biological parameters. The most recent data for 2000 are used to further assess the potential impact of open pit mining and waste rock piles on fish and benthic invertebrate populations of the Red River.

The New Mexico Environment Department (NMED) initiated a Total Maximum Daily Load (TMDL) study of the Red River in 1999. Molycorp, Inc. (Molycorp), through CEC, was responsible for collecting data on aquatic habitat in 1999, as well as the other biological parameters, to address the needs of the TMDL study. The aquatic habitat data were included in our report for last year (CEC 2000), and was provided to NMED. Aquatic habitat data were not collected in 2000.

The initial study included an analysis of historical information in addition to field sampling efforts (CEC 1997). The conclusions from the first year of the study (1997) indicated that observed negative impacts to fish and benthic invertebrates in the Red River were caused primarily by naturally occurring thermal scars downstream from the town of Red River, especially downstream of Hansen Creek. This pattern was evident during baseline (pre-1966) and present (1995-2000) periods. The open pit mine and waste rock piles did not appear to have measurably impacted the suitability of the Red River to support aquatic organisms.

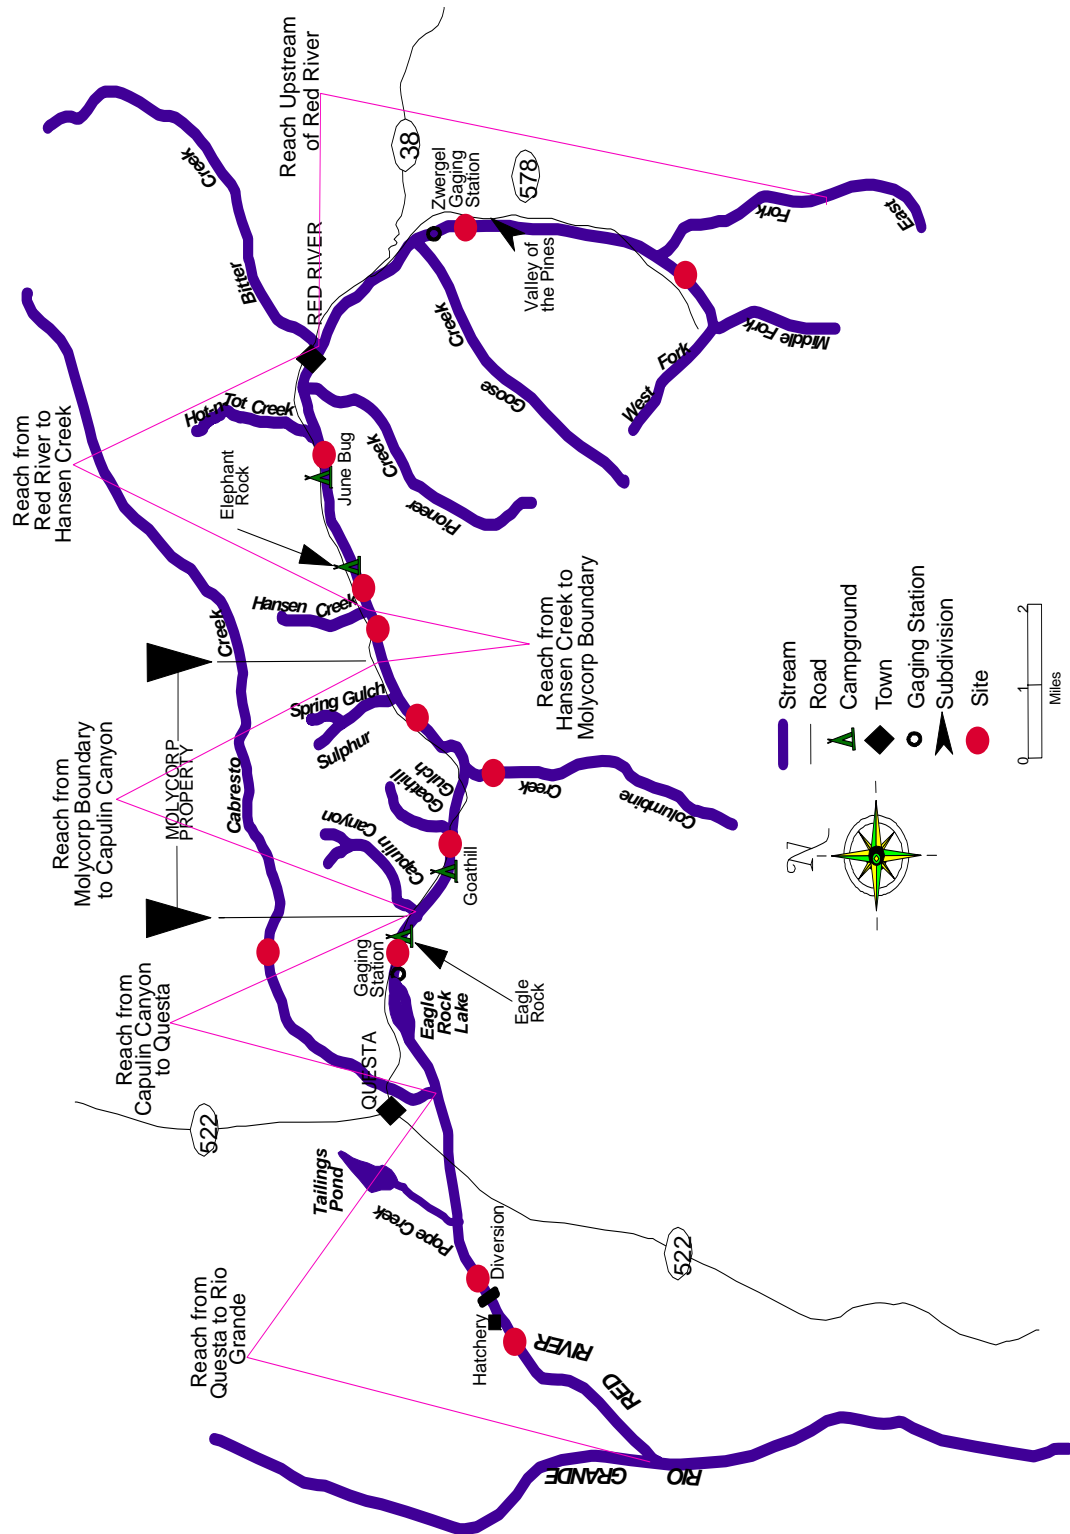

Although not part of regularly scheduled annual monitoring, toxicity testing of water and sediment samples was also conducted at six sites from the Red River in October 2000. Test organisms included the zooplankter *Ceriodaphnia dubia* and fathead minnows, *Pimephales promelas*. Sampling and testing were done in conjunction with NMED, at a total of six sampling locations. NMED was responsible for lab analysis

at three sites, and CEC was responsible for lab analysis at the remaining three sites. The results of the NMED and CEC tests are presented and evaluated in this report. In addition to sampling of sediment and water for toxicity testing, NMED also collected sediment and water samples for chemical analysis. The information on water quality is also presented in this report. The chemical analysis of the sediments are not yet finalized.

The Questa Molybdenum Mine began operations in 1919, using underground mining methods (Schilling 1990). Late in 1965, the mine initiated open pit mining operations that continued until 1983 (Slifer 1996). Tailings from the mill are piped down the valley to tailings ponds near the town of Questa (Fig. 1). Waste rock was deposited near the open pit on Molycorp property in areas which drain Spring Gulch, Sulphur Gulch, Goathill Gulch, and Capulin Canyon (Fig. 1).

In order to evaluate long-term trends in aquatic biological data, the historical information has been divided into three time periods: baseline (prior to open pit mining), open pit and underground mine operation, and present conditions (CEC 1997). Baseline conditions refer to the period prior to 1966. This includes fish data collected in 1960 by the New Mexico Department of Game and Fish [NMDGF] (1960) and benthic invertebrate data collected in 1965 by the U.S. Department of Health, Education, and Welfare [USDHEW] (1966). During the period of open pit and underground mine operation, benthic invertebrate data were collected from 1970 to 1992, and fish data were collected from 1974 to 1988 (CEC 1997).

Present conditions refer to the benthic invertebrate data collected in 1997, 1998, 1999, and 2000 by CEC and data collected in December 1995 by NMED and analyzed by Woodward-Clyde (1996). Present conditions for fish include data collected in 1997, 1998, 1999, and 2000 by CEC, as well as data collected in August 1997 by NMDGF. A detailed listing of all available data for baseline conditions, historic conditions in the intervening years of mine operation (data collected 1970-1992), and present conditions (through fall 1998) is contained in our previous reports (CEC 1997, 1998, 1999).

**FIGURE 1:** Red River study area with six river reaches and Chadwick Ecological Consultants, Inc. 1997-2000 fish, benthic invertebrate, and sediment sampling sites.

## STUDY AREA

The study area includes the Red River from its headwaters to the confluence with the Rio Grande. The Molycorp Questa Molybdenum Mine is adjacent to the north bank of the Red River in its middle reaches, between the towns of Red River and Questa (Fig. 1).

### Reach Descriptions

In order to organize the available historical fish and benthic invertebrate data in our previous report (CEC 1997), we segmented the Red River into six reaches (Fig. 1). These reaches are used to group data from multiple historical sampling sites into distinct, biologically significant parts of the river which contain roughly similar characteristics of channel morphology, habitat, potential impacts, etc. This allowed a more focused interpretation of the historical data. These same six reaches are also used to organize the monitoring data collected during 1997-2000. Summarized descriptions of the six reaches are presented below. More detailed descriptions were presented in our previous report (CEC 1997).

#### Upstream of Red River

This reach of the Red River includes its headwaters downstream to just upstream of the town of Red River. There is some residential development in this portion of the river, in the form of vacation homes (e.g., Valley of the Pines subdivision) and commercial lodges, but not to the extent present in the town of Red River. The substrate in this reach exhibited little accumulation of silt and sand, with low embeddedness. This reach provides good habitat for the different age classes of trout.

#### Red River to Hansen Creek

This reach extends from the town of Red River to just upstream of the confluence with Hansen Creek. Bitter Creek flows into the Red River at the town of Red River. It contains historical mining operations and natural hydrothermal scars, which apparently contribute sediment to the Red River. Potential impacts to this reach include channelization, erosion from the highway, outfall of the town of Red River's wastewater treatment plant, and runoff from natural hydrothermal scars drained by Bitter Creek and Hot-n-Tot Creek.

#### Hansen Creek to Molycorp Boundary

This reach extends from the confluence with Hansen Creek downstream to the eastern edge of the Molycorp property boundary. The major characteristic of this reach is the inflow of Hansen Creek, which drains a large area of hydrothermal scarring. Runoff from this scarring carries sediment into the Red River, creating a relatively large alluvial fan, as well as lower pH waters.

In addition to inputs from Hansen Creek, Hansen Spring also apparently introduces substances to the Red River in this reach. This spring is located in an overflow channel adjacent to the Red River, and appears to input directly into the Red River. Its channel contains a very evident white precipitate.

#### Molycorp Boundary to Capulin Canyon

Extending from the eastern Molycorp property boundary downstream to just upstream of the confluence with Capulin Canyon, this reach contains the confluence with Columbine Creek, which joins the Red River from the south side of the valley. Columbine Creek is a small, clear stream that adds diluting flows to the Red River.

#### Capulin Canyon to Questa

This reach extends from the confluence with Capulin Canyon downstream to just upstream of the confluence with Cabresto Creek, near the town of Questa. As with the reach from Hansen Creek to the Molycorp eastern property boundary, a major feature in this reach is a natural hydrothermal scar; in this case, the one drained by Capulin Canyon. Capulin Springs also enter the Red River in this reach. These seeps apparently introduce substances to the Red River, including those producing a white precipitate.

#### Questa to Rio Grande

This reach extends from the confluence with Cabresto Creek, near the town of Questa, downstream to the confluence of the Red River and the Rio Grande. At the upper end of this reach, Cabresto Creek adds clear, diluting flows to the Red River. The river valley widens at Questa, and portions of this reach through

Questa have areas of unstable stream banks, which contribute to more shallow average water depths compared to downstream portions of this reach. The river valley subsequently narrows again upstream of the state fish hatchery, and remains a narrow canyon down to the Rio Grande.

Study site locations for the twelve monitoring sites in 2000 (Fig. 1) are as follows:

<u>Middle Fork, Red River</u>	Located approximately 6 mi upstream of the town of Red River and approximately 0.6 mi upstream of the confluence with the East Fork, at an elevation of approximately 9,510 ft. This site was added in 1999 in conjunction with the TMDL study by the NMED.
<u>Red River</u>	
Upstream of town of Red River	Located approximately 0.6 mi upstream from Goose Creek and 0.2 mi upstream from the gaging station, at an elevation of approximately 8,900 ft.
June Bug Campground	Located near the upstream end of June Bug Campground at an elevation of approximately 8,530 ft.
Downstream of Elephant Rock Campground, upstream from Hansen Creek	Located 0.4 mi downstream from Elephant Rock Campground at an elevation of approximately 8,360 ft.
Downstream of Hansen Creek, upstream of mill	Located 0.8 mi upstream from the mill access road and 0.7 mi downstream from Hansen Creek, at an elevation of approximately 8,200 ft. This site corresponds to the "Bobita Campground" site of the New Mexico Game and Fish Department.
Downstream of mill, upstream of Columbine Creek	Located 1.1 mi downstream from the mill access road at an elevation of approximately 8,100 ft.
Goathill Campground	Located at the upstream end of Goathill Campground at an elevation of approximately 7,670 ft.
Upstream of Questa Ranger Station	Located 0.4 mi upstream from the ranger station access road, just upstream from where the tailings pipes cross over the Red River. The elevation of this site is approximately 7,480 ft.
Upstream of hatchery diversion	Located 0.3 mi upstream of the Red River fish hatchery diversion, at an elevation of approximately 7,120 ft.

Downstream of hatchery                      Located 0.3 mi downstream of the Red River fish hatchery adjacent to the USGS gage, at an elevation of 7,070 ft. The site was added in 1999 in conjunction with the TMDL study by the NMED.

#### Tributaries

Columbine Creek                              Located approximately 400 yards upstream from its confluence with the Red River, at an elevation of approximately 7,880 ft.

Cabresto Creek                                Located 1.6 mi upstream of the Carson National Forest boundary, at an elevation of approximately 7,640 ft.

In most cases, toxicity sampling sites from October 2000 correspond to NMED TMDL study site locations and CEC study site locations. The most upstream site was located at TMDL study Site RR-06, near the old Zweigle Dam. This site is a few hundred feet upstream of the CEC Red River sampling site (Fig. 1). The next site downstream was at TMDL location Site RR-16, which is just downstream of the CEC site at June Bug Campground. Sampling was also conducted at the CEC site downstream of Hansen Creek (corresponds to TMDL Site RR-20), at the Goathill Campground (TMDL Site RR-28), and the site upstream of the Questa Ranger Station (TMDL Site RR-29). The most downstream site was at TMDL Site RR-35, which is located just downstream of Molycorp's Outfall 001. CEC does not have a site at this location but it is just downstream from the mouth of Pope Creek, approximately 0.7 miles upstream from the CEC site upstream of the hatchery diversion.

## **METHODS**

### **Fish Sampling**

Fish populations were quantitatively sampled at twelve sites in September 2000, using methods nearly identical to those used in 1997, 1998, and 1999. Sampling provided data on species composition, density, biomass, and the size structure of the fish communities. The section of stream sampled at each site was chosen to be representative of the habitat present in that reach of stream, in terms of pool/riffle ratio, shading, bank stability, etc. Sites were of sufficient length to ensure a representative section of the available habitat features: 270 to 438 ft in length at the ten sites on the Red River, 282 ft in Cabresto Creek, and 284 ft in Columbine Creek.

Sampling was conducted by making two or three sampling passes through a representative section of stream using either bank or backpack electrofishing gear. Bank electrofishing equipment consisted of a 4,000-watt generator, a Coffelt voltage regulator (VVP-15), and two or three electrodes. Backpack electrofishing equipment consisted of a Coffelt BP-4 unit with one electrode. At almost all sites, sample sections were blocked with seines (1/8 inch mesh) on both the upstream and downstream ends to reduce the potential for fish to enter or leave the study section during sampling. However, in a few cases, a natural barrier to fish movement (e.g., steep riffle or plunge pool) was used as a site boundary.

Fish captured from each pass were kept separate to allow estimates of population density of each species using the maximum likelihood estimator in the "MicroFish" program developed by the U.S. Forest Service (Van Deventer and Platts 1983, 1989). All fish sampled were identified, counted, measured for length, weighed, and released. This sampling provided species lists, estimates of density (#/Mile, #/Acre), and biomass (Lbs/Acre).

### **Benthic Invertebrate Sampling**

Benthic invertebrates were sampled in April and September 2000, at the twelve sampling locations. Sampling in September 2000 was conducted concurrently with fish sampling. Sampling methods were similar to those used in 1995 by NMED (Woodward-Clyde 1996) and by CEC in 1997, 1998, and 1999 (CEC 1997, 1998, 1999, 2000), and are briefly described below.

Benthic invertebrates were quantitatively sampled at the twelve sites by taking five replicate samples from similar riffle habitats. A modified Hess sampler, which encloses 0.1 m<sup>2</sup> and has a net mesh size of 500 µm (Canton and Chadwick 1984), was used to collect the invertebrate samples. Five replicate Hess samples were also collected in 1995 by NMED (Woodward-Clyde 1996). Five replicates should provide a reliable estimate of both density and species composition (Canton and Chadwick 1988).

Collected organisms were preserved in the field with 95% ethanol and returned to Chadwick & Associates, Inc. (C&A) laboratory in Littleton, Colorado, for analysis. In the lab, organisms were sorted from the debris, identified to the lowest practical taxonomic level (depending upon the age and condition of each

specimen), and counted. Chironomids were mounted and cleared prior to identification and counting. Chironomids were sent to Dr. Leonard Ferrington at the University of Minnesota, St. Paul, for identification.

This analysis provided species lists, estimates of density ( $\#/m^2$ ), and the total number of taxa present at each site. Further analysis included calculation of the Shannon-Weaver Diversity Index ( $H'$ ), which the EPA recommends as a measure of the effects of stress on invertebrate communities (Klemm *et al.* 1990). This index generally has values ranging from 0 to 4, with values greater than 2.5 indicative of a healthy invertebrate community. Diversity values less than 1.0 indicate a stream community under severe stress (Wilhm 1970, Klemm *et al.* 1990).

In mountain streams, such as those near the MolyCorp Molybdenum Mine, the presence of mayfly (Ephemeroptera), stonefly (Plecoptera), and caddisfly (Trichoptera) taxa (collectively referred to as the EPT taxa) can be used as an indicator of water quality. These insect groups are considered to be sensitive to a wide range of pollutants (Plafkin *et al.* 1989, Wiederholm 1989, Klemm *et al.* 1990, Lenat and Penrose 1996, Wallace *et al.* 1996). Stress to aquatic systems can be evaluated by comparing the number of EPT taxa and the percent of EPT taxa (expressed as the percent of the number of EPT taxa relative to the total number of taxa) between unimpacted and potentially impacted sites. Impacted sites would be expected to have fewer EPT taxa and lower percent EPT taxa compared to unimpacted sites. These two parameters were also analyzed in this study. Clements (1991, 1994) and Clements *et al.* (1988) indicate that when specifically looking at impacts due to metals, mayflies are particularly sensitive and caddisflies are less sensitive, and this should be taken into account when interpreting EPT parameters.

To assess potential statistical differences in fish and benthic invertebrate population parameters between study sites and between population parameters and physical/chemical parameters, one-way analysis of variance (ANOVA) with Fisher's least significant difference test and/or simple regression analysis were performed (Hintze 1997). In this report, a level of 95% ( $p = 0.05$ ) was used to indicate significance. For the parameters of invertebrate density, number of taxa, number of EPT taxa, percent EPT taxa, and diversity, ANOVA was performed using the means of the five individual sample replicates. However, benthic invertebrates are often found in "clumped" or negative binomial distributions. Therefore, in order to fulfill the assumptions needed to use ANOVA, the invertebrate density data were assessed to determine if they needed to be transformed ( $\log_{10}$ ) prior to analysis (Elliott 1977). The statistical analysis was conducted on

the mean and variance of the data for the five replicates. The summary data table in this report presents composite mean density values (untransformed). However, for the other parameters analyzed (total number of taxa, number of EPT taxa, percent EPT taxa, diversity), the summary data table presents the results of pooled numbers from the total of the five replicates.

### **Sediment Sampling**

Sediment was sampled at all study sites in April and September 2000. Sampling in September 2000 was conducted concurrently with fish and benthic invertebrate population sampling. Sediment was collected from similar riffle habitat to where the benthic invertebrates were sampled. Sediment samples were obtained using a freeze core technique, similar to methods outlined in Grost *et al.* (1991). A stainless steel probe, with a hollow core and solid conical point at the bottom end, was driven into the substrate with a hammer, to a depth of approximately eight inches. Once the probe was in place, carbon dioxide was injected into the probe for up to one minute. The carbon dioxide was delivered to the probe by a narrow stainless steel tube placed inside the probe. The delivery tube was attached to a 20-pound cylinder of liquid carbon dioxide. After approximately 40-60 seconds, the frozen probe, along with the frozen sediment clinging to it (i.e., “freeze core”) was lifted from the substrate and placed into an enamel pan. The frozen sediment was then melted off the probe using a propane torch and placed into a plastic bag. Three or more freeze cores were taken at each site and combined into one composite sample from each site. Sediment samples were shipped to ACZ Laboratories in Steamboat Springs, Colorado, for analysis.

These sediment samples provided data on the extent of fine sediments as well as on metals concentrations in the fine particles. In the lab, the sediment samples were separated through a 2 mm sieve. The proportion of the sample passing through the sieve was used as a measure of the extent the substrate had accumulated fine sediment particles. The fines were analyzed for texture (i.e., sand, silt, clay).

The fine sediment particles passing through the sieve were also analyzed for metals concentrations by a weak acid leach process. The resulting leachate was analyzed for total concentrations of aluminum, cadmium, copper, lead, and zinc. The results were reported as the concentrations of these metals (mg/Kg) in the fine sediments.

Sediment and water samples from the six toxicity sites were tested using the two commonly used bioassay test organisms, the zooplankter *C. dubia* and fathead minnows, *P. promelas*. Samples were collected from six sites, with NMED responsible for lab analysis at the site upstream of Red River (RR-06), the site upstream of the Questa Ranger Station (RR-29), and the site upstream of the fish hatchery diversion (RR-35). Laboratory testing of these samples was conducted at the U.S. Environmental Protection Agency (USEPA) laboratory in Houston, Texas. CEC was responsible for lab analysis at the site near June Bug Campground (RR-16), the site downstream of Hansen Creek (RR-20), and the site at Goathill Campground (RR-28). Testing of these samples collected was conducted by the C&A aquatic biological laboratory.

### **Toxicity Testing**

Water column samples were collected from each sampling site in 1-gallon polyethylene jugs. Two gallons of water sample were collected from each site. After collection, the samples were placed in a cooler, on ice, and transported to the lab at approximately 4°C.

Composite sediment samples were collected from each sampling site using a polyethylene scoop. Samples were collected from the top 3 inches of sediment in depositional areas. Areas containing fine, organic sediments were sampled whenever available. A unique scoop was used at each site, and each scoop was acid-washed before use in the field. Samples were composited in acid-washed 2-liter polyethylene bottles. A total of 2 liters (by volume) of sediment were collected at each sampling site. After collection, the samples were placed in a cooler, on ice, and transported to the lab at approximately 4°C.

Both the water column and sediment toxicity testing methods were modifications of standard USEPA seven-day *C. dubia* chronic and seven-day *P. promelas* embryo-larval toxicity testing protocols (USEPA 1994). These modified protocols were provided by Terry Hollister at USEPA, Houston, Texas. While these procedures were similar to the standard USEPA whole effluent toxicity (WET) test protocols, there were substantial departures from standard protocols. These departures included: 1) use of one water sample rather than three over the course of a seven-day test; 2) renewal of the *C. dubia* test solutions on day four and renewal of the *P. promelas* test on days four and six, rather than daily renewals of both tests; and 3) observation of *C. dubia* on days four and seven of the test and observation of *P. promelas* on days four, six, and seven of the test, rather than daily observations.

Water column testing followed standard protocols, with the exception of the deviations indicated above. The sediment toxicity tests were conducted using sediment eluate. The eluate was prepared by diluting the sediment samples at a ratio of 1:4 with moderately hard reconstituted laboratory water (USEPA 1994). The sediment-water mixture was placed in 2-liter polyethylene bottles and rotated, end-over-end, at room temperature for 24 hours. After settling for 24 hours at 4°C, the supernatant to be used in the tests was decanted. Due to excessive turbidity, and in accordance with guidance from Terry Hollister at USEPA Houston, supernatant from the Goat Hill Campground and June Bug Campground samples were passed through a 1.5µm filter before being used in testing.

Testing at the C&A laboratory was initiated on the water column samples on October 26, 2000. Testing on sediment samples was initiated on October 31, 2000, following the sediment preparation procedure listed above. All tests were conducted over a seven day period using two treatments, a moderately hard synthetic freshwater control and 100% sample concentrations. The *C. dubia* test was renewed on day four, and organisms were checked for neonate production and mortality on days four and seven of the test. The *P. promelas* test was renewed on days four and six, and checked for number alive, number hatched, and terata (collectively known as number affected) on days four, six, and seven of the test.

## RESULTS AND DISCUSSION

### Fish

Four different trout species were collected in the Red River and its tributaries during sampling in September 2000 (Table 1). Overall, brown trout (*Salmo trutta*) and rainbow trout (*Oncorhynchus mykiss*) were the most common species collected. Brown trout were collected at eight of the ten sites in the Red River and in Columbine Creek and Cabresto Creek. Rainbow trout were collected at seven sites in the Red River and in Cabresto Creek. Brook trout (*Salvelinus fontinalis*) were the most abundant species at the site in the Middle Fork, and at the site in the Red River upstream of the town of Red River; they were present at one other site in the Red River (June Bug Campground) and in Cabresto Creek. Cutthroat trout (*Salmo clarki*) were present at one site in the Red River (upstream of the town of Red River) and in Columbine Creek. Hybrid rainbow/cutthroat trout were present at the site in the Red River upstream of the town of Red River, and were the most common taxa in Cabresto Creek, as was also true in 1997, 1998, and 1999 (CEC 1997, 1998, 1999, 2000). One hybrid was also collected at the site on the Red River just upstream of the hatchery diversion.

**TABLE 1:** Fish population parameters for study sites on the Red River and tributaries. Data collected in September 2000 by Chadwick Ecological Consultants, Inc. Data from all electrofishing passes. (CUT = cutthroat trout, BRK = brook trout, RBT = rainbow trout, BRN = brown trout, HYBRID = cutthroat/rainbow hybrid, WHS = white sucker).

Multiple size-classes of cutthroat, brook, brown, and hybrid trout were collected in 2000. This indicates the presence of resident, self-sustaining populations of these species in the Red River and its tributaries. The rainbow trout collected all were 6 inches in length or greater, with most in the 8- to 11-inch size group (Appendix A). This corresponds to the lengths of fish regularly stocked by NMDGF and the town of Red River (CEC 1997). As was true in 1997, 1998, and 1999, the rainbow trout collected during sampling in fall 2000 are probably stocked fish. In order to minimize the effect of stocked fish on the interpretation of the data, the following discussions are based on trends for resident trout (defined as all trout, excluding rainbow trout).

The fish population data from fall 2000 indicate a distinct pattern of trout density in the Red River from above the town of Red River, downstream to the Red River Fish Hatchery (Fig. 2). Estimates of total number of trout and resident trout generally have been higher at sites upstream of Hansen Creek, compared to the next four sites, downstream to and including the site just upstream of the Questa Ranger Station. A similar pattern was observed in previous years (CEC 1997, 1998, 1999, 2000). Density of resident trout at the four sites upstream of Hansen Creek ranged from 500 to 3,211 trout per mile (Table 1, Fig. 2), averaging 1,495 trout per mile in 2000.

At the June Bug Campground site, the density of resident trout was lower than at the two sites upstream of Red River (Table 1, Fig. 2). There was a decrease of 62% and 84% in the density of resident trout from the two sites upstream of the town of Red River to the site at the June Bug Campground. This pattern was also observed in previous years, suggesting an impact to trout populations is occurring adjacent to or near the town of Red River.

An increase in density of resident trout was evident at the Elephant Rock Campground site, which had a 77% higher density than at June Bug Campground (Fig. 2). At the next site downstream, below Hansen Creek, there was a decrease in resident trout density of 100%. In fact, a single rainbow trout was the only fish collected at this site in 2000. Total trout density (consisting only of brown trout) at the next two sampling sites downstream increased to a high of 675 trout/mile, then decreased at the site near the Questa Ranger Station, downstream of Capulin Canyon (Table 1, Fig. 2). At the next site downstream, just upstream of the fish hatchery diversion, resident trout density increased approximately 128% to a level that

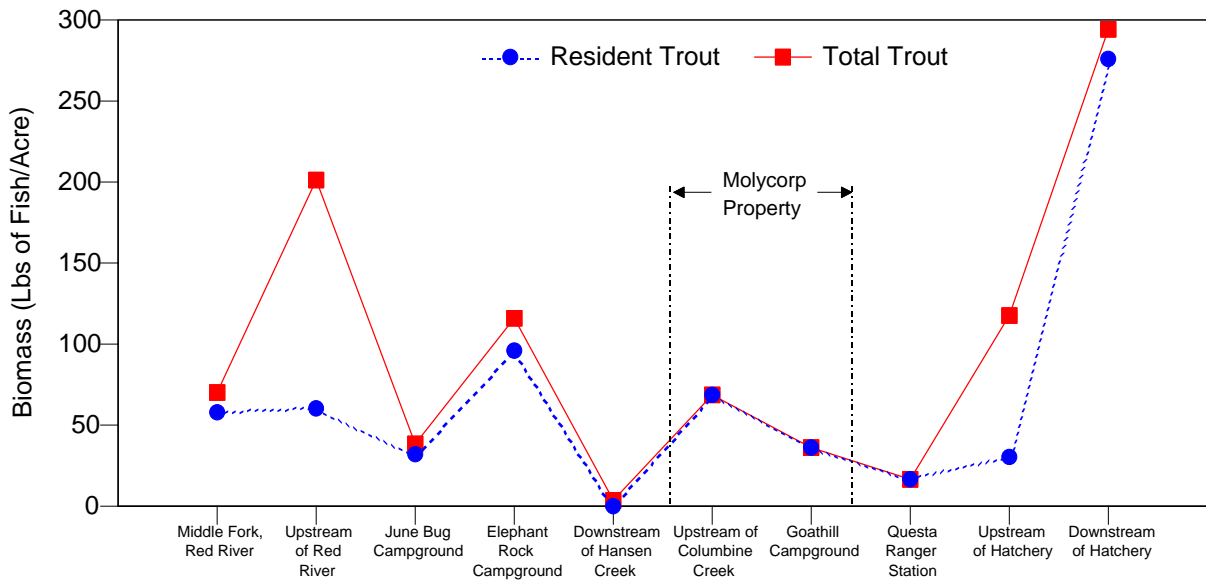

is within the range of the sites upstream of Hansen Creek. An increase of 358% was measured at the next site, just downstream of the hatchery. Resident trout density in the Red River in 2000 was the highest at the site downstream from the fish hatchery. A similar pattern was observed in 1999, and was attributed to productivity enrichment from the hatchery outflow (CEC 2000).

Trout biomass can be another useful indicator of the status of the aquatic environment. While density can be skewed by high numbers of small, young-of-the-year (YOY) fish or low numbers of older, larger fish, biomass accounts for fish size (weight) and can be a more stable and useful indicator from year to year. In past reports, trout biomass was not the focus of our evaluation because much of the historic sources reported only density data. However, the results of fish sampling by CEC in 1997, 1998, 1999, and 2000 (as well as the more recent results from NMDGF) include biomass data, allowing year-to-year comparisons using this parameter. The trend in trout biomass in 2000 was similar to that of trout density, exhibiting higher levels upstream of Hansen Creek and downstream of Questa (Fig. 3).

The patterns in both trout density and trout biomass suggest that there may be at least three sections of the Red River showing negative impacts to aquatic biota. The data from 2000 and previous years clearly indicate that Hansen Creek continues to result in a substantial impact to the aquatic biota of the Red River. Our earlier reports also suggested that there were impacts near the town of Red River and/or from Bitter Creek or Hot-n-Tot Creek that resulted in the reductions in trout populations evident at the June Bug Campground site. The data for 2000 support this. There also appears to be a third impact area downstream of Goathill Campground. In 2000, trout density and biomass levels in the Red River at the site upstream of Columbine Creek and at Goathill Campground indicated some recovery was occurring from the impacts of Hansen Creek (Figs. 2 and 3). Dilution effects from Columbine Creek and YOY brown trout spawned in Columbine Creek may contribute to this recovery. However, at the next site downstream, near the Questa Ranger Station, trout population levels decreased substantially, suggesting further impacts downstream of Goathill Campground. Capulin Canyon and Capulin Springs discharge into the Red River just upstream of the site near the Questa Ranger Station, and may be responsible for the reduction in trout populations.

**FIGURE 2:** Trend in trout density (number of fish/mile) for data collected in fall 2000. Data represent results from all electrofishing passes. Resident trout excludes rainbow trout.

**FIGURE 3:** Trend in trout biomass (pounds of fish/acre) for data collected in fall 2000. Data represent results from all electrofishing passes. Resident trout excludes rainbow trout.

Cabresto and Columbine creeks represent unimpacted streams in the area. Although they are both smaller in size than the Red River, they give some suggestion of the range of trout density and biomass that may be expected in the Red River if no impacts were present. Resident trout densities in 2000 at the sites in the Red River downstream of the hatchery and upstream of the town of Red river were higher than resident trout density in Cabresto Creek (Table 1). Biomass of resident trout in Cabresto Creek was much less than found at the site downstream of the fish hatchery, reflecting the fact that resident fish are larger in the Red River. Density and biomass values for resident trout in Columbine Creek generally fall into the upper portion of the range present in the Red River in 2000. These comparisons suggest that in 2000, some sections of the Red River (the Middle Fork, upstream of Red River, near Elephant Rock Campground, downstream of the fish hatchery) compared favorably to other streams in the region, especially with respect to biomass (Table 1, Fig. 3).

### **Benthic Invertebrates**

Columbine and Cabresto creeks represent relatively unimpacted streams in the Red River drainage. Therefore, benthic invertebrate population parameters for these two sites can be used as comparisons to evaluate the relative levels of impact in the Red River. The sites on the Middle Fork and on the Red River upstream of the town of Red River also are intended be used to represent conditions that are relatively unimpacted, at least with respect to the Molycorp mine. However, we tested this assumption by looking at the past and present data from these two sites on the Red River.

In 1999 and April 2000, population parameters were comparable between the site upstream of the town of Red River, the Middle Fork, and the two tributaries. Although some significant differences between these four sites were observed for density, number of taxa, and number of EPT taxa ( $p < 0.05$ ), there was no clear pattern, which suggests natural variation. Although diversities in Columbine and Cabresto creeks were significantly greater ( $p < 0.05$ ) than in the Middle Fork and in the Red River upstream of the town of Red River, they were all above the threshold value of 2.5 that generally indicates stress to benthic invertebrate communities (Wilhm 1970, Klemm *et al.* 1990).

In September 2000, an interesting pattern was observed, with values for most population parameters at the site on Columbine Creek having significantly lesser ( $p < 0.05$ ) values than the other reference sites. However, except for a slightly reduced density compared to the other reference sites, values in Columbine Creek for the other parameters were high, indicative of a relatively unimpacted site. These results indicate that the two upstream sites on the Red River are comparable to the two unimpacted tributaries, and these four sites combined should provide suitable in-stream comparison data in order to evaluate impacts at the other Red River sites.

#### April 2000

For one parameter (total number of taxa) in April 2000, the values at the four reference sites (combined) were significantly higher ( $p < 0.05$ ) than at all the sites on the Red River from the town of Red River downstream to past the hatchery. Three other parameters (density, number of EPT taxa, and diversity) exhibited patterns in April 2000 in which three of four reference sites were significantly greater ( $p < 0.05$ ) than most of the sites from the town of Red River to past the hatchery. This clearly indicates that there are significant impacts to benthic invertebrate populations along the length of the river downstream of the town of Red River. These parameters are commonly used to evaluate impacts due to water quality, and these significant differences imply that there are water quality impacts to the Red River along much of its length.

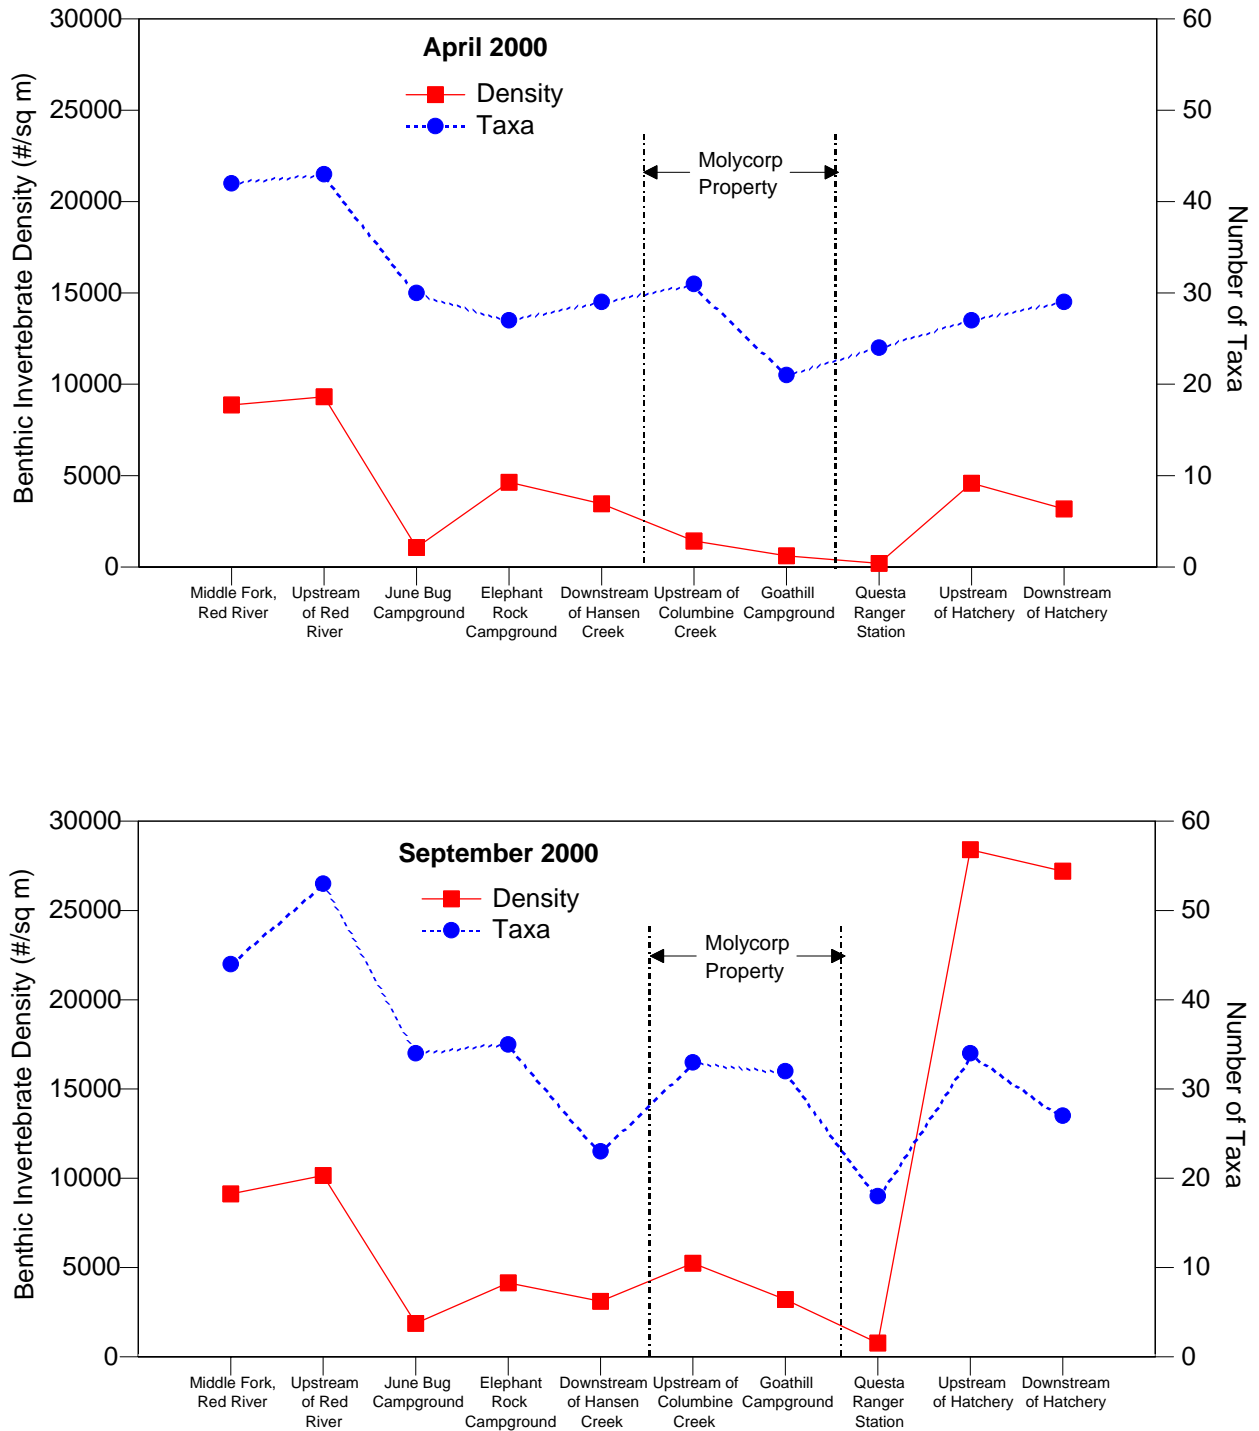

For the parameter of percent EPT taxa, surprisingly, the site at Goathill Campground had a significantly higher ( $p < 0.05$ ) value than all other sites, including the reference sites. Three of the four reference sites had significantly higher values than the sites at the Questa Ranger Station, Elephant Rock Campground, and upstream of the hatchery diversion. The site below Hansen Creek was significantly less ( $p < 0.05$ ) than only one reference site, at Columbine Creek. EPT data in metals-stressed streams can be complicated by the replacement of more sensitive Ephemeroptera (E) species by more tolerant Trichoptera (T) species (Clements 1994). However, this was not the case in the Red River in April 2000. The relative ratio of Ephemeroptera species to Trichoptera species did not change much along the length of the Red River (Appendix B). This ambiguous pattern of differences suggests there may be multiple physical and chemical impacts to benthic invertebrates along the length of the Red River, and that these impacts are not severe enough to eliminate the presence of some sensitive species.

Density was reduced in April 2000 at the first two sites downstream of the town of Red River, at June Bug and Elephant Rock campgrounds (Table 2, Fig. 4). Density at June Bug Campground was significantly less ( $p < 0.05$ ) than at all four reference sites. Density began to recover at Elephant Rock Campground (Table 2, Fig. 4), which had a significantly higher ( $p < 0.05$ ) density than at June Bug Campground, and which was significantly less ( $p < 0.05$ ) than only one reference site, the Middle Fork. Other population parameters (total number of taxa, number of EPT taxa, and percent EPT taxa) also appeared reduced at these two sites compared to the reference sites (Table 2, Fig. 4). Based on replicate data, values for total number of taxa and number of EPT taxa at June Bug and Elephant Rock campgrounds in April 2000 were significantly less ( $p < 0.05$ ) than at least three of the reference sites, although some sensitive taxa (i.e., EPT) are still able to survive at these two sites. Although mean diversity values were also significantly less ( $p < 0.05$ ) than at least three reference sites, overall diversities were greater than 2.5, indicating balanced populations. These population data indicate that some impacts (possibly enrichment and sedimentation) are occurring between the town of Red River and Hansen Creek, but that conditions are still adequate to support sensitive forms.

**FIGURE 4:** Trends in benthic invertebrate density and number of taxa for data collected in April 2000 (top) and September 2000 (bottom).

Downstream of Hansen Creek, benthic invertebrate populations were reduced compared to the reference sites (Table 2, Fig. 4). Density in April 2000 was significantly less ( $p < 0.05$ ) than three of four reference sites (Table 2, Fig. 4). Based on replicate data, values for total number of taxa, number of EPT taxa, and diversity downstream of Hansen Creek were significantly less ( $p < 0.05$ ) than all four reference sites. The value for percent EPT taxa was significantly less ( $p < 0.05$ ) than only one reference site, on Columbine Creek. Values for total number of taxa and diversity indicated similar population levels between the sites at Elephant Rock Campground and downstream from Hansen Creek (Table 2). There was a 25% reduction in density from the Elephant Rock Campground site to the downstream Hansen Creek site. However, replicate data indicated that neither density nor diversity were significantly different ( $p > 0.05$ ). Number of EPT taxa and % EPT taxa increased downstream of Hansen Creek compared to Elephant Rock Campground (Table 2), and this difference was significant ( $p < 0.05$ ), indicating further recovery in some population parameters. However, reduced population parameters downstream of Hansen Creek compared to most of the reference sites indicates the presence of water quality impacts.

At the two sites adjacent to the Molycorp property (the site downstream of the mill/upstream of Columbine Creek and the site at Goathill Campground) in April 2000, density was reduced relative to the reference sites and the site downstream of Hansen Creek (Table 2, Fig. 4), and these differences were significant ( $p < 0.05$ ). Although total number of taxa and number of EPT taxa at the sites adjacent to the Molycorp property were significantly reduced ( $p < 0.05$ ) relative to the reference sites (Table 2), they were not significantly different ( $p > 0.05$ ) from the site downstream from Hansen Creek. Diversities at both of these sites were greater than 2.5, indicating balanced communities (Table 2). In fact, based on replicate data, diversity at the site downstream of the mill/upstream of Columbine Creek was significantly greater ( $p < 0.05$ ) than at the site downstream of Hansen Creek. The species composition at the two sites adjacent to the Molycorp property included numerous mayfly species, which are considered to be particularly sensitive to metals impacts (Clements 1991, 1994; Clements *et al.* 1988) as well as stoneflies and caddisflies (Appendix B), which can be more tolerant. Although densities at these two sites were reduced relative to the site downstream of Hansen Creek, total number of taxa and number of EPT taxa were similar, and diversities indicated balanced populations. The high percentage of EPT taxa and the presence of multiple mayfly species indicate that this reach of the river is able to sustain sensitive aquatic insect species.

The site at the Questa Ranger Station had reduced values for density, total number of taxa, and number of EPT taxa in April 2000 compared to most other study sites (Table 2, Fig. 4), and these differences were significant ( $p < 0.05$ ). These data indicate significant impairment to the aquatic community. However, four taxa of mayflies were present, and overall diversity was among the highest observed for non-reference sites. These data indicate a continuing impact downstream of Capulin Canyon and Capulin Springs leading to reduced density, total number of taxa, and number of EPT taxa, but that some sensitive forms of benthic invertebrates are still present.

The final two sites on the Red River, upstream and downstream of the fish hatchery, demonstrated the recovery in density and total number of taxa in April 2000 (Table 2, Fig. 4), which had significantly greater values ( $p < 0.05$ ) than the sites at Goathill Campground and above the Questa Ranger Station. Number of EPT taxa was also significantly greater ( $p < 0.05$ ) at these sites than at the site above the Questa Ranger Station. This recovery is probably due, in part, to the input of diluting water from Cabresto Creek.

The overall longitudinal trend along the Red River in April 2000 shows a gradual declining pattern in the total number of taxa, with the lowest values at Goathill Campground and the Questa Ranger Station, and a recovery downstream of Cabresto Creek (Fig. 4). Although impacts are evident, these impacts do not render the river unsuitable to benthic invertebrates.

The trend in benthic invertebrate density in the Red River in April 2000 was more variable than that for number of taxa (Fig. 4). The greatest difference in densities between the highest and lowest sites was a 98% reduction, while the greatest difference for number of taxa was 51%. Four of the ten sites sampled in the Red River contained densities of invertebrates greater than 4,500/m<sup>2</sup>, while lower densities were found at June Bug Campground and the sites from Hansen Creek downstream to the Questa Ranger Station (Fig. 4).

The benthic invertebrate data in April 2000 indicate three general areas of impact on the Red River. However, trends in benthic invertebrate data, especially number of taxa, are not as clear as they were for fish population parameters. The first general area exhibiting impacts occurs downstream of the town of Red River (i.e., June Bug Campground), where impacts have consistently been documented in the past (CEC 1997, 1998, 1999, 2000). In April 2000, these impacts resulted in a substantial reduction in density, and

smaller differences in the other population parameters (Table 2). The most extensive section of impact in April 2000 occurs downstream of Hansen Creek. The most severe impact in this section appears downstream of Capulin Canyon and Capulin Springs, at the Questa Ranger Station. Density at this site exhibited a 98% reduction from the site upstream of the town of Red River.

### September 2000

The overall pattern in the Red River drainage in September 2000 indicated that values for number of EPT taxa and diversity were significantly greater ( $p < 0.05$ ) at all four reference sites compared to the sites on the Red River from June Bug Campground downstream to past the hatchery. Density and number of taxa were greater for at least three of the four reference sites compared to most of the sites from June Bug Campground downstream to the Questa Ranger Station. As in April 2000, these differences between the reference sites and the sites downstream of the town of Red River indicate significant impacts to the benthic invertebrate populations.

Density was reduced at June Bug and Elephant Rock campgrounds relative to the reference sites, similar to April 2000 (Table 3, Fig. 4). Density at June Bug Campground was significantly less ( $p < 0.05$ ) than all four reference sites. At Elephant Rock Campground, density was significantly less ( $p < 0.05$ ) than three of the four reference sites. Density was significantly higher ( $p < 0.05$ ) at Elephant Rock Campground compared to June Bug Campground, indicating a longitudinal recovery was occurring between these two sites. Values for the other population parameters also appeared reduced at these two sites (Table 3, Fig. 4). Replicate data showed diversity and number of EPT taxa at June Bug and Elephant Rock campgrounds were significantly less ( $p < 0.05$ ) than all four reference sites, and number of taxa significantly less ( $p < 0.05$ ) than at least two reference sites. However, sensitive taxa (i.e., EPT taxa) were still present, and diversity values greater than 2.50 indicated balanced populations (Table 3).

The overall pattern for percent EPT taxa in September 2000 was not as clear as the other parameters. All four reference sites had significantly higher ( $p < 0.05$ ) values than only three sites, at Elephant Rock Campground, below Hansen Creek, and below the hatchery.

Cabresto Creek (Reference)	7,700	47	26	55	4.22

Population parameters in September 2000 at the site downstream of Hansen Creek were reduced compared to the reference sites and Elephant Rock Campground (Table 3, Fig. 4). Density below Hansen Creek was significantly less ( $p < 0.05$ ) than all four reference sites. Although not significantly different from the density at Elephant Rock Campground, the trend data indicated a 25% decrease from Elephant Rock Campground to the site below Hansen Creek (Table 3). Based on replicate data, values for total number of taxa, number of EPT taxa, diversity, and EPT taxa as % of total taxa were significantly less ( $p < 0.05$ ) than all four reference sites. Compared to Elephant Rock Campground, values for total number of taxa and number of EPT taxa were significantly less ( $p < 0.05$ ) at the site downstream of Hansen Creek. Although not significantly different, diversity below Hansen Creek was also lower than at Elephant Rock Campground. Similar to April 2000, the reduced population below Hansen Creek compared to the reference sites indicates water quality impacts in this section of the Red River.

Benthic invertebrate populations were reduced in September 2000 at the two sites adjacent to the Molycorp property (the site downstream of the mill/upstream of Columbine Creek and the site at Goathill Campground) compared to the reference sites (Table 3, Fig. 4). Total number of taxa, diversity, and number of EPT taxa at these two sites were all significantly less ( $p < 0.05$ ) than at all four reference sites, and density was significantly less ( $p < 0.05$ ) than at least two reference sites. However, population parameters at these two sites adjacent to the Molycorp property were generally greater than the next site upstream, just below Hansen Creek (Table 3, Fig. 4). Total number of taxa, number of EPT taxa, and percent EPT taxa were all significantly greater ( $p < 0.05$ ) at both sites compared to the site below Hansen Creek. Additionally, density was significantly greater ( $p < 0.05$ ) below the mill compared to below Hansen Creek, and diversity was significantly greater ( $p < 0.05$ ) at Goathill Campground. These data indicate that populations adjacent to the Molycorp property were more abundant, and contained a higher proportion of sensitive taxa compared to the site below Hansen Creek. In addition, diversity values at these two sites indicated balanced populations.

The site at the Questa Ranger Station had a reduced population in September 2000 compared to the reference sites and most of the other sites (Table 3, Fig. 4). Values for density, total number of taxa, number of EPT taxa, and diversity were all significantly less ( $p < 0.05$ ) than all four reference sites. As in April 2000, these patterns indicate significant impairment to the aquatic community. However, EPT taxa were still present, including four mayfly taxa, indicating conditions sufficient to support at least some forms of sensitive taxa.

The furthest downstream sites, above the hatchery diversion and below the hatchery, had much greater densities than all the other sites, including the reference sites (Table 3, Fig. 4), with these differences being significant ( $p < 0.05$ ). The high densities were due to abundance assemblages of *Eukiefferiella* sp. (a true fly) at both sites, and due to *Ochrotrichia* sp. and *Hydropsyche* sp. (two caddisfly taxa) at the site below the hatchery (Appendix B). Although values for total number of taxa, diversity, and number of EPT taxa were all significantly less ( $p < 0.05$ ) at both sites compared to the reference sites, generally higher values compared to the site at the Questa Ranger Station indicated a recovery is occurring in this lower portion of the study reach.

The greater densities of the three taxa discussed above at the lowest two sites are probably related to several factors affected by low flows in 2000. Based on U.S. Geological Survey (USGS) data, flows in 2000 were relatively low (USGS unpubl. data). Since higher flows tend to dislodge benthic invertebrates, and taxa such as *Hydropsyche* sp. are better adapted to lower flows (Allan 1995), low flows in 2000 probably did not dislodge as many benthic invertebrates compared to previous years. Additionally, there are two sources of nutrient input downstream of the town of Questa - the Questa sewage treatment facility and the Red River Fish Hatchery. Low flows in the Red River in 2000 would have less of a dilution effect on these nutrient inputs, thus increasing productivity and probably increasing densities of at least some taxa. Low flows would also tend to increase water temperatures and, in kind, productivity. These three factors probably promoted higher densities of *Eukiefferiella* sp., *Hydropsyche* sp., and *Ochrotrichia* at the lowest two sites on the Red River.

The longitudinal patterns for benthic invertebrate populations in September 2000 were generally similar to April 2000, and reflect the overall pattern observed in 2000 and in previous years. There was a general declining pattern in density, total number of taxa, and number of EPT taxa, with the lowest values near the Questa Ranger Station, and the beginning of a recovery downstream of Cabresto Creek (Fig. 4). There were three general areas of impact on the Red River in September 2000: downstream of the town of Red River, downstream of Hansen Creek, and downstream of Capulin Canyon, extending down to the Questa Ranger Station.

## **Sediment**

### Fine Sediment and Texture Analysis

The percentage of fine sediment in riffles in April 2000 varied relatively little from site to site along the length of the Red River (Table 4). The percentage of fines in the Red River ranged from 4.0% at the site downstream of the mill and upstream of Columbine Creek to 30.4% at the site upstream of the hatchery diversion. The average value for the sites downstream of the town of Red River was 11.3% fines. This is similar to the average of 12.3% found in the four reference sites (Columbine and Cabresto creeks, the Middle Fork of the Red River, and the site upstream of the town of Red River). There is no clear longitudinal trend

in the percent of fine sediment in riffles along the length of the Red River. Regression analysis indicated that there was no relationship in April 2000 between percent fine sediment and benthic invertebrate density ( $p = 0.61$ ).

**TABLE 4:** Percentage of fines and texture analysis of sediment samples from the Red River and tributaries, April 2000.

Site	% Fines (<2 mm)	Texture		
		% Clay	% Silt	% Sand
<b>Middle Fork, Red River</b> (Reference)	9.2	4	15	81
<b>Red River</b>				
Upstream of Town of Red River (Reference)	12.8	5	15	80

<b>Tributaries</b>				
Columbine Creek (Reference)	15.0	2	10	88
Cabresto Creek (Reference)	12.3	0	5	95

The lack of a longitudinal trend in fine sediment, despite the presence of point sources of sediment in the drainage, is probably due to two factors. The first, and probably most important, factor is that the sediment samples were taken from riffle areas similar to the benthic invertebrate sampling locations. These areas of the stream are erosional; the fines apparently are not accumulating in riffles. Although there is sediment accumulation in other habitat types (runs and pools), especially at sites from the town of Red River downstream to the Questa Ranger Station (based on visual observation), the absence of a longitudinal trend indicates that the sediment load does not exceed the ability of the river to keep excessive levels of sediment from accumulating in the riffles.

The second factor is related to the actual sampling technique used. The freeze core method has been shown to be very effective in quantifying the amount of fine material in the substrate (Petts *et al.* 1989). The technique involves driving the core sampler into the substrate. While pounding the sampler with a sledge hammer, the deposited fine sediment on the surface of the substrate may be dislodged and lost downstream. Although this technique was the same at every sampling site, it would probably have a greater effect at sampling locations with higher current velocities and/or more densely packed substrate (which requires more pounding to drive in the sampler). However, based on our visual observations, this factor was minor and the riffles at the various sites appeared to be similar in the amount of fines present in 2000.

The texture of the fine sediment varied relatively little among sites in April 2000. Sand accounted for 80-98% of the fine material at all sites (Table 4). Clay particles were present at most sites in small amounts. The highest proportion of clay was found at the site downstream from the mill and upstream of Columbine Creek. Silt particles were more abundant than clay particles at most of the sites in April 2000.

In September 2000, the abundance of fines in the Red River ranged from 19.0% at the site just upstream of the Questa Ranger Station to 27.8% at Goathill Campground (Table 5). Three sites on the Red River were not analyzed for percent fines and texture in September 2000, due to accidental mixing of samples by the analytical laboratory, thus compromising the sample quality. Percent fines in September did not vary appreciably between sites. The average value for the sites downstream of the town of Red River was 21.8% fines. This is similar to the average of 21.9% for three of the four reference sites (Columbine and Cabresto creeks and the Red River upstream of the town of Red River). As in April, there was no discernable longitudinal trend in percent fines along the length of the Red River. Regression analysis indicated no significant relationship in September 2000 between percent surface fines and density of benthic invertebrates in the Red River ( $p = 0.99$ ).

Sediment texture varied little between sites in September 2000, similar to April (Table 5). Sand comprised 75 % to 90 % of the fine material at all sites. Clay comprised from 8 % to 12 % of the sediment, and silt usually less, comprising 0% to 13%.

**TABLE 5:** Percentage of fines and texture analysis of sediment samples from the Red River and tributaries, September 2000. NC = not calculated; due to lab error, samples for fines and texture compromised.

Stream sediment characteristics exhibited seasonal variability in 2000. Percent fines increased from April to September 2000 at all nine sites that had data for both sampling periods (Tables 4 and 5). This included sites on the Red River downstream of the town of Red River and the reference sites. The seasonal averages for percent fines in study sites in the Red River downstream of the town of Red River were 11.3% in April and 21.8% in September 2000. A similar increase was observed at the reference sites, increasing from an average of 12.3% in April to 21.9% in September. This increase could be due to lower flows, typical of fall, losing their capacity to carry sediment downstream, thus leading to deposition within the study area. Lower velocities, especially during low flow conditions during summer months, can lead to increased amounts of fines being deposited into stream substrates (Giles *et al.* 1991, as cited in Wood and Armitage 1997).

Sediment texture also varied between seasons in 2000. The percent abundance of silt in bottom sediments decreased from April to September at eight of the nine sites having data for both seasons (Tables 4 and 5). Conversely, percent abundance of clay increased at all nine of those sites over the same time period. Seasonal variability in the percentage of sand was not as clear, increasing at some sites and decreasing at others.

### Metals Analysis

Results of the sediment metals analysis from April 2000 indicated that concentration of metals was variable between sites, with only one clear longitudinal trend (Table 6, Fig. 5). Zinc exhibited the clearest longitudinal pattern for sediment concentrations, with values increasing in a downstream direction. Sediment from the study site downstream of the fish hatchery had the highest concentration (208 mg/Kg), followed by the sites near Goathill Campground and the Questa Ranger Station (136 and 124 mg/Kg, respectively). A similar pattern was observed in 1999.

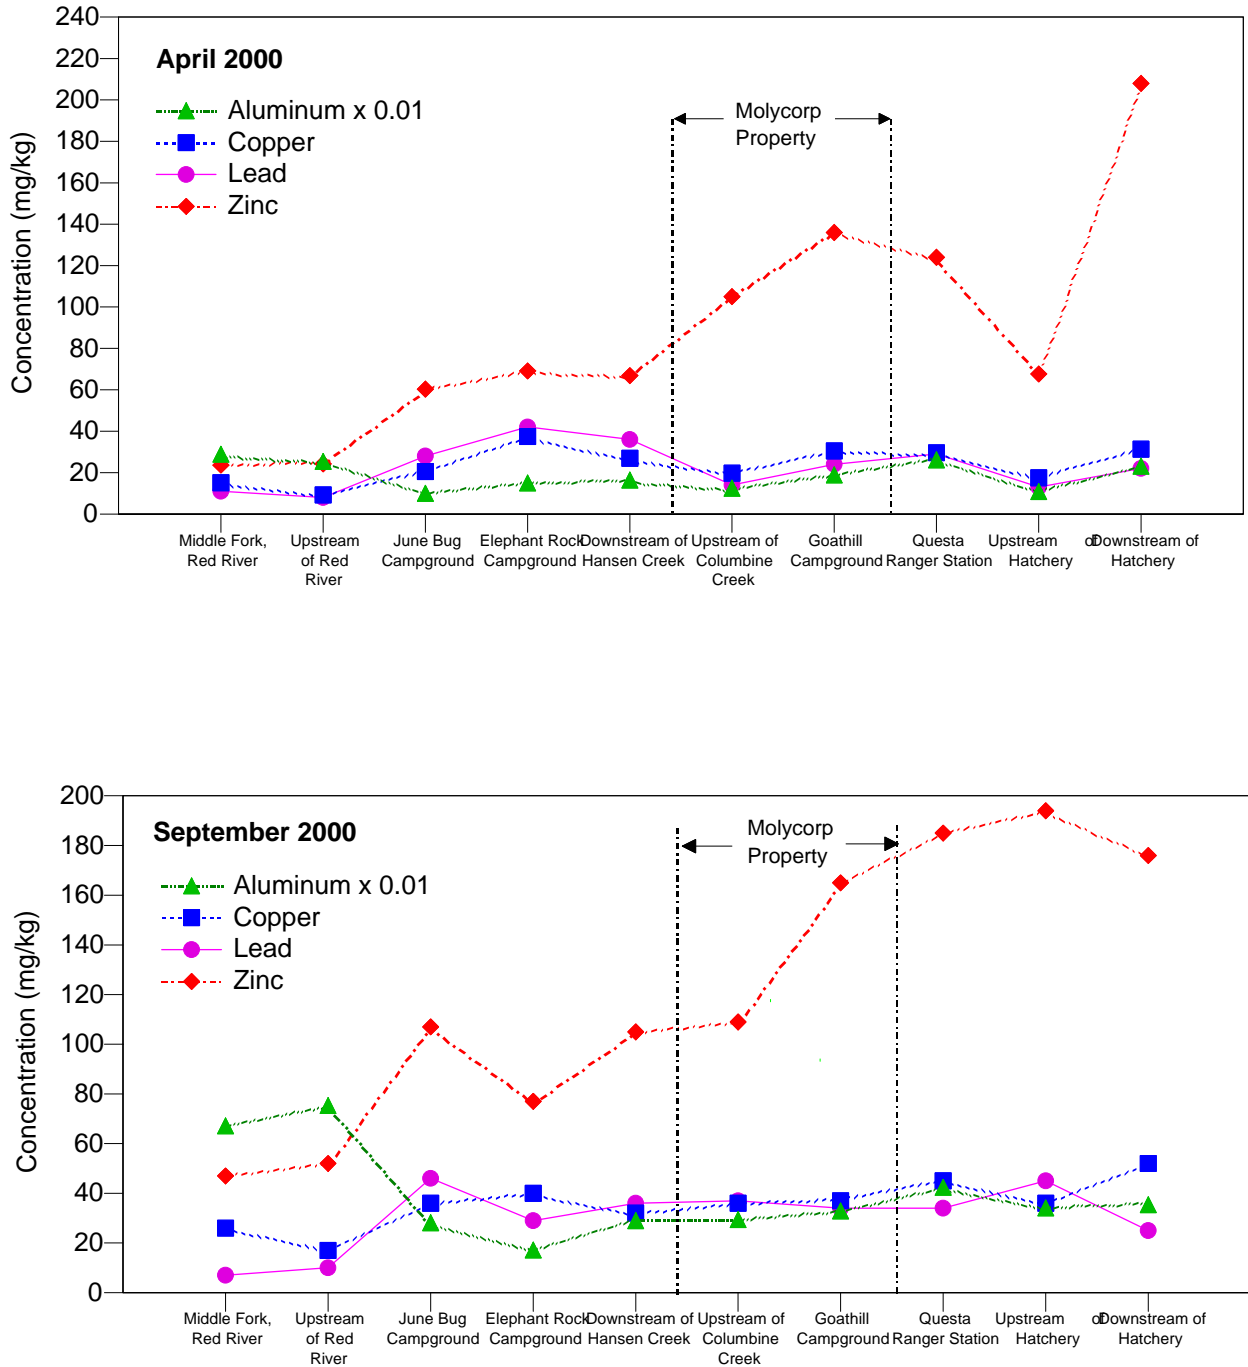

Cadmium concentrations were low,  $\leq 0.7$  mg/Kg at all sites. Aluminum concentrations did not have a clear longitudinal pattern, with some of the highest concentrations in the reference sites on the tributaries and the upper two sites on the Red River. The highest concentration of aluminum downstream from the town of Red River was measured at the study site downstream of Capulin Springs and upstream of the Questa Ranger Station, with a value of 2,610 mg/Kg (Table 6, Fig. 5). The lowest value (1,000 mg/Kg) was observed at June Bug Campground.

Copper, lead, and zinc sediment concentrations in April 2000 began to increase appreciably at the site just downstream of the town of Red River compared to the reference sites on the Red River (Fig. 5). Levels of copper in sediments downstream of the town of Red River in April 2000 were higher than in sediments from the reference sites on the upper Red River and in Columbine and Cabresto creeks (Table 6). Interestingly, levels of lead in sediments from all the sites on the Red River were less than from Columbine Creek (Table 6). Levels of zinc in sediments from the first three sites downstream of the town of Red River were substantially higher than the reference sites upstream of town, but closer in value (and still higher) than the reference sites on Columbine and Cabresto creeks (Table 6).

In regard to sediment criteria for heavy metals, very few reference criteria have been published to date, although Ontario, Canada has sediment criteria that include cadmium, copper, lead, and zinc (Persaud *et al.* 1993). Their sediment quality guidelines have three levels of effect - No Effect Level, Lowest Effect Level, and Severe Effect Level. The No Effect Level describes concentrations that do not affect fish or benthic invertebrates. Sediment at this level is considered clean. The Lowest Effect Level describes concentrations that have no effect on the majority of the fish and benthic invertebrates. Sediment at this level is considered clean to marginally polluted. The Severe Effect Level describes concentrations that are likely to effect the health of fish and benthic invertebrates. Sediment at this level is considered heavily polluted. The latter two levels are based on the long-term effects which the contaminants may have on the sediment-dwelling organisms (benthic invertebrates).

**FIGURE 5:** Sediment concentrations of aluminum, copper, lead, and zinc from study sites in the Red River drainage, April 2000 (top) and September 2000 (bottom).

The metal concentrations in the sediment samples from the Red River drainage in April 2000 were compared to the Ontario standards. Cadmium concentrations in April 2000 were all less than the Lowest Effect Level of 0.6 mg/Kg, except for the site downstream of the hatchery, which had a cadmium concentration of 0.7 mg/Kg (Table 6). Copper concentrations in the Red River drainage in April 2000 ranged from 6 to 37 mg/Kg, with sites downstream of the town of Red River being above the Lowest Effect Level of 16 mg/Kg, but much less than the Severe Effect Level of 110 mg/Kg. Concentrations of lead ranged from 8 to 45 mg/Kg in the drainage, with only three sites (Elephant Rock, downstream of Hansen Creek, and Columbine Creek) having levels higher than the Lowest Effect Level of 31 mg/Kg. These three sites had levels of lead just barely above the Lowest Effect Level, and much less than the Severe Effect Level of 250 mg/Kg. Zinc concentrations ranged from 24 to 208 mg/Kg, with three sites (Goathill, Questa Ranger Station, and downstream of the hatchery) surpassing the Lowest Effect Level of 120 mg/Kg. However, these concentrations were much less than the Severe Effect Level for zinc of 820 mg/Kg.

Sediment metals analysis from September 2000 also indicated variability between sites (Table 7, Fig. 5). Zinc was the only metal to exhibit a clear longitudinal trend, with values increasing in a downstream direction. The site upstream of the fish hatchery diversion had the highest concentration (194 mg/Kg), followed by the sites near the Questa Ranger Station and the site downstream of the hatchery (185 and 176 mg/Kg, respectively). This pattern of increased sediment zinc concentrations in a downstream direction is similar to the pattern observed in April 2000 (Fig. 5).

Cadmium concentrations in September 2000 were low,  $\leq 0.7$  mg/Kg at all sites. Aluminum concentrations in September 2000 were highest at the four reference sites upstream of the town of Red River and in the tributaries. There was a slight increasing trend in sediment aluminum concentrations from Elephant Rock Campground downstream to the Questa Ranger Station (Table 7, Fig. 5).

Similar to April, copper, lead, and zinc sediment concentrations in September 2000 increased appreciably at June Bug Campground, the first site downstream of the town of Red River (Table 7, Fig. 5). Copper concentrations in the Red River sediments downstream of town were all greater than in sediments from the reference sites (Table 7). Lead concentrations in sediments downstream of town were all greater than the reference sites in the Red River upstream of town, but similar to those in sediments from Columbine

Creek. Interestingly, sediment aluminum concentrations decreased dramatically downstream of the town of Red River, where they were all lower than three of the four reference sites (Fig. 5).

Upon comparison with the Ontario sediment standards, cadmium concentrations in September 2000 were less than or equal to the Lowest Effect Level of 0.6 mg/Kg, except for the site downstream of the hatchery, with a value of 0.7 mg/Kg (Table 7). Copper concentrations in the Red River drainage in September 2000 ranged from 9 to 52 mg/Kg, with almost all sites greater than the Lowest Effect Level of 16 mg/Kg, but much less than the Severe Effect Level of 110 mg/Kg. Lead concentrations ranged from 7 to 46 mg/Kg in the drainage, with seven sites having values greater than or equal to the Lowest Effect Level of 31 mg/Kg, including the reference site on Columbine Creek (Table 7). All lead concentrations were much less than the Severe Effect Level of 250 mg/Kg. Zinc concentrations in September 2000 ranged from 47 to 194 mg/Kg, with four sites (from Goathill Campground downstream to below the hatchery) surpassing the Lowest

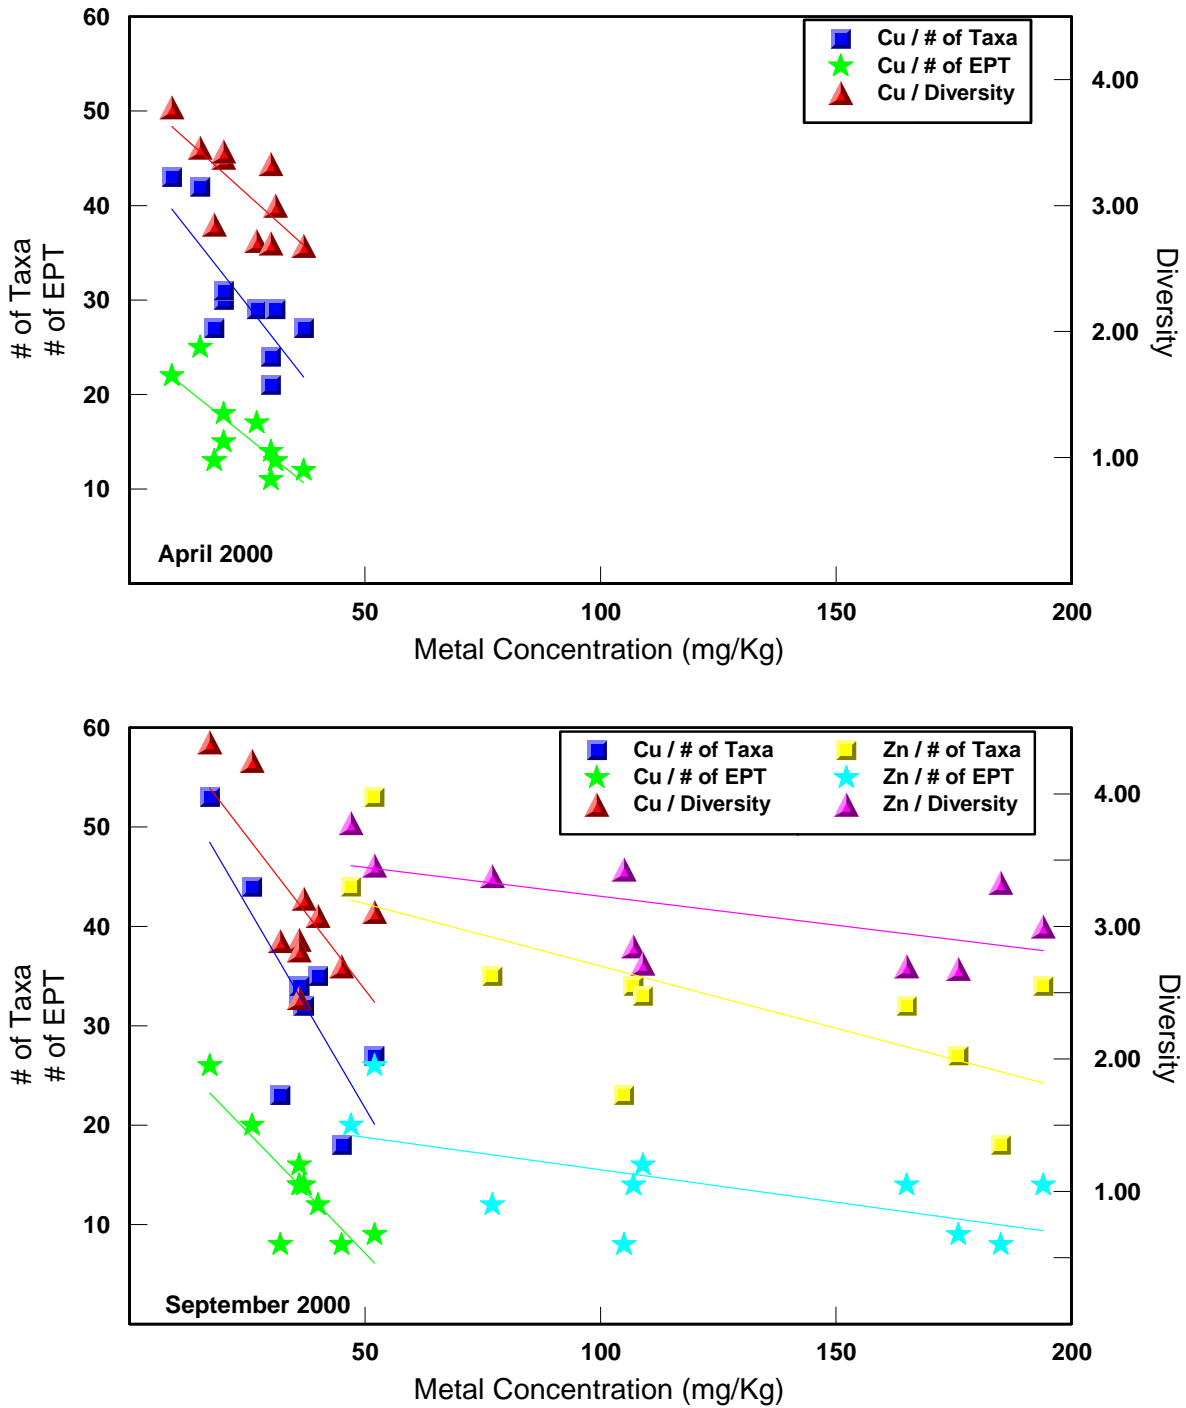

Effect Level of 120 mg/Kg (Table 7). However, all these concentrations were much less than the zinc Severe Effect Level of 820 mg/Kg.

The data from the April and September heavy metals analysis for sediments from the Red River drainage indicated that sediment metal concentrations sometimes exceeded the Lowest Effect Levels, but were always much less than the Severe Effects Levels. These results suggest that sediment metals concentrations do not pose a severe threat to fish and benthic invertebrates in the Red River drainage.

The Ontario guidelines did not include effect levels for aluminum, so sediment concentrations from the Red River drainage were compared to results from another study. In the lower Rio Grande Valley and Laguna Atascosa National Wildlife Refuge, Texas, sediment concentrations of aluminum ranged from 940 to 20,000 mg/Kg, which were within the baseline concentrations for soils in the western conterminous United States (Wells *et al.* 1988). Sediment concentrations in the Red River drainage in April and September 2000 ranged from 1,000 to 3,180 mg/Kg, and from 1,720 to 7,530 mg/Kg, respectively, with the higher levels from the tributaries and the upstream reference sites. All of these concentrations were within the range reported from Texas, and within baseline concentrations for the western United States.

There were some significant relationships ( $p < 0.05$ ) between levels of metals in sediments and benthic invertebrate population parameters (Fig. 6 and Appendix C). In April and September 2000, levels of copper had a significant, negative relationship with number of taxa, number of EPT taxa, and diversity. Aluminum and zinc had significant relationships in September 2000 with number of taxa, number of EPT taxa, and diversity. Although the relationship with zinc was negative, as with copper, the relationship with aluminum was positive. This means that sites with higher aluminum concentrations also had higher values for the benthic invertebrate population parameters, which challenges common sense. However, the highest aluminum levels in the Red River in September 2000 were at the two reference sites, above the town of Red River. These two sites artificially created the positive relationship. There may be other factors in this section of river positively affecting benthic invertebrate populations, overriding any potential effects from aluminum, thus producing the positive relationship. When these two sites were dropped as outliers from the analysis of aluminum (an accepted statistical method), there were no significant relationships between aluminum and any benthic invertebrate population parameters.

**FIGURE 6:** Significant ( $p < 0.05$ ) negative relationships between sediment metal concentrations and benthic invertebrate population parameters from study sites in the Red River drainage, April 2000 (top) and September 2000 (bottom).

As discussed above, there were significant negative relationships between two metals, copper and zinc, and three population parameters, number of taxa, number of EPT taxa, and diversity (Fig. 6). These data suggest that sediment levels of these metals have some impact on populations of benthic invertebrates in the Red River.

### **Toxicity Testing**

None of the *C. dubia* exposed to Red River water column samples were determined to have had significant ( $p < 0.05$ ) impacts on survival. All concentrations were observed to have between 90% and 100% survival at the end of seven days exposure (Table 8). However, mean *C. dubia* reproduction was significantly ( $p < 0.05$ ) reduced, relative to a corresponding control, at the Zweigle Dam reference site (11.8 vs. 18.2 neonates), at the site downstream of Hansen Creek (12.1 vs. 26.4 neonates), at Goat Hill Campground (11.7 vs. 28.9 neonates), and downstream of Outfall 001 (11.1 vs. 18.2 neonates). These data indicate that the water column in the Red River was chronically toxic to *C. dubia* at four of six sites sampled along its length.

The survival of *C. dubia* exposed to Red River sediment (Table 9) was significantly ( $p < 0.05$ ) reduced in samples from the Zweigle Dam site (60% survival) and by samples collected downstream of Capulin Canyon (30% survival). None of the other samples were determined to have a significant effect on *C. dubia* survival. In addition to causing a significant reduction in survival of *C. dubia*, sediment samples from the Zweigle Dam site (8.5 vs. 18.1 neonates) and downstream of Capulin Canyon (4.6 vs. 18.1 neonates) were observed to significantly reduce the mean number of neonates produced by the exposed organisms. While no significant effects were detected to the survival of organisms exposed to sediment samples from June Bug Campground, *C. dubia* exposed to this sample were observed to have significantly decreased reproduction (17.6 vs. 23.5 neonates).

Fathead minnow embryos were exposed to both water column and sediment samples from the same sites as the *C. dubia* discussed above. These organisms were checked for number alive, number hatched, and terata (collectively known as number affected) at the end of the seven-day test period (Table 10). None of the water column samples from the Red River were determined to have significantly ( $p < 0.05$ ) affected the fathead minnows exposed to those samples. Of the sediment samples, only the sample from the June Bug Campground was determined to have a significant ( $p < 0.05$ ), negative effect on the test organisms (55% vs.

7.5% affected). These results indicate that none of the water column samples collected were toxic to fathead minnows, while only the sediment sample from June Bug Campground was toxic to fathead minnows.

An extensive list of water quality parameters were measured in samples collected October 25, 2000 by the State of New Mexico Department of Health Water Quality Laboratory (Appendix D). Of these parameters, aluminum was the only one that was observed to exceed its chronic water quality criterion or be present at potentially toxic concentrations. Aluminum was observed to be present in levels exceeding the chronic water quality criteria of 0.087 mg/L (USEPA 1988) at three sites: downstream of Hansen Creek, (0.130 mg/L), Goat Hill Campground (0.120 mg/L), and downstream of Capulin Canyon (0.130 mg/L). Samples from each of these sites were observed to cause significantly decreased reproduction of *C. dubia* test organisms in the water column toxicity tests. It is possible that the elevated concentrations of aluminum in these samples was the cause of the chronic toxicity to *C. dubia* in the water column toxicity tests.

## RECENT TRENDS IN AQUATIC BIOTA

### Fish

Fish population sampling data from the fall of 1997, 1998, 1999, and 2000 collected by CEC and data collected in August 1997 by NMDGF (1997) were compared to evaluate year-to-year variability in fish populations. Resident trout data from spring 1997 collected by CEC are not included as these data are probably not directly comparable to data collected in fall. The presence of YOY fish tends to produce a

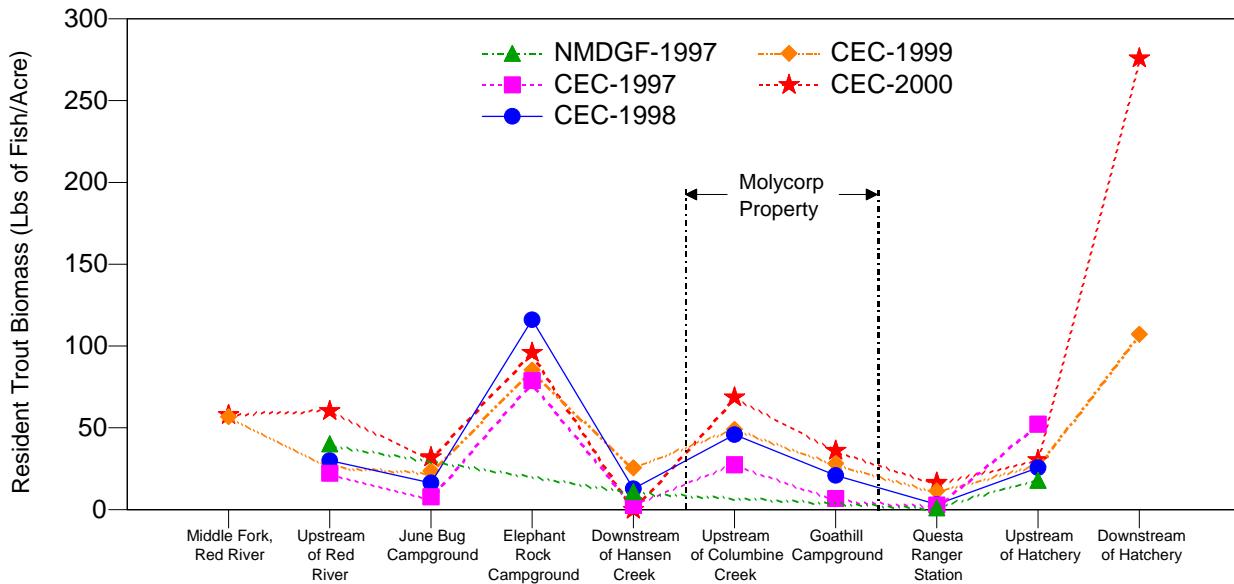

seasonal trend of more fish being collected in fall compared to spring in any given year, which could complicate annual comparisons.

The resident trout data from 1997, 1998, 1999, and 2000 exhibit nearly identical longitudinal trends for density and biomass (Figs. 7 and 8, respectively). Density and biomass data vary quite a bit over the length of the Red River. The variability suggests three areas of impacts resulting in decreases in trout density and biomass. Impacts appear to be occurring just downstream of the town of Red River, downstream of Hansen Creek, and downstream of Capulin Canyon (Figs. 7 and 8). High biomass of trout in all four years of CEC sampling occurred at the Elephant Rock Campground site (Fig. 8). Downstream of Hansen Creek, impacts result in substantial reductions in biomass. The high biomass found at Elephant Rock Campground is not matched again at any site along the remainder of the Red River downstream to the hatchery (Fig. 8). In 1997 and 1998, biomass at this site was higher than at all the other sites on the Red River. In 1999, the sampling site which was added to the monitoring program downstream of the hatchery had resident trout biomass that was comparable to that at the Elephant Rock Campground site (Fig. 7). In 2000, the site downstream of the hatchery had biomass more than twice as high as any other site on the river, including the Elephant Rock Campground site (Fig. 7). As discussed previously, the higher biomass is probably due to enriched productivity from the hatchery outflow. Decreased habitat quality (CEC 2000) or poor water quality below the town of Red River and below Hansen Creek could be related to decreased trout populations in these sections.

Lowest density and biomass occurred at the Questa Ranger Station Site from 1997 up through 1999 (Figs. 7 and 8). This site is downstream of Capulin Canyon and Capulin Springs. Density and biomass recover at the site upstream of the fish hatchery, probably due, in part, to the input of relatively clean water from Cabresto Creek, and increase even more downstream of the hatchery, probably aided by the inflow of nutrient rich water. Lowest density and biomass in 2000 was at the site downstream from Hansen Creek, indicating that, at least in some years, impacts in this section can be more severe than near the Questa Ranger Station.

**FIGURE 7:** Comparison of resident trout density (number per mile) for CEC data collected in fall 1997, 1998, 1999, and 2000 and data from August 1997 collected by NMDGF. Data represent results from all electrofishing passes. Sites on the Middle Fork and downstream of the hatchery added in 1999.

**FIGURE 8:** Comparison of resident trout biomass (pounds per acre) for CEC data collected in fall 1997, 1998, 1999, and 2000 and data from August 1997 collected by NMDGF. Data represent results from all electrofishing passes. Sites on the Middle Fork and downstream of the hatchery added in 1999.

Year-to-year variability in trout populations is common in the western United States (Hall and Knight 1981, Platts and Nelson 1988, Scarnecchia and Bergersen 1987). Based on data from 1997 to 2000 in the Red River, we attributed at least some of the variability in trout populations to variability in flow conditions from year to year (CEC 1999). There is frequently an inverse relationship between the timing and magnitude of spring snowmelt runoff flows and fish density (McCullough 1997, Pearsons *et al.* 1992). In years of lower spring runoff, trout generally exhibit higher density and biomass. This has been attributed to the vulnerability of trout fry to displacement during years with higher than normal spring runoff (Anderson and Nehring 1985). Variability between 1997 and 1998 and between 1999 and 2000 followed this pattern. At seven of the eight sites sampled on the Red River in 1998, resident fish density and biomass were higher than in 1997 (Figs. 7 and 8). We attributed this to the fact that in 1998, spring runoff was relatively low. USGS gaging records at the Questa gage (Fig. 1) indicate that peak daily flow was only 139 cfs in May and June 1998. In contrast, average peak daily flow over a 31-year period (1958-1988) was 209 cfs, and peak daily flow during runoff in 1997 was 347 cfs. The low runoff year in 1998 appears to have allowed trout density and biomass to increase at most locations in the Red River. A similar pattern was observed between 1999 and 2000. Peak spring runoff in 1999 was 288 cfs, much higher than in 2000 with a value of 48 cfs. This decrease in peak flows from 1999 to 2000 corresponded to higher density and biomass values at most of the study sites in 2000 compared to 1999 (Figs. 7 and 8).

However, this inverse relationship between peak runoff flows and density and biomass did not hold up as well between 1998 and 1999. In 1999, runoff flows were above the 31-year average (209 cfs), with a peak runoff flow of 288 cfs. Peak runoff in 1998 was 139 cfs, approximately 50% lower. Based on the pattern discussed above for the periods between 1997 and 1998 and between 1999 and 2000, the relatively high flows in 1999 compared to 1998 should have resulted in lower trout density and biomass in 1999. However, density was lower at only four sites in 1999, and biomass was lower at only one site in 1999. This lack of a strong pattern between 1998 and 1999 suggests that there may also exist additional environmental factors, other than peak runoff flow, that also control trout density and biomass in the Red River drainage.

The number of YOY resident trout does appear to vary with peak flows in the Red River. There were lower numbers of YOY collected at the eight sites on the Red River in the higher flow years of 1997 and 1999; many more were collected in the lower flow years of 1998 and 2000 (Table 11). The number of

YOY represents all resident trout (brook trout, brown trout, cutthroat trout, and hybrid trout) collected at the corresponding sites. Site lengths varied between years, but not substantially. The number of YOY collected seems to be inversely related to peak runoff flow (Table 11), although the relationship is not significant ( $p = 0.11$ ). In the two years with relatively high runoff flows, there were fewer young trout; and in 1998 and 2000, when runoff flows were substantially below average, the number of trout fry was much higher at the Red River sites. Although we have no flow records for the tributaries, assuming the flow years followed the same pattern in these two streams, the YOY catch pattern is not as strong in these streams, except in 2000, when very low runoff flows corresponded to a substantially higher number of YOY.

**TABLE 11:** Number of young-of-the-year resident trout collected during electrofishing at study sites on the Red River and tributaries, 1997-2000, and peak runoff flow data.

Site	1997	1998	1999	2000
<b>Red River</b>				
Upstream of Town of Red River	7	41	4	198
June Bug Campground	0	1	0	15
Downstream Elephant Rock Campground, upstream of Hansen Creek	3	10	3	17
Downstream of Hansen Creek, upstream of mill	7	7	0	0
Downstream of mill, upstream of Columbine Creek	0	8	0	0
Goathill Campground	0	3	2	13
Upstream of Questa Ranger Station	7	5	2	6
Upstream of hatchery diversion	6	5	3	18
<b>Total</b>	<b>30</b>	<b>80</b>	<b>14</b>	<b>267</b>
<b>Tributaries</b>				
Columbine Creek	5	7	10	66
Cabresto Creek	26	24	22	83
<b>Total</b>	<b>31</b>	<b>31</b>	<b>22</b>	<b>149</b>
<b>Peak Runoff Flow (cfs)</b>	<b>347</b>	<b>139</b>	<b>288</b>	<b>48</b>
<b>Average Peak Runoff Flow 1958-1988 (cfs)</b>	<b>209</b>	<b>209</b>	<b>209</b>	<b>209</b>

The implications of this variable pattern of peak flows versus density, biomass, and YOY abundance is that there may be a time lag between high flow years and resulting lower density and biomass of trout in future years. A single wet or dry year and the resulting year-class strength may have little effect on the variability of trout density and biomass in the long term, as other important factors may have a greater effect. However, a few consecutive wet years could result in several consecutive poor year-classes of trout, and thus

lower density and biomass in the future. Conversely, several low flow years may result in relatively high density and biomass.

### **Benthic Invertebrates**

Benthic invertebrate data from fall 2000, fall 1999, fall 1998, fall 1997 (CEC 1998, 1999, 2000) and early winter 1995 (Woodward Clyde 1996) are compared to evaluate year-to-year variability in invertebrate populations (Figs. 9 and 10). The year-to-year variability in density appears to be much greater for benthic invertebrate population parameters ( Figs. 9 and 10) than for fish parameters (Figs. 7 and 8).

The trends in all five years are generally consistent, with reduced densities and numbers of taxa downstream of the town of Red River and Hansen Creek, reaching a minimum at the Questa Ranger Station site (Figs. 9 and 10). This site is downstream of the confluence with Capulin Canyon and Capulin Springs, and consistently represents the most impacted section of the Red River. A trend of low benthic invertebrate population parameters was also found in this section of the river by Jacobi *et al.* (1998).

The trends in all five years are also consistent in exhibiting substantial recovery at the site upstream of the fish hatchery. This site is downstream of the confluence with Cabresto Creek. Apparently, the recovery pattern is enhanced by dilution water from Cabresto Creek, which allows the benthic invertebrate populations to recover to levels comparable to those found in the reaches of the Red River upstream of Hansen Creek. This trend was also demonstrated in Jacobi *et al.* (1998).

During four of the five years, including 2000, there was a substantial decrease in density downstream of Hansen Creek as compared to the site immediately upstream (Fig. 9). A corresponding sharp decrease in number of taxa did not necessarily occur every year (Fig. 10). Impacts that affect density appear to be occurring in some years; however, the fact that density was relatively high at this site in 1997 suggests that these impacts may be alleviated in other years.

**FIGURE 9:** Comparison of benthic invertebrate density ( $\#/m^2$ ) for data collected by CEC in fall 1997, fall 1998, fall 1999, and fall 2000, and at corresponding sites by NMED in December 1995.

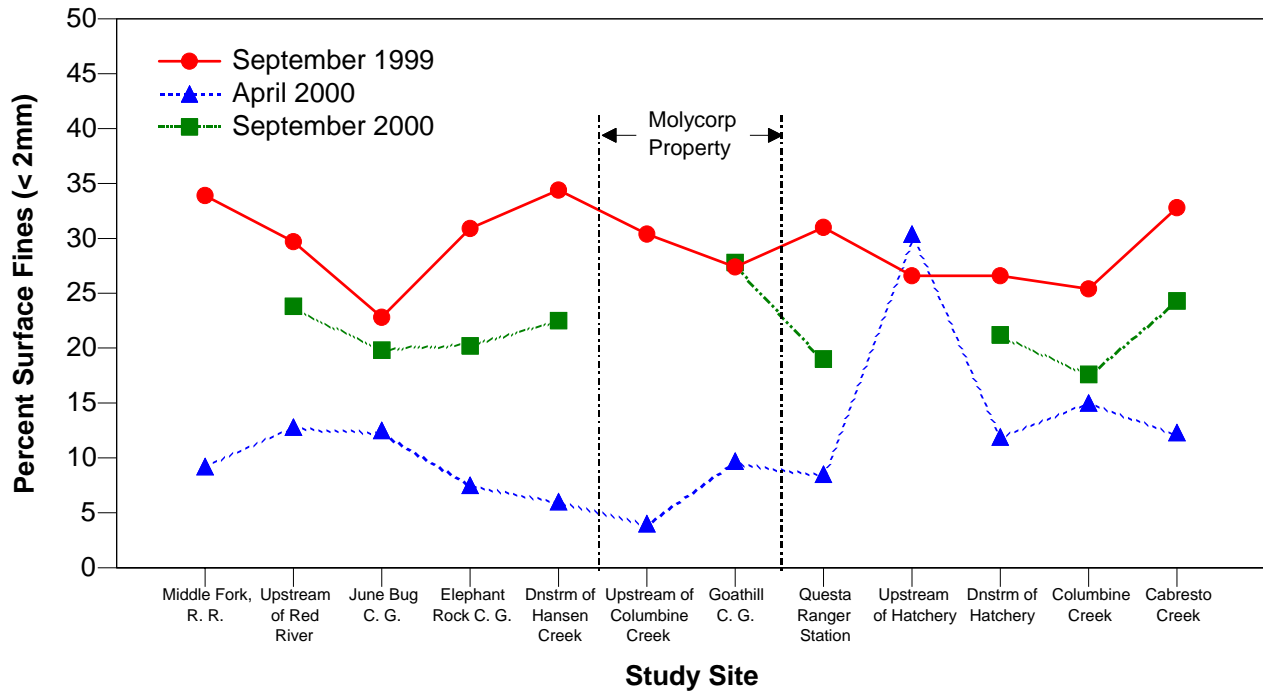

**FIGURE 10:** Comparison of number of benthic invertebrate taxa for data collected by CEC in fall 1997, fall 1998, fall 1999, and fall 2000, and at corresponding sites by NMED in December 1995.

During four of the five years, (1995, 1997, 1999, 2000) density was relatively low at the June Bug Campground site, just downstream of the town of Red River (Fig. 9). The number of taxa present at that site was reduced in 1995, 1999, and 2000 relative to the upstream reference sites (Fig. 10). As with Hansen Creek, it appears that the section of the river near the town of Red River may be experiencing impacts. In a previous report (CEC 2000), we stated that the low density years corresponded to the years with higher runoff flows, and that these flows may explain some of the variation in density from year to year. However, 2000 experienced the lowest runoff flows since this study began, but density in the fall was still low. The correlation between density at June Bug Campground and runoff flows may not be as strong as previously thought.

Regressions were conducted to determine if there was a statistical relationship between peak runoff flow and density or number of taxa of benthic invertebrates. When data from all sites on the Red River were combined, there was no significant relationship between flow and density or number of taxa. Likewise, when sites were analyzed separately, no statistically significant relationships were found. These results indicate that some factor or combination of factors, other than peak runoff flows, are affecting annual variability of benthic invertebrate populations along the entire length of the Red River.

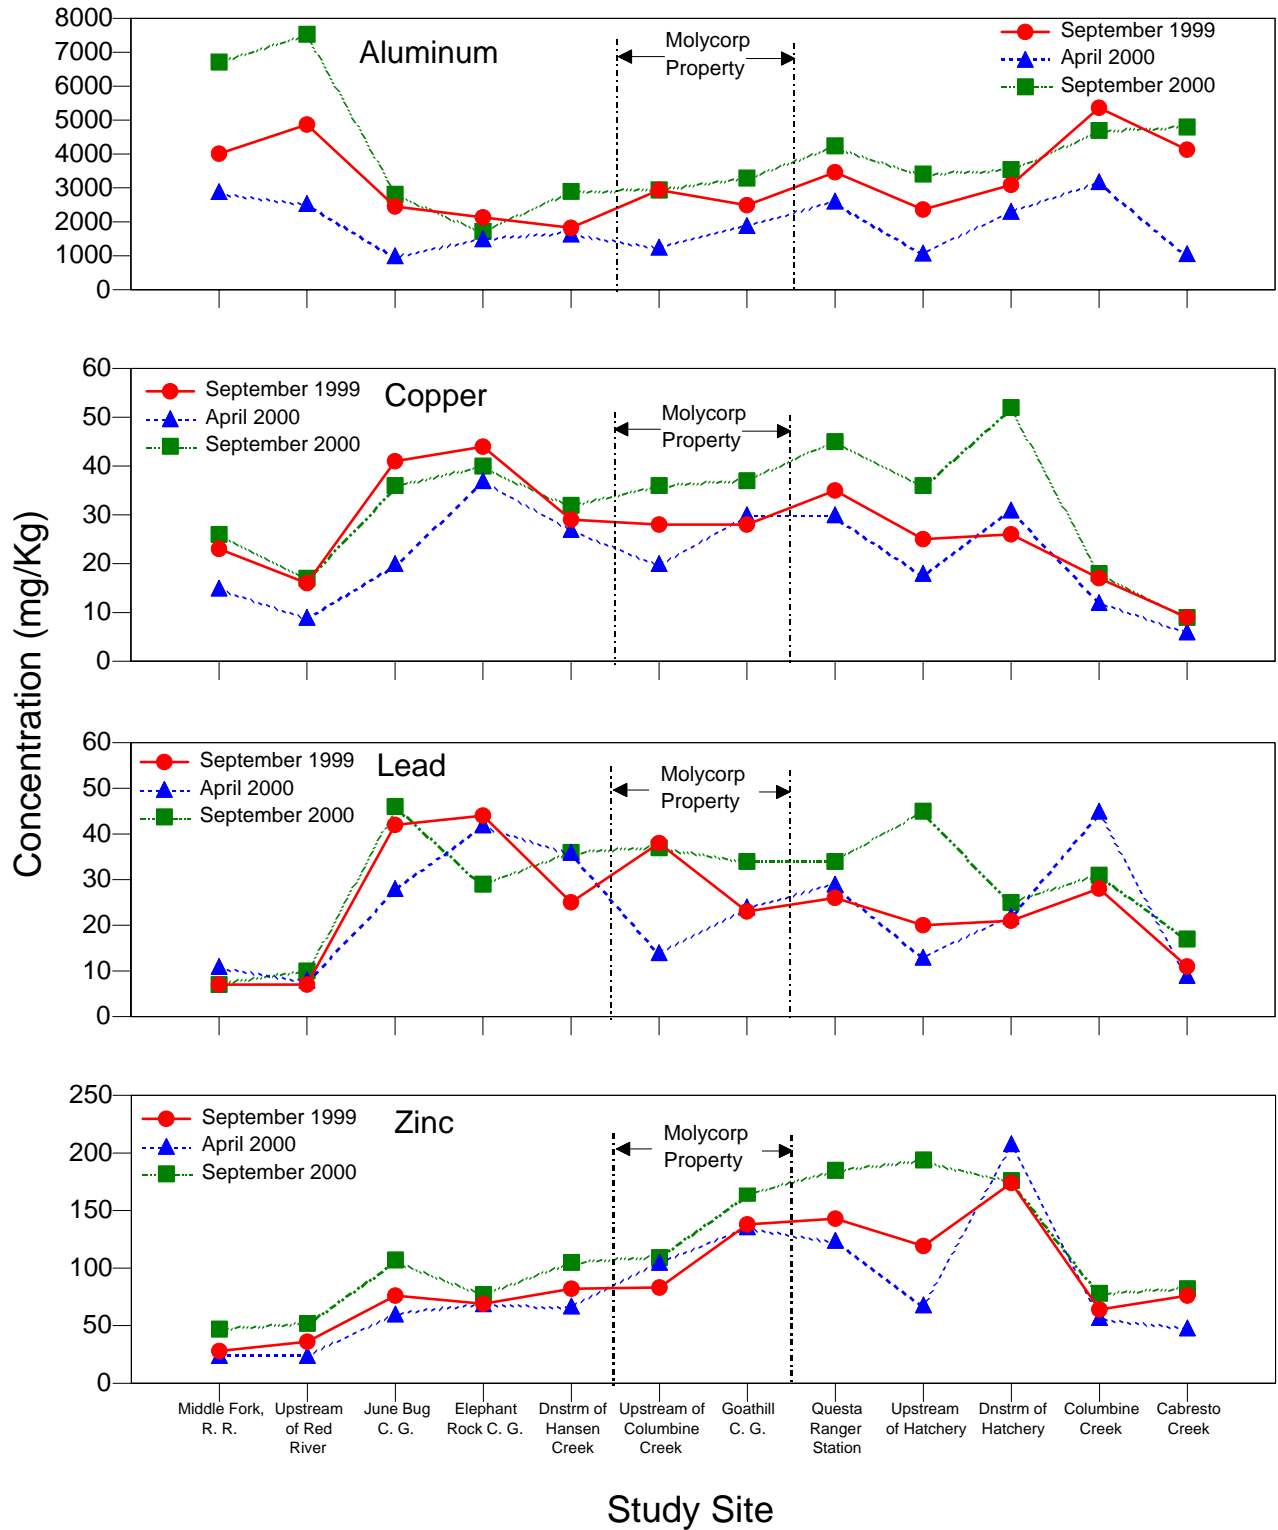

### **RECENT TRENDS IN SEDIMENT**

Annual variability (i.e., from 1999 to 2000) in sediment characteristics was also observed at the study sites. Percent fines decreased from September 1999 to September 2000 at eight of the nine Red River sites having data for both periods (Fig. 11). A similar decrease was observed for the reference sites on Columbine and Cabresto creeks. This decrease from September 1999 to September 2000 is opposite of what one would expect, based on USGS data from the stream gage at Questa. Annual flows in 2000 were much less than in 1999, leading one to expect greater levels of surface fines in September 2000. However, this was not the case, with higher levels occurring in 1999, the year with the higher annual flows. Texture also varied between years. Percent abundance of clay and silt increased from September 1999 to September 2000 at all nine sites having data for both periods. Conversely, percent abundance of sand decreased at those same sites.

**FIGURE 11:** Percent surface fines (<2 mm) from sieve analysis on freeze core sediment samples from the Red River and tributaries, 1999-2000.

The metal concentration data from the sediments from September 1999, April 2000, and September 2000 generally show the same trends between seasons and between years (Fig. 12). However, the actual levels of metal concentrations in sediments were variable between seasons and between years (Fig. 12). For example, sediment concentrations for aluminum, copper, and zinc in April 2000 were lower at most sites compared to values from September 1999 and September 2000. This pattern was not as evident for lead. These lower concentrations in April 2000 could be related to the seasonality of flows in the Red River drainage. Some spring snowmelt runoff had occurred by April 2000, which allowed access for sampling the streams. These early runoff flows may have washed some metals-laden sediments downstream out of the study area, thus decreasing sediment concentrations. The lower flows typical of the fall season probably do not have the capacity to wash metals-laden sediments downstream, thus depositing them within the study area. The higher flows in spring probably contribute to the seasonally lower sediment concentrations in April 2000 compared to September 1999 and September 2000, similar to the seasonally lower levels of percent fines in the substrate discussed earlier.

**FIGURE 12:** Seasonal variations in concentrations of aluminum, copper, lead, and zinc from sediments in the Red River and tributaries, 1999 and 2000.

Sediment metal concentrations in September 1999 and September 2000 indicated another interesting temporal variation. For aluminum, copper, lead, and zinc, concentrations at most sites in September 2000 were greater than in September 1999 (Fig. 12). These differences are also most likely due to streamflows in the Red River drainage. Stream gaging records by the USGS at the Quest gage indicate that annual flows in 2000 were much lower than in 1999 (USGS, unpubl. data). Flows in 2000 probably had less capacity to carry metals-laden sediments out of the study area, resulting in higher levels in September 2000 compared to September 1999.

## HISTORICAL TRENDS IN AQUATIC BIOTA

### Fish

Fish population data providing longitudinal patterns of fish density are available from three different time periods of mine operation (Fig. 13). Data from 1960 were collected prior to the initiation of open pit mining, and represent baseline data. Present conditions are represented by data collected in fall 1997, 1998, 1999, 2000 by CEC and in August 1997 by NMDGF. Data collected during the intervening period of open pit mine operation (1974-1988) are also plotted.

As in past reports (CEC 1997, 1998, 1999, 2000), in order to make the data sets for the four periods comparable, only first-pass electrofishing data were used, since this was the primary sampling method used during the earlier studies. Also, since rainbow trout are largely maintained by stocking, and are not as directly controlled by habitat and water quality conditions as are resident fish, rainbow trout numbers have been omitted from the comparison. Lastly, since most of the historic data only present density data, longitudinal comparisons of biomass could not be made.

As stated in our past reports (CEC 1997, 1998, 1999, 2000), data collection techniques over the years have varied in methods used and efficiency of collecting fish. This makes direct comparisons between the three different historical periods more difficult. However, assuming that the methods and sampling efficiencies were at least consistent within each historical time period, comparisons of the longitudinal trends are reasonable.

**FIGURE 13:** Longitudinal trends in fish density (#/mile) for baseline conditions (1960 data), open pit mine operation (1974-1988 data), and present conditions (1997-2000). First pass data only, rainbow trout excluded

The longitudinal trends in fish density (number of fish/mile) are similar during all three time periods. The trends all indicate relatively high fish density upstream of the town of Red River, decreasing density downstream of Hansen Creek, and increasing density downstream of Questa (Fig. 13). This trend holds for baseline conditions (1960 data), during the intervening period of open pit mine operation (1974-1988), and present conditions (spring, summer, and fall 1997, fall 1998, fall 1999, and fall 2000 data). These are the same trends identified in our earlier reports (CEC 1997, 1998, 1999, 2000).

The trends in trout density in all three periods indicate that impacts are first occurring to the suitability of the Red River to support trout near the town of Red River. The trends in trout density in all three periods also indicate further impacts to trout downstream of Hansen Creek (Fig. 13). Downstream of Hansen Creek and through the section of the Red River adjacent to the Molycorp property, trout density remains low. During all three sampling periods, there was also a substantial increase in resident trout density in the reach of the Red River downstream of Questa. In this lower reach of the river, trout density returned to levels comparable to or higher than those found in the reach upstream of the town of Red River (Fig. 13).

As stated previously, these longitudinal patterns in fish abundance could, in part, be related to habitat differences between sites. However, there are probably other factors (e.g., water quality, nutrient enrichment) also closely related to fish abundance at some sites.

### **Benthic Invertebrates**

For benthic invertebrates, the collected data also were divided into three time periods. Baseline conditions were represented by data collected in 1965, apparently prior to the initiation of open pit mining. Benthic invertebrate data collected in 1995, fall 1997, fall 1998, fall 1999, and spring and fall 2000 represent present conditions. Data available from the intervening period (1970-1992) represent conditions during open pit mining.

Comparisons are made between the two population parameters of density ( $\#/m^2$ ) and number of taxa. As with the historical fish data, techniques for sampling and analyzing invertebrates may have varied between the periods, making direct comparisons over time difficult. However, assuming similar techniques were employed within each historical time period, comparisons of the downstream trends are reasonable.

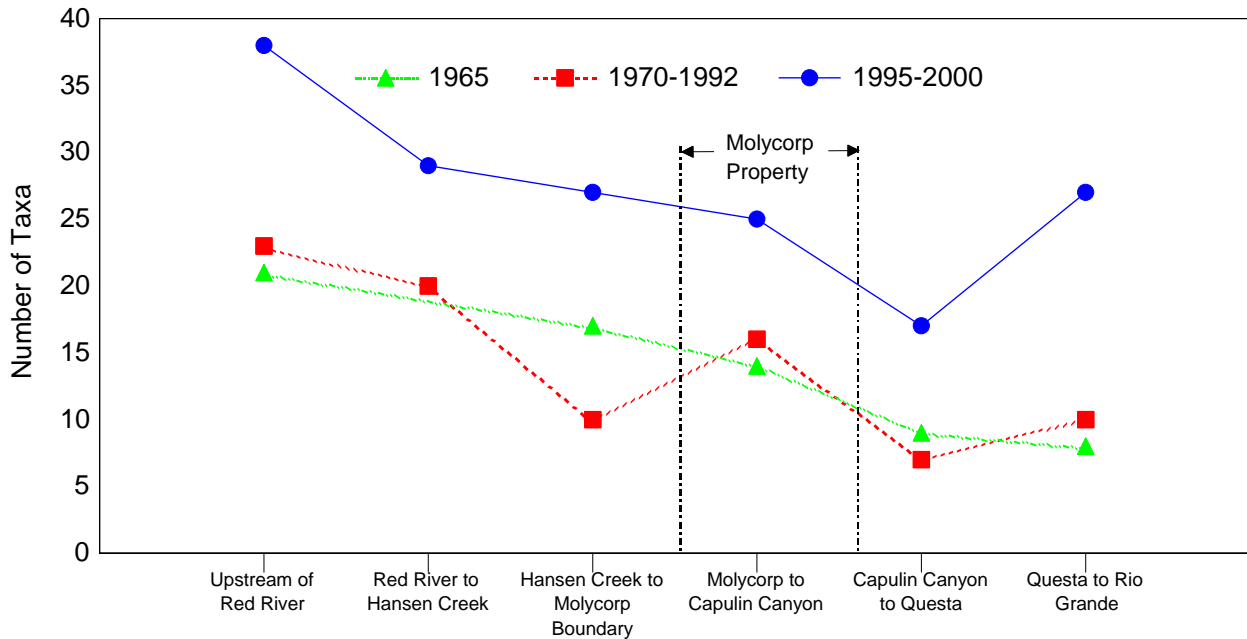

The longitudinal trends in density for the three sampling periods (1965, 1970-1992, and 1995-2000) show a similar pattern of decreasing density downstream from the headwaters of the Red River, with low densities of benthic invertebrates downstream of Hansen Creek (Fig. 14). In the remainder of the Red River from the MolyCorp property downstream past Questa, the data from the three sampling periods also have a similar trend (Fig. 14). Low densities continue to occur adjacent to the MolyCorp Mine, and lowest densities are found near the Questa Ranger Station in the reach of the river downstream of Capulin Canyon. This is followed by an increase in density in the reach downstream of Questa, after Cabresto Creek inputs relatively clean water into the Red River. This general trend has not changed since 1965. These are the same trends identified in our earlier reports (CEC 1997, 1998, 1999, 2000).

The trend in number of taxa for three sampling periods (1965, 1970-1992, and 1995-2000) indicates a gradual decrease in taxa along the length of the Red River to the reach downstream of Capulin Canyon (Fig. 15). This is followed by an increase in number of taxa downstream of Questa for two of these periods (1970-1992, 1995-2000).

**FIGURE 14:** Longitudinal trends in benthic invertebrate density ( $\#/m^2$ ) for baseline conditions (1965 data), open pit mine operation (1970-1992 data), and present conditions (fall 1995, fall 1997, fall 1998, fall 1999, spring and fall 2000 data). Analysis includes sites on Middle Fork and downstream of hatchery.

**FIGURE 15:** Longitudinal trends in number of benthic invertebrate taxa for baseline conditions (1965 data), open pit mine operation (1970-1992 data), and present conditions (fall 1995, fall 1997, fall 1998, fall 1999, and spring and fall 2000 data). Analysis includes sites on Middle Fork and downstream of hatchery.

In all six reaches for data collected in 1995-2000, densities and number of taxa are substantially higher than during the baseline period (1965) and the period of open pit and underground mine operation (Figs.14 and 15). As mentioned in our earlier reports, this may be partly due to different methods of data collection and analysis. However, these data indicate that the Red River is at least as suitable for sustaining benthic invertebrates at present as it was prior to the initiation of open pit mine operations.

## **CONCLUSIONS**

The lower reaches of the Red River, especially the sections adjacent to the Molycorp Mine downstream to Questa, have been referred to as biologically impoverished, devoid of aquatic life, or even a biological desert. This is not true. Data for 2000 indicate the presence of resident populations of fish and benthic invertebrates at all sites along the length of the Red River. At the most impacted site on the river, the site at the Questa Ranger Station downstream of Capulin Canyon, 24 species and 18 species of benthic invertebrates were collected in April and September, respectively, and one species of fish was present in 2000. There were no sections of the Red River that were severely impacted to the point of biological impoverishment. There seems to be multiple areas and pathways (chemical, physical) of minor to moderate impacts along the river that affect fish and invertebrates to varying degrees. The fact that these impacts do not reduce the Red River to a biological desert, and the fact that multiple species of fish and invertebrates, including sensitive species, are present along the length of the Red River tend to make interpretation of the data more difficult.

Our previous reports (CEC 1997, 1998, 1999, 2000) concluded that the primary impacts to the suitability of the Red River to sustain aquatic biota were occurring just downstream of the town of Red River, downstream of Hansen Creek, and downstream of Capulin Canyon. Downstream of the confluence of Cabresto Creek, conditions improved for both fish and benthic invertebrates. The cause of these impacts appeared to be the input of excess sediment from a number of sources and decreased water quality, especially at locations receiving drainage from hydrothermal scars. Those reports further concluded that baseline data indicated these impacts were present prior to the initiation of open pit mining at the Molycorp Questa Mine, and in reaches of the Red River upstream of the mine. Those reports also concluded that present population

levels of fish and benthic invertebrates are higher than during baseline conditions, suggesting that there have been improvements in the suitability of the Red River to support aquatic biota since the 1960s (CEC 1997).

Resident trout populations in each year from 1997-2000 showed similar trends, indicating three areas of impact resulting in decreases in trout abundance. Impacts appear to be occurring downstream of the town of Red River, downstream of Hansen Creek, and downstream of Capulin Canyon. The trout data collected in fall 2000 exhibited nearly the same longitudinal trend in density as that found for baseline conditions (1960) and the period of open pit operation (1974-1988). The most recent density and biomass data from fall 2000 support the conclusions of our previous reports; the trends have not changed. Data from 1999 and 2000 suggested variability in abundance of YOY trout may be negatively related to peak runoff flows.

The trends in benthic invertebrate population parameters from data collected in the fall 2000 were similar to the trends from the baseline (1965) and open pit mine operation periods (1970-1992). Density data indicates impacts near the town of Red River, downstream of Hansen Creek and downstream of Capulin Canyon. All three data sets indicate increasing density at sites downstream of Questa. Trends in the number of taxa are more gradual than for density. Data from all three periods indicate a general decrease in the number of benthic invertebrate taxa from upstream of Red River downstream to the site near the Questa Ranger Station, downstream of Capulin Canyon.

At all sites along the river, including the sites in the most impacted reaches, numerous species of sensitive EPT taxa are present. This includes several species of mayflies, which are especially sensitive to metals impacts, as well as more tolerant caddisfly species. This indicates that the impacts occurring along the length of the Red River are not severe, and the river is suitable for sustaining invertebrate species along its entire length.

Benthic invertebrate data from 1995 - 2000 indicate similar patterns in the downstream reaches of the Red River. In the upstream reaches of the river, population parameters seem to be more variable from year to year. Data from 1999 and 2000 indicated that benthic invertebrate population levels may be negatively related to sediment concentrations of some metals.

Sediment metals concentrations exhibited some longitudinal variation along the length of the Red River in 2000, with zinc showing the clearest trend, increasing in a downstream direction, with its highest values at the sites bracketing the fish hatchery. Aluminum concentrations were highest at the upstream and tributary reference sites. Annual comparisons between 1999 and 2000 showed lowest sediment concentrations in April 2000, followed by September 1999 and September 2000. These seasonal differences may be related to the ability of streamflows to carry metal-laden sediments downstream, out of the study area, with higher flows in spring and lower flows fall.

Sediment concentrations of metals were compared to sediment quality guidelines from Ontario, and to another sediment study. Sediment concentrations of copper, lead, and zinc in the Red River sometimes exceeded the Lowest Effect Level, but not by much, and were always much less than the Severe Effect Level. Aluminum concentrations in the Red River were comparable to those in a wildlife refuge in Texas, and within baseline concentrations from the western United States.

Toxicity testing of water and sediment at sites along the Red River indicated conditions that are chronically toxic existed at several locations for invertebrates and fish. Both water and sediment tests indicated toxicity to zooplankton upstream and downstream of the Molycorp mine, including a site upstream of the town of Red River. Sediment tests identified toxicity to fish at the June Bug Campground, upstream of Molycorp. The results of these tests are further evidence of multiple areas of impacts to aquatic organisms along the length of the Red River.

**APPENDIX C**

**Sediment Metals and Benthic Invertebrate**

**Regression Analysis**

**TABLE C-1:** Results of regression analysis between sediment metals in 2000 and benthic invertebrate population parameters. Only significant ( $p \leq 0.05$ ) results are shown.

Date, Sediment Metal	Density	Number of Taxa	Number of EPT Taxa	EPT Taxa as % Total Taxa	Diversity
<b>April 2000</b>					
Aluminum	--	--	--	--	--
Cadmium	--	--	--	--	--
Copper	--	(-) $p < 0.01$ $R^2 = 0.60$	(-) $p = 0.01$ $R^2 = 0.58$	--	(-) $p = 0.01$ $R^2 = 0.55$
Lead	--	--	--	--	(-) $p = 0.05$ $R^2 = 0.41$
Zinc	(-) $p = 0.05$ $R^2 = 0.39$	--	--	--	--
<b>September 2000</b>					
Aluminum	--	(+) $p = 0.04$ $R^2 = 0.42$	(+) $p = 0.01$ $R^2 = 0.55$	--	(+) $p < 0.01$ $R^2 = 0.70$
Cadmium	--	--	--	--	--
Copper	--	(-) $p < 0.01$ $R^2 = 0.61$	(-) $p < 0.01$ $R^2 = 0.70$	--	(-) $p = 0.03$ $R^2 = 0.48$
Lead	--	--	--	--	(-) $p < 0.01$ $R^2 = 0.85$
Zinc	--	(-) $p = 0.03$ $R^2 = 0.48$	(-) $p = 0.05$ $R^2 = 0.41$	--	(-) $p = 0.02$ $R^2 = 0.54$

**APPENDIX D**

**Water Quality Data, Toxicity Sampling Sites**

**TABLE D-1:** Summary of water quality parameters analyzed on water column samples collected in conjunction with toxicity samples on October 25, 2000, at six sites on the Red River, New Mexico.
